**Figure 20-20 Measurement of LV diameters. A,** Parasternal long-axis view by 2D echocardiography used to guide M-mode evaluation. The cursor cannot be aligned perpendicular to the septum and posterior wall (*dotted line*); in this case it is better to measure ventricular diameters directly from 2D echocardiography (*continuous line*). **B,** Parasternal short-axis view acquired at the mitral chordae level is an alternative option to measure diameters, directly or by M-mode echocardiography, provided that LV has a circular shape. **C,** M-mode allows a clear identification of endocardial borders and excellent temporal resolution. However, it is crucial for correct measurement of diameters (*lines*) to align the M-mode cursor perpendicular to the long axis of the LV.

the apical biplane approach. If image quality is suboptimal, left-sided contrast can be infused to enhance endocardial definition. It is important to emphasize that 2D echocardiographic methods have limitations that militate against their routine use for quantitation in the clinical setting. Apical images may foreshorten true LV length. On serial studies, a review of previous images minimizes measurement variability resulting from changes in the echocardiographic image plane, measurement site, or foreshortening of the apical view. Slight changes in measurements may not be clinically significant. Decision making is based on consistent directional changes on serial studies.[27] If measurements are approaching a value that would indicate surgical intervention, a repeat evaluation at a shorter time interval or confirmation by an alternative imaging technique is appropriate. LV wall stress may also be estimated from blood pressure and echocardiographic measurements. However, such wall stress measurements are difficult to reproduce, have methodologic and conceptual problems, and should not be used for diagnosis or management decision making in clinical practice.

Although LVEF is the fundamental parameter for evaluating LV contractility, new parameters obtained by tissue Doppler and strain rate imaging may be useful in borderline LVEF values; however, data remain scant. Two studies have shown peak systolic wave velocity less than 9 cm/s at the mitral annulus to be a predictor of complications and related to LV contractile reserve.[61,62] These studies suggested that in patients with asymptomatic chronic AR, estimation of LV long-axis contraction could unmask subnormal LV functional status at baseline that was prone to becoming more evident 12 months later. Recent studies suggested that the strain rate may be useful not only for estimating subclinical myocardial dysfunction but also for predicting postoperative LV systolic dysfunction.[63-65] Indexed volume by deformation could predict increasing LV dilatation. A cutoff value of the ratio of strain rate to end-diastolic volume less than 0.006 had 90% sensitivity and specificity. for detecting subclinical changes in deformation of the lateral wall, In another study,[64] systolic radial strain rate derived from tissue Doppler was a good predictor of postoperative LV dysfunction, with the cutoff value being 1.82 per second.

In cases with suboptimal echocardiographic images or unclear results, MRI may be indicated. MRI has become the gold standard in EF quantification.[26] Furthermore, measurement of LV and RV volumes provides the opportunity to obtain the regurgitant volume by their subtraction.

In cases with discrepancies between AR severity and LV function, other imaging techniques such as computed tomography (CT) or MRI could be useful to diagnose coronary artery disease or dilated cardiomyopathy.[66-69]

## CONTRACTILE RESERVE EVALUATION

Exercise testing may be useful when the relationship between symptoms and LV systolic function is uncertain. In this subset of patients, exercise testing may be very useful in eliciting symptoms or determining functional capacity.[69] Assessment of contractile reserve may be helpful in patients with severe AR and equivocal symptoms or borderline values in terms of LV EF (50% to 55%) or end-systolic diameter close to 50 mm or 25 mm/m$^2$. The absence of contractile reserve seems to be predictive of LV function after surgery.[70] The main limitation is the measurement variability in EF at exercise by echocardiography. Radionuclide ventriculography overcomes these limitations[71]; however, further studies are required for these findings to be used in clinical practice. Nevertheless, a decrease in EF during exercise should not be used as the only indication for surgical treatment in asymptomatic patients with normal LV systolic function at rest, because exercise EF is multifactorial and the strength of the evidence is limited. On the other hand, the change in EF with exercise is a relatively nonspecific response related to both severity of volume load and exercise-induced changes in preload and peripheral resistance.

## Aortic Root and Ascending Aorta Evaluation

Assessment of aortic root and ascending aorta dilatation is an important part of the evaluation of patients with AR. Echocardiography is accurate in the assessment and follow-up of aortic root size. MRI or CT scanning are recommended for ascending aorta evaluation in patients with an enlarged aorta detected by echocardiography, particularly when enlargement may indicate surgery.

### AORTIC VALVE AND ROOT FUNCTION

The aortic root may be defined as the portion of the aorta that supports the leaflets of the aortic valve, delineated superiorly by the sinotubular junction and inferiorly by the aortoventricular junction.[72] It is made up of the sinuses, leaflets, commissures, and interleaflet triangles. The sinotubular ridge is circular, composed primarily of elastic tissue, and supports the peripheral attachments of the valve leaflets. The valve leaflets are inserted into the aortic wall in semilunar fashion, and their closure determines a complete central coaptation. The level of coaptation is midway between the nadir of their insertion and the commissural areas.[73] The aorta-ventricular junction or base of the aortic root is defined by the nadirs of attachments of these leaflets and the inter-leaflet triangles (Fig. 20-21). The term *aortic annulus* is frequently used to describe this area; however, this term is not strictly accurate because it implies a circular structure. Approximately 45% of the circumference of the aortic root is attached to the muscular interventricular septum and 55% to fibrous tissue. This fibrous tissue is the membranous interventricular septum and the fibrous body that connects the anterior leaflet of the mitral valve to the aortic root.[74]

The function of the aortic root has been well described, because it acts as an individual hemodynamic entity.[72] The integrity of all components of this entity is essential for normal function. An aneurysm of the ascending aorta can cause dilatation of the sinotubular junction with consequent AR due to lack of coaptation of the cusp, but the aortic annulus remains normal. The mechanism of AR in patients with aortic root aneurysm is more difficult to define. Dilatation of the aortic root often starts at the level of the sinuses of Valsalva. As wall tension increases, the sinotubular junction begins to dilate. The aortic annulus may also dilate in these patients and further complicate the mechanism of AR by widening the fibrous subcommissural triangles.[75]

Echocardiography can offer dynamic evaluation of the AR mechanism.[13] Accurate aortic root measurement is important for understanding functional AR mechanisms and targeting the optimal time and strategy for aortic valve–sparing surgery. The following parameters should be measured:

- Aortic annulus: distance between insertion of the basal valve cusps into the aortic root
- Sinuses of valsalva: maximum diameter of the sinuses
- Sinotubular junction: dimension of the aortic root at the level of commissural cusp-tip insertion into the aortic wall
- Tubular tract: maximum diameter of the ascending aorta distal to the sinotubular junction (Fig. 20-22)
- Coaptation height: maximum distance between the first point of protodiastolic coaptation of the leaflet tips and the annulus plane corresponding to the basal insertion of the leaflets
- Tented area: the maximum area subtending the ventricular surface of the leaflets as far as the annular plane

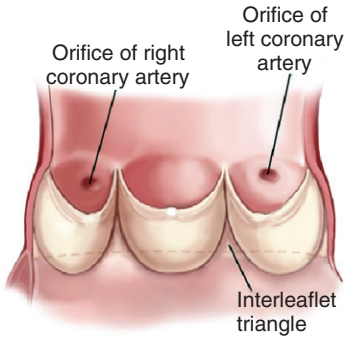

**Figure 20-21** Diagrammatic representation of the aortic valve and root that illustrates how the semilunar attachment of the valvar leaflets incorporates aortic wall in the intersinusal triangles, and the base of each of the coronary aortic sinuses. *(From Otto CM, Bonow RO:* Valvular Heart Disease, *ed 3. Philadephia, 2009, Elsevier, Fig. 12-1D, p. 188.)*

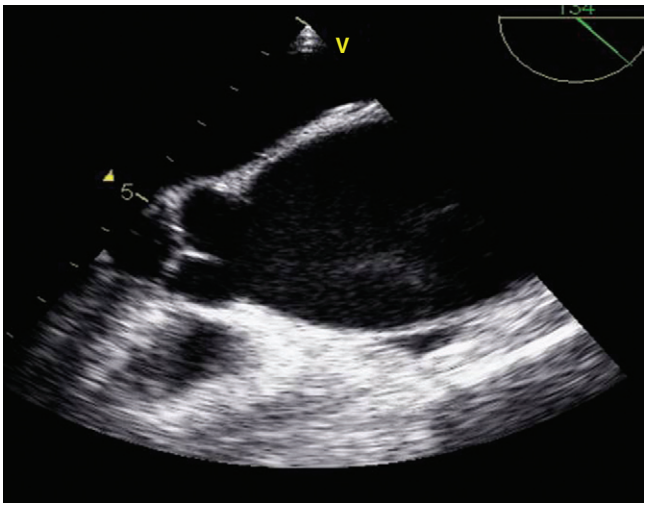

**Figure 20-22 TEE showing an ascending aorta aneurysm (50 mm) distal to the sinotubular junction.** Note the normal size of the sinuses of Valsalva.

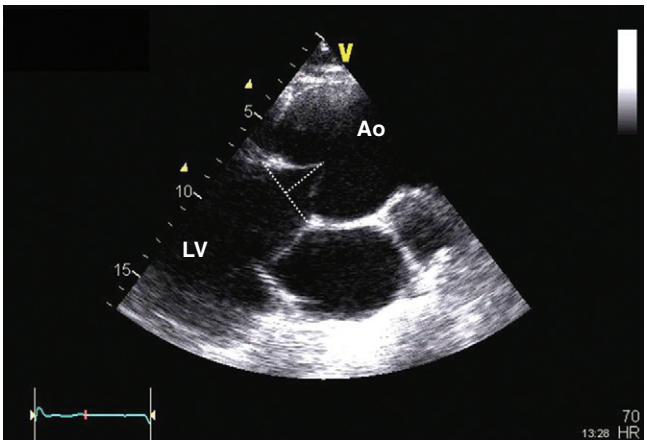

**Figure 20-23 Functional aortic regurgitation.** Parasternal long-axis view showing the aortic valve and the ascending thoracic aorta in a patient with diastolic cusp tenting with a coaptation height of 14 mm. *Ao*, Aorta.

The variable most strongly associated with functional AR severity is diastolic leaflet tenting, measured as coaptation height (Fig. 20-23). Sensitivity and specificity are over 95% using a cutoff value of 11 mm. In turn, tethering of the leaflets depends on the mismatch of sinotubular junction/

annulus diameters rather than the absolute dimension of the proximal aorta. A cutoff value greater than 1.6 strongly identifies diastolic leaflet tenting and is significantly associated with AR severity.[76,77]

## Natural History and Serial Testing in Chronic AR

Progression of AR involves a complicated interaction of several variables, including AR severity, aortic root disease, and the adaptive response of the LV. AR severity may worsen as a result of progressive leaflet deterioration and/or further dilatation of the aortic root.[78] Reimold and co-workers[79] showed that quantitative measurements of AR severity by echocardiography worsen over time. Padial and colleagues[80] showed that patients with more rapidly progressive increases in aortic root size also tend to have significant worsening of AR severity and LV dilatation.

Patients with chronic AR typically have slow LV dilatation and a prolonged asymptomatic phase. The LV adapts to the volume overload of chronic AR with a series of compensatory mechanisms, including an increase in end-diastolic volume and compliance and eccentric hypertrophy that accommodates the increased volume and maintains cardiac output without raising filling pressures. This compensated phase may last for decades. However, in most patients, the balance among afterload excess, preload reserve, and hypertrophy cannot be maintained indefinitely. Eventually, preload reserve is exhausted and/or hypertrophy becomes inadequate; thus, further increases in afterload result in a reduction in EF. This transition may be insidious, and some patients remain asymptomatic until severe LV dysfunction has developed. The decompensated stage is characterized by substantial and progressive LV enlargement, more spherical geometry, elevated LV diastolic pressures, increased systolic wall stress (i.e., afterload excess), and a decline in the EF.[81]

There are no large studies evaluating the natural history of asymptomatic patients in whom LV systolic function was normal. The current recommendations[69,82] derive from nine published series involving 593 patients with a mean follow-up period of 6.6 years[3,83-91] (Table 20-2). The rate of progression to symptoms and/or LV systolic dysfunction averaged 4.3% per year, development of asymptomatic LV dysfunction 1.2% per year, and sudden death 0.2% per year.[69] It should be emphasized that more than one fourth of patients who died or developed systolic dysfunction did so before the onset of symptoms.[84-86,90] LV size measured by echocardiography had a major predictive value. Patients with initial end-systolic dimension greater than 50 mm had a likelihood of death, symptoms, and/or LV dysfunction of 19% per year. In those with end-systolic dimension of 40 to 50 mm, this was 6% per year, and when the dimension was less than 40 mm, it was zero.[84] Thus, serial evaluation of asymptomatic patients by echocardiography is mandatory. On the other hand, 25% of asymptomatic patients with depressed systolic function developed symptoms per year.[83-94] In symptomatic patients with medical treatment, mortality over 10% to 20% per year has been reported.[89,93,94]

In asymptomatic patients with preserved systolic function, initial measurements of LV dimensions and function represent the baseline information with which future serial measurements can be compared. Patients with mild-to-moderate AR can be seen on a yearly basis and echocardiography performed every 2 to 3 years. All patients with severe AR and normal LV function should be seen for follow-up at 6 months after their initial examination. If LV diameter and/or EF show significant changes or become close to the threshold for intervention, follow-up should be continued at 6-month intervals.[69,82] Patients with stable parameters can be followed annually. In patients with dilated aorta, and especially in patients with Marfan syndrome or bicuspid valve, echocardiography should be performed on a yearly basis. CT or MRI are advisable when the

ascending aorta is not well visualized at the upper part of the sinotubular junction or when surgical indication may be based on aortic enlargement rather than LV size or function.[9]

## Management and Timing of Surgery

### MEDICAL TREATMENT

It has been hypothesized that reducing afterload by vasodilators will reduce LV wall stress, reduce LV dilatation, and delay the need for surgical treatment.[95-100] However, clinical and echocardiographic data supporting this approach have been inconclusive. Medical therapy is not able to significantly reduce regurgitant volume in chronic severe AR, because the regurgitant orifice area is relatively fixed and diastolic blood pressure is already low.[97] Only two randomized, controlled studies demonstrated significant reductions on LV end-diastolic diameters and an increase in EF with hydralazine or nifedipine.[87,95] However, a more recent randomized trial showed no benefit of therapy with enalapril or nifedipine compared to placebo[91] (Fig. 20-24). Thus, their use in not advised except in the presence of systemic hypertension (systolic blood pressure greater than 140 mm Hg) or overt heart failure en route to surgery.[69,82]

Beta blockers have been considered contraindicated in AR because cardiac output is maintained through an increase in heart rate, and lowering the heart rate may increase diastolic time and regurgitation volume.[69] However, a recent retrospective observational study[101] indicated that beta-blocker therapy was associated with better survival in patients with severe AR, mainly in the subgroup with higher heart rates. In patients with Marfan syndrome, beta-blockers can slow aortic root dilatation and reduce the risk of aortic complications. Preliminary findings suggest that ARA-II have an intrinsic effect on the aortic wall by preserving elastin fibers.[102-103] However, their clinical benefit remains to be proven by ongoing trials.[104,105]

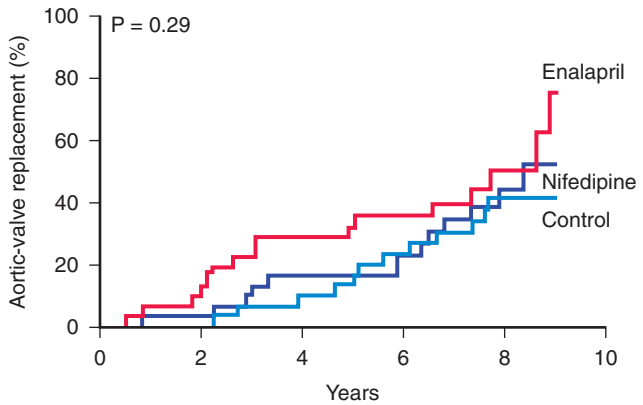

**Figure 20-24 Effect of vasodilator therapy on time to aortic valve replacement in adults with chronic aortic regurgitation (AR).** The Kaplan Meier curves show the percent of patients undergoing aortic valve replacement in a prospective, randomized, open label study of 95 adults with asymptomatic severe AR randomized to nifedipine (20 mg every 12 hours), enalapril (20 mg daily), or no treatment. *(From Evangelista A, Tornos P, Sambola A, Permanyer-Miralda G, Soler-Soler J: Long-term vasodilator therapy in patients with severe aortic regurgitation.* N Engl J Med *353(13):1342-1349, 2005.)*

### INDICATIONS FOR SURGERY

There are no randomized controlled trials to guide surgical decision making for adults with chronic AR. However, reasonable guidelines have been proposed on the basis of natural history, retrospective studies, and expert opinion.[69,80] Indication for surgery is based on three aspects: symptoms, LV function and size, and aortic dilatation. Determining LV function and dimensions should be paramount for the correct management of AR. A curvilinear relationship exists between the preoperative degree of LV dilation and postoperative EF[106] (Fig. 20-25). End-systolic ventricular size is less load dependent and thus a more robust predictor of outcome compared to end-diastolic measurements. Indexing for body surface area (BSA) could be recommended, particularly in patients of small body size and women.[94,107-109]

#### *Symptomatic Patients with LV Dysfunction*

Surgery should not be denied in symptomatic patients with severe LV dysfunction (EF less than 30%) or marked LV dilatation after careful ruling out of other possible causes. Postoperative outcome is worse in these patients,[110,111] and the likelihood of recovery of systolic function is lower than in patients operated on at an earlier stage. Patients with markedly low EF have higher long-term likelihood of postoperative heart failure; however, at 10 years only a minority of patients (25%) had this complication. Even in patients with NYHA functional class IV, improvement in LV function and clinical symptoms can be achieved, although mortality associated with aortic valve replacement approaches 10%.[110-112]

#### *Symptomatic Patients with Normal LV Systolic Function*

Surgical treatment is indicated in patients with normal LV systolic function, defined as EF greater than 50% at rest, who have NYHA functional class III or IV. In many cases of patients with NYHA functional class II dyspnea, the cause of symptoms is often unclear. Although a period of observation may be reasonable, an exercise imaging test could be helpful in identifying the causes of symptoms. Evaluation of new parameters obtained by tissue Doppler and strain rate imaging may be useful in borderline LVEF values.

#### *Asymptomatic Patients with Reduced Ejection Fraction*

Surgical treatment in asymptomatic patients is indicated in those with LV dysfunction (LVEF less than 50%). However, it is important to consider the variability of echocardiographic measurements, and exercise tests or other imaging techniques could be performed to confirm LV systolic dysfunction.

#### *Asymptomatic Patients with Normal Ejection Fraction*

Surgical treatment is also recommended in patients with normal EF and severe LV dilatation (end-diastolic dimension greater than 75 mm or end-systolic dimension greater than 55 mm).[69] Patients with severe AR in whom the degree of LV dilatation has not reached, but is approaching, these threshold values (end-diastolic dimension 70 to 75 mm or end-systolic dimension of 50 to 55 mm) should be followed with frequent echocardiograms every 4 months. In the ESC Guidelines, end-diastolic diameter greater than 70 mm or end-systolic diameter greater than 50 mm (or greater than 25 mm/m$^2$) are considered

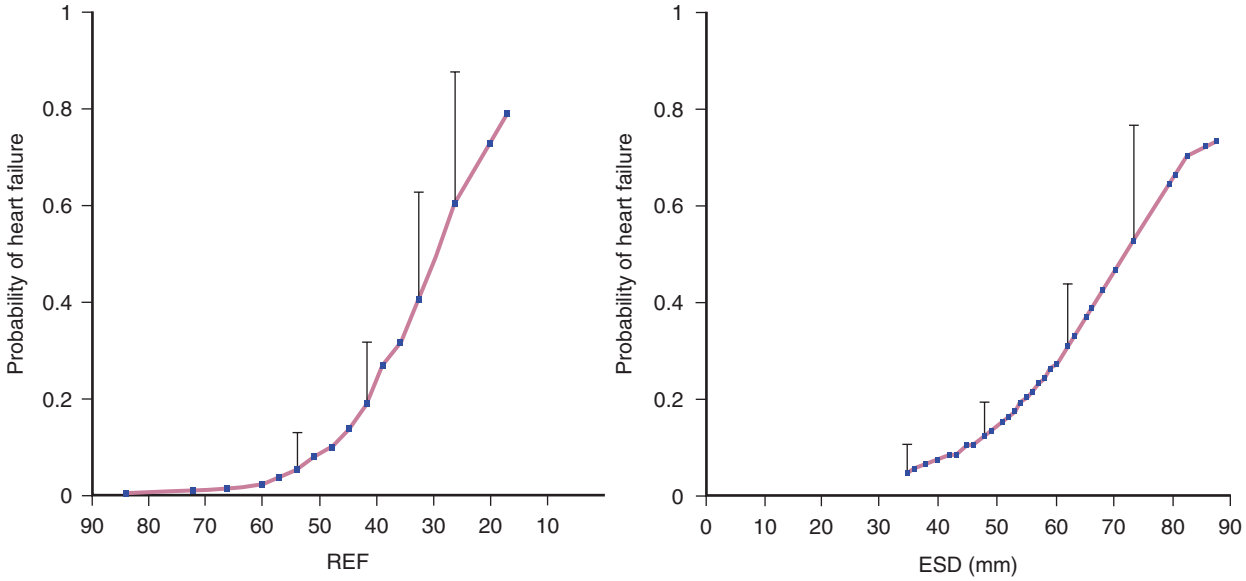

**Figure 20-25** Probability of heart failure during follow-up (*y*-axis) plotted against (*left*) preoperative radionuclide ejection fraction (REF) and (*right*) preoperative end-systolic diameter of LV in patients undergoing aortic valve replacement for severe aortic regurgitation. *(From Tornos MP, Olona M, Permanyer-Miralda G, et al: Heart failure after aortic valve replacement for aortic regurgitation: prospective 20-year study.* Am Heart J *136(4):681-687, 1998.)*

indications for surgery (class IIa)[82]. Despite preserved EF, a higher LV end-systolic volume index (45 mL/m$^2$ or higher) predicts more cardiac events within each AR grade.[13] Most patients with this severe LV dilatation and preserved EF have a high risk of outcome complications and reduced exercise tolerance. Some patients develop LV systolic dysfunction without marked LV dilatation. Women tend to develop symptoms and/or LV dysfunction with less LV dilatation than men. Anthropometric normalization of the LV end-diastolic dimension should be considered.[94,113] However, normalization for BSA may not be appropriate in patients with obesity. The use of height and a consideration of gender are likely to be more appropriate than BSA.[114]

Adherence to these guidelines for intervention in asymptomatic patients with evidence of LV dysfunction has been shown to improve long-term outcomes.[111] When ventricular dimensions of EF are used to recommend surgery, the variability in these measurements must be considered. Data are most convincing when serial studies, with side-by-side comparison of measurements, show a consistent directional change.

### *Concomitant Aortic Root Disease*

Dilatation of the ascending aorta is one of the most common causes of isolated AR. In these cases, AR is not severe, and surgical indications should be based more on aortic enlargement than on AR severity. Aortic root or ascending aorta dilatation greater than 55 mm should be a surgical indication, regardless of the degree of AR.[69] In cases of Marfan syndrome or bicuspid valves, smaller aortic diameters (at least 50 mm) have been proposed.[69,82] In Marfan patients with a family history of aortic dissection or with a rapid increase in aortic diameter (greater than 5 mm/year), aortic surgery is recommended when aortic root diameter is at least 45 mm.[82] Formulas based on patient height and the cross-sectional area of the aorta have been developed to define the thresholds for surgery, although they are less frequently used.[115,116] Indexing aortic diameters for BSA has been proposed for individuals with Turner syndrome.[117] This appears reasonable for all aortic aneurysms.[118,119]

The level of evidence for this aggressive approach is better defined in patients with Marfan syndrome than in patients with bicuspid valves.[7,20,120-124] In patients with BAV, indication for surgery in aortic diameters between 50 and 55 mm should be adapted according to patient age, body size, comorbidities, type of surgery, and presence of additional risk factors, including coarctation of the aorta, systemic hypertension, aortic valve stenosis, or rapid increase in aortic diameter at least 5 mm per year.

When valve replacement is required on the basis of AR severity, replacement of the ascending aorta should be considered when aortic diameter is greater than 50 mm, or greater than 45 mm depending on age, BSA, valvular disease etiology, presence of a BAV, and intraoperative shape and thickness of the ascending aorta.[125] Lower thresholds may be used for root replacement if repair of the aortic valve is planned in surgical centers with established expertise in repair of the aortic root and ascending aorta.[126]

## Selecting and Guiding Surgical Treatment

Treatment of isolated AR has traditionally consisted of valve replacement with a mechanical or biologic prosthesis. Replacement with a pulmonary autograft has been an operation reserved for special instances, primarily in children or very young adults.[127,128] Repair strategies for the regurgitant aortic valve have been developed in the past 20 years for different morphologies.[129-130] Potential advantages of aortic valve repair over replacement include a lower incidence of subsequent thromboembolic events, avoidance of long-term anticoagulation, and reduced risk of endocarditis. Aortic valve repair is increasingly favored over replacement with a prosthetic valve for a variety of lesions causing significant AR.[131-133] Despite these potential benefits, the durability of aortic repair procedures has been a matter of concern, with their success rate being varied and greatly dependent on the etiology and mechanisms of aortic valve dysfunction and experience of the surgeons.[130,131]

Aortic valve repair is possible in patients undergoing repair of aneurysms of the aorta or aortic root or in selected patients, such as those with bicuspid valves with prolapsing leaflets with minimal sclerosis. Dilatation of the aortic root, regardless of its etiology, has been treated by composite replacement of the valve and root/ascending aorta with a mechanical or biologic valve conduit.[134] Valve-sparing aortic replacement is increasingly being employed as an alternative. Supracoronary replacement of the ascending aorta can be used to treat aortic aneurysm when the sinuses of Valsalva are preserved.

The type of surgical treatment should also take patient age into consideration.[132] If valve repair or a valve-sparing intervention is considered, TEE may be performed preoperatively to define the anatomy of the cusps and ascending aorta.[13]

## FUNCTIONAL CLASSIFICATION OF AR

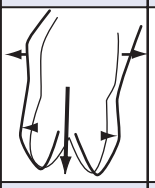
Analysis of the mechanism of AR influences patient management, particularly when the ascending aorta is dilated or when conservative surgery is considered. Several functional classifications have been proposed. The adapted Carpentier classification for AR is the most widely used[75]: type I, aortic root dilatation or leaflet perforation; type II, prolapse of one or more cusps; and type III, restricted motion as the consequence of rheumatic disease or secondary significant calcification (Fig. 20-26).

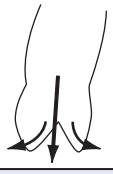
## ROLE OF ECHOCARDIOGRAPHY

The main roles of echocardiography are to evaluate regurgitation mechanisms, describe valve anatomy, and determine the feasibility of valve repair.[13] 2D TTE does not always show the lesion responsible for leaflet malcoaptation. Evaluation of the mechanisms of AR by TEE[13] follows the same principles:

1. Type I dysfunction: identified when the dimensions of a component of the aortic root, including the aortic annulus, sinuses of Valsalva, and sinotubular junction exceed the upper limits of published normal values and no other cause of AR is identified. Abnormalities in the type I group are further subdivided into type Ia, aneurysm of the ascending aorta (see Fig. 20-22); type Ib, aneurysm of the aortic root (see Fig. 20-23); type Ic, isolated dilatation of the annulus; and type Id, perforation of the leaflet due to either trauma or endocarditis.
2. Type II dysfunction: considered in the presence of an eccentric AR jet and either a cusp prolapse or cusp fenestration. Cusp prolapse is considered whenever the free edges of one or more of the aortic cusps override the plane of the aortic annulus. As in surgery, three subtypes of cusp prolapse are identified on TEE: cusp flail, whole cusp prolapse, and partial cusp prolapse. Cusp flail is defined as the complete eversion of a cusp into the LVOT in long-axis views. Partial cusp prolapse is considered whenever the distal part of a cusp is prolapsing into the LVOT. This is usually associated with clear bending of the cusp body on long-axis views, and with the presence of a small circular or oval structure near the cusp free edge on short-axis views. Whole-cusp prolapse is considered when the free edge of the entire body of the same cusp is billowing into the LVOT. Billowing of the cusp body is best seen on short-axis views of the LVOT, immediately beneath the valve, where it appears as a large circular or oval structure (see Fig. 20-17). Fenestration of a cusp free edge is considered in the presence of an eccentric AR jet, but with no definite evidence of cusp prolapse. Careful inspection of long-axis gray-scale and color Doppler images usually permits the identification of small defects near the free edge of the affected cusp.
3. Type III dysfunction: considered whenever quality or quantity of the cusp tissue are judged to be poor. Thickened and rigid valves with reduced motion, valves whose leaflet tissue has been destroyed by endocarditis, and severely calcified valves are included in this category.

Intraoperative TEE should be mandatory after repair to assess the functional result and identify patients at risk for early recurrence of AR.[135] The primary interest is in the





| AR Class | Type I Normal cusp motion with FAA dilatation or cusp perforation | | | | Type II Cusp prolapse | Type III Type II restriction |

number and location of jets and whether these are deflected. Jet deflection is a surrogate for cusp tissue redundancy and prolapse. A central nondeflected jet suggests restriction and cusp tissue deficiency relative to the root. The accuracy of TEE compared with surgical observation is high, even for identification of the various subtypes of aortic cusp prolapses. This identification is of paramount importance for the success of valve-sparing surgery since failure to identify and correct a preexisting cusp prolapse is a frequent cause of failure in valve-sparing operations.[136]

## SURGICAL IMPLICATIONS

In type I lesions, whenever the AR jet is central and perpendicular to the LVOT, absence of associated type II is supposed, and surgical correction is based on replacement of the ascending aorta and subcommissural annuloplasty (Fig. 20-27). If the AR jet is not perpendicular to the LVOT, a type II lesion must be suspected and treated. Direction of the jet toward the mitral valve or septum determines the responsible prolapsing cusp; in this case, concomitant surgical repair of type II is mandatory.[75]

In type Ib secondary to aortic root aneurysm, the indication for surgery is often diameter rather than AR severity. Even in patients with severe AR, one or more cusps remain nearly normal owing to the asymmetric nature of aortic root dilatation. After sparing surgery is achieved, by either remodeling or reimplantation procedures, a missed prolapse could be present and necessitate repair to avoid an immediate valve repair failure. Type Ib lesions with significant AR are best treated by reimplantation techniques.[74]

Among patients undergoing AR repair, those with Marfan syndrome or type III dysfunction are more likely to exhibit recurrent moderate to severe AR. The primary cause of failure, in patients with recurrent significant AR, is the persistence or induction of some degree of cuspal prolapse at the time of the initial operation. Immediate postrepair intraoperative TEE permits identification of certain functional and morphologic features associated with late repair failure, including the persistence of a residual AR jet, coaptation length less than 4 mm, coaptation level occurring below the level of the aortic annulus, and an enlarged aortic annulus. Pliability of each cusp is estimated as an apparent change in its area from systole to diastole and is termed the *tissue normality index* (TNI): TNI = (diastolic area − systolic cusp area)/diastolic cusp area. Adequacy of cusp tissue for coaptation is estimated by measuring the curvilinear height of anterior and posterior cusps in a plane parallel to the aortic orifice. A coaptation deficiency index (CDI) is calculated using the formula CDI = (conjoint cusp height + reference cusp height)/diastolic aortic "annulus" diameter. Redundant or sufficient cusp tissue offers greater potential for valve repair than restricted cusps with deficient tissue.[137] 3D echocardiography and gated high-resolution CT are promising technologies to improve aortic valve imaging.

## Results of Surgery and Follow-up

Operative mortality is low (1% to 4%) in isolated aortic valve surgery. In the presence of advanced age or impaired LV function, and in patients with concomitant coronary artery bypass grafting, operative mortality ranges from 3% to 7%.[138,139] In patients with ascending aortic aneurysm, an ascending aortic graft with prosthesis is associated with 1% to 10% mortality depending on symptoms, LV size and function, and AR severity, with the most important determinants being the skill and experience of the surgical team.[138-141] With the advent of conservative aortic valve surgery, including valve-sparing operations and aortic cusp repair, the management of severe AR has changed significantly. These operations have low operative mortality and good long-term durability. Data on reconstructive surgery from expert centers show hospital mortality of less than 2% for isolated valve repair and valve-sparing aortic replacement.[129-131,134] Mortality after pulmonary autograft is approximately 2% and thus apparently not increased despite the complexity of the operation.[140,141]

The incidence of valve-related complications after aortic valve reconstruction and valve-sparing aortic replacement at experienced centers is lower than those published for conventional valve replacement.[130,131] A linearized risk of reoperation of 1% per year has been published by experienced centers.[142,143]

After aortic valve replacement, close follow-up is recommended during the early and long-term postoperative course to evaluate prosthetic valve and LV function. An echocardiogram should be performed soon after surgery to assess the results. In the first weeks postsurgery, there is little change in LV systolic function. A better predictor of subsequent LV systolic function is the reduction in LV end-diastolic dimension, which declines significantly in the first 2 weeks postsurgery. After initial postoperative reevaluation, the patient should be seen and examined at 6 and 12 months and then on a yearly basis if the clinical course is uncomplicated.[69] After isolated surgery for a BAV, patients should have serial CT or MRI evaluation every 2 years. Patients who have ascending aorta replacement with or without aortic valve surgery should be evaluated annually with echocardiography to assess the size of the retained aortic root and should also undergo CT scans or MRI of the remaining thoracic and abdominal aorta every 3 to 5 years.

## Acute Aortic Regurgitation

In acute severe AR, the sudden large regurgitant volume is imposed on a normal-sized LV that has not had time to adapt to the volume overload. Thus, the acute increase in diastolic flow into a nondilated LV leads to a marked rise in end-diastolic pressure, and forward cardiac output is decreased. In severe cases, the increased ventricular filling pressures in conjunction with the decrease in aortic diastolic pressure lead to a rapid equalization of aortic and LV pressures at end-diastole.[144] Compensatory tachycardia tries to correct the decline in forward cardiac output; however, it is often insufficient, and patients may suffer cardiac shock. Pulmonary edema results from elevated LV end-diastolic pressure. Furthermore, coronary flow reserve is impaired, and subendocardial myocardial ischemia may result. The causes of acute AR are shown in Box 20-2.

Many of the physical signs of chronic AR are absent in the acute setting. Therefore, the diagnosis of acute severe AR can be difficult or underestimated. Physical signs include tachycardia, a sometimes difficult-to-hear diastolic murmur, and heart failure signs, but with normal pulse pressure and absence of peripheral signs of AR. The lack of physical signs of chronic severe AR renders acute AR difficult to identify, and the diagnosis is usually made by echocardiography.

Echocardiography is essential to confirm the presence and severity of AR, assess its cause, and determine the impact of acute AR on LV hemodynamics.

Echocardiographic findings of acute severe AR are shown in Box 20-3. In acute AR, premature mitral valve closure, before ventricular systole, results from the rapid rise in LV diastolic pressures from the aortic regurgitant volume and is indicative of acute severe AR. Premature mitral valve closure is best demonstrated by M-mode, because its greater temporal resolution compared to 2D imaging permits delineation of the early closure of the valve.[27] Quantitative measures of regurgitant severity that are useful in chronic AR are less useful in acute regurgitation. Hemodynamic data have demonstrated the variability in regurgitant orifice area and regurgitant volume depending on afterload and loading conditions.[41,79] TEE is indicated in most cases of acute AR to define the causes, mainly when acute dissection, endocarditis, or trauma are suspected or in other situations of uncertain etiology.

Patients with acute AR require emergent or urgent surgery to correct the underlying disease and relieve the acute volume overload of the LV. The type of surgery will depend on the underlying cause.

### ACUTE TYPE A AORTIC DISSECTION

AR frequently complicates acute type A aortic dissection, occurring in 41% to 76% of patients.[45] Although the need for early aortic surgery is well established, the optimal management of associated AR is controversial (see Chapter 36). For many years, aortic valve replacement was preferred; however, several

**Box 20-2**

**CAUSES OF ACUTE AORTIC REGURGITATION**

- Aortic dissection
- Native valve infective endocarditis
- Prosthetic valve infective endocarditis
- Trauma
- Spontaneous rupture or prolapse of an aortic cusp with bioprosthetic valve degeneration
- Leaflet perforation in the setting of connective tissue disorders
- Rupture of a fenestrated cusp
- Spontaneous dehiscence of valve commissures
- After surgical or catheter valvuloplasty

**Box 20-3**

**ECHOCARDIOGRAPHIC FINDINGS IN ACUTE AORTIC REGURGITATION**

- Vena contracta greater than 6 mm
- Pressure half-time less than 200 ms
- Holodiastolic flow reversal in abdominal aorta
- Premature mitral valve closure
- Normal left ventricular size and function

investigators have more recently reported favorable short- and long-term results with aortic valve preservation. TEE can define the mechanisms and severity of AR that complicate acute type A aortic dissection. These findings may help the surgeon to distinguish valve and geometry distortion amenable to repair from those with fixed abnormalities that require replacement. Five mechanisms of AR are identified by TEE, the first three of which are considered repairable without the need for valve replacement:

1. Incomplete closure of intrinsically normal leaflets due to leaflet tethering by a dilated sinotubular junction
2. Leaflet prolapse due to disruption of leaflet attachment by a dissection flap that extends below the sinotubular junction and into the aortic root
3. Prolapse of the dissection flap through intrinsically normal leaflets that disrupts leaflet coaptation (see Fig. 20-6)
4. BAV with associated leaflet prolapse unrelated to the dissection process
5. Degenerative leaflet thickening resulting in abnormal leaflet coaptation

Some patients have more than one mechanism of AR.

In the series of Movsowitz and co-workers,[145] the aortic valve was spared in 77% of 43 patients undergoing aortic surgery with excellent results. Therefore, TEE should play an important role in determining the optimal management of patients with type A aortic dissection and significant AR.

## INFECTIVE ENDOCARDITIS

Heart failure, caused by severe aortic or mitral regurgitation, is the most common complication of infective endocarditis and represents the most frequent indication for surgery (see Chapter 22). Heart failure is more often present when infective endocarditis affects the aortic rather than the mitral valve.[146,147] Moderate to severe heart failure is the leading predictor of in-hospital and 6-month mortality. Acute AR in the setting of infective endocarditis may occur as a result of leaflet rupture, leaflet perforation, or, more rarely, interference of the vegetation mass with leaflet closure. In patients with infective endocarditis on prosthetic valves, acute AR can occur as a result of large prosthetic dehiscence. In addition to the clinical signs of heart failure, TTE and TEE are of crucial importance for the diagnosis and evaluation of AR and for defining the presence of vegetations and perivalvular complications.

In acute severe AR due to infective endocarditis, patients need immediate antibiotics and aggressive medical management. If the hemodynamic situation does not immediately improve, emergency aortic valve replacement may be lifesaving. If the clinical situation stabilizes, patients may benefit from several days of antibiotic treatment before surgery, under strict clinical and echocardiographic surveillance.[148-150] The beneficial impact of surgery in patients with endocarditis and heart failure is clearly established.[151]

Intraoperative TEE and direct assessment of annular involvement are crucial for planning the surgical procedure. Assessment of the annulus is essential to ensure that it is intact and that there are no undrained abscesses.

## OTHER INFREQUENT CAUSES OF ACUTE AORTIC REGURGITATION

Acute AR can result from traumatic disruption of the aortic valve,[152,153] inflammation and perforation of leaflets in the setting of connective tissue diseases,[154] after surgical or catheter valvuloplasty,[155,156] or as a result of rupture of a fenestrated cusp[157] or spontaneous dehiscence of valve commisures.[158,159] Disrupted leaflets due to trauma or a fenestration can be repaired, but valvular replacement is the norm. As with other causes of AR, surgery should be tailored according to the intraoperative TEE and anatomic findings.

## KEY POINTS

- AR may be caused by abnormalities of the aortic leaflets, aortic root, or ascending aorta. Isolated AR most often is due to alterations in aortic geometry.
- Color Doppler proximal jet width with measurement of the vena contracta is the most useful method to quantify AR in clinical practice.
- Intermediate vena contracta values need confirmation by a more quantitative method, when feasible, optimally with integration of several Doppler methods.
- Measurement of diastolic flow reversal in the descending aorta is the strongest additional parameter for quantifying AR severity.
- CW Doppler density relative to antegrade flow is also useful, but pressure half-time is influenced by chamber compliance and pressures.
- The flow convergence method (PISA method) is less sensitive to loading conditions but is more technically demanding.
- Cardiac MRI provides quantitative assessment of regurgitant severity and LV function when echocardiography is nondiagnostic.
- Symptoms are the indication for surgical intervention in most patients with chronic AR, but some patients have impaired ventricular contractility in the absence of symptoms. LV diameters, volumes, and EF are the most useful parameters for clinical decision making. Indexed end-systolic diameter is recommended when BSA is less than 1.65 $cm^2$.
- Exercise echocardiography may be useful in patients with severe AR and equivocal symptoms or in patients with borderline values for LVEF (50% to 55%) or end-systolic diameter (close to 50 mm or 25 $mm/m^2$).
- Accurate aortic root measurements are important for understanding functional AR mechanisms and targeting the optimal time and strategy for aortic valve–sparing surgery.
- Conservative aortic valve surgery, including valve-sparing operations, and aortic cusp repair have improved the management of severe AR. Intraoperative TEE is mandatory after repair to assess the functional result and identify patients at risk for early AR recurrence.

Results of Balloon Mitral Valvotomy
Implications for Patient Selection
**Research Applications**
Stress Echocardiography
Evaluation of Valve Anatomy
**Potential Limitations, Future Directions**
**Alternative Approaches**

Echocardiography plays a key role in the assessment of mitral stenosis (MS). As in other heart valve diseases, it has superseded invasive investigations for assessing the severity and consequences of MS. Echocardiography is also used to analyze valve anatomy, which contributes to the selection of the most appropriate intervention. This has been of particular interest with the development of balloon mitral valvotomy (BMV). Growing experience from large series reporting results of BMV in a variety of patient subsets enables the type and timing of interventions for MS to be clarified in guidelines.

## Background

Unlike for other valve diseases, the main etiology of MS remains rheumatic heart disease, even in Western countries.[1] Despite the sharp decrease in the incidence of rheumatic fever in Western countries, rheumatic heart disease has not disappeared, in particular because of the presence of immigrants from countries where rheumatic fever remains endemic. The prevalence of MS has been estimated at 0.1% in a population-based based study in the United States,[1,2] and MS accounted for 9% of native valve diseases in Europe. The burden of rheumatic heart disease remains high in developing countries, where its prevalence is estimated at between 1 and 7 per 1000 in school-age children when using clinical screening, and between 20 and 30 per 1000 when using systematic echocardiographic screening.[3-5] In Western countries, MS affects older patients who have more severe impairment of valve anatomy than in countries where rheumatic fever remains endemic.[6,7]

In addition to epidemiologic changes, the management of MS has dramatically changed with the development of BMV since its first description in 1984.[8] The possibility of treating MS using a low-risk procedure progressively led to the extension of indications for interventional treatment. At the same time, technical refinements in ultrasonographic examinations have improved the possibility of assessing the severity of valve disease and its consequences noninvasively and describing the anatomic lesions.

## Basic Principles and Echocardiographic Approach

The aims of echocardiographic examination in MS can be summarized as follows: diagnosis, evaluation of the severity and consequences of valve lesions, and assessment of valve anatomy and of associated diseases.

### DIAGNOSIS

Transthoracic echocardiography (TTE) is mandatory for any clinical suspicion of MS. Given the decreased awareness of MS in Western countries and the difficulties of auscultatory diagnosis, MS might only be diagnosed when TTE is performed to

establish the cause of unexplained dyspnea or thromboembolic events.

The diagnosis of rheumatic MS relies mainly on two-dimensional (2D) echocardiography that shows leaflet thickening and decreased mobility, commissural fusion, and involvement of the subvalvular apparatus, as assessed using parasternal and apical views. The parasternal short-axis view is of particular importance in assessing commissural fusion. The same views are used for the detailed anatomic evaluation of the leaflets and subvalvular apparatus (see Assessment of Valve Anatomy, later). Anatomic analysis also enables rheumatic MS to be distinguished from rare congenital or degenerative MS.

## EVALUATION OF THE SEVERITY

The assessment of the severity of MS is based on the estimation of valve area (Table 21-1).[9,10] Gradient is not a reliable marker of the severity of valve stenosis because it is highly dependent on heart rate and cardiac output. Various techniques can be used to assess mitral valve area.

- Planimetry of the mitral orifice, using the transthoracic parasternal short-axis view, is the reference measurement because it is the only direct measurement of valve area and correlates closely with anatomic findings.[9,11] Planimetry does not involve hypotheses concerning loading conditions, compliance of cardiac chambers, or associated valve disease. However, planimetry requires particular expertise to ensure that the cross-sectional area corresponds to the leaflet tips.[9]
- The pressure half-time method is frequently used because it is easy to perform, provided the Doppler signal of transmitral flow is of good quality with a well-defined linear slope of the Doppler E wave. However, the pressure half-time depends not only on valve area but also on chamber compliance and associated aortic regurgitation.[12]
- The continuity equation is based on the ratio between stroke volume in the left or right ventricular outflow tract and velocity-time integral to the mitral flow.[13] Its accuracy is limited by potential errors on the numerous measurements and hypotheses on the circularity of left ventricular (LV) outflow tract and mitral annulus.[9] It is valid only in the absence of significant mitral regurgitation (MR), and it tends to give smaller estimations of valve area as compared with planimetry.[10]
- The proximal isovelocity surface area method is based on the hemispherical shape of the convergence of mitral flow as shown by color Doppler. This method can be used in the presence of significant MR. However, it is technically demanding and requires multiple measurements. The use of M-mode improves its accuracy, enabling simultaneous measurement of flow and velocity.[14]

**TABLE 21-1 Recommendations for Classification of Mitral Stenosis Severity**

| | Significant | | |
|---|---|---|---|
| | *Mild* | *Moderate* | *Severe* |
| **Specific Findings** | | | |
| Valve area ($cm^2$) | >1.5 | 1.0-1.5 | <1.0 |
| **Supportive Findings** | | | |
| Mean gradient (mm Hg)* | <5 | 5-10 | >10 |
| Systolic pulmonary artery pressure (mm Hg) | <30 | 30-50 | >50 |

Adapted from Baumgartner H, Hung J, Bermejo J, et al: Echocardiographic assessment of valve stenosis: EAE/ASE recommendations for clinical practice. *J Am Soc Echocardiogr* 22:1-23; quiz 101-102, 2009.

*At heart rates between 60 and 80 bpm and in sinus rhythm.

## ASSESSMENT OF CONSEQUENCES

Mean mitral gradient, as assessed by pulsed- or continuous-wave Doppler, gives information on the consequences of MS, because it is the main determinant of the increase of upstream pressures in left atrium (LA) and pulmonary circulation.

LA enlargement is due to chronic pressure overload. Time-motion measurement may be inaccurate because enlargement does not follow a spherical pattern in most cases. The assessment of LA volume using biplane area-length method should be preferred because it is more accurate and is strongly related to other markers of the thromboembolic risk.[15]

Systolic pulmonary artery pressure is estimated from the velocity of Doppler tricuspid flow. Diastolic and mean pulmonary artery pressures can be derived from pulmonary flow.

## ASSESSMENT OF VALVE ANATOMY

A detailed analysis of the different components of the mitral valve is necessary for diagnosis, but also contributes to the choice of the type of intervention (Fig. 21-1):

- Leaflet mobility is particularly well analyzed using the long-axis parasternal view.
- Leaflet thickening is considered significant if thickness if 5 mm or more.
- Leaflet calcification is suspected in the presence of increased echocardiographic brightness.
- The extent of commissural fusion is analyzed using the short-axis parasternal view.
- The impairment of subvalvular apparatus is analyzed from long-axis parasternal and apical views, which show thickening, fusion, or shortening of chordae.

The echocardiographic report should accurately describe the extent and location of each abnormality, with particular regard to commissural areas.

The definition of calcification using ultrasonographic criteria may be debated. Only acoustic shadowing is specific to calcification alone, whereas localized brightness can also be due to fibrosis. For this reason, certain teams require the confirmation of calcification using fluoroscopic examination.[16]

Different scoring systems combine the features of mitral valve anatomy. Their value and limitations in the prediction of the results of BMV and patient selection are addressed further.

## MITRAL REGURGITATION

The detection and quantitation of associated MR have important implications for the choice of intervention. Quantitative measurements should be combined and are preferred over methods using color flow mapping of the regurgitant jet in the LA.[17,18] The presence of MR does not alter the validity of the quantitation of MS, except in regard to the continuity equation.

## ASSOCIATED LESIONS

Dysfunction of the tricuspid valve is frequently associated with MS. It is most often functional tricuspid regurgitation, which is due to chronic increase in pulmonary artery pressure through right ventricular dilatation and lack of coaptation of tricuspid

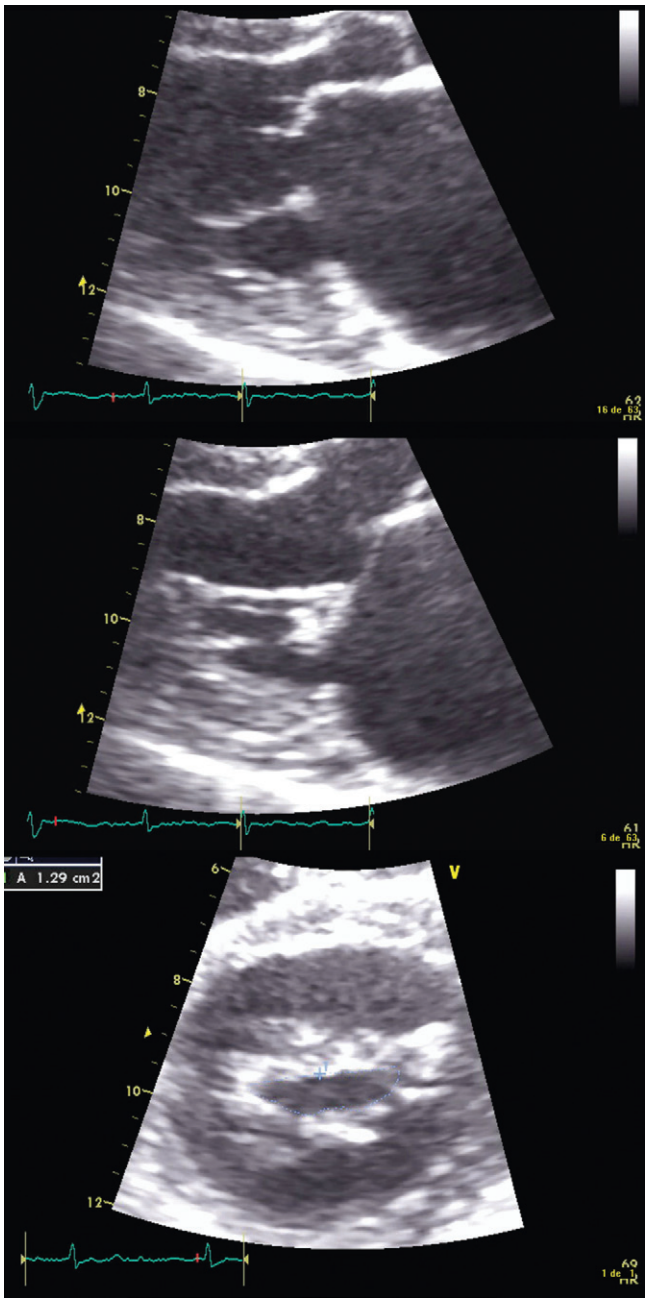

**Figure 21-1 Evaluation of valvular anatomy before balloon mitral valvotomy.** Favorable anatomic conditions. TTE. *Top:* Parasternal long-axis view showing pliable, noncalcified valve. *Middle:* Parasternal long-axis view showing moderate impairment of subvalvular apparatus. *Bottom:* Parasternal long-axis view showing moderate and homogeneous thickening of the leaflet tips and fusion of both commissures.

leaflets, despite normal valve anatomy. Whatever the method used, quantitation of tricuspid regurgitation is highly dependent on loading conditions.[17,18] This explains the current trend to rely more on the measurement of the tricuspid annulus than on the quantitation of regurgitation, particularly in regard to decision making for combining the correction of functional tricuspid regurgitation with left heart valve surgery.[19] However, the three-dimensional (3D) shape of the tricuspid annulus raises concerns regarding the reliability and reproducibility of the usual 2D measurements of the tricuspid annulus diameter.[20] Rheumatic tricuspid disease is far less frequent and is characterized by thickening and decreased mobility of tricuspid leaflets. Quantitation of tricuspid stenosis relies mainly on mean gradient.[9]

Associated rheumatic aortic valve disease is quantitated, if required, using standard techniques. Severe aortic stenosis may be associated with a low gradient because stroke volume is often decreased in MS. Thus, careful quantitation of the aortic valve area is needed, using the continuity equation and/or planimetry of the aortic valve with TTE or transesophageal echocardiography (TEE).[9]

LV enlargement and systolic dysfunction are unusual in MS, and the first reaction should be to search for an associated valvular regurgitation or coronary artery disease.

### THROMBOEMBOLIC COMPLICATIONS

The diagnosis of LA thrombosis relies on TEE, which has a much higher sensitivity than TTE, in particular for location in the left appendage. Echocardiography also plays an important role in risk stratification of thromboembolism. LA enlargement is a risk factor of thromboembolism. A LA volume greater than 60 mL/m$^2$ of body surface area is associated with the presence of surrogate markers of the thromboembolic risk.[15] LA spontaneous contrast is a strong predictor of thromboembolic risk in patients with MS.[21]

### USE OF THE DIFFERENT ECHOCARDIOGRAPHIC TECHNIQUES

A comprehensive evaluation of MS can be performed using TTE in most cases; TTE also plays an important role during the BMV procedure to monitor valve opening and to quantitate MR.

In the rare cases where TTE is of poor quality, TEE may be required. However, the main indication for TEE is the detection of LA thrombosis before BMV.

Other than for research purposes, the main indication for stress echocardiography is exercise echocardiography in asymptomatic patients.

## Technique, Quantitation, and Data Analysis

The respective parts of various features analyzed by echocardiography differ according to whether echocardiography is performed as an initial evaluation or to assess the results of an interventional procedure, immediately or during later follow-up.

### BEFORE BALLOON MITRAL VALVOTOMY

#### *Valve Function*

Moderate MS is defined by a valve area between 1.0 and 1.5 cm$^2$ and severe MS by a valve area less than 1.0 cm$^2$.[9] The threshold of 1.5 cm$^2$ is the most relevant in practice, because this is the value above which hemodynamics are not affected at rest,[22] and there is a consensus for considering intervention when mitral valve area is less than 1.5 cm$^2$.[23,24] It is advised to take the patient's body size into account. Although no value indexed on body surface area can be firmly established from the literature, it is generally admitted that MS is significant when index valve area is below 0.9 to 1.0 cm$^2$/m$^2$ body surface area.

The main pitfall when using planimetry is the overestimation of valve area because of inappropriate positioning of the measurement plane above the leaflet tips. The best way to avoid this

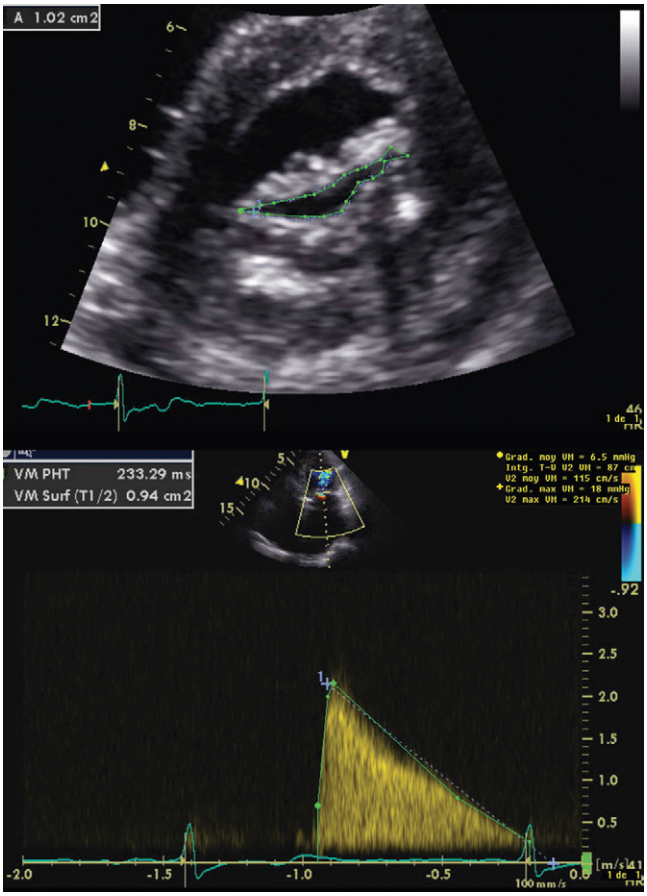

**Figure 21-2 Evaluation of mitral valve area before balloon mitral valvotomy.** Consistency between estimations using planimetry (valve area = 1.02 $cm^2$) (*Top:* TTE, parasternal short-axis view) and pressure half-time (*Bottom:* continuous-wave Doppler of the diastolic mitral flow, valve area = 0.94 $cm^2$). Mean gradient is 6.5 mm Hg.

is to scan slowly from the apex to the base and to select the narrowest orifice. Real-time 3D echocardiography is helpful to optimize the positioning of the measurement plan, which improves the accuracy of planimetry, in particular for less experienced echocardiographers.[25-27]

Technical difficulties inherent in planimetry justify the systematic use of the pressure half-time method, keeping in mind its limitations due to confounding factors. In our experience, its most important discrepancies with planimetry are observed in patients older than 60 and in those in atrial fibrillation, not only after but also before BMV.[28]

In current practice, 2D planimetry and the pressure half-time method are recommended in the standard evaluation of MS (Fig. 21-2). Other methods are used only if usual measurements are inconclusive or inconsistent with clinical data (Table 21-2).[9] The estimation of valve resistance is not considered as a relevant marker of stenosis severity.

### *Valve Anatomy*

Different approaches have been developed to combine the anatomic features of MS, aiming to predict the results of BMV and, therefore, to improve patient selection.

The most widely used scoring system is the Wilkins score, in which four components are graded from 1 to 4: leaflet mobility, thickness, calcification, and impairment of subvalvular apparatus (Table 21-3).[29] Another approach relies on a global assessment of mitral valve anatomy, with a classification into three groups according to the best surgical alternative: patients in group 1 are optimal candidates for closed-heart commissurotomy, patients in group 2 are more likely to be candidates for open-heart commissurotomy, and patients in group 3 are usually treated using prosthetic valve replacement (Table 21-4).[16,30] These two scores were developed at the beginning of the development of BMV.

A common limitation of these two scoring systems is the lack of information on the location of leaflet thickening and calcification, in particular in relation to the commissures, which may influence the results of BMV.[31-34] Another drawback of the current scoring systems is that the respective weights of each abnormality may be debated. In particular, the importance of subvalvular apparatus impairment is probably underestimated.[35]

At the present time, there are no large-scale comparative evaluations of the predictive value of different scoring systems, which could lead to recommending the use of a particular one. For the echocardiographer, the best solution is to use a method of analysis with which one is familiar and to include valve anatomy among other clinical and echocardiographic findings. The echocardiographic report should include a comprehensive description of mitral anatomy and not summarize it using a score alone.

### *Evaluation on Exercise*

Semisupine exercise echocardiography enables mitral gradient and systolic pulmonary artery pressure to be recorded for increasing levels of exercise. This approach is now favored over postexercise echocardiography, which is hampered by rapid changes in loading conditions and heart rate.[36,37]

Stroke volume and valve area are more difficult to obtain during exercise, and they are analyzed only for research purposes.

## DURING BALLOON MITRAL VALVOTOMY

Echocardiography also plays an important role in the catheterization laboratory, in particular with the Inoue technique (Fig. 21-3).[38,39] The main advantages of the Inoue balloon are its ease of use, partly related to self-positioning, and the possibility of performing stepwise inflations with a progressive increase in balloon diameter. TTE enables valve area, the degree of commissural opening, mean gradient, and MR to be assessed after each balloon inflation, leading to continued balloon inflation or stopping the procedure (Fig. 21-4). Planimetry should be used to monitor BMV, because the pressure half-time method is not reliable in this context and mean gradient is influenced by changes in loading conditions or heart rate.

Echocardiography is also helpful in the catheterization laboratory to promptly detect pericardial effusion, which is a rare but severe complication of transseptal catheterization.

In rare instances, TEE can be required during BMV, mainly to guide transseptal catheterization in difficult situations. Given the discomfort for the patient, the procedure is generally conducted under general anesthesia when TEE is used.

## EARLY AFTER BALLOON MITRAL VALVOTOMY

Even more than in other situations, planimetry using 2D echocardiography is the reference measurement of mitral valve area immediately after BMV. It enables the commissural opening to be visualized; valvular area tracing should include opened commissures (Fig. 21-5). The pressure half-time method is

**TABLE 21-2 Approaches to Evaluation of Mitral Stenosis**

| *Measurement* | *Units* | *Formula / Method* | *Concept* | *Advantages* | *Disadvantages* |
|---|---|---|---|---|---|
| **Valve area** | | | | | |
| Planimetry by 2D echocardiography | $cm^2$ | Tracing mitral orifice using 2D echocardiography | Direct measurement of anatomic MVA | Accuracy<br>Independence from other factors | Experience required<br>Not always feasible (poor acoustic window, severe valve calcification) |
| Pressure half-time | $cm^2$ | $220/T_{1/2}$ | Rate of decrease of transmitral flow is inversely proportional to MVA | Easy to obtain | Dependence on other factors (AR, LA compliance, LV diastolic function…) |
| Continuity equation | $cm^2$ | $MVA = CSA_{LVOT} \cdot VTI_{Aortic} / VTI_{Mitral}$ | Volume flows through mitral and aortic orifices are equal | Independence from flow conditions | Multiple measurements (sources of errors)<br>Not valid if significant AR or MR |
| PISA | $cm^2$ | $MVA = \pi r^2 \times (V_{aliasing} / \text{peak } V_{Mitral}) \times (\alpha/180°)$ | MVA assessed by dividing mitral volume flow by the maximum velocity of diastolic mitral flow | Independence from flow conditions | Technically difficult |
| **Mean gradient** | mm Hg | $\Delta P_{Mitral} = 4v^2_{Mitral}$ | Pressure gradient calculated from velocity using the Bernoulli equation | Easy to obtain | Dependent on heart rate and flow conditions |
| **Systolic pulmonary artery pressure** | mm Hg | $sPAP = 4v^2_{TR}$ + RA pressure | Addition of RA pressure and maximum gradient between RV and RA | Obtained in most patients with MS | Arbitrary estimation of RA pressure<br>No estimation of pulmonary vascular resistance |
| **Mean gradient and systolic pulmonary artery pressure at exercise** | mm Hg | $\Delta P_{Mitral} = 4v^2_{Mitral}$<br>$sPAP = 4v^2_{Tricuspid}$ + RA pressure | Assessment of gradient and sPAP for increasing workload | Incremental value in assessment of tolerance | Experience required<br>Lack of validation for decision-making |
| **Valve resistance** | dynes $s^{-1}.cm^{-5}$ | $MV_{res} = \Delta P_{Mitral} / (CSA_{LVOT} \cdot VTI_{Aortic} / DFT)$ | Resistance to flow caused by MS | Initially suggested to be less flow dependent, but not confirmed | No prognostic value<br>No clear threshold for severity<br>No additional value vs. valve area |

Level of recommendations: 1, appropriate in all patients (light green); 2, reasonable when additional information is needed in selected patients (green); 3, not recommended (dark green).

A predictive model on a series of 1514 patients. *Circulation* 94:2124-2130, 1996.

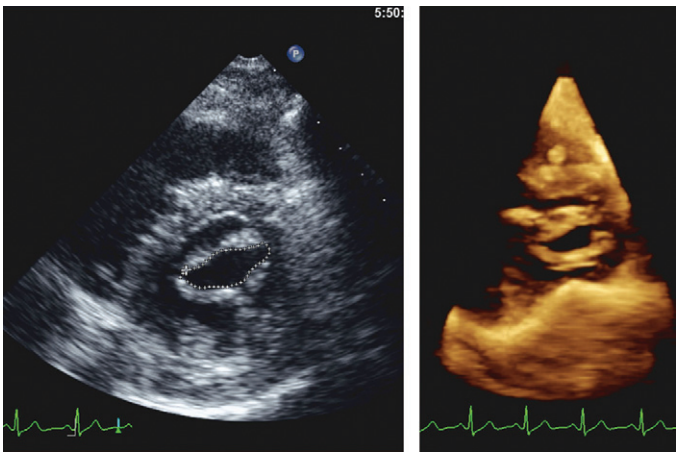

**Figure 21-5 Successful balloon mitral valvotomy (BMV) with bicommissural opening.** TTE, parasternal short-axis view. *Left:* After BMV (2D echocardiography). *Right:* After BMV (3D echocardiography).

inaccurate in this setting, the possible explanations being acute changes in cardiac chamber compliance or the presence of right-to-left shunt at the site of the transseptal puncture.[40] However, the pressure half-time method has a good specificity, although a low sensitivity, for identifying good valve opening, which may be helpful in technically difficult examinations.[28]

The echocardiographic assessment of the degree of opening of each commissure is strongly related to the quality of the immediate results of BMV and to late functional results.[41] The degree of commissural opening is thus an additional marker of the immediate results of BMV (Fig. 21-6). It is also useful as a baseline evaluation for the interpretation of echocardiographic follow-up. The assessment of the degree of commissural opening is improved by real-time 3D echocardiography.[26]

Although gradient is not a reliable marker of the severity of MS, it should be assessed after BMV because of its prognostic value on late functional results. In patients who had initial pulmonary hypertension, there is a frequent early decrease in pulmonary artery pressure, although it is generally more pronounced after several months.[42]

In most cases, there is little or no increase in MR after BMV. Moderate MR is often related to incomplete closure of free edges or commissures because of thickening and rigidity.[43] In these cases, color Doppler shows central and/or commissural small jets, and 2D echocardiography does not suggest traumatic lesion. If MR is severe (Fig. 21-7), its mechanism should be carefully assessed, using TEE if needed, looking at traumatic lesions. Traumatic MR is mainly caused by a noncommissural leaflet tear and is frequently associated with an absence of commissural opening, as shown by surgical or echocardiographic findings.[43,44] Lesions of the subvalvular apparatus are also frequent in traumatic MR, being mainly rupture of chordae, whereas partial or total papillary muscle rupture is rare (Fig. 21-8). These lesions cause particularly severe MR in patients with pliable leaflets.

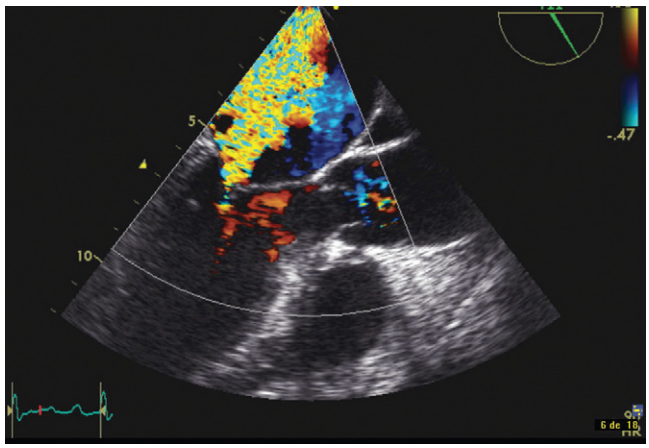

**Figure 21-7 TEE showing severe mitral regurgitation due to traumatic tear of the posterior leaflet.**

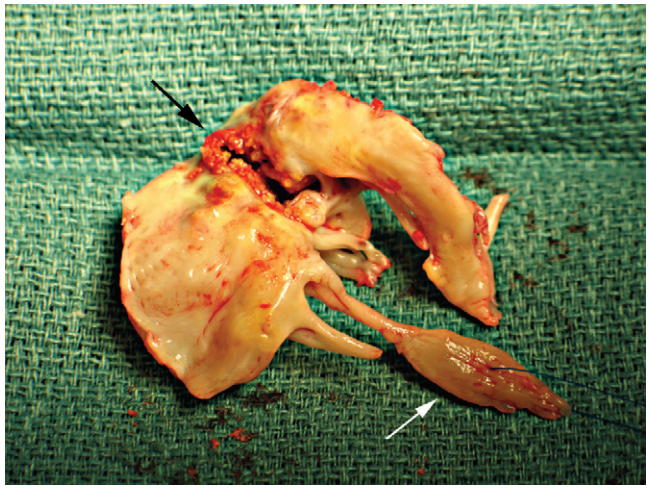

**Figure 21-8 Partial papillary muscle rupture** (*white arrow*) following balloon mitral valvotomy on a calcified mitral stenosis (calcification: *black arrow*).

Other findings from postprocedural echocardiography have less important consequences for patient management. Interatrial shunts can be visualized at the transseptal puncture site, in particular when using TEE. These are generally small shunts, which progressively disappear in the majority of cases.[45] The intensity of LA spontaneous contrast frequently decreases after successful BMV, and there is a further decrease until the sixth month.[46]

### DURING FOLLOW-UP

Echocardiographic follow-up assesses the usual features of valve function and its consequences.

The most frequent event is the occurrence of restenosis, which is generally defined as a valve area less than 1.5 $cm^2$ and greater than a 50% loss of the initial gain in valve area, although there is no standardized definition.[38,39,47] In patients with restenosis, the assessment of valve anatomy should pay particular attention to the degree of commissural fusion.

## Clinical Utility

Single- or multicenter series have analyzed immediate and late results of BMV and enable predictive factors to be identified, thereby contributing to an improvement in patient selection.

### RESULTS OF BALLOON MITRAL VALVOTOMY

#### *Failure and Complications*

The two main causes of failure are the impossibility of performing transseptal puncture or positioning the balloon across the mitral orifice. Failure rate is approximately 1% in series from experienced teams.[47-51] Higher rates were reported during early experience, which illustrates the importance of the learning curve.[30,52,53]

Severe complications are rare and, thus, need to be assessed using large series (Table 21-5).[47-52,54-59] In-hospital death occurs in less than 1% of patients, who are frequently in very poor clinical condition because of advanced age and/or severe hemodynamic impairment. Tamponade is a consequence of perforation by the transseptal needle or metallic guidewires. The risk of thromboembolic events is generally below 2%. Embolism leaving sequelae are mainly caused by fibrinothrombotic clots. They may occur despite systematic screening of LA thrombosis using TEE. Procedural complications are highly dependent on the experience of the interventional cardiologist, as shown by their relationship with the number of cases performed.[52] Technical simplifications inherent to the Inoue technique contribute to low complication rates, in particular tamponade, and partly account for the wide use of this technique.[22,60]

Severe traumatic MR is the most frequent severe complication of BMV, occurring in between 1% and 10% of cases. Attempts to identify predictive factors have not led to consistent results, which may be related to the small number of cases analyzed and differences in the methods used to define severe MR.[43,44,61-63] Severe MR is more frequent in patients with very tight MS and in those with severe impairment of leaflets and subvalvular apparatus, in particular when there is a heterogeneous distribution of leaflet abnormalities.[61] However, severe MR remains largely unpredictable in any given patient. Severe acute MR frequently requires surgery within weeks or months, but seldom in emergency.

#### *Immediate Results*

After BMV, there is approximately a doubling of mitral valve area in patients who underwent the different techniques (Table 21-6).[47-51,54-59,64-68] Series including heart catheterization demonstrated significant decreases in LA and pulmonary artery pressures and an increase in cardiac output. However, invasive investigations are now unlikely to be performed in routine assessment.

To simplify the interpretation and comparison of series, immediate results are also expressed following a binary endpoint, which is most often the association of final valve area 1.5 $cm^2$ or greater without MR greater than grade 2/4.

Mitral valve anatomy, as assessed by echocardiography whatever the scoring system used, is a strong predictor of immediate results of BMV.[30,49,54-58] The discriminant cutoff point of the Wilkins score has been set at 8 according to analyses

of immediate results of BMV. However, all scoring systems are of limited predictive value, as shown by the low correlation (r = –0.15) between the Wilkins score and final valve area (Fig. 21-9).[69] Large series including patients with diverse characteristics have shown that other factors strongly influence immediate results of BMV.[30,69-71] Older age and smaller valve area not only are significant predictors of poor immediate results, but have similar or greater predictive strengths for valve calcification.[30,71] There were less consistent associations between poor immediate results and previous commissurotomy or baseline MR, which may be related to a differential effect according to other characteristics, as shown by significant interactions. In our experience, the interaction between age and previous commissurotomy means that previous commissurotomy is a factor in poor immediate results only in patients aged over 50 years.[30]

Consistently with the predictors identified, series including a majority of young patients with favorable anatomic conditions report particularly good immediate results.[48-50,58]

### *Late Results*

The assessment of late outcome following BMV is based on clinical endpoints in most series, because standardized echocardiographic follow-up raises obvious difficulties when a number of patients are followed over a long time period.

Late results should be interpreted according to the quality of immediate results. The majority of patients with residual stenosis or severe MR after BMV require surgery, the timing of which depends largely on comorbidities and the policy of the medical team. Conversely, cardiovascular events seldom occur following successful BMV, and most patients experience sustained functional improvement (Fig. 21-10). Mitral restenosis is the most frequent cause of late clinical deterioration, as it was after successful surgical commissurotomy.[47,63,72-74]

Overall, late results of BMV are satisfying; however, there is a wide range in clinical outcome (Table 21-7).[49,54-56,58,63,75-79] Apparent discrepancies are related to differences in patient characteristics. Series from developing countries include a majority of young patients with favorable anatomic conditions and report higher rates of event-free survival than series from Western countries which include older patients with less favorable anatomic conditions. Series comprising a wide range of patient characteristics enable predictive factors of late results to be identified. As for the prediction of immediate results, valve anatomy is a strong predictive factor of late clinical outcome, but it is only one factor among others (Fig. 21-11).[47,49,54-56,58,63,75-79] Besides impaired anatomy, baseline predictors of poor late outcome are higher age and the consequences of MS, such as a high functional class and the presence of atrial fibrillation (Table 21-8). These predictors are consistent with previous experience with surgical commissurotomy.[74]

From Iung B, Garbarz E, Michaud P, et al: Late results of percutaneous mitral commissurotomy in a series of 1024 patients. *Circulation* 99:3272-3278, 1999.
*NYHA,* New York Heart Association.

Even in patients with good immediate results, the degree of valve opening has an impact on late outcome.[47,75,79] Besides postprocedural valve area, gradient is also a strong predictor of late clinical results, suggesting that it provides additional information.[75] The degree of commissural opening is strongly linked with postprocedural valve area and gradient but does not have an incremental prognostic value in multivariate analysis.[41] The persistence of a high gradient following BMV despite good valve opening can be related to limited valve reserve in relationship with a loss of pliability, which is likely to influence late restenosis.

Series including serial echocardiographic examinations showed a progressive decrease in mean mitral valve area over time, following a linear pattern.[47,72] The yearly decrease in valve area varies between series according to differences in patient characteristics, leading to inhomogeneous estimations of restenosis rates.[47,72] Conversely, there is generally no increase in mild-to-moderate MR.[47]

## *Particular Subgroups*

### Restenosis after Previous Commissurotomy

In patients with restenosis following prior closed- or open-heart commissurotomy, BMV is feasible and has the attraction of avoiding iterative surgery, providing restenosis is related to bicommissural fusion (Fig. 21-12).[80-82] Even if the results are less satisfying than in native valves, we reported a 48% rate of 8-year good functional results.[81] The possibility of deferring surgery by at least 8 years in half of the patients enables prosthesis-related complications to be postponed, because surgery consists of prosthetic valve replacement in most patients with restenosis. Young patients are likely to derive the greatest benefit from BMV for restenosis.[81]

Restenosis after previous BMV becomes more frequent. Repeat BMV can be performed in selected patients and gives

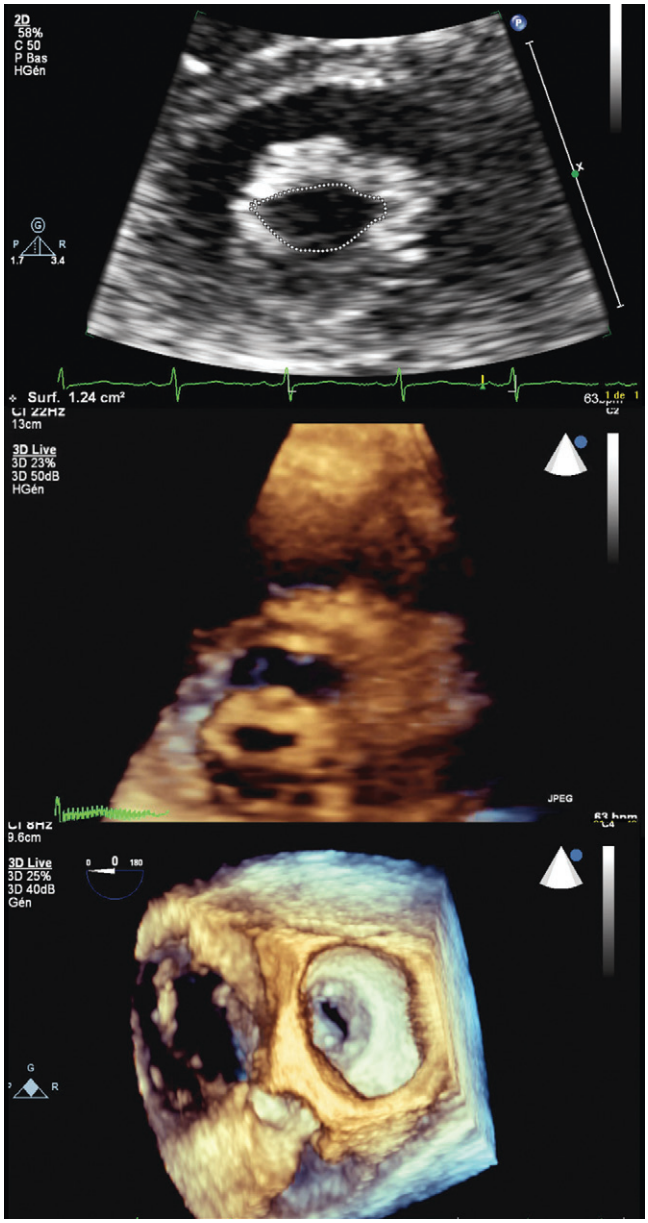

**Figure 21-12 Mitral restenosis after previous balloon mitral valvotomy, related to refusion of both commissures.** *Top:* TTE, parasternal short-axis, 2D echocardiography. *Middle:* TTE, parasternal short-axis, 3D echocardiography, view from the LV. *Bottom:* TEE, 3D echocardiography, view from the LA.

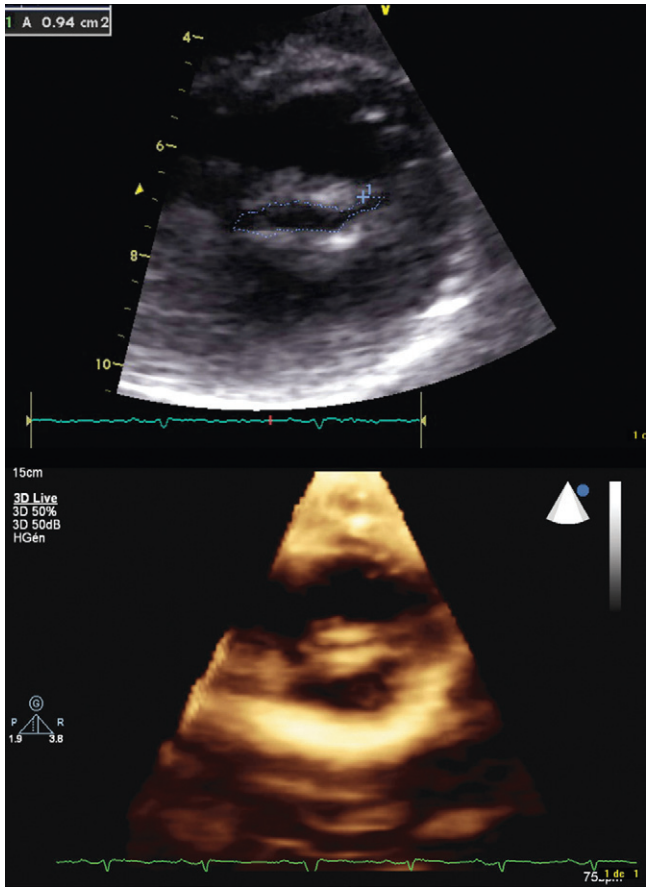

**Figure 21-13 Mitral restenosis after previous open-heart commissurotomy.** TTE, parasternal short-axis view. Both commissures are opened, and restenosis is due to rigidity of valvular and subvalvular apparatus. *Top:* 2D echocardiography. *Bottom:* 3D echocardiography, view from the LV.

good midterm clinical results, particularly in young patients with mild or no calcification,[82,83] whereas its efficacy is less convincing in older patients with calcified valves.[84-86]

Echocardiographic analysis of valve anatomy should carefully look at the extent of commissural refusion. Results of repeat BMV are less satisfying in patients who have incomplete commissural fusion.[85] Whatever the type of initial commissurotomy, BMV should not be considered in case of persistent opening of both commissures (Fig. 21-13).

## The Elderly

Theoretically, elderly patients are not good candidates for BMV because they combine predictive factors of poor immediate and late outcome, in particular, besides old age, frequent valve calcification, atrial fibrillation, and severe symptoms. Despite unfavorable anatomic conditions, good immediate results are frequently obtained, but subsequent deterioration occurs more rapidly than in younger patients.[87-89] However, these results should be weighed against the alternative of surgery, which is a high-risk option in this population. Even with unfavorable mitral anatomy, BMV can be considered as a palliative procedure in older patients with severely symptomatic MS.

Echocardiographic examination should pay particular attention to confirm the rheumatic etiology and distinguish it from degenerative MS. This disease is frequent in the elderly but seldom causes severe MS.[90] Degenerative MS is characterized by an extensive calcification of the mitral annulus, a stiffened anterior leaflet, and opened commissures (Fig. 21-14). Because there is no commissural fusion in these cases, degenerative MS is not amenable to BMV.

## Young Patients

Severe rheumatic MS may be encountered in young patients in countries where rheumatic fever is endemic. Two series have reported consistent results of BMV in patients aged below 20, who were followed up for 12 years.[91,92] Results tended to be better than in adults, and late functional results did not differ, with event-free survival rates ranging from 70% to 80% at 10 years. BMV is also a valid treatment of MS in children less than 12 years of age.[93]

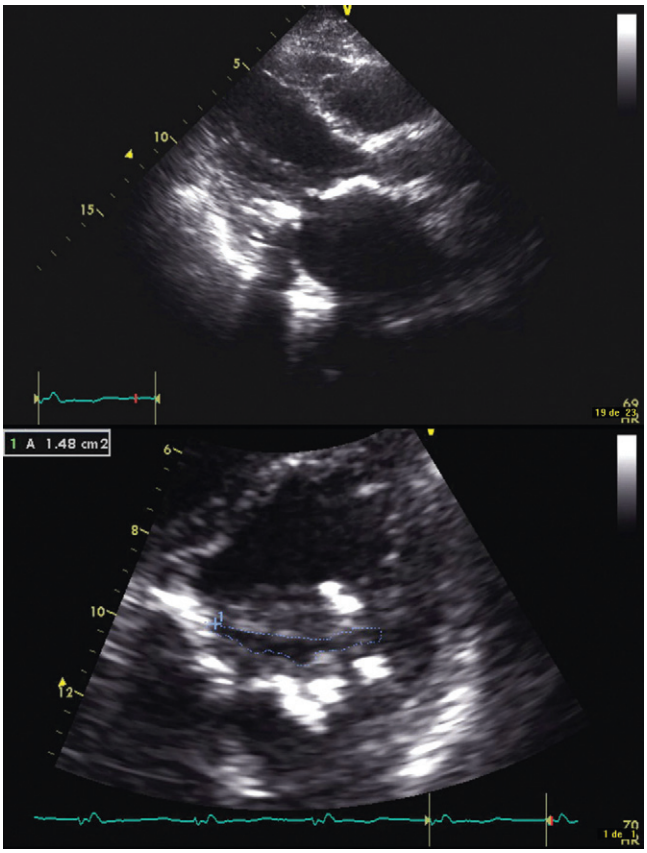

**Figure 21-14 Degenerative mitral stenosis.** Severe calcification of the posterior part of the mitral annulus, calcification of the external part anterior leaflet and absence of commissural fusion. *Top:* TEE, parasternal long-axis view. *Bottom:* Short-axis view.

### Pregnant Women

Hemodynamic changes during pregnancy worsen the clinical tolerance of MS, which may compromise the prognosis of both mother and fetus, in particular at delivery.[94] Therefore, intervention is required during pregnancy in women who remain symptomatic despite medical therapy. BMV can be safely performed during pregnancy, and fetal tolerance is good.[95,96] The increase of thromboembolic risk during pregnancy underscores the need for TEE, which is best performed under anesthesia just before the procedure to reduce the mother's discomfort.

## IMPLICATIONS FOR PATIENT SELECTION

### *Contraindications*

Contraindications to BMV are summarized in Box 21-1. Although cases of BMV using the Inoue balloon have been reported in patients with thrombosis located in the left appendage,[97] the experience remains limited. The potential hazards related to thrombus migration should lead to the consideration of persistent thrombus of LA, even when localized to the LA appendage, as a contraindication in most cases.[23,24] However, if the patient is in stable condition, the decision should be postponed until after repeat TEE following at least 2 months of optimal anticoagulant therapy. LA thrombosis has been shown to disappear in approximately 1 in 4 patients after 6 months of anticoagulant therapy, in particular when patients had a small thrombus and low grade LA spontaneous contrast.[98]

**Box 21-1**

**CONTRAINDICATIONS TO BALLOON MITRAL VALVOTOMY**

- Persistent LA thrombosis (including in the LA appendage)
- More than mild mitral regurgitation
- Massive or bicommissural calcification
- Severe concomitant aortic valve disease
- Severe organic tricuspid stenosis or severe functional regurgitation with enlarged annulus
- Severe concomitant coronary artery disease requiring bypass surgery

More than mild MR, or MR with a grade above 2/4 when using a semiquantitative approach, is a contraindication to BMV.[23,24] Although no study has validated thresholds based on quantitative echocardiography, this corresponds to an effective regurgitant orifice larger than 20 $mm^2$ and/or a regurgitant volume greater than 30 mL/beat. In patients who have borderline MR, BMV is more likely to be considered if valve anatomy is favorable.

Valve calcification contraindicates BMV in the rare cases where it is massive or localized in both commissures.[23,24]

Other contraindications are related to associated heart diseases needing surgical correction. Particular care should be taken to avoid underestimating the degree of aortic stenosis. Conversely, associated moderate aortic regurgitation without consequences on the LV does not contraindicate BMV, because its progression is slow.[99] Surgery is preferred if there is severe associated organic tricuspid disease or severe functional tricuspid regurgitation with major enlargement of the tricuspid annulus. In other cases, severe functional tricuspid regurgitation can decrease after BMV.[100]

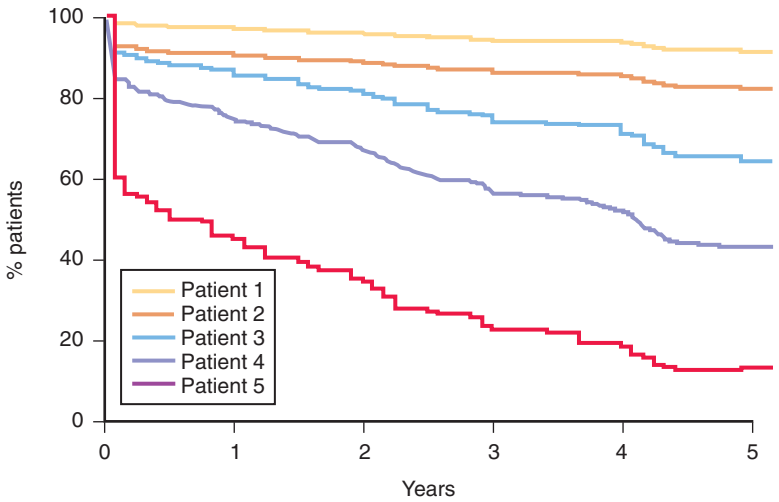
### *Choice of Procedure*

There is now evidence supporting BMV as the procedure of choice in young patients. Young age is frequently associated with favorable valve anatomy, both features being strong predictors of good immediate and late results.[89] Randomized trials conducted in these homogeneous populations showed that mid- and long-term results of BMV were as good as those obtained with open-heart commissurotomy and similar to or better than those with closed-heart commissurotomy.[101-104] Moreover, the possibility of performing conservative treatment that can be repeated in selected patients is particularly attractive in young patients, including children and adolescents, to avoid iterative surgical interventions. However, a number of good candidates for BMV cannot benefit from the procedure for financial reasons in developing countries, which cannot always afford the cost of the balloon. This justifies attempts to lower the cost of the device, such as the Multi-Track system and the metallic commissurotome.[64,65,67] The possibility of reusing the metallic part of the percutaneous commissurotome significantly lowers the cost of the procedure.

The decision is more difficult in older patients, who have frequent impairment of the anatomy of the leaflets and subvalvular apparatus, and who represent the majority of patients with MS in Western countries.[1,51,88] They form a heterogeneous group for whom no randomized studies are available and comparative studies do not enable all potential confounding factors to be taken into account.[105] Patients should not be denied BMV

on the sole basis of unfavorable valve anatomy, given the low predictive value of valve anatomy alone. Good immediate and midterm results can be obtained in patients with unfavorable mitral anatomy, even with calcified valves.[89,106-109] Patient selection should rely on a global assessment, which can be aided by the use of predictive analyses and derived multivariate models enabling the results of BMV to be estimated according to individual patient characteristics.[23,71,110]

In patients with impaired valve anatomy, BMV can be considered in particular when their other characteristics are favorable, in particular age below 70 years, mitral valve area between 1.0 and 1.5 $cm^2$, moderate symptoms (NYHA class II), and sinus rhythm. Predictive models show a high likelihood of good immediate and late results in these patients.[30,75,81] This enables surgery to be postponed for several years, thereby affecting prosthesis-related complications, because the surgical alternative in these patients is valve replacement in most cases. This is illustrated by the simulation of midterm results of BMV in patients with calcified mitral valves according to the extent of calcification and other characteristics (Fig. 21-15).[109] Conversely, there is a much lower likelihood of sustained long-term improvement in old patients who have unfavorable mitral anatomy, tight stenosis, severe symptoms, and atrial fibrillation.[56,75] Moreover, the relevance of deferring surgery may be debatable in this age group. Thus, mitral surgery, often combined with tricuspid repair, can be considered as the first-line treatment provided the operative risk is acceptable. The choice between BMV and surgery in these difficult situations should also take into account the local expertise of interventional cardiologists and surgeons as well as the wishes of the patient.



In Western countries, there is a trend for BMV to be performed in older patients with more severe impairment of valve anatomy.[51] In the Euro Heart Survey, surgical commissurotomy accounted for only 4% of the interventions performed for MS in 2001, whereas BMV was used in 34% of patients and prosthetic valve replacement in 62%.[1]

### *Timing of Procedure*

There is a consensus to advise intervention, whether it is percutaneous or surgical, in patients who have significant, that is, moderate or severe MS (valve area less than 1.5 $cm^2$) and symptoms.[23,24] Better insights into the prognosis of MS, with particular regard to the risk of thromboembolic complications or hemodynamic decompensation, and the availability of intervention at low risk have led to consideration of the indications for BMV at an earlier stage in selected patients. Intervention is generally not considered in mild MS because the variability of the progression does not support prophylactic BMV.[23,24,111] However, BMV can be considered in patients with borderline valve area in the presence of symptoms or pulmonary hypertension.[24]

The efficacy of BMV has been demonstrated on various markers of the thromboembolic risk in MS: LA spontaneous contrast, LA size and contractility, LA appendage flow velocity, and activation of coagulation in the LA.[46,112-114] Although the efficacy of BMV on the thromboembolic risk has not been demonstrated by randomized studies, a retrospective and prospective series showed that the performance of BMV was strongly associated with a decreased thromboembolic risk in patients with MS and atrial fibrillation.[115,116]

It is more difficult to evaluate the risk of acute hemodynamic complications in MS, apart from particular cases such as pregnancy. Exercise echocardiography is of potential interest because it provides additional information as compared with baseline evaluation. ACC/AHA guidelines recommend BMV, when anatomic conditions are favorable and systolic pulmonary artery pressure is greater than 60 mm Hg at peak exercise.[24] However, such thresholds are debatable because they can be reached in patients without heart disease, and their prognostic value in MS has not been validated in large series.[117,118] In addition, this is the reason why no particular recommendation is given in the ESC guidelines regarding the evolution of systolic pulmonary pressure at exercise.[23]

| Patient | Age (years) | NYHA class | Rhythm | Calcification | Valve area ($cm^2$) |
|---|---|---|---|---|---|
| 1 | <50 | II | Sinus | 1 | 1.25-1.5 |
| 2 | <50 | II | Sinus | 2 | 1-1.25 |
| 3 | 50-70 | III | Sinus | 2 | 1.25-1.5 |
| 4 | 50-70 | III | A. fib | 2 | 1.25-1.5 |
| 5 | ≥70 | III | A. fib | 3 | 0.75-1 |

**Figure 21-15 Long-term predicted outcome based on baseline clinical factors and procedural success.** Predicted probability of good immediate results (valve area ≥ 1.5 $cm^2$ without regurgitation > grade 2/4) and good late functional results (survival with no intervention and in NYHA functional class I or II) after balloon mitral valvotomy in calcified mitral stenosis, according to patient characteristics. The extent of calcification is graded from 1 (small nodule) to 4 (extensive calcification). *(From Iung B, Garbarz E, Doutrelant L, et al: Late results of percutaneous mitral commissurotomy for calcific mitral stenosis.* Am J Cardiol *85:1308-1314, 2000.)*

Recommendations on BMV according to current guidelines are summarized in Table 21-9.

## Research Applications

### STRESS ECHOCARDIOGRAPHY

Changes in the severity of MS and its consequences can be observed according to changes in hemodynamic conditions, as shown by exercise or pharmacologic stress combined with invasive measurements. They have been replaced by stress echocardiography, which has the advantage of allowing for repeated noninvasive measurements.

Exercise echocardiography is the most physiologic approach. Different series consistently showed an increase in mean gradient and systolic pulmonary artery pressure at submaximal effort or peak effort.[119-121] However, there is an important heterogeneity in the progression of mitral gradient and systolic pulmonary artery pressure on exercise, as well as stroke volume, which does not relate to baseline severity of MS.[119-121] A possible explanation comes from differences in the evolution of mitral valve area, as assessed by the continuity equation, and stroke volume. The increase in valve area on exercise is associated with an increase in stroke volume. Conversely, stroke volume does not increase when there is no significant change in valve area during exercise.[121,122] These two different patterns are not related to differences in baseline severity of MS, but to the impairment of valve anatomy.[122] A study[121] using exercise echocardiography to evaluate atrioventricular compliance demonstrated that systolic pulmonary artery pressure at rest, and even more so on exercise, was strongly correlated with atrioventricular compliance, but not with mitral valve area. Finally, the level of increase in systolic pulmonary artery pressure on exercise seems to be related to the type of limiting symptoms, whether they are dyspnea or fatigue.[120]

Most previous studies used treadmills and were based on postexercise data. Semisupine bicycle ergometry now enables hemodynamic changes to be assessed for each workload. Our experience suggests that the type of limiting symptom (dyspnea or fatigue) is more related to the pattern of increase of mitral gradient than to the level of mean gradient or systolic pulmonary artery pressure at peak exercise.[123]

Dobutamine stress echocardiography (DSE) is a less physiologic approach than exercise echocardiography in MS, but it is also associated with significant increases in mean gradient and systolic pulmonary artery pressure, as compared with resting values.[124] The only study thus far that has analyzed the relationship between findings from stress echocardiography and clinical outcome was based on DSE.[125] This study showed that mean mitral gradient during DSE was an independent predictor of clinical events during a 5-year follow-up, the cutoff value being 18 mm Hg. The incremental prognostic was particularly marked in patients who had a valve area between 1.0 and 1.5 $cm^2$.[125] Another study[126] using DSE showed a more important valve reserve, that is, a more important increase in valve area, in patients who had had previous commissurotomy as compared with those who had native MS.

Stress echocardiography is useful to refine the knowledge of the hemodynamic consequences of MS. However, at the present time, its implications for decision making need to be assessed by further prospective studies. This is particularly needed to validate thresholds of gradient and pulmonary artery pressure leading to the consideration of intervention in asymptomatic patients with MS in guidelines.

*See Table 21-1.

†Favorable characteristics for percutaneous mitral commissurotomy can be defined by the absence of several of the following: clinical characteristics—old age, history of commissurotomy, NYHA class IV, atrial fibrillation, severe pulmonary hypertension; anatomic characteristics—echocardiographic score ≥8, Cormier score 3 (calcification of mitral valve of any extent, as assessed by fluoroscopy), very small mitral valve area, severe tricuspid regurgitation.

### EVALUATION OF VALVE ANATOMY

Given the limitations of commonly used scoring systems for the prediction of the results of BMV, alternative approaches have been developed, in particular taking into account the location of valve abnormalities in relation to the commissures. Series have shown that commissural location of valve thickening and calcification influences immediate results of BMV.[31-33] However, no scoring system including these findings has been validated on large series in comparison with commonly used scoring systems. Another scoring system has been developed to predict the occurrence of severe MR, which is the most frequent complication following BMV.[61,62] It has the advantage of taking into account the heterogeneity of leaflet impairment and the presence of commissural fibrosis or calcification (Table 21-10). Nevertheless, its predictive value for immediate valve opening and late functional results has not been studied, and its usefulness in the prediction of severe MR has not been confirmed in large series.

Besides the location of valvular abnormalities, mechanical properties of valvular tissue probably influence immediate and late results of BMV. Resting atrioventricular compliance is closely related to upstream pressures; however, its impact on late outcome is not known.[127,128]

Thus, there are various approaches to refining the assessment of valve anatomy, combining more detailed scoring systems and evaluations of valvular mechanical properties. However, more complex analyses raise concerns regarding their applicability in current practice and their reproducibility. Moreover, it will be necessary to demonstrate their incremental predictive value on outcome, as compared with current validated multifactorial approaches.

## Potential Limitations, Future Directions

Despite technical refinements, there remain limitations in the feasibility or the relevance of certain echocardiographic analyses in MS.

Although planimetry is the reference measurement, it may not be feasible in patients with poor echocardiographic windows and/or in case of severe valve deformity, even with experienced operators. Other methods of measurement should be used, and their interpretation should take their own limitations into account.[129]

Doppler enables pulmonary artery pressure to be assessed in most patients. However, it is not possible to reliably assess capillary wedge pressure, and thus pulmonary vascular resistance, using ultrasonographic techniques. Pulmonary hypertension is passive in most patients, due to an increase in LA pressure with normal pulmonary vascular resistance. However, in certain patients, who frequently have long-standing disease, pulmonary vascular resistance is increased because of pulmonary vascular disease. The risk of surgery is higher in these patients, and BMV should be favored when feasible, because it provides functional improvement and progressive improvement in hemodynamics.[42,130] Estimation of pulmonary vascular resistance, using cardiac catheterization, is useful in patients who present with severe pulmonary hypertension seeming out of proportion with the degree of MS or pulmonary congestion as assessed by chest radiograph.

The limitations of anatomic scoring systems for the prediction of immediate and late results of BMV were reviewed earlier. Given the multiple determinants of the results of BMV, there is a low likelihood that any echocardiographic scoring system will ensure an optimal prediction of the results of BMV. A combined assessment using multislice computed tomography to quantitate valve calcification might be an interesting approach.

Future improvements in patient selection will probably come from the incorporation of improved anatomic evaluation using echocardiography and other imaging techniques, as well as other variables, such as stress hemodynamics indices, in multivariate models, rather than the optimization of a single scoring system.

## Alternative Approaches

Right and left heart cardiac catheterization enables valve area to be evaluated using the Gorlin formula. The Gorlin formula is sometimes considered as the reference method; however, this is mainly for historical reasons. Experimental as well as clinical data raise concerns regarding the validity of the Gorlin formula in cases of low output and immediately after BMV.[131,132] This explains why guidelines advise limiting invasive evaluation of the severity of MS to the rare situations where echocardiography is inconclusive or when there are discrepancies between different measurements and clinical evaluation.[23,24] Right heart catheterization is indicated in cases of suspected vascular pulmonary hypertension. In current practice, the main indication

**TABLE 21-10 Echocardiographic Score Proposed by Padial and Colleagues for the Prediction of Severe Mitral Regurgitation**

| *Grade* | *Anterior Leaflet* | *Posterior Leaflet* | *Commissural Calcification* | *Subvalvular Disease* |
|---|---|---|---|---|
| 1 | Leaflet near normal (4-5 mm) or with only a thick segment | Leaflet near normal (4-5 mm) or with only a thick segment | Fibrosis and/or calcium in only one commissure | Minimal thickening of chordal structures just below the valve |
| 2 | Leaflet fibrotic and/or calcified evenly; no thin area | Leaflet fibrotic and/or calcified evenly; no thin area | Both commissures mildly affected | Thickening of chordae extending up to one third of chordal length |
| 3 | Leaflet fibrotic and/or calcified with uneven distribution; thinner segments are mildly thickened (5-8 mm) | Leaflet fibrotic and/or calcified with uneven distribution; thinner segments are mildly thickened (5-8 mm) | Calcium in both commissures, one markedly affected | Thickening to the distal third of the chordae |
| 4 | Leaflet fibrotic and/or calcified with uneven distribution; thinner segments are near normal (4-5 mm) | Leaflet fibrotic and/or calcified with uneven distribution; thinner segments are near normal (4-5 mm) | Calcium in both commissures, both markedly affected | Extensive thickening and shortening of all chordae extending down the papillary muscle. |

The total score is the sum of the four items and ranges between 4 and 16.

From Padial LR, Freitas N, Sagie A, et al: Echocardiography can predict which patients will develop severe mitral regurgitation after percutaneous mitral valvulotomy. *J Am Coll Cardiol* 27:1225-1231, 1996.

for invasive investigations is the assessment of associated coronary disease using coronary angiography.[23,24] However, cardiac catheterization is still frequently performed, in particular as a systematic evaluation associated with coronary angiography, although this is not supported by guidelines.[1]

Magnetic resonance imaging and computed tomography are valid alternative noninvasive methods used to perform planimetry of the mitral valve. These methods could be useful when planimetry using 2D echocardiography is not feasible or not reliable.[133,134] Mitral gradient may also be assessed using velocity-encoded phase-contrast cine magnetic resonance imaging, but the reliability of this estimation is not certain.[135]

Experience with intracardiac echocardiography is limited (see Chapter 6). It is helpful to rule out LA thrombosis or to monitor transseptal puncture in difficult cases, thereby avoiding the use of TEE under general anaesthesia.[136,137] However, the high cost of the single-use device limits its use.

In conclusion, experience acquired with BMV for more than 20 years has confirmed its efficacy not only in young patients with favorable valve anatomy, but also in less optimal candidates. The prediction of the results of BMV is intrinsically multifactorial, which underscores the need for a complete assessment combining clinical and echocardiographic findings. Continuing evaluation of the results of BMV in large series or in selected subgroups is needed to improve decision making for the choice of the most appropriate procedure as well as its timing at different stages of the disease.

## KEY POINTS

- Planimetry using 2D echocardiography is the reference measurement for valve area and can be guided by 3D echocardiography.
- The use of cardiac catheterization should be limited to situations where noninvasive measurements are inconsistent or discordant with clinical findings.
- Patient selection should not overstress the assessment of valve anatomy, but it should take into account a number of clinical and echocardiographic variables, the predictive value of which has been validated in large series.
- BMV should be considered in patients who have MS with unfavorable anatomy, provided their other characteristics, in particular age, are favorable.
- Severe MR is the most frequent complication of BMV. It is difficult to predict in a given patient.
- The most frequent cause of late functional deterioration after BMV is mitral restenosis, the occurrence of which follows an approximately linear pattern.
- Exercise echocardiography is a promising method to refine indications for intervention in asymptomatic patients. However, there is still a need for validation through prognostic studies.
- BMV and surgery should not be considered as concurrent, but complementary techniques, which should be used at different times of the evolution of MS.

# Clinical Decision Making in Patients with Infective Endocarditis: The Role of Echocardiography

ZAINAB SAMAD, MD | ANDREW WANG, MD

Background
Basic Principles and Echocardiographic Approach
Technical Details, Quantitation and Data Analysis
Clinical Utility and Outcome Data
Utility in Diagnosis
Utility in Management
Utility in Follow-up
Research Applications
Potential Limitations and Future Directions
Alternative Approaches

## Background

Infective endocarditis (IE), a noncontagious infection of the endocardium and heart valves, has an incidence ranging from 2.6 to 11.6 per million[1,2] and a high in-hospital mortality rate of approximately 20% despite medical and surgical advances. The contemporary epidemiology of IE has changed significantly compared to earlier eras, and these changes have an important influence on the evaluation and outcome of this condition. In the large, prospective, multinational International Collaboration on Endocarditis (ICE) registry, the mean age of diagnosis of definite IE is the sixth decade, with approximately 2:1 male predominance and frequently occurring in the presence of comorbid conditions such as kidney disease and diabetes mellitus.[3] The major predisposition to IE is underlying degenerative valvular disease (particularly mitral valve disease), present in approximately 30% of cases, but a very low prevalence of underlying rheumatic heart disease.[3] The microbiology of the condition has shifted toward more virulent organisms, particularly *Staphylococcus aureus* as the most common cause, reflecting the growing influence of health care–associated infection as a cause of bacteremia.

The diagnosis and management of this condition has greatly improved with the advent of echocardiography. The first use of echocardiography in the diagnosis of IE was described in 1973 by Dillon and colleagues,[4] who applied M-mode echo to visualize evidence of vegetations. The high-frequency oscillations of vegetative lesions and/or destruction of aortic or mitral leaflet integrity could be documented using this technique (Fig. 22-1). M-mode, however, did not allow estimation of lesion size, morphology, and localization of specific leaflet involvement, which was provided by real-time, two-dimensional (2D) echocardiography first described by Gilbert and colleagues.[5] Over time, with the widespread use of 2D echocardiography and the improved spatial resolution offered by transesophageal echocardiographic (TEE) approaches,[6] echocardiography has become the diagnostic modality of choice in all cases of suspected IE. Echocardiography not only provides noninvasive evidence of endocardial infection but also offers important hemodynamic information regarding the presence and severity of valvular regurgitation and other structural complications, findings key to the management decision-making process in these patients. For these reasons, echocardiography is considered essential in all cases suspected of IE.[7]

## Basic Principles and Echocardiographic Approach

Clinical characteristics may identify the host at risk for IE and guide the use of echocardiography for diagnostic confirmation. IE is associated with fever in more than 90% of cases, and a similar percentage will have positive blood cultures for a microorganism associated with this condition.[3] Most patients present with symptom duration of less than 1 month.[3] Approximately half of patients will have evidence of a new or changing heart murmur reflecting valvular regurgitation or other endocardial damage, but a very small percentage will have peripheral manifestations of classical, subacute IE (Osler nodes, Janeway lesions, splinter hemorrhages, Roth spots).[3]

Historically, the association between infective lesions on the endocardium and the clinical manifestations of IE has been recognized for over a century. However, the clinical manifestations of the disease remained nonspecific and challenged accurate clinical diagnosis of the disease antemortem.[8] In 1977, Pelletier and Petersdorf[9] proposed case definitions for IE that relied mainly on clinical characteristics and, specifically, on the demonstration of continuous bacteremia. Although a first step in standardization of the diagnosis of IE, these criteria were highly specific but lacked sensitivity. In 1981, Von Reyn and colleagues[10] expanded on these clinical criteria and offered levels of diagnostic certainty (rejected, possible, probable, and definite) for suspected IE. These modifications improved sensitivity and specificity, but did not incorporate evidence of endocardial involvement by the relatively novel application of echocardiography at the time. Subsequently, in 1994, the Duke Criteria proposed by Durack and colleagues[11] incorporated visualization of endocardial involvement by echocardiography

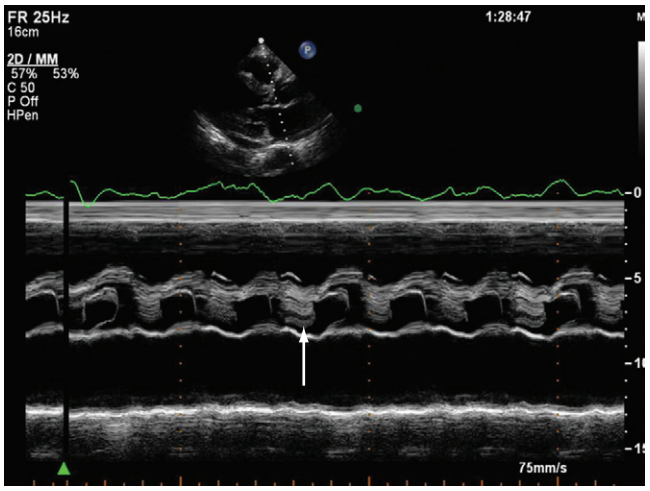

**Figure 22-1 M-mode echocardiogram recorded in a patient with aortic valve endocarditis.** Note mass of shaggy echoes (vegetation) in diastole.

with microbiologic and clinical criteria for the first time. Indeed, evidence of endocardial involvement, including new valvular regurgitation, intracardiac vegetation, paraannular abscess, or new dehiscence of prosthetic valve, became one of the two major diagnostic criteria for IE by the Duke case definition, along with microbiologic criteria.

Several comparative studies of the Von Reyn and Duke Criteria in various cohorts have subsequently established the superior sensitivity of the Duke criteria compared to earlier case definitions.[12-19] The negative predictive value of these criteria was more than 92% with a high sensitivity (100%) and specificity (88%).[20,21] Recent modifications of the Duke criteria (Box 22-1) have added greater specificity to the schema.[22]

## Technical Details, Quantitation, Data Analysis

Echocardiographic features of IE include vegetations, abscess, aneurysm, fistula, leaflet perforation, and valvular dehiscence (Table 22-1).[23] *Vegetations* occur at a region of endocardial denudation, often resulting from preexisting valvular disease (Figs. 22-2, 22-3, and 22-4). Disruption of the endocardial

**Box 22-1**

### THE MODIFIED DUKE CRITERIA AND CASE DEFINITIONS OF INFECTIVE ENDOCARDITIS

#### Modified Duke Criteria

**Major Criteria**

***Blood Culture Positive for Infective Endocarditis (IE)***

Typical microbes consistent with IE from 2 separate blood cultures: viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; community-acquired enterococci in absence of another focus; or

Microorganisms consistent with IE from persistently positive blood cultures defined as follows: at least 2 blood cultures drawn >12 hr apart or all of 3 or majority of >4 separate blood cultures

Single positive blood culture for *Coxiella burnetii* or antiphase IgG antibody titer >1:800

***Evidence of Endocardial Involvement***

Echocardiography positive for IE defined as follows:

Oscillating intracardiac mass on valve or supporting structure

Abscess

New partial dehiscence of prosthetic valve

New valvular regurgitation

***Minor Criteria***

Predisposition; predisposing heart condition or injection drug use

Fever, temperature >38°C

Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, rheumatoid factor

Microbiologic evidence: positive blood cultures but does not meet a major criterion as noted above, or serologic evidence of active infection with organism consistent with causing IE

#### Case Definitions

**Definitive Infective Endocarditis**

***Pathologic Criteria***

1. Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized or an intracardiac abscess specimen; or
2. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis

***Clinical Criteria***

1. 2 major criteria; or
2. 1 major and 3 minor criteria; or
3. 5 minor criteria

***Possible Infective Endocarditis***

1. 1 major criterion and 1 minor criterion; or
2. 3 minor criteria

***Rejected***

1. Firm alternate diagnosis explaining evidence of infective endocarditis; or
2. Resolution of infective endocarditis syndrome with antibiotic therapy for ≤4 days; or
3. No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for <4 days; or
4. Does not meet criteria for possible infective endocarditis, as above

**TABLE 22-1 Pathologic Features of Infective Endocarditis: Echocardiographic Appearance and Clinical Significance**

| *Echocardiographic Finding* | *Pathology* | *Echocardiographic Appearance and Measurements* | *Pitfalls* | *Clinical Significance* |
|---|---|---|---|---|
| Vegetation | Collection of microorganisms embedded with platelets, fibrin and other inflammatory cellular material adherent to an endothelial surface within the heart | Irregularly shaped, discrete echogenic mass<br>Adherent to, yet distinct from cardiac surface<br>Oscillation of mass supportive, not mandatory<br>Measure maximum size | False (−):<br>Small size; sessile, not oscillating; degenerated valve; inappropriate gain setting<br>False (+):<br>Post-surgical changes; valve calcification; Libman-Sacks; Lambl's excrescence; thrombus; tumor | Size and location associated with embolic risk<br>Large size may suggest lower likelihood of cure with antibiotics alone |
| Abscess | A cavity with purulent exudates formed by liquefactive necrosis | Thickened area or mass within the myocardium or annular region<br>Appearance is nonhomogeneous with both echogenic and echolucent characteristics | False (−):<br>Absence of flow; early in abscess formation; gain settings; posterior mitral valve annulus when calcification present<br>False (+):<br>Postsurgical change after valve replacement, including paravalvular regurgitation; gain settings | May be associated with new conduction abnormality<br>Indication for surgery |
| Fistula | Abnormal connection between two distinct cardiac blood spaces through a nonanatomic channel | Left-to-right shunt visible on color Doppler imaging<br>Recorded loops should contain sweeps of the region of interest<br>Continuous-wave Doppler to show high-velocity jet across defect | False (−):<br>Small defect; masking by valvular regurgitation or flow turbulence<br>False (+):<br>Valvular regurgitation or other turbulent flow; no confirmation by high Doppler jet velocity across defect | Heart failure due to left-to-right shunting<br>Indication for surgery |
| Leaflet perforation | Defect in body of a valve leaflet with evidence of flow through defect | Color Doppler to document regurgitant flow through perforation<br>Multiple views to differentiate perforation from leaflet regurgitation<br>3DE may help locate precise location preoperatively<br>Quantify regurgitation | False (−):<br>High gain setting; small defect; regurgitant jet masks flow through perforation<br>False (+):<br>Echo dropout; commissure or cleft | Increases severity of regurgitation and possibility of heart failure |
| Prosthetic valve dehiscence | Rocking motion of prosthetic valve with excursion >15° in at least one direction | Regurgitant jets visible by color Doppler imaging<br>Quantify regurgitation | False (−):<br>No paravalvular regurgitation visualized<br>False (+):<br>Normal annulus motion during cardiac cycle | Paravalvular regurgitation may result in heart failure, hemolysis<br>Urgent indication for surgery |
| Cardiac implantable electronic device infection | Mobile mass seen on intracardiac device (lead) in setting of fever, bacteremia, and/or embolic events | Vegetation seen adherent to device lead<br>Careful search for vegetations throughout intracardiac course of device<br>Evaluate for concomitant valve infection | False (−):<br>Vegetation on extracardiac region of device<br>False (+):<br>Thrombus | Generally treated with device extraction and antibiotic therapy |

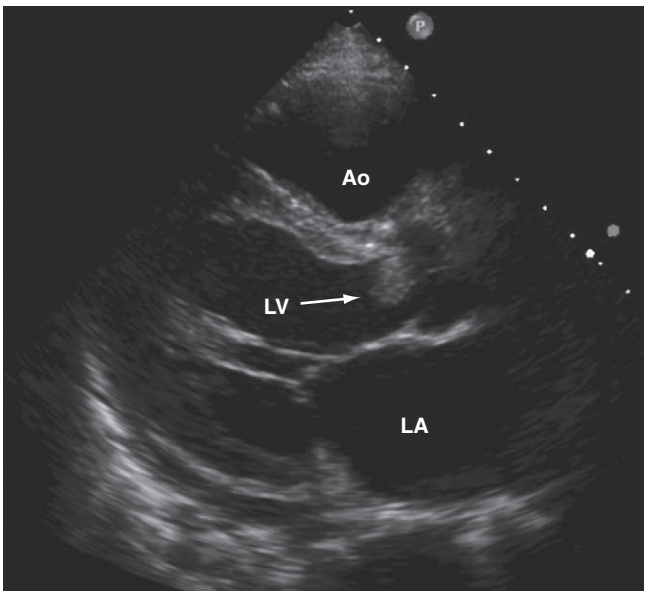

**Figure 22-2 2D TTE parasternal long-axis view recorded in a patient with aortic valve endocarditis.** *Arrow* points to a heterogeneous irregularly shaped mass attached to aortic valve leaflet prolapsing into the LV outflow tract. *Ao*, Aorta.

surface results in platelet adhesion and fibrin deposition, to which microorganisms adhere during transient bacteremia to form infected vegetation. Vegetations are visualized in nearly 90% of patients with definite IE.[3] By echocardiography, vegetations appear as irregularly shaped, discrete, oscillating, echogenic masses that are adherent to valves, chordate, or other endocardial surfaces in the path of turbulent jets passing through regurgitant valves or septal defects. They are typically located on the low-pressure side of high-velocity jets; hence, in cases of regurgitation, they are located on the atrial aspect of the mitral and tricuspid valves and on the ventricular aspect of the aortic and pulmonic valves. They often display the same echogenicity as midmyocardial structures and may be heterogenous with echodense or echolucent areas. Vegetations may also be found on noncardiac structures such as intracardiac devices. In the presence of vegetation, *perforation* of a valve leaflet may be visualized as a defect in the body of a valve leaflet with evidence of flow through the defect (Fig. 22-5).

Machine settings such as frame rate, sector arc size, gray scale, and focal zones must be optimized, and a careful examination including nonstandard views should be conducted to exclude the presence of vegetations. Increased gain settings and improper focal zones can make vegetations appear larger than actual size. On the other hand, color flow imaging may change pulse

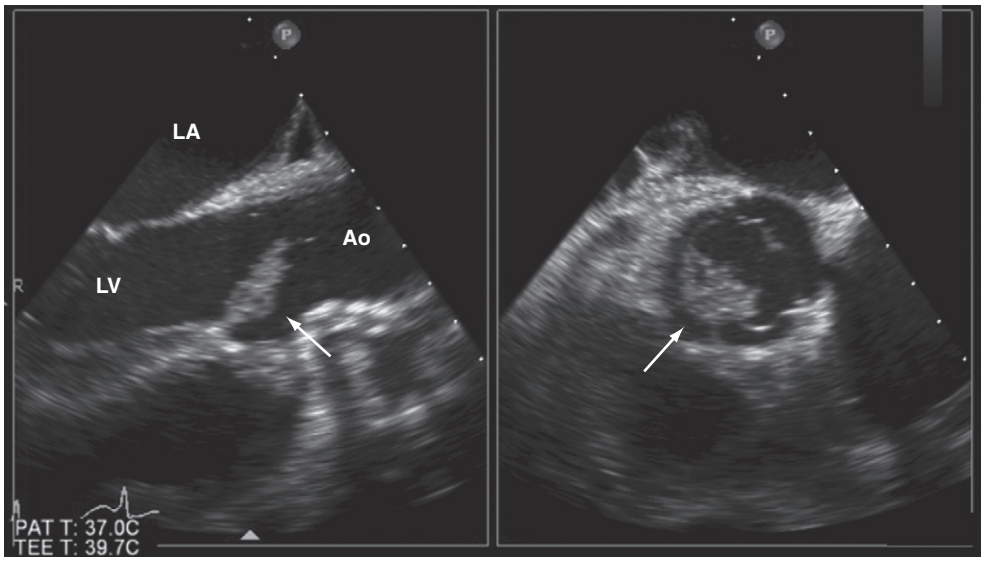

**Figure 22-3 TEE views of an aortic valve vegetation.** The 2D images show a heterogeneous mass, in the long-axis (*left*) and short-axis (*right*) views. Attachment of vegetation to the right coronary cusp is evident (*arrows*). *Ao*, Aorta.

repetition frequency and impair visualization of the vegetation. The size of the vegetations should be measured within the resolution characteristics of the transducer so that machine settings can be duplicated for future comparative studies, if clinically indicated.

Vegetations may be present in patients with negative blood cultures, which is termed *culture-negative endocarditis* and represents approximately 10% of definite IE. Culture-negative endocarditis results from prior antibiotic therapy, fastidious organisms such as HACEK species, or unusual organisms such as *Coxiella burnetii* (Q fever) or *Bartonella quintana*. Vegetations also need to be differentiated from other masses with similar appearance on echocardiography such as Libman-Sacks (noninfective) endocarditis, degenerative change, Lambl's excrescences, thrombus, or tumors. Because there are no echocardiographic features that can reliably differentiate infective from noninfective endocardial lesions, the key to a proper diagnosis lies in integrating imaging data and clinical information. Visualization of distinct vegetation may be impaired by severe, underlying valvular degeneration, particularly prominent calcification of valve leaflets.

Tissue destruction in IE may result in other structural complications that can be identified on echocardiography. *Paravalvular abscess* complicated 30% to 40% of cases of IE in earlier reports[6] but were found in 14% of patients with definite IE in a larger, contemporary study[3] (Fig. 22-6). An abscess is a result of invasive infection that spreads generally along contiguous tissue planes, particularly with aortic valve infection. Development of a new atrioventricular conduction abnormality, worsening clinical picture, persistent bacteremia/fever in the setting of aortic valve endocarditis, injection drug use, infection with an invasive pathogen (staphylococcal), or prosthetic valves should prompt a search for an aortic root abscess.[24]

TEE is the diagnostic test of choice when an abscess is suspected clinically. An abscess is diagnosed by TEE as the visualization of a "thickened area" or "mass with a heterogeneous echogenic or echolucent appearance" within the myocardium or annular region.[6] On color Doppler imaging, flow within the area is supportive of the diagnosis. Abscesses complicating native valve IE most commonly involve the aortic valve annulus at the junction of aortic root and anterior mitral valve leaflet. Hence, they may extend into the adjacent interventricular septum, the right ventricular outflow tract, the interatrial septum, and the anterior mitral valve leaflet. Location of the abscess, particularly in the posterior annulus of the mitral valve when calcification is present, may limit its visualization by echocardiography.[25] In the ICE cohort, 22% of cases of definite aortic valve IE were complicated by a paravalvular abscess.[24]

These patients were more likely to have prosthetic valves and coagulase-negative staphylococcal infection. Surgical experience suggests an even higher prevalence of abscess formation not visualized by TEE.[25] New paravalvular regurgitation around a prosthetic valve may also suggest the presence of an abscess or infected sewing ring of the prosthesis.

If an abscess is identified, a careful examination is required to rule out extension into these areas, because this additional information has considerable implications for the type of reparative surgery to be undertaken. Loss of structural integrity of the valve, presence of valvular regurgitation and vegetations, and thickening of adjacent tissues help differentiate a native aortic valve abscess from fluid in the transverse pericardial sinus. These associated findings are also helpful in evaluating the presence of an abscess in patients with prosthetic valves in the aortic position. Postsurgical changes, including an echolucent space between a prosthetic valve sewing ring and the aortic root with or without paravalvular regurgitation, may pose a diagnostic dilemma in a patient with prosthetic valve and fever. In such cases, comparison with an intraoperative TEE, if available, may be very helpful to document the chronicity of the abnormality.

In rare cases, exposure of abscesses to high intravascular pressures and progressive burrowing infection may lead to *pseudoaneurysm formation* (color flow imaging demonstrating flow in echolucent space that is contiguous with the bloodstream). Because of further tissue invasion, these paravalvular cavities or pseudoaneurysms can form fistulous connections (aortoatrial or aortoventricular), leaflet perforation and even myocardial perforation. *Fistula formation* complicated 1.6% of cases of native valve IE and 3.5% of cases of prosthetic valve endocarditis in a cohort of 4681 cases of definite IE[26] (Fig. 22-7). These occurred with similar frequency in the three sinuses of Valsalva. Fistulas from the right or noncoronary sinus generally track or exit into the right ventricle, whereas fistulas from the left sinus exit to the left atrium.[27] TEE is the modality of choice to investigate these structural complications. Color flow Doppler imaging demonstrates flow turbulence, abnormal flow in echolucent spaces, and shunting of blood flow in cases of fistulous connections between cardiac chambers.

Progressive tissue destruction due to infection can also result in mitral chordal rupture in native valve IE and valvular dehiscence in prosthetic valve endocarditis. *Valvular dehiscence* is an uncommon, serious complication and portends poor outcome for the patient. On echocardiography, valvular dehiscence is defined as rocking motion of the valve with excursion of at least 15° in at least one direction (Fig. 22-8, *A*). This structural deterioration is often accompanied by severe, paravalvular regurgitation (Fig. 22-8, *B*).

In addition to these complications of IE, it is important to recognize that new valvular regurgitation may represent endocardial infection and is a major diagnostic Duke criterion for IE. Determining the mechanism of regurgitation as well as quantifying its severity is important: Severe regurgitation is poorly tolerated clinically because of acute onset without time for ventricular compensation and is an indication for surgical intervention.

In patients with mechanical prosthetic valves, a complete examination requires using a combination of transthoracic and transesophageal approaches. Transthoracic echocardiography (TTE) allows visualization of the ventricular aspect of the valve but is limited for examining the atrial aspect because of beam attenuation and shadowing. For the same reason, assessment of valvular regurgitation in case of mitral and triscuspid valve prosthesis is problematic with a transthoracic approach. Doppler echocardiography may be used to interrogate prosthetic valves for the presence of regurgitation using the velocity-time integral. TEE allows for much better assessment of valvular regurgitation and evaluation for vegetations on the atrial aspect of valve prostheses.

In patients with cardiac implantable electronic devices, there is substantial artifact generation, and TEE is superior to TTE in suspected infection in such devices.[28-30] Visualization of the lead in the proximal superior vena cava from TEE views may identify vegetations attached to cardiac implantable electronic device leads that are difficult to visualize by other modalities. During the examination, it is important to visualize the entire course of the prosthetic device throughout the vasculature and cardiac structures. A careful evaluation of the cardiac valves is also important because of the high rate of

concomitant valve infection, particularly tricuspid valve (Figs. 22-9 and 22-10).

## Clinical Utility and Outcome Data

### UTILITY IN DIAGNOSIS

#### *General Considerations*

The diagnostic yield of echocardiography is dependent on several variables including echocardiographic modality, vegetation size, vegetation location, native or prosthetic valve, presence of valve calcification (increases the sensitivity, but reduces the specificity of identifying vegetations), and preexisting valvular degeneration. With TTE, in approximately 15% of cases, variable sound transmission due to patient-related factors such as obesity, presence of lung disease, and chest wall deformities may limit diagnostic capability. Although vegetations as small as 2 to 5 mm can be detected, the sensitivity of TTE is low (approximately 40%) with such small lesions.[31] The sensitivity of TTE is highest for tricuspid valve infection because of the proximity to the chest wall. In a study of injection drug users with suspected right-sided IE,[32] TTE detected the presence of vegetations at the same rate as TEE; however, TEE was more effective at characterizing the vegetations. The diagnostic utility of TTE for suspected IE is highest in patients with intermediate to high likelihood of this disease[33] (e.g., a patient with a new or changed heart murmur and bacteremia). The limited sensitivity of TTE for the visualization of an intracardiac vegetation or abscess precludes "ruling out" the diagnosis of IE based on a negative study. Despite its poor sensitivity, TTE is often performed as the initial diagnostic study to assess for the presence and severity of valvular lesions and determine ventricular function. In a patient with a low pretest probability for IE and a normal TTE examination, a diagnosis other than IE should be pursued rather than proceeding to TEE examination (Fig. 22-11). TTE is also recommended for the reassessment of high-risk patients with definite IE (those with virulent organisms, clinical deterioration, persistent or recurrent fever, new murmur, or persistent bacteremia).

Although TTE and TEE have concordant results in approximately half of patients with suspected IE, TEE results in additional diagnostic information in a high percentage of patients.[34] TEE has several major advantages over TTE for the assessment of IE. These include better spatial resolution due to

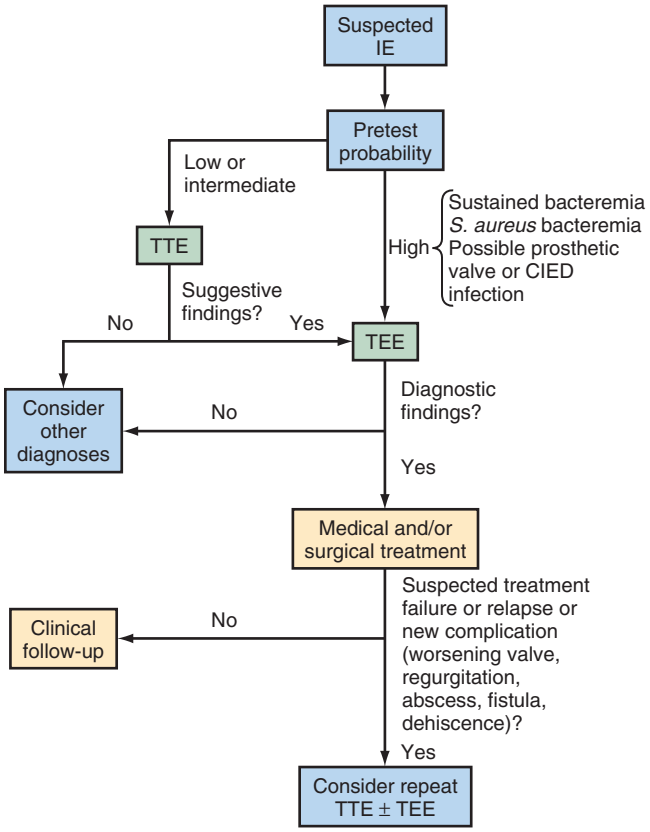

**Figure 22-11** Clinical applications of echocardiography in the evaluation and management of infective endocarditis (*IE*). *CIED*, Cardiac implantable electronic device.

**TABLE 22-2 Pretest Probability Estimates for Infective Endocarditis According to Patient Characteristics**

| *Clinical Feature* | *Estimate of Pretest Probability* |
|---|---|
| Viridans group streptococcal bacteremia | 14% (95% CI: 6-22%) |
| Unexplained bacteremia | 5-40% |
| Bacteremia and recent injection drug use | 31% (95% CI: 19-44%) |
| Admission with fever and recent injection drug use | 13% (95% CI: 7-19%) |
| Persistently positive blood cultures and predisposing heart disease | >50% |
| Persistently positive blood cultures and a new regurgitant murmur | >90% |
| Collective absence of vasculitic/embolic phenomena, central venous access, recent history of injection drug use, a prosthetic valve, and positive blood cultures | 0% |
| Firm alternate diagnosis or resolution of endocarditis syndrome within 4 days | <2% |
| Gram-negative bacteremia with clear noncardiac source of infection | <2% |

Adapted from Heidenreich PA, Masoudi FA, Maini B, et al: Echocardiography in patients with suspected endocarditis: a cost-effectiveness analysis. *Am J Med* 107:198-208, 1999; and Greaves K, Mou D, Patel A, Celermajer DS: Clinical criteria and the appropriate use of transthoracic echocardiography for the exclusion of infective endocarditis. *Heart* 89:273-275, 2003.

a higher-frequency transducer, lack of acoustic interference from adjacent structures such as the lungs and chest wall, and proximity to posterior structures such as the mitral valve and left atrium. TEE can detect vegetations as small as 1 to 2 mm and can detect vegetations 2 to 5 mm with a sensitivity of nearly 100%.[31] TEE should be performed in patients with a high clinical probability of IE and a negative TTE.[35]

Specific subsets of patients in whom TEE should be performed, even as the primary imaging modality (without preceding TTE) for diagnosis of IE, include (1) patients with prosthetic heart valves and suspected IE; (2) patients with persistent staphylococcal bacteremia without known source, or nosocomial staphylococcal bacteremia; and (3) patients with suspected infection in a cardiac implantable electronic device. Evidence suggests that TEE is also better than TTE for diagnosing native pulmonic valve IE,[36] although this is the least commonly infected valve and typically is associated with congenital heart disease as a predisposing condition. In patients with suspected culture-negative IE (approximately 10% of all cases of definite IE), TEE has higher sensitivity than TTE for visualizing diagnostic findings of endocardial involvement.[37]

Cost-effective analyses also support a diagnostic approach using echocardiography, particularly TEE. Heidenreich and coworkers[38] have shown that in suspected IE, a diagnostic strategy that focuses on TEE as the initial imaging modality is more cost effective than a staged procedure with TTE and is a superior strategy compared with empiric antibiotic therapy alone. In this study, TEE was optimal for patients who had a prior probability of IE that is observed commonly in clinical practice (4% to 60%) with a modestly reduced cost compared with the use of TTE as initial study.

It is important to note that the utility of a diagnostic tool such as echocardiography is optimal in the appropriate clinical context or pretest probability of disease (greater than 2% to 3%). Although there are few empiric data to quantify the pretest probability of disease, there is general consensus that certain characteristics increase the likelihood of disease (Table 22-2). Recent literature suggests that imaging technologies such as echocardiography can be overused in certain clinical scenarios, such as the evaluation of suspected IE. Kurupuu and colleagues[38a] have shown that 53% of echocardiograms could be avoided without loss of diagnostic accuracy by using a simple algorithm in patients with a low pretest probability of disease. Similarly, Greaves and associates[39] have shown that the absence of five simple clinical criteria was associated with a zero probability of a TTE demonstrating evidence of IE: (1) vasculitic/embolic phenomena, (2) central venous access, (3) a recent history of injection drug use, (4) prosthetic heart valve, and (5) positive blood cultures. Collectively, these studies have shown that in patients with very low pretest probability of disease, echocardiography may be avoided without the loss of diagnostic accuracy. Recommendations for the appropriate use of TTE and TEE in cases of suspected or known IE are provided in Tables 22-3 and 22-4. The evaluation of possible IE in specific clinical scenarios is discussed next.

### *Evaluation of the Patient with Bacteremia*

Because the clinical presentation of endocarditis is highly variable, early suspicion of IE is critical for an early diagnosis. A history of predisposing factors, including prosthetic valves, previous episode of endocarditis, congenital heart disease, and heart failure, or other stigmata of endocarditis with fever for more than 72 hours should prompt a search for the diagnosis with blood cultures and imaging.

Bacteremia with typical organisms including viridans streptococci, *Streptococcus bovis*, HACEK group, *S. aureus*, or

**TABLE 22-3 ACC/AHA Practice Guidelines and the Appropriateness Criteria for the Use of TTE in Suspected or Known IE**

| *Indications* | *Level of Evidence* |
|---|---|
| **Class I** | |
| 1. TTE to detect valvular vegetations with or without positive blood cultures is recommended for the diagnosis of infective endocarditis | B |
| 2. TTE is recommended to characterize the hemodynamic severity of valvular lesions in known infective endocarditis | B |
| 3. TTE is recommended for assessment of complications of infective endocarditis (e.g., abscesses, perforation, and shunts). | B |
| 4. TTE is recommended for reassessment of high-risk patients (e.g., those with virulent organisms, clinical deterioration, persistent or recurrent fever, new murmur, or persistent bacteremia) | C |
| **Class IIa** | |
| TTE is reasonable to diagnose infective endocarditis of a prosthetic valve in the presence of persistent fever without bacteremia or a new murmur | C |
| **Class IIb** | |
| TTE may be considered for the reevaluation of prosthetic valve endocarditis during antibiotic therapy in the absence of clinical deterioration | C |
| **Class III** | |
| TTE is not indicated to reevaluate uncomplicated (including no regurgitation on baseline echocardiogram) native valve endocarditis during antibiotic treatment in the absence of clinical deterioration, new physical findings, or persistent fever | C |
| *Appropriateness Criteria* | *Appropriateness Score (1-9)* |
| 1. Initial evaluation of suspected infective endocarditis with positive blood cultures or a new murmur | A (9) |
| 2. Transient fever without evidence of bacteremia or a new murmur | I (2) |
| 3. Transient bacteremia with a pathogen not typically associated with infective endocarditis and/or a documented nonendovascular source of infection | I (3) |
| 4. Re-evaluation of infective endocarditis at high risk for progression or complication or with a change in clinical status or cardiac exam | A (9) |
| 5. Routine surveillance of uncomplicated infective endocarditis when no change in management is contemplated | I (2) |

Levels of evidence are defined as:
A, Data derived from multiple randomized clinical trials or metaanalysis.
B, Data derived from a single randomized study or from nonrandomized studies.
C, Consensus opinion of experts, cases studies or standards of care.
For the appropriateness score, A indicates the test is considered appropriate and I indicates it is inappropriate.

community-acquired enterococci in the absence of a primary focus constitute a major criterion for IE. Thus, bacteremia with typical organisms should be investigated for endocardial involvement with TTE. If the TTE is technically inadequate, nondiagnostic, or negative, TEE should be obtained.

*S. aureus* bacteremia of any origin or setting is a risk factor for IE, and thus the diagnosis should be ruled out by careful clinical evaluation and diagnostic testing. With virulent organisms such as *S. aureus,* which is capable of causing IE on apparently normal cardiac valves, the incidence of IE is high (approximately 30%).[40,41] Among 59 prospectively identified patients with *S. aureus* IE, the presumed source of the bacteremia was an intravascular catheter in 39%. Similarly, in a prospectively identified cohort of 922 patients with definite IE from 39 sites in 16 countries, *S. aureus* was the most common cause of IE, accounting for 35.7% of all cases, and it was associated

with a presumed intravascular catheter source in 39%.[42,43] These studies also underscore the association between catheter-associated bacteremia and IE. In cases where there is low clinical suspicion and blood culture data suggest skin contaminants (coagulase-negative *Staphylococcus*), a technically adequate TTE should be sufficient to exclude IE, and other diagnoses should be considered.

### *Evaluation of the Patient with Prosthetic Valves*

Prosthetic valves are a predisposing factor for IE and inevitably place the patient in a high risk group. Such valves were previously thought to account for only 1% to 5% of all IE cases. However, a recent prospective, multinational, observational cohort study[44] showed that of 2670 patients with IE, approximately 20% had definite prosthetic valve endocarditis. As compared to native valve IE, in-hospital mortality was high (23%) in this group of patients despite similar rates of complications and surgical intervention. These data emphasize the aggressive nature of prosthetic valve endocarditis and reiterate the need for an early diagnosis and intervention. *S. aureus* is the most the most common causative organism in prosthetic valve endocarditis. *S. aureus* infection and health care–associated infection were strong predictors of mortality in a large cohort.[44] In another study,[45] among patients with a prosthetic valve and *S. aureus* bacteremia, 50% were found to have endocarditis regardless of time since prosthetic valve implantation. Fever in a patient with prosthetic valves that is not otherwise explained along with risk factors such as bacteremia and indwelling catheters should heighten clinical suspicion and prompt an aggressive search for IE.

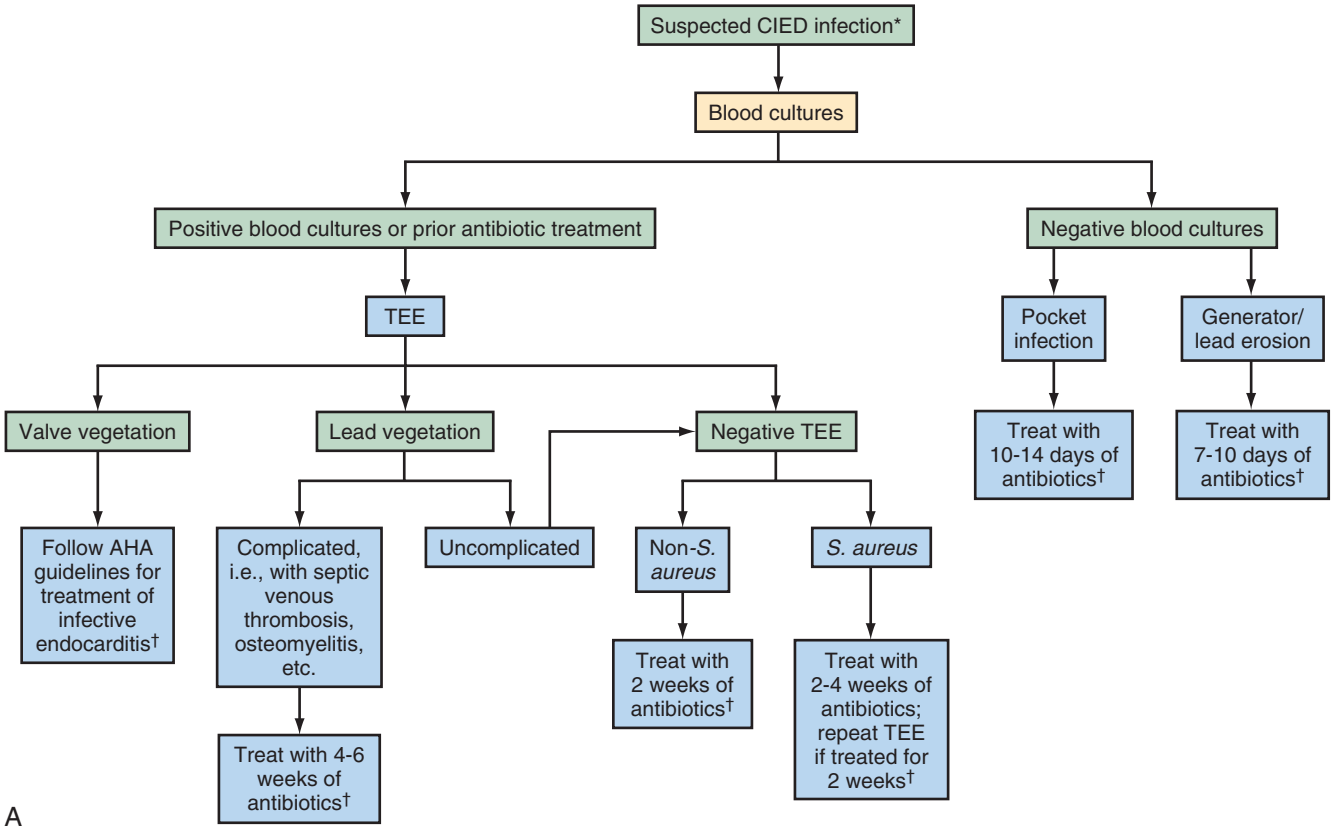
Prosthetic valve endocarditis also poses an imaging diagnostic challenge, because identification of the pathology that chiefly involves the paravalvular tissue and the usual complications such as paraprosthetic leaks, dehiscence, ring abscesses, and fistula formation can be masked by acoustic shadowing and reverberation artifacts caused by the prosthetic material. Vegetations on prosthetic valves cannot be reliably detected by TTE. TEE is preferred for the evaluation of suspected prosthetic valve IE and has been shown to have greater sensitivity for detecting vegetations than TTE.[46,47] Because of the greatly improved accuracy with TEE, it is recommended as a first-line diagnostic study to diagnose prosthetic valve endocarditis and assess for its complications.[48]

It should be noted that echocardiographic differentiation between tissue degeneration and small vegetations is sometimes not possible, even with TEE. In addition, paraprosthetic strands, which can be observed in early postoperative months, can cause false-positive interpretations.[49,50]

### *Evaluation of the Patient with a Cardiac Implantable Electronic Device*

An increase in the rate of cardiac device infections (permanent pacemakers, implantable cardioverter-defibrillators, prosthetic heart valves or material, and ventricular assist devices) has been observed in recent years. Cabell and colleagues[51] reported an increase from 0.94 to 2.11 per 1000 Medicare beneficiaries between 1990 and 1999. The rate of native valve IE, however, remained stable over that period (0.26 to 0.36 per 1000 beneficiaries).

Imaging with echocardiography, particularly TEE, is integral in evaluating patients with suspected infection of a cardiac implantable electronic device.[28-30] TEE examination is particularly useful among patients with *Staphylococcus aureus* bacteremia and presence of such a device, because the rate of underlying IE is significant.[40]



Importantly, failure to visualize a mass adherent to a lead with TEE does not exclude lead infection.[29] Conversely, visualization of a mass adherent to a cardiac lead by echocardiography may indicate either a thrombus or infected vegetation. Because it is impossible to distinguish between these two entities by echocardiography alone, and recognizing that 5% of adherent masses were deemed thrombus in one retrospective survey,[52] careful clinical judgment must be employed for the diagnosis of infection of a cardiac implantable electronic device. Masses that are detected in patients without positive blood cultures or other suggestive features for infection are likely to represent thrombus and, in isolation, do not indicate the need for lead extraction or antibiotic treatment without clinical suspicion for infection. Because of its poor sensitivity, TTE is less useful to rule out the diagnosis of infection of a cardiac implantable electronic device, particularly in adults. However, several prognostic features may be better defined on TTE than on TEE, such as pericardial effusion, ventricular dysfunction, pulmonary vascular pressure estimations, and quantitation of valvular regurgitation. Figure 22-12 depicts a suggested approach for the diagnosis and management of infection of a cardiac implantable electronic device using TEE. Importantly, complete CIED removal is recommended in cases of definite device or valve infection; pocket abscess, erosion, or draining sinus; and occult staphylococcal bacteremia.[29]

## UTILITY IN MANAGEMENT

Prompt diagnosis, initiation of appropriate antibiotics, and consideration of surgical intervention along with a cohesive, multidisciplinary approach forms the basis of management. From determining the duration of antibiotic therapy to identification of complications needing prompt surgery, echocardiography has an important role in the management of this complex disease, particularly with regard to prognostic factors that may require surgical intervention rather than medical therapy alone.

The Duke criteria were developed to provide a more sensitive case definition of IE, but their possible prognostic influence was evaluated in a single-center study[53] from our institution. In 267 patients with definite or possible IE by Duke criteria, early echocardiographic findings of IE, such as presence of vegetation and new valvular regurgitation as categorical variables, were not associated with in-hospital mortality.

Diagnostic imaging for evidence of IE typically occurs within the first few days after hospital admission with suspected IE, and approximately 90% of patients with definite IE have vegetations visualized. In this setting, vegetation characteristics such as size, mobility, attachment site, and shape and have been extensively studied as tools for risk stratification of patients with IE, particularly risk of embolic events. Vegetation size greater than 10 mm and increased mobility have been shown in several series to predict embolic events.[54,55] Embolic events in IE have been found to a strong, independent predictor of in-hospital mortality.[53] In one multicenter prospective study[56] of 384 patients with definite IE, vegetation length greater than 15 mm was independently associated with 1-year mortality (Fig. 22-13). In another recent observational study[57] of 132 patients with left-sided IE and approximately 40% with vegetation length of at least 15 mm, early surgery within 7 days of diagnosis was associated with a significantly lower

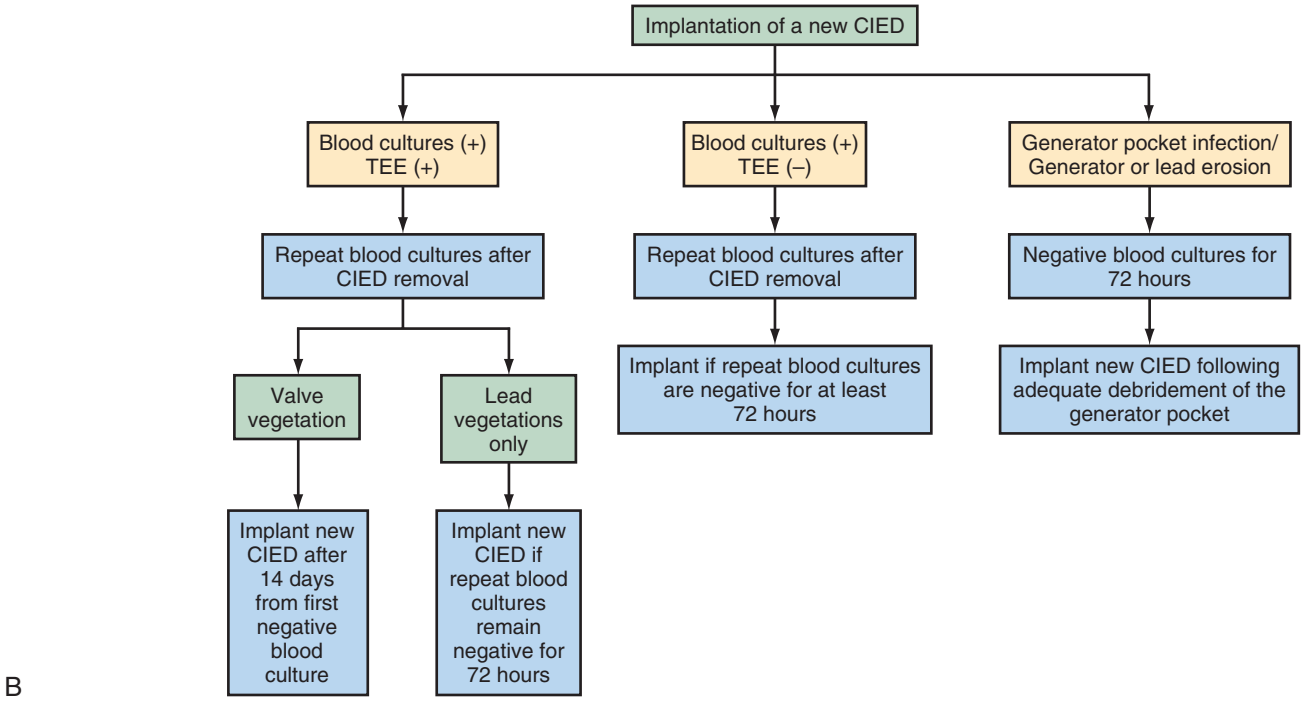


**Figure 22-12** **A,** Approach to management of adults with cardiac implantable electronic device (*CIED*) infection. **B,** Approach to implantation of a new device in patients after removal of an infected CIED. *(From Baddour LM, Epstein AE, Erickson CC, et al: Update on cardiovascular implantable electronic device infections and their management: a scientific statement from the American Heart Association. Circulation 121:458-477, 2010.)* *A history, physical examination, chest radiograph, electrocardiogram, and device interrogation are standard baseline procedures before CIED removal. †Duration of antibiotics should be counted from the day of device explantation. Treatment can be extended to 4 or more weeks if there are metastatic septic complications (i.e., osteomyelitis, organ or deep abscess, etc.) or sustained bloodstream infection despite CIED removal.

risk of embolic events compared to conventional treatment, with surgery deferred until complications occurred (Fig. 22-14). Therefore, current ACC/AHA guidelines recognize that surgery for native valve IE may be considered in patients who present with mobile vegetations more than 10 mm in size with or without emboli (class IIb recommendation, level of evidence C).

Although vegetation characteristics are clearly important in risk stratification, basing clinical decisions regarding surgery solely on this parameter is problematic, because of the considerable interobserver variability on echocardiographic features of vegetations. In a study by Heinle and colleagues,[58] complete observer agreement was achieved on vegetation size in only 73%, mobility in 57%, shape in 37%, and attachment in 40% of cases. These data also emphasize the need for careful standardization of exams. In addition, the risk of embolism has been found to decrease rapidly within the first week of antibiotic therapy (Fig. 22-15),[59] a beneficial effect of medical therapy that should be considered when considering surgery for the prevention of embolic events in IE.

After an embolic event has occurred, the residual presence of a vegetation poses a risk for recurrent embolism. However, routine surveillance for embolism in IE has demonstrated that approximately 50% of cases are associated with an embolic

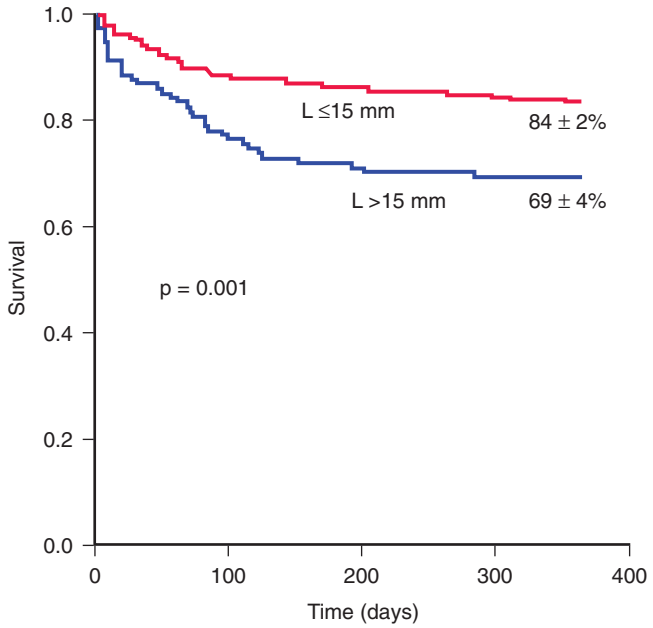

**Figure 22-13 Survival in infective endocarditis stratified by vegetation size.** *(From Thuny F, Di Salvo G, Belliard O, et al: Risk of embolism and death in infective endocarditis: prognostic value of echocardiography: a prospective multicenter study.* Circulation *112:69-75, 2005.) L,* Vegitation length.

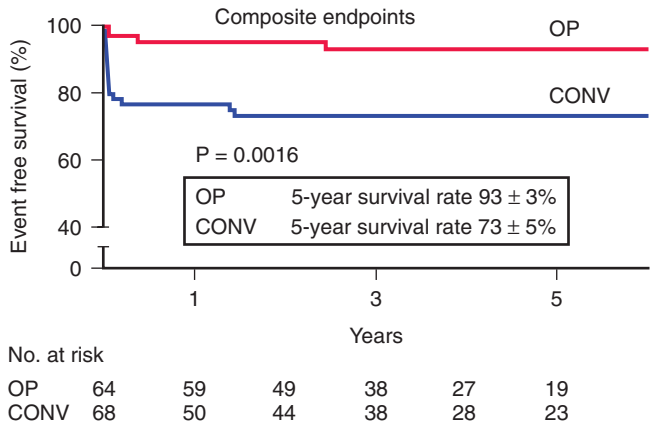

**Figure 22-14 Impact of early surgery on event-free survival in IE.** Patients treated with early surgery (*OP*) had lower rate of embolic events but similar mortality as patients treated with conventional (*CONV*) strategy of expectant surgery. *(From Kim D-HK, Lee M-Z, Yun S-C, et al: Impact of early surgery on embolic events in patients with infective endocarditis.* Circulation *122:S17-S22, 2010.)*

event (typically to brain, spleen, kidney, or lungs), and that most of these embolic events are clinically silent or asymptomatic. In this situation, the decision as to whether to proceed with cardiac surgery is again challenged by the subclinical nature of these events and the progressively lower risk of embolic events with antibiotic therapy. Conversely, asymptomatic brain infarcts have been associated with a poorer prognosis in IE and generally do not increase the risk of cardiac surgery in the absence of cerebral hemorrhage, abscess, or major neurologic impairment.[60] In comparison to TTE, TEE has improved ability to detect complications of IE such as paravalvular abscesses[6] or regurgitation, valvular perforation,[61] intracardiac shunt, and secondary involvement of the mitral-aortic intervalvular fibrosa.[62] The diagnosis of an abscess has significant prognostic and management implications. Rarely, antibiotic therapy may be used to treat an intracardiac abscess, though this treatment alone is generally reserved for patients who are poor surgical candidates. The vast majority of patients with an intracardiac abscess require cardiac surgery for débridement (class I recommendation, level of evidence C), and failure to diagnose an abscess by echocardiography is associated with delayed time to surgery.[25] In a recent study,[62a] the impact of early surgery on survival of patients with native valve IE was evaluated using propensity score and instrumental variable methods to adjust for treatment selection bias. In this prospective, multinational cohort, the investigators found a significant in-hospital mortality benefit associated with early surgery compared to medical therapy alone (12.1% versus 20.7%) and for those with paravalvular complications (intracardiac abscess or fistula formation—determined by echocardiography) (absolute risk reduction 17.3%, $P < 0.001$). In addition, surgery represents the gold standard for the confirmation of abscess visualized by echocardiography.

In IE complicated by fistula formation, the left-to-right shunting of blood flow generally augments the risk and/or severity of heart failure complicating IE. As a result, in-hospital mortality rate is very high (41%) despite the use of surgical therapy in the overwhelming majority of cases.[24] The development of cavitary fistulas thus heralds a poor outcome and should prompt urgent surgical intervention.

Finally, quantification of regurgitation severity and determining its impact on heart failure as a complication of IE are important prognostic factors. Acute regurgitation of IE that develops without the compensatory eccentric hypertrophy in chronic regurgitation is poorly tolerated clinically, potentially resulting in life-threatening pulmonary edema and cardiogenic shock. Acute aortic valve regurgitation is particularly ominous in its poor outcome and is an accepted criterion for surgical intervention. In patients with advanced heart failure symptoms (NYHA 3 or 4) complicating left-sided, native-valve IE, surgical therapy has clearly been shown to improve survival compared to medical therapy, whereas surgery for patients with no or mild heart failure appears to have little benefit for overall survival.[63] Even in patients without overt evidence of heart failure, severe regurgitation of either left-sided heart valve is a poor prognostic finding and an indication for surgical intervention. If severe mitral or aortic valve regurgitation is evident by echocardiography, close observation of the patient's hemodynamic status should be performed, often in an intensive care unit setting. In this situation, blood pressure that is lower than baseline or sinus tachycardia may herald acute decompensation even in the absence of more classic signs of heart failure. For these patients, use of intravenous afterload reduction agents (nitroprusside or nitroglycerine) may reduce the regurgitant volume and stabilize hemodynamic status. If severe heart failure or cardiogenic shock ensues, use of inotropic agents may be needed, and an intraaortic balloon pump can be used in severe mitral regurgitation as a bridge to cardiac surgery. Finally, new-onset atrial fibrillation is poorly tolerated in patients with acute, severe, valvular regurgitation; restoration of sinus rhythm with antiarrhythmic therapy and/or direct-current cardioversion may significantly improve hemodynamic stability.

In IE cases complicated by mechanical complications such as abscess, fistula, severe valvular regurgitation, or valve dehiscence, intraoperative TEE is indicated to assess complete repair of these defects. Indeed, an intraoperative TEE is now considered routine in most centers. Shapira and coworkers[64,65] analyzed the impact of TEE in 59 patients diagnosed with IE. In their experience, intraoperative TEE before cardiopulmonary bypass led to the modification of the surgical plan in 11.5% of cases. Intraoperatively, echocardiographic goals include assessment of not only the obviously dysfunctional valve but also the other valves and contiguous structures. Post–cardiopulmonary bypass images should confirm the adequacy of the repair or replacement and document the successful closure of fistulous tracts. Paravalvular leaks related to technical factors should be recognized and documented to avoid future uncertainty as to whether the leaks are the result of recurrent infection. During imaging after cardiopulmonary bypass, it is often necessary to augment afterload to reach representative ambulatory levels to avoid underestimation of regurgitant jet size and significance and to ensure that abnormal communications have been closed. It should be noted, however, that afterload augmentation may not always mimic actual awake physiology and may still lead to an inaccurate evaluation of the conscious postoperative state.[7,66]

Echocardiography has been used to analyze cost effectiveness in establishing the duration of treatment in the setting of acute IE as well as determining the need for a surgical intervention. Rosen and colleagues[66a] evaluated the cost effectiveness of TEE in establishing the duration of therapy for catheter-associated bacteremia. In this study, three management strategies were compared: (1) empirical treatment with 4 weeks of antibiotics (long course); (2) empirical treatment with 2 weeks of antibiotic therapy; and (3) TEE-guided therapy. In the TEE-guided strategy, a positive TEE dictated a long course of antibiotic therapy, and a negative TEE dictated a short course of therapy. The effectiveness of an empiric long-course strategy and a TEE-guided strategy were both superior to empiric short-course therapy. When costs were taken into account, the TEE-guided strategy was superior to the empiric long-course strategy, which cost more than $1.5 million per quality-adjusted life year saved. In a similar study, using a decision tree and Markov analysis, Liao and associates[67] showed that echocardiographically guided risk stratification to assess for complications that might benefit from early surgical intervention was a cost-effective treatment strategy, improving outcome for an incremental cost less than $50,000 per quality-adjusted life year saved.

Approximately 50% of patients with IE undergo cardiac valve surgery during the index hospitalization. Once the decision to proceed to surgery is made, it is important to provide the surgeon with an accurate assessment of valve anatomy for the purpose of operative planning. This preoperative assessment may be especially valuable when repair, rather than replacement, of a diseased mitral valve is considered. In addition, for patients with an aortic abscess, consideration of a homograft

replacement may be facilitated by accurate measurement of the annulus diameter. After valve surgery for IE, outpatient TTE is indicated early after surgery. The results of this study serve as a useful baseline hemodynamic assessment of the replaced or repaired valve's function as well as ventricular function for future comparisons, as clinically indicated.

### UTILITY IN FOLLOW-UP

There are no conclusive data to support serial echocardiographic examinations for surveillance in uncomplicated IE. The diagnostic value of TEE in monitoring the clinical course was evaluated in 83 patients with echocardiographic evidence of IE by Rohmann and colleagues.[68] Each patient in this cohort received at least two consecutive TEE studies. The study found that patients with an increase or no change in vegetation size had a higher incidence of complications after diagnosis and initiation of therapy, including valve replacement, embolic events, paravalvular abscess formation, and mortality, as compared to the cohort that demonstrated a decrease in vegetation size. Although these data suggest that multiple echocardiographic evaluations may be useful in determining the prognosis of patients with IE, there is great potential for inappropriate overuse of the test. Vieira and co-workers[69] evaluated the diagnostic contribution of repeated TTE and TEE examinations among patients with suspected IE. Over a 3-year period, they evaluated 262 patients with 266 episodes of suspected IE referred for echocardiography. They found that repeat echocardiography was frequent: TTEs were repeated at least once in 192 (72.2%) patients, whereas TEEs were repeated in 49 (18.4%) of patients. A mean of 2.4 TTE and 1.2 TEE examinations were performed for each episode of suspected IE. The second and third TTEs added diagnostic information in 34 (26.7%) and the second and third TEEs added diagnostic information in 25 (19.7%) of 127 episodes with definite IE. After the third TTE or TEE, no additional diagnostic information was obtained.

Therefore, a TTE or TEE as routine surveillance of uncomplicated IE when no change in management is contemplated is deemed inappropriate by the recently published appropriateness criteria for echocardiography. In patients with an established diagnosis of IE who develop worrisome clinical features such as a new atrioventricular block, persistent fever or bacteremia, progression of heart failure symptoms, or a change in cardiac murmur during or after the course of therapy, repeat echocardiography (TTE or TEE) to evaluate for structural complications is warranted (class I recommendation, level of evidence A). Because all patients with a history of IE remain at high risk for recurrent infection indefinitely, a TTE examination should be conducted to establish a new baseline for valve morphology and cardiac function, after completion of antimicrobial therapy (class IIb recommendation, level of evidence C).

## Research Applications

With the advent of real-time, three-dimensional (3D) TEE, which allows acquisition of full volume data, it is possible to precisely define anatomic structures, as well as vegetation characteristics and location. Cropping through the images may reveal structures and flows not visualized with TEE or TTE. 3D TEE appears to be a promising technique in examining prosthetic valves and patients with intracardiac devices. Initial experience using 3D TEE in patients with prosthetic valve endocarditis suggests that 3D TEE may provide additional information not readily appreciated on standard 2D TEE imaging.[70] Liu and associates[70a] performed 2D and real-time 3D TTE in 46 patients with definite IE. The sensitivity for both modalities was 91.6%, but specificity using real-time 3D echocardiography was higher (100% versus 88.2%, respectively). Although these data are encouraging, further research is needed to define the role of 3D echocardiography in the diagnosis as well as management of IE. In addition, from a clinical-outcome perspective, additional studies are needed to better define the prognostic influence of echocardiographic findings in IE and their severity over time after treatment.

## Potential Limitations and Future Directions

Echocardiography is an important tool for diagnosis of endocarditis when used in the correct clinical scenario with an appropriate pretest probability of disease. However, its overuse is associated with avoidable costs. False-positive results can lead to unnecessary treatment, potential complications, and increased medical costs. In addition, with an invasive procedure such as TEE, there is a small but definable risk to the patient of complications related to sedation and probe insertion, including aspiration, esophageal perforation, induction of cardiac arrhythmia, respiratory compromise, and patient discomfort. Approximately 10% of patients with IE will not have evidence of vegetation or other endocardial involvement at the time of diagnosis, perhaps because of the limitations of imaging. Treatment of these patients should be guided by the clinical suspicion for IE, particularly for patients with prosthetic heart valves and those who meet criteria for definite IE by other major and minor criteria.

## Alternative Approaches

Other imaging modalities such as cardiac magnetic resonance imaging with contrast appear promising for the detection of paravalvular abscesses, thrombus associated with vegetations, valvular complications, and aortocameral fistulas, although temporal resolution may limit their use for detection of vegetation (level of evidence C). The role of cardiac magnetic resonance imaging with contrast is also limited in the evaluation of patients with cardiac implantable electronic devices, and the procedure is often not feasible in critically ill patients. Cardiac computed tomography has also been used to detect aortic root abscesses, but radiation risk as well as temporal resolution are again limiting factors in its widespread use.

Clinical experience with these techniques in IE patients is limited, and their operating characteristics (sensitivity and specificity) in comparison to echocardiography are not well defined.[71-73] As a result, no other imaging modality for the visualization of endocardial involvement or complications of IE is an acceptable alternative to echocardiography in clinical practice.

## KEY POINTS

- Echocardiography is essential for the diagnosis and management of infective endocarditis.
- Echocardiographic findings that are major diagnostic criteria for endocarditis include vegetations, abscess, new partial dehiscence of prosthetic valve, and new valvular regurgitation.
- Echocardiography should be considered for patients with an intermediate or high pretest probability for endocarditis, including clinical features of fever, positive blood cultures, or new or changing regurgitant heart murmur.
- Approximately 90% of patients with definite endocarditis have evidence of vegetation by echocardiography.
- The sensitivity of TEE (greater than 95%) is superior to the sensitivity of TTE (40% to 60%) for the diagnosis of endocarditis.
- TEE is appropriate as the primary diagnostic test (without preceding transthoracic study) for patients with prosthetic heart valves, patients with staphylococcal bacteremia without known source or that is nosocomial in origin, and patients with possible infection of a cardiac implanted electronic device (permanent pacemaker or implantable cardioverter-defibrillator).
- Findings on echocardiography that suggest a poor prognosis for the patient with endocarditis include large vegetations (greater than 10 mm), severe valvular regurgitation (particularly aortic valve), abscess or fistula formation, or prosthetic valve dehiscence. Any of these findings should trigger prompt surgical evaluation for urgent valve surgery.
- TEE is an important tool for preoperative planning in patients undergoing valve surgery for endocarditis.
- In the absence of clinical findings suggesting relapse of endocarditis or worsening cardiac involvement (e.g., atrioventricular conduction block, changing heart murmur, or evidence of heart failure), routine, repeat echocardiography during or after the course of antibiotic therapy has little clinical utility.

## ACKNOWLEDGMENTS

Valve Implantation

Aortic stenosis (AS) is the most frequent heart valve disease in developed countries, with an incidence of about 2% to 9% in elderly patients. Aortic sclerosis, which is the precursor of AS, is present in 29% of patients older than 65 years. With an ageing population, the widespread use of echocardiography and percutaneous treatment options, referrals of patients with AS are increasing.

Clinically, AS is suspected when a systolic murmur is detected or when compatible symptoms such as angina pectoris, exertional dyspnea, or syncope occur.

AS is coincidentally diagnosed in patients referred to echocardiography for other reasons. Echocardiography is the standard exam for diagnosis and quantification of AS, of associated valve lesions, and of implications for the left ventricle (LV). For an adequate interpretation, the limitations and pitfalls of the technique must be considered and are therefore treated in this chapter. The prognostic value of these echocardiographic findings is discussed, together with the natural history and progression of the disease, so as to be comprehensively included in an optimized management strategy. Echocardiography is essential in the screening of patients for transcatheter aortic valve implantation and the monitoring of the procedure.

## Imaging Aortic Stenosis

Calcific AS is the most common etiology of AS that is diagnosed, followed by rheumatic stenosis (which is in decline in Western societies) and congenital stenosis.[1] Roberts and Ko[2] report an incidence of bicuspid aortic valves of 53% in a large series of surgically excised stenotic aortic valves. These data suggest that in morphologically calcified aortic valves, an underlying congenital abnormality is not uncommon. At more advanced disease stages, also congenitally stenotic valves calcify, and mechanisms of calcification resemble those observed in calcific AS, making morphologic characterization of the aortic valve challenging.

### CALCIFIC AORTIC STENOSIS

AS is an active and progressive disease, showing parallels with atherosclerotic disease, such as inflammation, lipid infiltration, dystrophic calcification, and even ossification.[3] Thus, the historical concept that degenerative AS results from mechanical stress due to wear and tear of the aortic valve is outdated, and the term *calcific AS* is more appropriate. The stenotic valve

is indeed characterized by thickened and calcified cusps with reduced systolic opening and reduced leaflet motion (Fig. 23-1).

### CONGENITAL AORTIC STENOSIS

Congenitally stenotic aortic valves present as unicuspid, bicuspid, tricuspid, and quadricuspid valves.[4] Bicuspid valves, which account for the majority of these cases, are characterized by two cusps that are typically of different size, the larger cusp often containing a raphe (left over along the fusion line of two leaflets) (Fig. 23-2). A prominent raphe may make the differentiation from a tricuspid aortic valve difficult, and therefore the aortic valve opening should be displayed. Transesophageal echocardiography (TEE) may be required for an exact morphologic description.

Typically the leaflets in bicuspid aortic valves are oriented in an anterior-posterior or right-left manner.[5] Other malformations that are associated with a bicuspid aortic valve and that should be systematically ruled out are presence of an aortic coarctation, a persistent ductus arteriosus, or a ventricular septal defect. Unicuspid valves may present without an identifiable commissure (acommissural) or as unicommissural valves.

### RHEUMATIC AORTIC STENOSIS

Rheumatic AS is characterized by commissural fusion and thickening of the leaflet edges and sometimes leaflet retraction (Fig. 23-3). Not all the commissures are necessarily fused. Associated aortic regurgitation and mitral valve involvement are common in rheumatic disease.

### ASSESSMENT OF AORTIC VALVE CALCIFICATION

Aortic valve calcification is best assessed in a parasternal short-axis view. The degree of calcification can be classified into mild (isolated, small spots), moderate (multiple bigger spots), and severe calcification (extensive thickening/calcification of all cusps)[6] (Fig. 23-4). Because of its prognostic importance, the degree of aortic valve calcification should be routinely described. In the presence of severe calcification, an exact etiologic characterization of stenosis may be difficult.

### AORTIC ROOT

Echocardiography allows the assessment of the aortic annulus, aortic root, and ascending aorta. Aortic root dilation is present in about 50% of cases of bicuspid[7] but also unicuspid aortic valves.[8] Although the concept of a poststenotic dilatation due to hemodynamic factors is accepted, primary tissue abnormalities of the aortic media that are present in patients with congenitally malformed aortic valves contribute to further aortic dilation.[7]

### INDIRECT ECHOCARDIOGRAPHIC FINDINGS SUGGESTIVE OF AORTIC STENOSIS

Several indirect echocardiographic findings are suggestive of the presence of AS. Among them, an aliasing in the left ventricular (LV) outflow tract, LV hypertrophy, and, importantly, an increased aortic velocity should be noted.

### DIFFERENTIAL DIAGNOSIS

Although valvular AS accounts for most cases of LV outflow-tract obstruction, potential differential diagnoses include subvalvular or supravalvular stenosis and hypertrophic cardiomyopathy. Coexisting subvalvular obstruction, which may be present in addition to valvular AS should be ruled out.[9]

## Quantification of Aortic Stenosis Severity

A normally opening aortic valve is not obstructive to blood flow. It has an opening area of 3 to 4 $cm^2$ and the transvalvular flow is laminar with a peak velocity below 2 m/s. When the valve becomes stenotic, and thus obstructive to blood flow, a pressure drop occurs across the valve (Fig. 23-5). Aortic jet velocities increase with decreasing aortic valve area. When the aortic valve area becomes smaller than 1 $cm^2$, the increase of aortic jet velocity is most significant, indicative of the hemodynamic relevance of the obstruction. Several parameters have been proposed for the quantification of AS.[10] For an appropriate interpretation, understanding the theoretical background and the limitations of the respective measures is required. Some parameters, such as aortic jet velocity and aortic valve area have been extensively validated in clinical studies, whereas others are experimental. The integration of additional measures of severity can be helpful in selected cases.

### CLASSICAL ECHOCARDIOGRAPHIC MEASURES OF STENOSIS SEVERITY

#### *Doppler Measurements*

##### Transaortic Velocities and Gradients

Transaortic jet velocities are directly recorded by using a continuous-wave (CW) Doppler probe. Transvalvular gradients are derived from velocities using the Bernoulli equation, which is based on the conservation of energy principle in a closed system. In practice, accurate gradient calculations are performed using the simplified Bernoulli equation that ignores viscous losses and the effects of flow acceleration, both of which can generally be neglected in the clinical setting:

$$\Delta P = 4v^2$$

These Doppler-derived gradients have been shown to correlate well with invasively measured pressure gradients, both in the experimental and in the clinical setting.[11-16] Furthermore, the Doppler gradients also accurately reflect pressure gradient changes appearing with a change in flow rate.[11,12,17]

The simplified Bernoulli equation ignores the flow velocity proximal to the stenosis, which is an acceptable assumption when the transvalvular velocity is significantly greater than the proximal flow velocity. However, if this difference is less accentuated (i.e., in the presence of accelerated flow or less significant stenosis), the use of a more complete form of the Bernoulli equation is more appropriate, where $v_2$ and $v_1$ represent the transvalvular and the proximal flow velocities, respectively:

$$\Delta P = 4(v_2^2 - v_1^2)$$

The peak transaortic pressure gradient corresponds to the maximal pressure difference between the aorta and the LV. With increasing stenosis severity, the peak of the gradient occurs later during systole.[18]

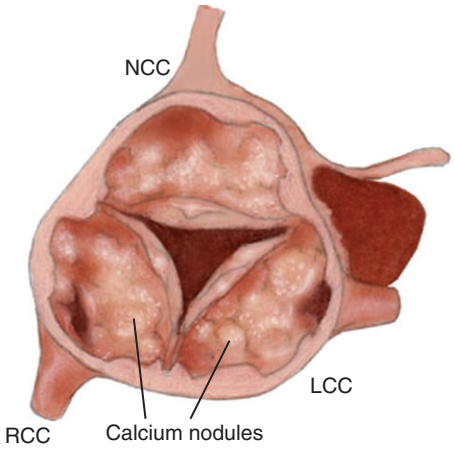

**Figure 23-1** Calcific aortic stenosis with thickened and calcified cusps in TEE short-axis view orientation. *LCC*, Left coronary cusp; *NCC*, noncoronary cusp; *RCC*, right coronary cusp.

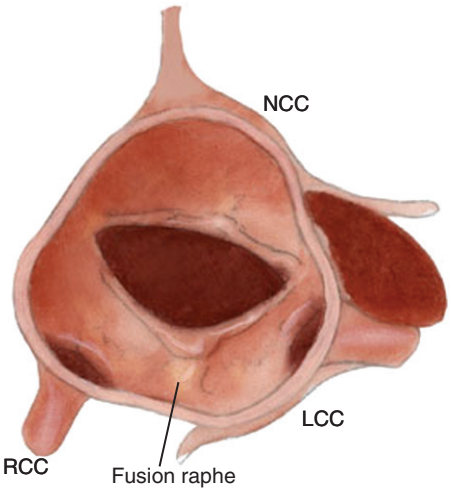

**Figure 23-2** Bicuspid aortic stenosis with anteroposterior orientation and raphe in TEE short-axis view orientation. *LCC*, Left coronary cusp; *NCC*, noncoronary cusp; *RCC*, right coronary cusp.

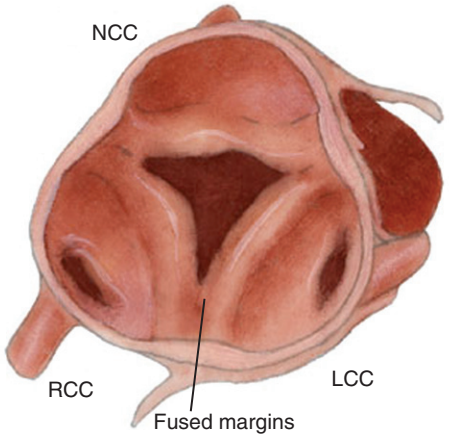

**Figure 23-3** Rheumatic aortic stenosis with commissural fusion, thickening of leaflet edges, and leaflet retraction in TEE short-axis view orientation. *LCC*, Left coronary cusp; *NCC*, noncoronary cusp; *RCC*, right coronary cusp.

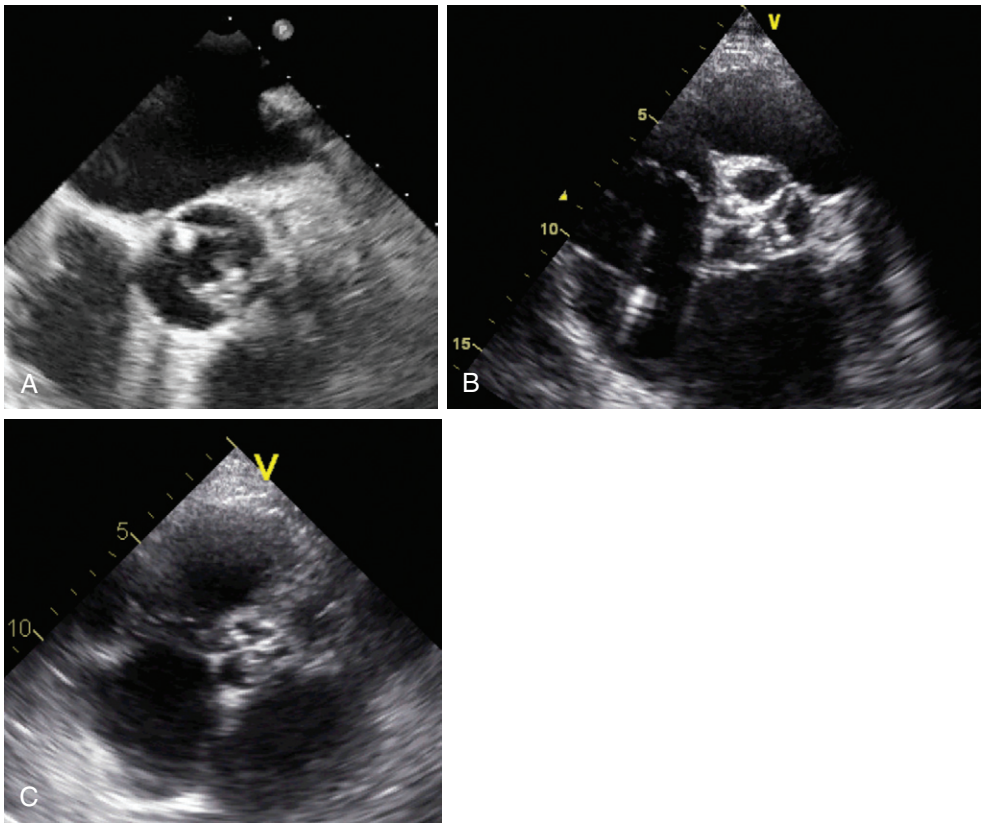

**Figure 23-4** **A,** Parasternal short-axis view of mildly calcified stenotic aortic valve showing isolated spots of calcification**. B,** Parasternal short-axis view of moderately calcified stenotic aortic valve showing multiple spots of calcification. **C,** Parasternal short-axis view of severely calcified stenotic aortic valve showing extensive calcification of all cusps.

The mean gradient is obtained by integrating the peak gradient over the duration of the entire systole. The relationship between peak and mean transaortic gradients is linear and can be expressed by the following equations (they apply to native aortic valve stenosis with its typical shape of the velocity curve over time only)[14,15,19]:

$$\text{Mean } \Delta P = (\text{Max } \Delta P/1.45) - 2.2 \quad \text{and}$$

$$\text{Mean } \Delta P = 2.4 \times V_{max}$$

This close relationship between mean and peak transaortic gradients on the one hand and peak aortic jet velocity on the other emphasizes the value of peak aortic jet velocity as a flow-dependent expression of stenosis severity in clinical decision making.

## Pitfalls

**Technical Considerations.** Care is required to record the maximal AS jet velocity, which requires aligning the Doppler probe with the jet direction. Any alignment error leads to an angle-dependent underestimation of the Doppler gradient. Multiple transducer positions (i.e., right parasternal, suprasternal, apical, and even subcostal) have to be used to obtain the peak signal, because the exact orientation of the aortic jet cannot be predicted from the two-dimensional (2D) image. The use of a small, dedicated CW Doppler transducer (so-called "pencil" probe) is mandatory to avoid a misclassification of AS severity, which may otherwise occur in about 20% of cases[20] (Fig. 23-6). The image window used to record peak transaortic velocity should be mentioned in the report. When determining rates of hemodynamic progression, measurements recorded from the same window must be used.

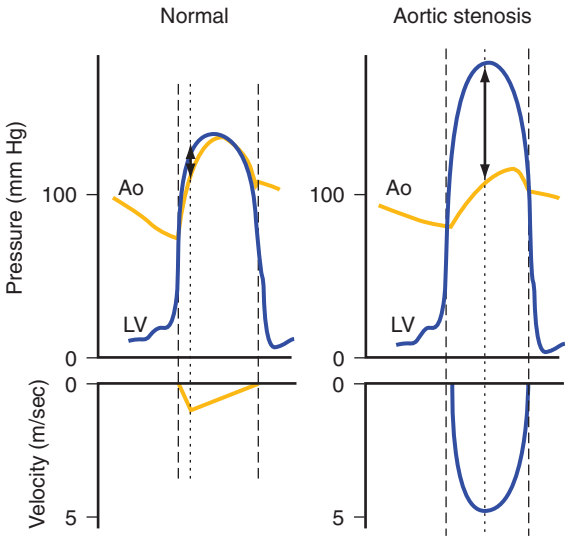

**Figure 23-5 Relationship of pressures to Doppler velocities in normal and aortic stenosis.** Note that maximum pressure gradient (*double-headed arrow*) corresponds to maximum Doppler velocity in both situations, but timing of the LV-to-Ao pressure gradient is quite different when valve obstruction is present. *Ao*, Aorta.

Even with an experienced operator and attention to technical details, there is some degree of measurement variability, so that a change in jet velocity of more than 0.2 m/s indicates actual progression of the disease in the absence of interval physiologic changes.[21]

**Other Signals.** While recording the Doppler signal, care has to be applied not to confound the signal with that of another form of obstruction or another flow signal such as that of mitral or tricuspid regurgitation. If the patient has atrial fibrillation, several consecutive beats need to be averaged to obtain a representative result.

**Pressure Recovery.** Pressure recovery may explain discrepancies between catheter and Doppler pressure gradients in patients with AS.[22-25] In valvular AS, a laminar high-velocity jet is present across the narrowed orifice.[26] The minimal cross-sectional area of the jet is called vena contracta: it has a smaller diameter and occurs distal to the anatomic valve orifice. Pressure is lowest and velocity is greatest at that level.

Distal to the vena contracta, the jet expands and decelerates. Because total energy remains constant according to Bernoulli's law, the velocity reduction is paralleled by an increase in aortic pressure. The Doppler gradient corresponds to the peak gradient at the site of the vena contracta and overestimates the catheter gradient that is measured farther downstream. In most cases the observed magnitude of pressure recovery is in the range of 10 mm Hg and does not affect clinical decision making.[22] However, pressure recovery may be significant in the presence of less severe AS and a small ascending aorta.[27] The phenomenon can be predicted from Doppler velocity, aortic valve area, and the size of the ascending aorta.[24] Thus, patients with severe AS and poststenotic aortic root dilation may show less pressure recovery than patients with mild-to-moderate stenosis and a small or normal aortic root dimension.

**Flow Dependence of Measurements.** Doppler measurements of AS severity are limited by their flow dependence. The presence of a high flow rate such as in hyperdynamic states or in the presence of significant aortic regurgitation may lead to an overestimation of AS severity. On the other hand, a low flow rate that can be observed in the presence of a depressed LV function or coexisting mitral regurgitation may lead to an underestimation of AS severity. Furthermore, there are intraindividual variations of aortic jet velocity due to changes in transaortic flow volume such as those occurring during exercise. If the patient is not in sinus rhythm—atrial fibrillation being common—there is a beat-to-beat variability in flow

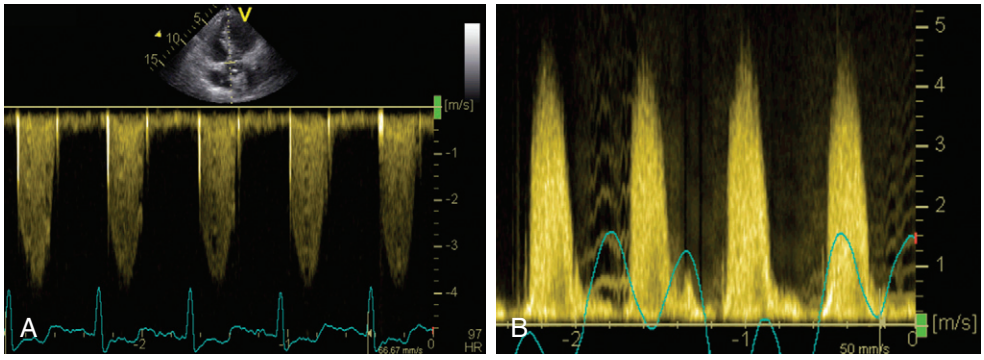

**Figure 23-6** CW Doppler tracings of aortic stenosis velocity obtained from apical (**A**) and right parasternal recording using dedicated CW probe (**B**) in the same patient. This example emphasizes importance of alignment of Doppler probe with aortic jet direction in order to record maximal signal and not to underestimate severity of stenosis.

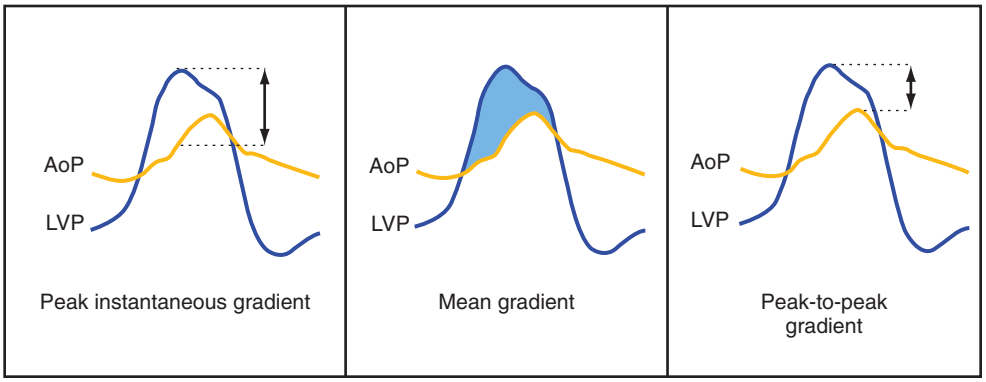

**Figure 23-7** Peak Doppler echocardiographic gradient corresponds to maximal difference between aortic pressure (*AoP*) and instantaneous LV pressure (*LVP*) (*left*). Mean gradients represent average pressure difference between aorta and LV over systolic ejection (*middle*). "Peak-to-peak" gradient corresponds to difference between peak aortic pressure and peak LV pressure (*right*).

measurements, and several consecutive beats need to be averaged.

It is therefore important to rely not only on a flow-dependent but also on a relatively flow-independent measure of AS severity: the calculated aortic valve area.

### Comparison with Catheter-Measured Gradients

Doppler and invasively measured mean gradients both represent the average pressure difference between the aorta and the LV over the systolic ejection period and should ideally be identical when simultaneously recorded in practice.

The peak Doppler echocardiographic gradient corresponds to the maximal instantaneous difference between the aortic and the LV pressure.

The catheter-derived "peak-to-peak" gradient, which cannot be determined by Doppler echocardiography, does not exist physiologically and corresponds to the difference between peak aortic pressure and peak LV pressure (Fig. 23-7).

### *Valve Area Calculation*

Calcific AS is characterized by stiff leaflets that open to a variable degree depending on the force applied on the valve. This limits attempts at direct measurement of aortic valve area and even applies to the situation where the surgeon applies direct force, inspecting the valve with the finger.

### Continuity Equation

The continuity equation method for the calculation of valve area[11,15,28-31] is based on the consideration that the same stroke volume crosses the LV outflow tract and the aortic valve.

Aortic valve area (AVA) is calculated as

$$AVA = (CSA_{LVOT} \times VTI_{LVOT})/VTI_{AS}$$

where $VTI_{LVOT}$ and $VTI_{AS}$ represent velocity time integrals at the levels of the LV outflow tract and the stenotic aortic valve, respectively, and $CSA_{LVOT}$ represents the cross-sectional area in the outflow tract.

A simplified form of the continuity equation in which velocities are measured instead of velocity-time integrals can be used in clinical routine where velocities in the LV outflow tract and across the aortic valve are measured:

$$AVA = (V_{LVOT} \times CSA_{LVOT})/V_{AS}$$

where $V_{LVOT}$ and $V_{AS}$ represent the velocities in LV outflow tract and at the level of the stenotic aortic valve, respectively.

The LV outflow tract flow velocity profile is measured from an apical approach using pulsed-wave (PW) Doppler ultrasound. The AS jet velocity profile is measured with CW Doppler from the echocardiographic window that yields the highest velocity signal (Fig. 23-8). Theoretically, volume flow rate can be measured at several intracardiac sites (pulmonary artery, mitral annulus, and LV outflow tract). Flow measurements just proximal to the stenotic aortic valve are technically feasible in nearly all adult patients, whereas volume flow-rate calculations at other intracardiac sites often are limited by image quality. Furthermore, when coexisting aortic regurgitation is present (encountered to some degree in more than 80% of adults with AS), volume flow measured across other valves may not equal the volume flow rate across the aortic valve.[21] Thus, in practice, the LV outflow tract is used for measurement of transaortic volume flow rate in nearly all cases. Volume flow measurement proximal to the stenotic aortic valve assumes that (1) the cross-sectional area of flow is circular in systole and flow fills the anatomic cross-sectional area, (2) the pattern of blood flow is laminar with uniform parallel stream lines of flow, (3) cross-sectional area and flow velocity are measured at the same site, and (4) the spatial flow velocity profile is relatively "flat" (same flow velocities in the center and at the edges of the flow stream) during ventricular ejection. The assumptions of a circular cross-sectional area with flow filling the anatomic area have been corroborated by short-axis 2D and color flow imaging in animal models and in patients with valvular obstruction.[15] Laminar flow is confirmed by recording a narrow band of velocities throughout ejection on the PW Doppler spectral tracing.

For the determination of $CSA_{LVOT}$, the LV outflow tract diameter is measured in midsystole from a 2D parasternal long-axis view, parallel and adjacent to the aortic valve plane. In this view the outflow tract is perpendicular to the ultrasound beam, and axial resolution provides a more accurate diameter measurement than the use of apical views. In practice, zooming in on the area of interest and confirmation of the diameter from an apical five-chamber view is recommended.

Continuity equation valve area calculations assume accurate recording of the maximum aortic jet velocity, as discussed earlier for pressure gradients. The area is then calculated assuming a circular outflow tract, although it is oval in most patients.

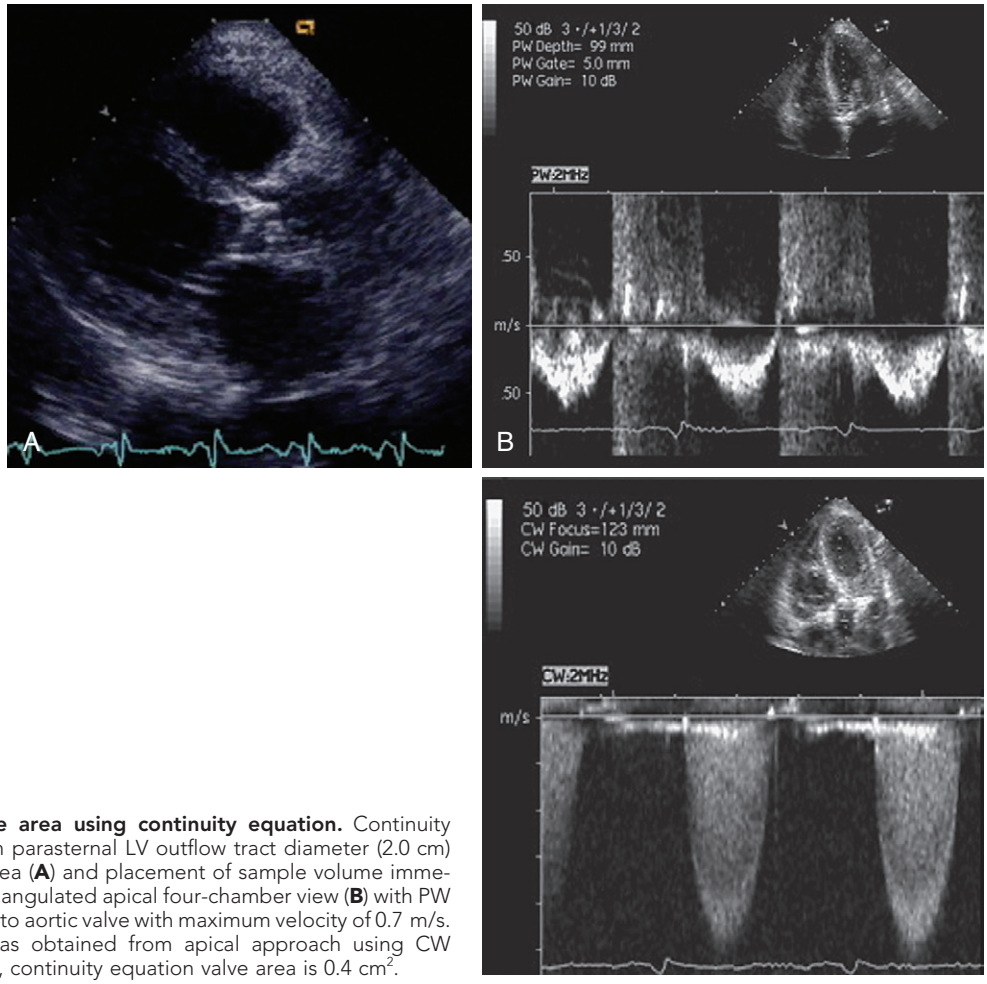

**Figure 23-8 Calculation of aortic valve area using continuity equation.** Continuity equation valve area is calculated based on parasternal LV outflow tract diameter (2.0 cm) for calculation of circular cross-sectional area (**A**) and placement of sample volume immediately proximal to aortic valve in anteriorly angulated apical four-chamber view (**B**) with PW Doppler recording of laminar flow proximal to aortic valve with maximum velocity of 0.7 m/s. Highest velocity aortic signal (5.2 m/s) was obtained from apical approach using CW Doppler (**C**) in this patient. In this example, continuity equation valve area is 0.4 $cm^2$.

In addition, the mean inter- and intraobserver variabilities of the outflow tract diameter measurement are in the range of 5% to 8%, resulting in a variability of about 0.15 $cm^2$ for a calculated valve area of 1.0 $cm^2$. In an individual patient, the outflow tract diameter remains relatively constant over time, such that a change of more than 0.1 $cm^2$ most likely represents an actual change in valve area over time.

For the calculation of the circular cross-sectional outflow tract area, the LV outflow tract diameter is measured in the parasternal long-axis view, immediately adjacent and parallel to the aortic valve plane in midsystole. To ensure that diameter and flow measurements are recorded from the same anatomic site, both measurements should be made as close to the aortic valve as possible. In theory, the tapering of the outflow tract and the acceleration of blood during systole, both of which result in blunt flow profiles at the entrance to large vessels, allow the assumption of a relatively "flat" spatial flow profile in the outflow tract. A direct examination of the spatial flow profile in the LV outflow tract proximal to the stenotic aortic valve was initially performed with conventional PW Doppler by recording flow at sequential sites across the outflow tract.[21,32] Another study, using color flow mapping in patients with AS both before and after aortic valve replacement, showed variable skewing in the spatial flow profile, with highest velocities most often encountered in the region from the center of the outflow tract toward the septum[33] (Fig. 23-9). Patients with predominant AS were found to have relatively flat flow profiles, whereas normal subjects and patients with aortic regurgitation had skewed velocity profiles with the highest velocities occurring anteroseptally.[34] For clinical practice, even when the flow profile is skewed to some extent, a reasonably accurate volume flow rate can be calculated if the recorded flow velocity reasonably approximates the spatial and temporal flow velocity in the outflow tract.

Ideally, the accuracy of Doppler transaortic volume flow measurements should be validated by comparison to an established standard of reference. This is difficult in clinical studies, because most patients with AS have coexisting aortic and/or mitral regurgitation. Even a hemodynamically "insignificant" regurgitation will lead to an inaccurate assessment of forward (Fick or thermodilution) and of total (angiographic) cardiac output, thereby inadequately representing the volume flow rate across the aortic valve. In the research setting, transaortic volume flow rate can be measured directly, using an electromagnetic or a transit time flow meter. In both acute and chronic models of valvular AS, Doppler transaortic volume flow rates have been shown to be accurate (Table 23-1)[15,17] with a standard error of the estimate of 2 to 4 mL for stroke volume and of 0.25 to 0.5 L/min for cardiac output over a wide range of flow rates (Fig. 23-10).

## Comparison of Valve Areas Calculated by the Continuity Equation and by the Gorlin Formula

Aortic valve areas calculated from invasive hemodynamic data using the formula of Gorlin and Gorlin,[35] which was published in 1951, have been used as the standard of reference for validation of continuity equation valve areas.[21,31,36]

Understanding the different underlying principles of these equations is important (Fig. 23-11). According to the formula by Gorlin and Gorlin, aortic valve area is calculated as

$$AVA = (\text{cardiac output}) \Big/ \left(HR \times SEP \times 44.3 \times \sqrt{\Delta P_{mean}}\right)$$

where $\Delta P_{mean}$ represents the manometrically measured mean pressure gradient, SEP is the systolic ejection period, and HR is the heart rate.

Accurate pressure gradient measurements depend on careful attention to frequency response, damping, and catheter positioning. The use of a double-lumen catheter as opposed to measurement of the femoral artery pressure as a surrogate for the aortic pressure provides more accurate results. Cardiac output should reflect transaortic volume flow rate. Although the Fick or thermodilution methods can be used to calculate cardiac output in isolated AS, an angiographically assessed cardiac output is more appropriate in the presence of aortic regurgitation. In the presence of both mitral and aortic regurgitation, an accurate invasive determination of the transaortic volume flow rate is not possible in the clinical setting.

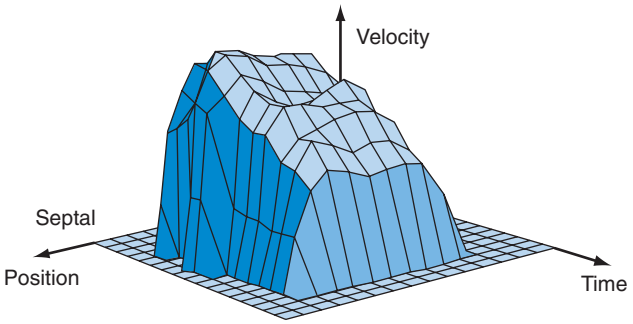

**Figure 23-9 3D plot of velocity distribution in LV outflow tract close to level of aortic annulus.** Velocity is plotted against position in LV outflow tract diameter and against time. There are 20-ms intervals along time axis and approximately 2 mm between each observation along diameter axis. *(From Wiseth R, Samstad S, Rossvoll O, et al: Cross-sectional left ventricular outflow tract velocities before and after aortic valve replacement: a comparative study with two-dimensional Doppler ultrasound.* J Am Soc Echocardiogr *6:279-285, 1993.)*

The Gorlin formula contains an empirically derived constant (C) incorporating the coefficient of contraction, reflecting the difference between the anatomic valve area and the area of the vena contracta; the coefficient of velocity, relating to the conversion of potential to kinetic energy; measurement of pressure in mm Hg; and an empiric "correction" factor. Both in vitro and in vivo studies suggest that the Gorlin constant may vary with changes in volume flow rate, orifice shape, and stenosis severity.[37,38]

When comparing Gorlin and continuity-equation valve areas, it is fundamental to bear in mind that they measure different parameters: The Gorlin formula examines the hydraulic load and calculates an anatomic orifice area, whereas the continuity equation describes the physiologic flow area of the vena contracta.[39,40] Thus, one cannot expect these two measurements to yield identical results. Pressure recovery is contributing to this discrepancy.[41] In terms of clinical decision making, their precision, reproducibility, and ability to predict patient outcome are more important than agreement or disagreement. As Gorlin and Gorlin[42] note:

> *We need not be frustrated when valve areas derived by two different methods are not the same. Rather, we should, like the princes of Serendip, seize upon the difference for what it reveals about the anatomy of the valve orifice as opposed to the physiology of the total obstructing valve tract under active pressure and flow conditions.*

## Definition of the Degree of Severity

Quantification of AS severity is fundamental in the clinical context. Conceptually AS severity can be considered as a continuum ranging from aortic sclerosis to hemodynamically significant disease. Thus, the actual measure of severity should be integrated in the decision-making process. The categorical differentiation between severe and nonsevere stenosis is of particular importance because of direct implications for patient management. Information from aortic jet velocity, mean gradient, and valve area should be integrated and is ideally concordant. In the past, "severe" or "critical" AS has been defined in terms of a specific valve area. Recent clinical studies have used a peak aortic jet velocity of 4 m/s or more to define severe AS.[6,43,44]

Cutoff values for the effective aortic valve area in the range of 0.8 to 1 $cm^2$ to define severe AS are encountered in the literature, but more recent guidelines recommend an area of 1 $cm^2$.[45,46] However, a marked overlap in hemodynamic severity between symptomatic and asymptomatic patients indicates that the "critical" degree of valve narrowing varies from patient to patient (Fig. 23-12). This observation has been confirmed in prospective studies showing that symptom onset occurs with a jet velocity lower than 4.0 m/s or may be delayed until the jet velocity is over 5.0 m/s. The variability of valve areas for a given aortic jet velocity is large.[47] In addition, even among patients with very advanced disease, defined by an aortic jet velocity of 5 m/s, valve areas ranged between 0.3 and 0.9 $cm^2$, further emphasizing the limited accuracy of calculated valve area in clinical routine use.[48] Nevertheless, a valve area below 1.0 $cm^2$ has a high sensitivity to identify patients with severe AS. In the presence of a preserved transaortic flow, peak aortic jet velocity is probably the most robust and predictive measure of severity. Because of the increasing likelihood of symptom development with increasing aortic jet velocities, the entity of very severe AS might be defined. In this context, using a threshold for the peak aortic jet velocity of 5 m/s or more has been suggested. The transaortic gradient almost doubles with an increase of peak aortic velocity from 4.0 to 5.5 m/s: Because of the quadratic relationship, the gradients corresponding to velocities of 4.0, 5.0, and 5.5 m/s are 64, 100, and 121 mm Hg, respectively. Although all of these velocities correspond to "severe" AS, it is obvious that the hemodynamic repercussions are different, further supporting the concept of a delineation of "very severe" AS.

It has been suggested that an aortic valve area indexed to body surface area of less than 0.6 $cm^2/m^2$ defines severe AS.[49] However, because of a distortion of indexed valve areas at the extremes of the spectrum of body surface area, such as in slim and small or in obese persons, the value is inherently limited. From a pragmatic approach, it is recommended to consider patient stature and build when quantifying AS severity. The quantification of AS needs to be individualized, particularly when the measured values are in the borderline zone between

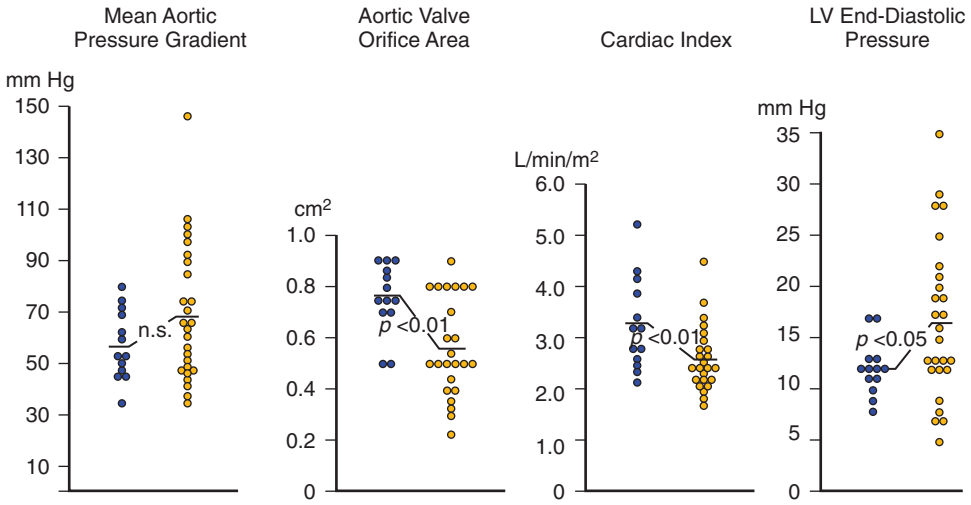

**Figure 23-12** Hemodynamically severe aortic stenosis: mean aortic pressure gradient, valve orifice area, cardiac index, and LV end-diastolic pressure in severely symptomatic (*open circles*) and asymptomatic or mildly symptomatic (*closed circles*) patients. Mean value (*horizontal line*) and statistical difference between both groups are indicated. *n.s.*, Not significant. *(From Turina J, Hess O, Sepulcri F, et al: Spontaneous course of aortic valve disease.* Eur Heart J *8:471-483, 1987.)*

moderate and severe stenosis. In this regard, consideration of the symptomatic status of the patient is essential.

The differentiation between different degrees of nonsevere stenosis (i.e., aortic sclerosis, mild and moderate stenosis) is less critical with regard to immediate therapeutic choices but is relevant to determine prognosis and schedule follow-up exams.[43,50,51] Mild AS is defined by a valve area of more than 1.5 $cm^2$, a mean gradient of less than 25 mm Hg, and an aortic jet velocity of less than 3.0 m/s.

## OTHER MEASURES OF SEVERITY

### *Velocity Ratio*

The velocity ratio is defined as the ratio of velocities in the LV outflow tract and across the aortic valve:

$$\text{Velocity ratio} = V_{LVOT}/V_{AS}$$

or

$$\text{Velocity time integral ratio} = VTI_{LVOT}/VTI_{AS}$$

Severe stenosis is defined by a velocity (or VTI) ratio of less than 0.25.

This measure has the theoretical advantages of being flow independent and of not requiring LV outflow tract measurements (in contrast to the continuity equation). However, its prognostic value has not been validated in large clinical series.

### *Aortic Valve Resistance*

Valve resistance (expressed in dynes-s-$cm^{-5}$) is calculated from invasive or Doppler data as[52,56,57]

$$\text{Resistance} = (\Delta P_{mean}/Q_{mean}) \times 1333$$

where $\Delta P_{mean}$ (in mm Hg) and $Q_{mean}$ (in mL/s) represent the mean transaortic pressure gradient and the mean volume flow rate, respectively, and 1333 is a conversion factor. The concept of valve resistance offers the advantage that no empirical constant is involved as compared to the Gorlin formula. Several investigators have observed a curvilinear relationship between valve resistance and valve area (with invasive and Doppler data).[52] This observation is supported by the mathematical derivation of the valve area and resistance concepts. In fact, the concepts of valve area and valve resistance are to some extent mutually exclusive. Valve area calculations with the Gorlin formula assume a quadratic relationship between pressure gradient and flow rate. Conversely, the valve resistance concept assumes a linear relationship between these two variables. Most clinical and experimental data support the concept of a quadratic, rather than linear, relationship between pressure gradient and flow rate across a stenotic valve[53] (Fig. 23-13). More complete modeling of the interaction among the LV, the valve, and the peripheral vasculature may enhance our understanding of the hemodynamics of valvular AS.[54] From several studies, it appears that valve resistance is flow dependent and thus does not offer a direct advantage over valve area calculations.[55,56] Because of a lack of consensus among studies as to whether it adds information to conventional measures of severity, valve resistance has not gained widespread clinical acceptance.[52,57]

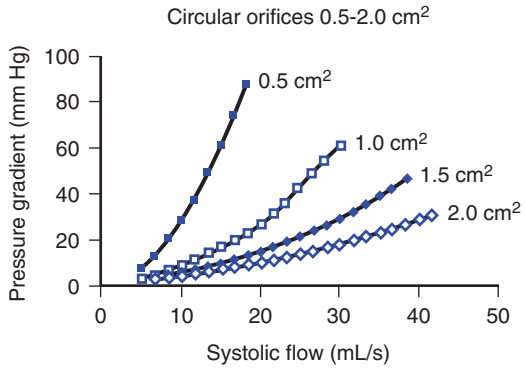

**Figure 23-13** Plot of square-law dependence of pressure gradient on flow demonstrated for circular stenoses with orifices from 0.5 to 2.0 $cm^2$. *(From Voelker W, Reul H, Nienhaus G, et al: Comparison of valvular resistance, stroke work loss, and Gorlin valve area for quantification of aortic stenosis. An in vitro study in a pulsatile aortic flow model.* Circulation *91:1196-1204, 1995.)*

### *Stroke Work Loss*

Based on the energy-loss concept, the amount of work expended by the LV to keep the aortic valve open during systole compared to the amount of work resulting in effective forward blood flow has been proposed as a potential measure of stenosis severity. This measure would reflect the intrinsic stiffness of the valve leaflets and thus be less dependent on volume flow rate.[58,59] For a stenotic aortic valve, the difference between work calculated from LV pressures and aortic pressures represents the amount of work "lost" in opening the stiff leaflets. When the aortic valve opens normally, this difference is not significant. Work is calculated by generating a power curve, multiplying instantaneous flow with pressure. Total potential stroke work is calculated by integrating power over the systolic ejection period[59] either using LV (for total work) or aortic (for effective work) pressures. The steady component of work is defined as mean systolic pressure multiplied by stroke volume; pulsatile work is defined as total minus steady work. Stroke work loss then represents the difference between LV and effective work and can be calculated for total, steady, and pulsatile components[58] as

$$\text{LV stroke work loss} = \text{LV work} - \text{effective work}$$

Because potential work increases with an increasing flow rate, the potential work loss across the stenotic valve is indexed for volume flow rate and expressed as the percent LV stroke work loss.

$$\%\ \text{LV stroke work loss} = (\text{stroke work loss}/\text{LV stroke work}) \times 100$$

Given that stroke work is the instantaneous product of pressure and flow, and stroke work loss is the difference of LV and aortic work, this proposed index of stenosis severity is likely to vary with volume flow rate if the actual degree of valve opening varies. Note that when the ratio of LV to aortic work is calculated, the terms for transaortic volume flow rate cancel each other, so that stroke work loss can be determined from Doppler pressure calculations alone. A new index of energy loss that takes body surface area into account and can be calculated from Doppler-derived data was evaluated in an experimental model[60] assessing fixed stenoses and bioprosthetic valves of two sizes at different flow rates.

### *Planimetry of the Aortic Valve Area*

The opening surface of a stenotic aortic valve represents a complex three-dimensional (3D) structure that cannot be reliably assessed with a planar 2D image. The presence of valvular calcification may further limit an accurate delineation of the valve orifice.[61]

Whereas some investigators have reported favorable correlations between planimetered stenotic orifice areas obtained on multiplane TEE and continuity equation valve areas and/or Gorlin valve areas,[62] others have found planimetry of the aortic orifice to be difficult and less accurate than continuity-equation valve areas obtained from transthoracic imaging.[63] However, valve area planimetry may be helpful when transthoracic imaging quality is poor, such as in ventilated patients.

### *3D Echocardiography*

3D echocardiography is increasingly integrated in commercial echocardiographic systems, and good imaging quality can be obtained, particularly when using a transesophageal approach. Recent series report the feasibility of the method in the majority of patients with a good correlation of the valve area derived by flow-derived methods or standard TEE.[64]

## Physiologic Variability in Measures of Stenosis Severity

### EXERCISE HEMODYNAMICS IN VALVULAR AORTIC STENOSIS

Exercise testing is contraindicated in symptomatic patients with valvular AS, because of the high risk of complications.[65] However, it can be safely performed in asymptomatic patients, where a number of studies have provided an insight into the relationship between hemodynamic severity and clinical symptoms[66,67] (Table 23-2). In asymptomatic patients with AS, exercise results in an appropriate rise in heart rate and cardiac output. The increase in cardiac output with upright exercise is mediated almost entirely by heart rate, with little change in stroke volume. However, even though stroke volume remains constant, transaortic volume flow rate is increased because of the shortening of the systolic ejection period. Thus, exercise results in an increase in peak aortic jet velocity, with a corresponding increase in the mean transaortic gradient as predicted by the Bernoulli equation.

The continuity equation predicts a linear relationship between maximum volume flow rate ($Q_{max}$) and maximum jet velocity ($V_{max}$) for any given valve area.[66] In clinical studies—where normally only two data points can be acquired—the slope of the change in $V_{max}$ relative to $Q_{max}$ parallels the slope predicted by the continuity equation in patients when the valve area remains constant with exercise. If the valve area increases with exercise, the observed slope is greater than that predicted for a fixed valve area.

### CHANGES IN AORTIC VALVE AREA WITH CHANGES IN VOLUME FLOW RATE

The effect of changes in volume flow rate on valve areas calculated using the Gorlin and the continuity equations has been examined in in vitro and animal models[68] and in patients with valvular AS (Fig. 23-14). These studies consistently show an increase in valve area with an increase in transaortic volume flow rate.[56,58,69-75] Although these apparent increases could be due to some extent to errors inherent to the valve area formulas, the concept that valve area itself, both anatomic and physiologic, varies with transaortic volume flow rate is supported by in vitro pulsatile flow model data[53] and video imaging of flow-dependent changes in valve opening.[76] The effects of flow-rate changes on valve area are not due to artifacts but can be explained by an actual increase in leaflet opening with increasing flow rates and to unsteady effects at low flow rates.[77] This finding is in agreement with the observation that even normal aortic valve leaflets open less when volume flow rate is decreased—for example, in patients with a dilated cardiomyopathy.

### CHANGE IN OTHER MEASURES OF STENOSIS SEVERITY WITH CHANGE IN VOLUME FLOW RATE

Some investigators have suggested that valve resistance is independent of flow rate,[78] whereas others have shown changes in valve resistance with changes in volume flow rate in in vitro models,[53] in animal models, and in patients with asymptomatic AS.[17,71] In part, the relative stability of valve resistance with changes in flow rate observed in some studies[52] may relate to the range of stenosis severity evaluated. Because of the

curvilinear relationship between resistance and valve area, for "larger" valve areas (right side of curve) resistance changes very little even with substantial changes in valve area, whereas for smaller valve areas (left side of curve) large changes in resistance are expected with only small changes in valve area.

Similarly, LV stroke work loss varies with changes in volume flow rate.[53,56,79] Overall, there is an inverse correlation between valve area and both total and steady LV stroke work loss. However, for a specific valve anatomy, work loss increases with an increase in stroke volume despite a concurrent increase in valve area. This suggests that for a given degree of leaflet stiffness, greater opening of the valve is achieved at the expense of greater work loss. Alternatively, because work includes both potential and kinetic energy, a decrease in the percentage of potential work converted to kinetic work would lead to this observation. In studies to date, only potential work has been measured because of the conceptual and technical difficulties in measurement of kinetic work. Changes in the effective frictional loss component with changes in volume flow rate also may affect calculated measures of stenosis severity.

### THEORETICAL CONSIDERATIONS FOR A MEASURE OF STENOSIS SEVERITY

Degenerative calcific aortic valve stenosis is characterized by thickened, stiff leaflets without commissural fusion. Given this anatomic substrate, it is not surprising that the degree of valve opening varies with the amount of "force" applied to the valve, whether this force is represented by the surgeon's finger, a balloon valvuloplasty catheter, or the rate and volume of blood ejected by the LV. Most proposed measures of stenosis severity, when examined in detail, vary with changes in volume flow rate. These measures include peak LV-to-aortic pressure gradient, mean transaortic pressure gradient, maximum Doppler aortic jet velocity, Gorlin valve area, continuity equation valve area, LV stroke work loss, and valve resistance. Despite this theoretical limitation, most clinical decisions can be made with a high degree of reliability using these imperfect indices of disease severity.

The ideal measure for AS quantification accurately reflects disease severity and even more importantly predicts clinical outcome, at the same time having an acceptable intra- and interobserver reproducibility. In addition, it should be noninvasive, easy to perform, readily available, and inexpensive. Doppler-echocardiographic measures of jet velocity and valve area meet these criteria. In the clinical setting, the impetus to derive a flow-independent measure of stenosis severity arises from the relatively unusual clinical situation in which there is coexisting LV systolic dysfunction and an anatomically abnormal aortic valve. Potential approaches to this clinical dilemma are discussed next.

Determination of hemodynamic progression is important, both in the clinical setting[6] and in research applications. Hemodynamic progression is related to clinical outcome, and its assessment is of interest for the identification of potential predictors of progression as well as of potential therapies aiming at preventing or slowing the hemodynamic progression of AS. In this context, measures of stenosis severity with a high reproducibility over time and between institutions are needed.

## The LV Response to Valvular Aortic Stenosis

### DIASTOLIC FUNCTION

The initial physiologic response to chronic pressure overload of the LV is impaired early diastolic relaxation as manifested

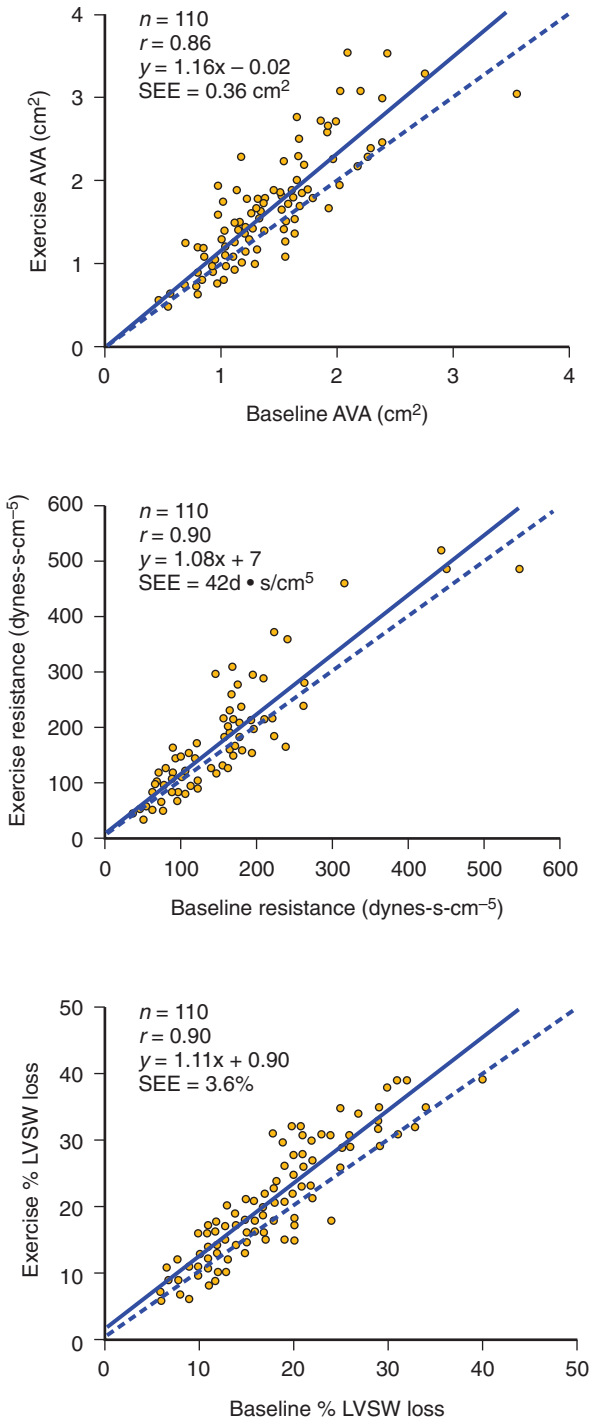

**Figure 23-14** Relation of rest and continuity equation aortic valve area (*AVA*) (*top*), aortic valve resistance (*middle*), and percent left ventricular stroke work (*LVSW*) loss (*bottom*) in 110 exercise studies. Slopes of regression lines (*solid line*) are greater than line of identity (*dashed line*), demonstrating increase in all three indexes with exercise. *SEE*, Standard error of estimate. *(From Burwash IG, Pearlman AS, Kraft CD, et al: Flow dependence of measures of aortic stenosis severity during exercise.* J Am Coll Cardiol *24:1342-1350, 1994.)*

by a prolonged time constant of relaxation, a lengthened isovolumic relaxation time, and a reduced early diastolic filling velocity, similar to the changes seen in patients with systemic hypertension.[80-83] Changes in diastolic function typically precede evidence of systolic dysfunction and thus may be present early in the disease course. Although some investigators suggest that Doppler measures of early and late diastolic filling velocities (or rates) may not be sensitive for detection of early diastolic dysfunction,[83] others propose that diastolic parameters can distinguish symptomatic from asymptomatic patients.[84] Tissue Doppler imaging has been reported to allow estimation the diastolic performance and LV filling pressures in these patients.[85] Using tissue Doppler imaging, diastolic dysfunction is even detected in patients with moderate AS.[86] Later in the disease course, decreased diastolic compliance plus a rightward shift on the passive diastolic pressure-volume relationship may result in a filling pattern characterized by a shortened isovolumic relaxation time, increased early diastolic filling velocity, rapid early deceleration slope, and reduced atrial contribution to diastolic filling, a pattern often referred to as "pseudonormalization."[82]

## WALL STRESS AND CONCENTRIC HYPERTROPHY

With increasing stenosis severity, concentric LV hypertrophy develops in response to chronically elevated LV systolic pressures. Normal wall stress is maintained given that wall stress is directly related to chamber pressure and dimension, but inversely related to wall thickness. LV hypertrophy is reliably assessed by calculation of LV mass, although simple chamber dimensions and diastolic wall thickness may be adequate for clinical evaluation.

LV hypertrophy in patients with AS is associated with abnormalities in coronary microcirculatory function.[87] This microcirculatory dysfunction may not necessarily be explained by the presence of hypertrophy itself but rather by an increased extravascular compression and a reduced diastolic perfusion time.[88]

In some individuals, the degree of hypertrophy appears out of proportion to AS severity. In these patients, other causes for hypertrophy should be considered, such as hypertension, coexisting hypertrophic cardiomyopathy, or an infiltrative myocardial process. The high prevalence of arterial hypertension in AS patients may explain some extent of hypertrophy, in particular when AS is not severe.[89] Genetic factors may also play a role in the degree of LV hypertrophy. Associations between polymorphisms of the angiotensin-converting enzyme gene and LV hypertrophy have been described.[90,91] Excessive hypertrophy was associated with an increased risk of cardiac events in patients with asymptomatic severe AS.[92] However, LV mass and tissue Doppler measures of LV systolic and diastolic function provided limited predictive information when considering the AS severity.[93]

## GENDER DIFFERENCES IN THE LV RESPONSE TO AORTIC STENOSIS

Significant gender differences in the LV response to the chronic pressure overload of AS have been reported.[94] In symptomatic patients referred for aortic valvuloplasty, women had higher transaortic gradients despite similar valve areas, higher relative wall thicknesses, and a higher prevalence of LV hypertrophy using gender-specific hypertrophy criteria. In addition, women had a lower functional status score for the same degree of aortic valve obstruction.[95] Another study observed higher peak LV pressures, higher ejection fractions, smaller LV end-diastolic dimensions, and a higher relative wall thickness in women with AS compared to men with the same condition.[96]

In a series of consecutive asymptomatic AS patients,[97] in the presence of comparable stenosis severity, women reported more functional limitation, had smaller LV end-diastolic and end-systolic volumes and mass index, but had a higher relative wall thickness and fractional shortening compared to men. In addition, women had a shorter treadmill exercise duration and a smaller increase in cardiac output with exercise even though heart rate and blood pressure responses were similar in men and women.[97]

The importance of gender differences in the LV response to chronic pressure overload are illustrated by the observation that after aortic valve replacement in patients with depressed LV systolic function (ejection fraction less than 45%), women had a greater improvement in ejection fraction after valve replacement, although survival was similar between men and women. The ejection fraction increased from 33% ± 8% to 48% ± 15% in women and from 32% ± 9% to 42% ± 15% in men (p less than 0.02).[98]

In summary, the degree of LV hypertrophy is variable in both men and women. However, women tend to have small ventricles with thick walls, low wall stress, and normal or hyperdynamic systolic function. In contrast, men tend to have LV dilation with normal wall thickness, increased wall stress, and depressed systolic function.

### SYSTOLIC DYSFUNCTION

Manifest LV systolic dysfunction due to valvular AS usually occurs late in the disease course. However, subclinical myocardial dysfunction identified by reduced myocardial strain has been described even in patients with mild AS with progressive impairment, with increasing degrees of AS severity, and in symptomatic patients.[99] Given the high ventricular afterload due to the stenotic valve, LV contractility typically remains normal despite a low ejection fraction. Relief of the high afterload with valve replacement leads to rapid normalization of systolic function in the majority of patients. However, LV systolic dysfunction may be caused by mechanisms other than AS, such as coronary artery or myocardial disease. Under these circumstances, LV function often fails to improve with valve replacement, and the outcome remains poor. In the setting of a moderate aortic valve gradient, distinguishing poor LV systolic function due to severe AS from that of concurrent ischemic or myocardial disease with only moderate aortic valve disease remains a difficult dilemma. One approach is to use a flow-independent measure of stenosis severity or to look at the change in stenosis severity with a change in volume flow rate. The theoretical alternate approach to use a load-independent measure of LV contractility to evaluate myocardial function has proven as elusive as a flow-independent measure of stenosis severity.[83]

## Natural History, Progression, and the Role of Echocardiography in Clinical Decision Making

### NATURAL HISTORY OF AORTIC STENOSIS

The natural history of AS is characterized by an asymptomatic phase of variable duration, during which the LV is subjected to increasing outflow obstruction and adaptive mechanisms[100-102] (Table 23-3). The occurrence of symptoms presents a change in the natural history of the disease. Patients with congenital AS may become symptomatic in early childhood or adolescence; patients with unicuspid valves are particularly likely to present with early symptoms. Later, these patients may also present with symptoms due to restenosis after a surgical valvotomy in childhood. In patients with a bicuspid AS, surgery is typically needed at age 50 to 70 years.[2,103,104] In the elderly patient with

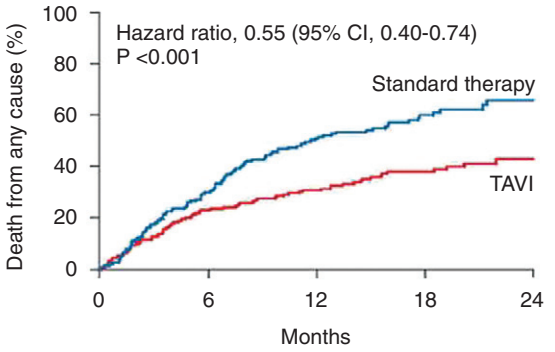
This graph reflects outcomes in the presurgical era based on autopsy data with primarily rheumatic valve disease. *(From Ross J Jr, Braunwald E: Aortic stenosis.* Circulation *38:61-67, 1968.)*

degenerative calcific valve disease, symptom onset may have occurred at an age of 50 years but typically occurs at age 60 to 90 years.[2]

Rheumatic valvular AS has a variable course with significant aortic valve obstruction (in conjunction with mitral valve involvement) occurring over a wide age range.



### *Asymptomatic versus Symptomatic Aortic Stenosis and Severe versus Nonsevere Aortic Stenosis*

With an ageing population, the incidence of calcific aortic valve disease is increasing. Furthermore, with the widespread use of echocardiography, the diagnosis is made more commonly in asymptomatic patients as coincidental finding or after suspicion due to a systolic murmur. Its spectrum ranges from severe symptomatic stenosis to aortic sclerosis without hemodynamic implications. In between are the asymptomatic patients with severe, moderate, and mild AS. The incidence of AS in the population of advanced age is estimated to be between 2% and 9%. Aortic sclerosis is present in up to 25% of patients over 65 years of age.[50,105,106]

The first step in the clinical decision-making process for the timing of intervention in a patient with valvular AS is a careful history as to whether symptoms (angina, exertional dizziness, exercise intolerance, or heart failure) are present or absent. Exercise testing may be appropriate and safe in apparently asymptomatic patients and may unmask latent symptoms in up to one third of these.[107,108] The greatest predictive value of exercise testing can be derived in physically active patients who are younger than 70 years.[108] It must be emphasized that exercise testing is contraindicated in symptomatic patients.

### *Symptomatic Aortic Stenosis*

The poor outcome of patients with severe symptomatic AS was well described in a postmortem analysis in 1968.[101] After symptom onset, the average survival has been reported to be less than 2 to 3 years (Fig. 23-15). Additional data were derived from studies of patients who refused surgical intervention.[100,109-114] In a recent contemporary series of symptomatic

| No. at risk | | | | | |

patients with severe AS who were managed conservatively because they were considered not to be candidates for surgery, the 1-year mortality was 50.7% as compared to 30.7% for patients receiving a transcatheter aortic valve implantation[115] (Fig. 23-16). Surprisingly, 83.8% of the patients that were managed "conservatively" underwent balloon aortic valvuloplasty in this series. In patients with severe, symptomatic AS, predictors of survival include the transaortic gradient or velocity, LV systolic function as assessed qualitatively on echocardiography, age, and gender.[116] Among symptomatic patients who are managed conservatively, higher levels of B-type natriuretic peptide (BNP) are associated with increased mortality.[117] Of note, patients with a higher transaortic gradient have a better prognosis, most likely because when severe stenosis is present,

a low gradient indicates a low transaortic stroke volume. On the other hand, current results of aortic valve replacement for acquired AS have been shown to be excellent.[110] Thus, it is generally accepted that surgery must be strongly recommended for patients with critical AS who develop symptoms. Only rarely does severe comorbid disease result in an unacceptably high operative morbidity and mortality. Nevertheless, about one third of patients with symptomatic severe AS are denied surgery.[118,119] Transcatheter aortic valve implantation techniques are an accepted treatment option for selected patients with high surgical risk or in whom surgery is contraindicated.

## *Asymptomatic Aortic Valve Disease*

### Aortic Sclerosis and Mild-to-Moderate Aortic Stenosis

A number of older studies have reported a relatively benign course of moderate AS, suggesting a stable course of the disease.[100,109,110] These data suggested that mild and moderate AS represent a relatively benign disease, although one study described a poor outcome of moderate AS, with 14 deaths attributed to AS among 66 patients followed for 35 months.[112] However, most of these studies date back to catheter era and are limited by small patient numbers and their retrospective nature.[100,109,110,112]

More recent studies have shed new light on the seriousness of the disease. A community-based study showed that the presence of aortic valve sclerosis is associated with a significantly increased cardiovascular and all-cause mortality in the absence of hemodynamic obstruction to blood flow.[50] Recent studies have also shown that mild-to-moderate AS is not a benign disease, with increased cardiovascular and noncardiac mortalities.[43,51] Thus, aortic sclerosis and mild-to-moderate AS must be viewed as indicators of poor overall prognosis.

In addition, the prognosis of these patients is influenced by hemodynamic disease progression. In fact, the progression of aortic sclerosis to AS affects about 16% of patients within a short time period.[120] The interval between observing aortic valve "sclerosis" and clinical evidence of severe AS may be as short as 5 years. The progression from mild to severe AS is also common and may be rapid.[51]

As long as AS is not severe, these patients can be managed conservatively. However, knowing that a rapid progression to severe AS may occur, it is important to instruct even patients with mild-to-moderate AS about potential symptoms of AS and the necessity to immediately report to a physician after their onset. Performing a repeat echocardiography is warranted after a change in symptomatic status to assess a potential hemodynamic disease progression.

### Asymptomatic Severe Aortic Stenosis

The management of asymptomatic patients with severe AS remains a matter of controversy. Overall, it is relatively safe to delay surgery in patients with severe AS until symptoms develop, following a watchful waiting strategy.[6] However, there are concerns when following such patients conservatively.[121] Among these concerns is the risk of sudden death, which may occur even in the absence of preceding symptoms. However, this appears to be an uncommon event, occurring at a rate of less than 1% per year during the asymptomatic disease phase.[6,43,48,108,111,122-127] (Table 23-4). Finally, sudden death may also occur after successful valve replacement, with an incidence of about 0.3% per year.[128,129]

### Asymptomatic Very Severe Aortic Stenosis

AS severity represented by peak aortic jet velocity is an important predictor of event-free survival across the spectrum of mild to severe AS.[43] Peak aortic jet velocity allows risk stratification among asymptomatic patients with severe stenosis.[48] Event-free survival rates at 3 years were 49%, 33%, and 11% for patients with peak aortic jet velocities between 4.0 and 5.0 m/s, between 5.0 and 5.5 m/s, or above 5.5 m/s, respectively (Fig. 23-17). Most patients with an aortic jet velocity greater than 5.0 m/s are already symptomatic at presentation, and those who are still asymptomatic have a high likelihood of a rapid symptom onset. These findings strongly support defining the entity of "very severe" AS. Kang and colleagues[127] reported a better outcome for 102 patients with asymptomatic AS with a peak aortic jet velocity of more than 4.5 m/s who underwent elective aortic valve replacement as compared to patients who were initially followed conservatively. However, this study was nonrandomized, and mortality in the group of patients who were initially

managed conservatively was unexpectedly high, with a mortality of 24% at 6 years.

## PROGRESSION OF AORTIC STENOSIS

Echocardiography, which is an accurate, noninvasive method to evaluate hemodynamic severity, has allowed large and detailed studies on the rate of hemodynamic progression.[6,51,122,130-136] Recent intervention studies, designed to assess the effects of statin therapy in halting or delaying the progression of AS, provide additional information on hemodynamic progression[137-143] (Table 23-5). Overall, these studies showed an average rate of increase in aortic jet maximum velocity ranges of 0.2 to 0.4 m/s/year, in mean pressure gradients of about 8 mm Hg per year, and a decrease in valve areas of about 0.15 $cm^2$ per year. However, there was marked individual variability in the rate of hemodynamic progression (see Figs. 23-7 and 23-8). Although Doppler-echocardiographic studies have the advantage of larger patient numbers and potentially less selection bias (a repeat echocardiographic study is likely to be requested more often than a repeat cardiac catheterization), many of these are retrospective with data extracted from ongoing clinical databases. Thus, patients with rapid progression, those developing symptoms, or those requiring surgical intervention may be overrepresented. Conversely, repeat studies may not have been performed in clinically stable patients. The prospective studies may avoid some of these biases.[6,43,139]

As the disease progresses, increasing obstruction to LV outflow most often is reflected by a decrease in valve area and an increase in jet velocity and pressure gradient. However, if there is a

concurrent decrease in transaortic volume flow rate, a decrease in valve area alone may be seen with no change in jet velocity. This situation may occur secondary to comorbid disease (e.g., increasing mitral regurgitation or myocardial infarction) or decreasing LV function late in the disease course. On the other hand, an increase in jet velocity and pressure gradient with no change in valve area may be observed if transaortic stroke volume is increased in hyperdynamic states (e.g., anemia, fever, pregnancy) or with increasing aortic regurgitation.

## RISK STRATIFICATION

### *Rationale for Risk Stratification*

One concern when following patients with severe AS is the possibility of delayed symptom-onset reporting with the associated increased risk of mortality. Similar considerations apply to the issue of waiting lists for surgery, with estimated mortality rates for symptomatic patients of around 14% per year.[144] Operative mortality is also significantly lower for mildly symptomatic patients in whom surgery is electively scheduled as compared to an increased surgical risk for patients with advanced symptoms needing urgent surgery.

However, although the operative risk has dramatically decreased over recent decades, it must be considered to be in the range of 2% to 3% and may be as high as 5% to 10% in the elderly.[145] In an asymptomatic patient, this risk has to be outweighed by a proven benefit.

After valve replacement with a mechanical or bioprosthetic valve, valve-related complications such as thromboembolism, bleeding, endocarditis, valve thrombosis, paravalvular regurgitation, and valve failure occur at a rate of 2% to 3% per year. Death directly related to the prosthesis has been reported at a rate of up to 1% per year. The individual disease course is highly variable, and some patients may remain asymptomatic for many years. Early elective surgery is thus not generally recommended, and risk stratification may be required to identify patients likely to benefit from such an intervention.

### *Predictors of Hemodynamic Progression*

Hemodynamic progression of AS is highly variable for individual patients (Fig. 23-18). The exact rate of hemodynamic progression in an individual patient cannot be precisely anticipated (Fig. 23-19). Patterns of progression may be nonlinear with episodes of rapid progression following phases of steady and slow progression. Clinical factors such as elevated serum lipid levels, hypertension, smoking, and diabetes have been found to be associated with AS[146] but have not been convincingly proven to affect disease progression.

Most patients with a bicuspid stenotic valve require surgical intervention at a younger age than those with calcific AS.[104] However, this may relate to a disease onset at an early age. In the early disease phase, when bicuspid aortic valves are only mildly calcified, progression can be expected to be slower. Yet, these bicuspid valves also tend to calcify, and valve calcification predicts disease progression.[6,51,147] Other factors associated with disease progression are the severity of AS (advanced disease results in earlier symptom onset), age, and coronary artery disease[51]—these factors are directly associated with aortic valve calcification.

### *Predictors of Clinical Outcome*

Predictors of outcome are particularly relevant in asymptomatic patients with severe AS because they allow optimal

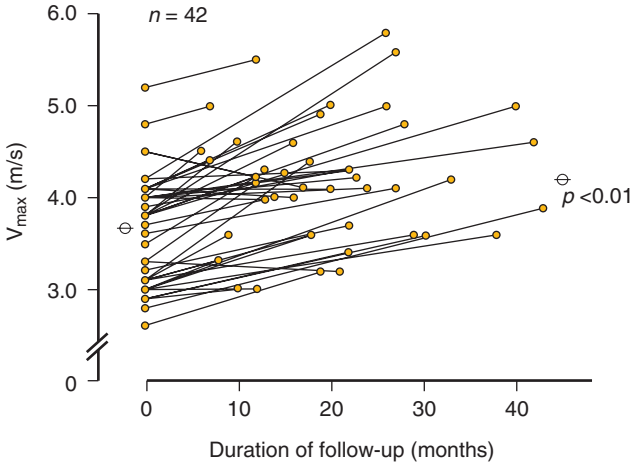

**Figure 23-18** Peak aortic jet velocity ($V_{max}$) plotted for initial and final Doppler studies in 42 asymptomatic patients. Group means indicated by the symbol ⊖. *(From Otto CM, Pearlman AS, Gardner CL: Hemodynamic progression of aortic stenosis in adults assessed by Doppler echocardiography.* J Am Coll Cardiol *13:545-550, 1989.)*

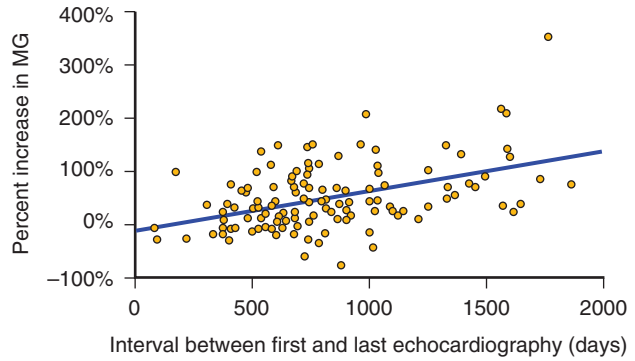

**Figure 23-19** Change in mean aortic gradient (*MG*) in 394 consecutive patients with aortic stenosis represented according to follow-up duration. Despite strong correlation predicting increase of gradient over time (r = 0.40, p < 0.0001), interindividual variability of hemodynamic progression can be appreciated. *(From Brener SJ, Duffy CI, Thomas JD, et al: Progression of aortic stenosis in 394 patients: relation to changes in myocardial and mitral valve dysfunction.* J Am Coll Cardiol *25:305-310, 1995.)*

scheduling of follow-up exams and the identification of candidates for early elective surgery.

Stenosis severity is one of the most robust predictors of outcome in patients with AS. Several studies have confirmed that the likelihood of aortic valve surgery is related to peak aortic jet velocity across the entire disease spectrum: Event rates are lowest in patients with mild stenosis, followed by moderate, severe, and very severe stenosis[6,43,48,51] (Fig. 23-20).

Significant valve calcification, rapid hemodynamic progression, and the presence of coronary artery disease predict high event rates in patients with mild to moderate AS.[51]

In a prospective study including 126 patients with asymptomatic severe AS, it was shown that moderate-to-severe aortic valve calcification detected by echocardiography was associated with an 80% rate of either symptom onset warranting aortic valve replacement or death within 4 years (Fig. 23-21). The finding that aortic valve calcification is associated with poor outcome was confirmed by a study assessing the degree of aortic valve calcification by electron-beam tomography.[148] Patients

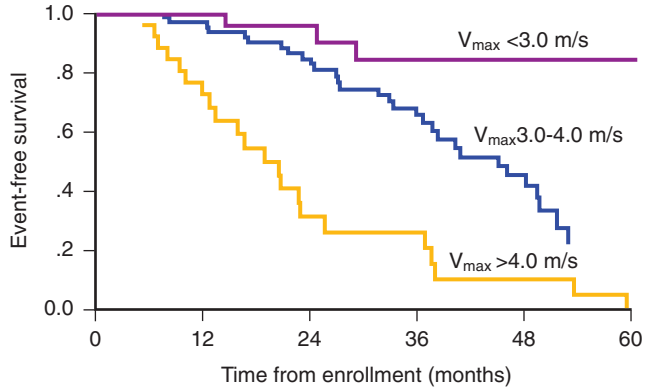

**Figure 23-20** Kaplan-Meier event-free survival of 123 asymptomatic patients with aortic stenosis according to their degree of severity expressed by peak aortic jet velocity ($V_{max}$) ($p < 0.0001$). *(From Otto CM, Burwash IG, Legget ME, et al: Prospective study of asymptomatic valvular aortic stenosis. Clinical, echocardiographic, and exercise predictors of outcome.* Circulation *95:2262-2270, 1997.)*

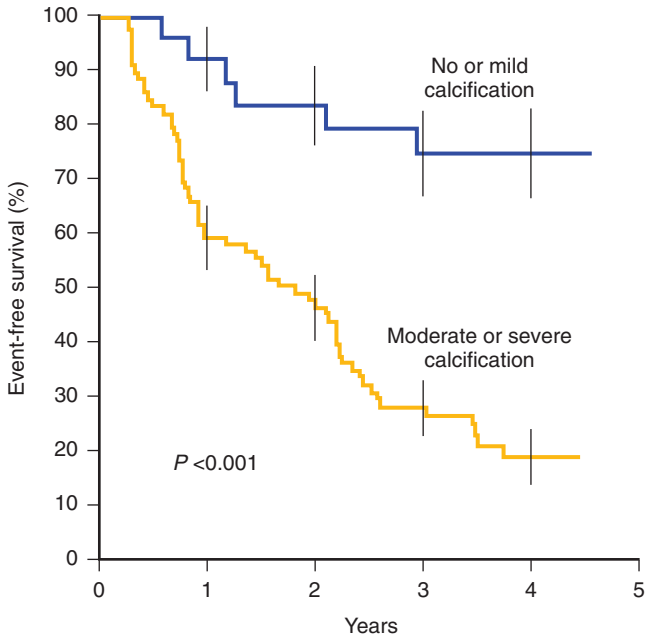

**Figure 23-21** Kaplan-Meier analysis of event-free survival among 25 patients with no or mild aortic valve calcification, as compared with 101 patients with moderate or severe calcification. Vertical bars indicate standard errors. All subjects in this study had initial aortic jet velocity of at least 4.0 m/s (mean 5.0 ± 0.6 m/s). *(From Rosenhek R, Binder T, Porenta G, et al: Predictors of outcome in severe, asymptomatic aortic stenosis.* N Engl J Med *343:611-617, 2000.)*

with calcified aortic valves are more likely to have a rapid hemodynamic progression.[51,147] The combined presence of a calcified aortic valve with a rapid hemodynamic progression (defined as an increase in peak aortic jet velocity of more than 0.3 m/s/year) characterizes a high-risk group with an event rate of 79% within 2 years[6] (Fig. 23-22). Although the echocardiographic determination of aortic valve calcification is semiquantitative, it has the advantage of being quickly and easily obtainable. Furthermore, the clinically relevant differentiation between no or mild calcification and moderate to severe calcification is easily performed. Ultimately, calcification is related to

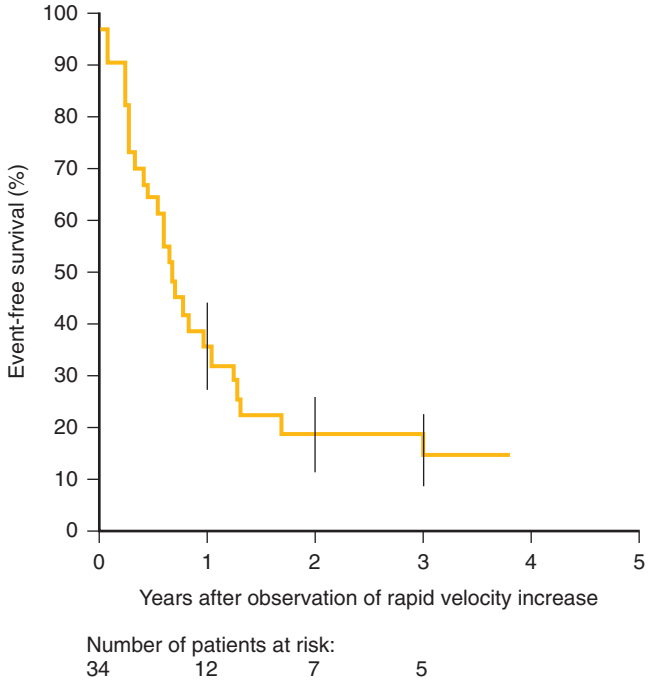

**Figure 23-22** Kaplan-Meier analysis of event-free survival among patients with moderately to severely calcified aortic valves and rapid hemodynamic progression defined by increase in peak aortic jet velocity of more than 0.3 m/s within 12 months. Vertical bars indicate standard errors. *(From Rosenhek R, Binder T, Porenta G, et al: Predictors of outcome in severe, asymptomatic aortic stenosis.* N Engl J Med *343:611-617, 2000.)*

hemodynamic progression, which in turn results in more severe stenosis as reflected by a higher transaortic jet velocity. Peak aortic jet velocity is probably the most robust and extensively studied predictor of outcome in asymptomatic patients with AS.[6,43,48,51,125]

Using exercise Doppler echocardiography in severe asymptomatic AS,[67] an exercise-induced increase of mean transaortic gradient of18 mm Hg or greater, an abnormal exercise test, and an aortic valve area of less than 0.75 $cm^2$ were independent predictors of events, with an incremental value when occurring together. The predictive value of an exercise-induced increase of mean transaortic gradient of 20 mm Hg or more among was confirmed in a group of 135 asymptomatic patients with at least moderate AS.[124]

There is an undisputed role for exercise testing in asymptomatic patients with severe AS for risk stratification and in unmasking symptoms. Patients who have a negative exercise test have a relatively good outcome.[107] Exercise testing has the best positive predictive value for active patients under the age of 70 years and may unmask latent symptoms, which are present in up to 30% of apparently asymptomatic patients.[108] The occurrence of an ST-segment depression, of abnormal blood pressure regulation, or of arrhythmias during exercise had a lower predictive value in this study.[108]

Finally, BNP levels have been shown to correlate with symptomatic status in patients with AS.[149] In asymptomatic patients, low BNP levels are associated with a good short-term outcome.[150,151] However, their positive predictive value needs to be viewed cautiously because of the nonspecificity of this measure and the fact that several cutoff values were proposed in different studies to indicate a poor outcome. Recently, Monin and colleagues[125] proposed a risk score for the identification of

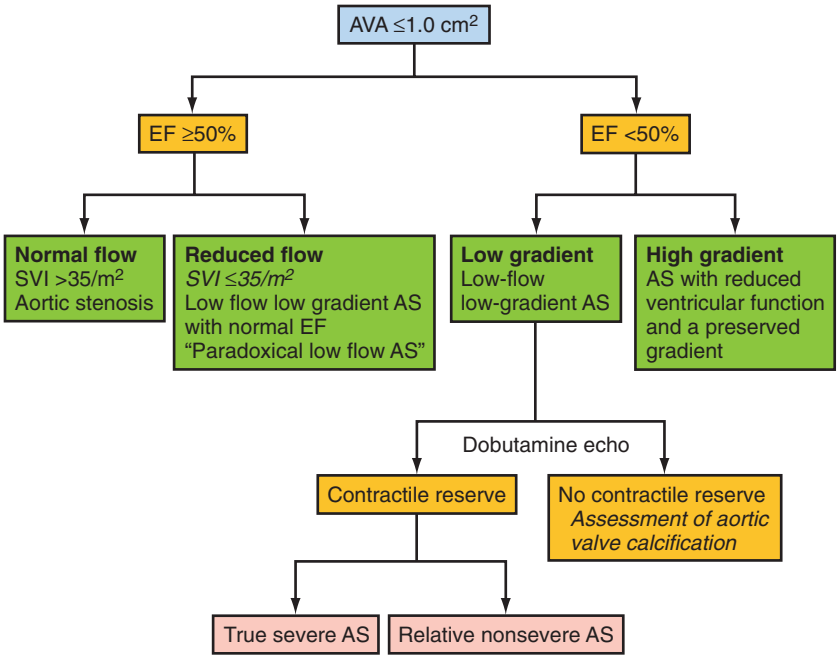

**Figure 23-23** Classification of aortic stenosis (*AS*) defined by calculated aortic valve area (*AVA*) ≤1.0 $cm^2$ according to ventricular function, transvalvular gradients, and flow. *EF*, Ejection fraction; *SVI*, stroke volume index.

high-risk patients that includes information on both stenosis severity and BNP levels.

Valvuloarterial impedance, which is a measure of global systemic load that integrates information on LV pressure burden from AS and systemic arterial compliance,[152] has been suggested to be of additional predictive value.[126]

## TIMING OF SURGERY IN PATIENTS WITH NONSEVERE AORTIC STENOSIS UNDERGOING CARDIAC SURGERY

It is evident that a severely stenotic aortic valve should be replaced at the time of cardiac surgery performed for another reason. The decision as to whether an aortic valve replacement should be performed in the presence of a valve that is not severely stenotic is more complex, given the interindividual variability of disease progression. "Prophylactic" valve replacement for moderate AS is considered to avoid repeat surgery that may be needed within less than 5 years.[153] However, the risks of combined surgery and of potential prosthesis-related complications have to be weighed against the likelihood and risk of two separate operations. The degree of severity, but also risk factors associated with hemodynamic progression, should be considered in this decision.[154,155] In this context, the degree of disease severity, valve calcification, and data on previous hemodynamic progression should be used to define patients likely to benefit from a combined procedure.

## AORTIC STENOSIS WITH REDUCED LV FUNCTION OR FLOW

Impaired LV function in patients with AS is generally associated with poor outcome. However, differentiation according to presence of either a preserved or a reduced transaortic gradient is fundamental in this setting (Fig. 23-23).

### *In the Presence of a Normal Transaortic Gradient*

It is recognized that patients with severe AS who have beginning systolic dysfunction should undergo valve replacement. These patients generally benefit from surgery with an improvement of LV function.

When LV function is significantly impaired, operative risk is significantly increased. However, improvement of LV function and of symptoms can be expected in the majority of patients. Patients with reduced systolic function and a history of prior myocardial infarction experience a particularly poor outcome following valve replacement.[156] Also, the presence of atrial fibrillation has been reported to predict a higher operative risk and worse postoperative outcome in patients with AS and reduced LV function.[157]

### *Low-Flow, Low-Gradient Aortic Stenosis*

The situation of low-flow, low-gradient AS is clinically challenging. It is defined by a small calculated valve area (less than 1 $cm^2$), which is a flow-independent measure of stenosis severity, and a mean transvalvular gradient in the range of 25 to 40 mm Hg in the presence of a reduced LV ejection fraction. In this setting, differentiation between restricted valve opening due to excessive leaflet stiffness and limited leaflet motion due to low transaortic stroke volume is warranted.

The risk of aortic valve replacement in the setting of low-flow, low-gradient AS is high, with an operative mortality in the range of 9% to 33%.[158-160] However, symptoms and LV function typically improve in the patients surviving surgery.[159,160]

Improvement after valve replacement is expected if LV systolic dysfunction is due to AS, but only to a limited extent when it is due to end-stage ischemic disease or a primary cardiomyopathy.

Stress echocardiography with low-dose dobutamine (maximal dose 20 mcg/kg/min) is useful for the evaluation and risk stratification of such patients. It allows the assessment of contractile reserve, defined by an increase in stroke volume of 20% or more.[161] In the presence of contractile reserve, true severe and relative AS can be differentiated.[162,163] If the ventricle fails to respond to inotropic stimulation (i.e., no increase in cardiac output), interpretation is difficult.[72,162,164]

In patients with relative or pseudosevere AS, the augmentation of transaortic volume flow rate results in a significant

increase (at least 0.2 $cm^2$) of valve area as the flexible leaflets open to a greater extent, while the transaortic gradient remains more or less unchanged. Conversely, when true severe AS is present, valve area will change little despite an increased transaortic volume flow due to stiff, rigid valve leaflets, and the transaortic gradients will increase significantly.

However, a small increase in aortic valve area can be seen in some patients with surgically confirmed severe AS and therefore does not exclude fixed valve disease.[165] Dobutamine infusion leads to a variable increase in transaortic flow rate; in some patients, normalized flow rates might not be reached. In an attempt to standardize these findings, the use of a projected effective orifice area (at a normal flow rate of 250 mL/s), which is determined by plotting (and extrapolating if necessary) the effective orifice area against transvalvular flow at the different exam stages, has been proposed to improve accuracy for distinguishing true severe from pseudosevere AS.[166]

In two small studies, 8 of 24[163] and 5 of 12[162] patients with contractile reserve had relative AS. In these studies, surgery led to an improved outcome in patients with true severe AS and preserved LV function. In a large multicentric study, patients with a contractile reserve had a significantly improved survival when they underwent surgery as compared to medically treated patients[161] (see Fig. 23-24). Patients without contractile reserve had poor overall survival, although a trend toward slightly improved outcome was described for patients undergoing surgery. In this study only 7 of 136 patients had relative AS. The failure of volume flow rate to increase may be due to a flow limitation of a severely stenotic valve or to an unresponsive myocardium. Importantly, despite a high operative risk, LV function and symptomatic status may even improve in patients without contractile reserve surviving aortic valve replacement surgery. This suggests that even in this subgroup, selected patients may benefit from surgery, which should thus not be generally precluded.[167-169] In the absence of contractile reserve, extensive aortic valve calcification may be indicative of severe AS.[170]

Although stress echocardiography may not always give all the expected answers in an unambiguous way, a pragmatic clinical approach to this patient group that includes looking at the valve, at the patient, and at the options might be helpful. A heavily calcified valve will be an argument in favor of valve replacement, whereas thin, flexible leaflets argue against valve surgery. Angiographic assessment of the coronary arteries is an integral part of the diagnostic workup.

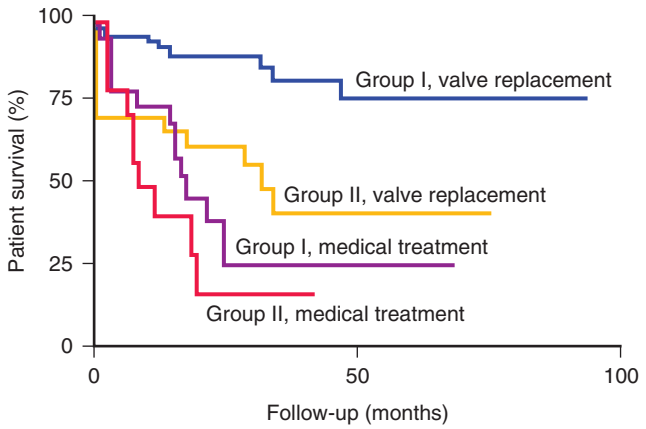

**Figure 23-24 Kaplan-Meier survival estimates of 136 consecutive patients with low-flow, low-gradient aortic stenosis.** Group I (n = 92) represents patients with contractile reserve determined by low-dose dobutamine echocardiography. Group II (n = 44) represents patients with absent contractile reserve. Survival estimates represented according to contractile reserve and treatment strategy (aortic valve replacement versus medical therapy). *(From Monin JL, Quere JP, Monchi M, et al: Low-gradient aortic stenosis: operative risk stratification and predictors for long-term outcome: a multicenter study using dobutamine stress hemodynamics.* Circulation *108:319-324, 2003.)*

### *Low-Flow, Low-Gradient Aortic Stenosis Despite Preserved Ejection Fraction (Paradoxical Low-Flow Aortic Stenosis)*

The concept of low-flow, low-gradient AS despite a preserved ejection fraction has been described.[171] Like classical low-flow, low-gradient AS, it is characterized by a small calculated aortic valve area, while the transaortic gradients correspond to nonsevere stenosis. In contrast to classical low-flow, low-gradient AS, however, ejection fraction is normal but stroke volume is nevertheless reduced (a stroke volume index of 35 $mL/m^2$ or less has been proposed to define a low stroke volume). This situation may be observed in the presence of severe LV hypertrophy with a small LV cavity or when a concomitant atrial septal defect with left-to-right shunting is present. Before diagnosing paradoxical low-flow AS, it is important to rule out potential underestimation of peak aortic jet velocity and measurement error in LV outflow tract area, both of which may also lead to a similar constellation of measurements. In the initial retrospective study, a worse outcome was described in patients with paradoxical low-flow AS who were managed conservatively as compared to those undergoing aortic valve replacement surgery. However, a recent analysis of data from the prospective SEAS cohort described an outcome that was comparable to moderate AS.[172] Although it is premature to draw final conclusions with regard to the management of these patients, decisions need to be individualized. In particular, it seems unlikely that asymptomatic patients would benefit from surgery.

## Assessment of Interventional Risk and Choice of the Procedure

The introduction of transcatheter aortic valve implantation techniques has expanded the options for the management of high-risk patients with AS. An optimal decision-making process depends on an interdisciplinary team approach including cardiac surgeons, interventional cardiologists, and noninterventional cardiologists.[173] In specific cases, additional consultation with an anesthesiologist, a geriatrician, or other specialties might be recommended. Currently available surgical risk scores do not reliably predict the risk of valve procedures in an individual patient and should thus only be used as part of an integrated approach.[174] An objective assessment of frailty should be integrated in the decision-making process.

### PREINTERVENTIONAL ASSESSMENT OF CORONARY ARTERY DISEASE

Coronary artery disease is frequent in patients with calcific AS. Concurrent coronary artery bypass grafting is recommended in the presence of significant coronary artery disease. If concomitant coronary artery disease is present at the time of aortic valve replacement for AS, operative mortality is significantly lower when additional coronary bypass grafting is performed (1.1% to 4.8%) in contrast to when valve replacement is performed alone (4.0% to 13.2%).[175,176] Also, risk of sudden death after

valve replacement is significantly higher when patients with coronary artery disease are not revascularized at the time of surgery.[177] Furthermore, the need for early reoperation for coronary artery disease is averted.

In AS patients with angina, the prevalence of significant coronary artery disease ranges from 40% to 80%. Preoperative coronary angiography is therefore definitely needed.

However, even in the absence of angina the prevalence of significant coronary artery disease ranges between 0% and 54% (average 16%). The appropriate diagnostic approach to these patients is less clear. Exercise treadmill testing is contraindicated in symptomatic patients with AS. It is of note that even in asymptomatic patients, ST-segment depression during exercise is often nondiagnostic for the presence of coronary artery disease and is possibly related to LV hypertrophy.[66,178] Multidetector computed tomography coronary angiography is becoming increasingly available as a noninvasive technique for the assessment of the coronary anatomy. Recently, several small studies have reported high negative predictive values for this technique to rule out the presence of significant coronary artery disease in patients with AS.[179,180] With further improvements in image quality, this technique might become an alternative to coronary angiography in patients at low to moderate risk for the presence of coronary artery disease. In patients with a moderate to high likelihood of coronary artery disease, conventional preoperative coronary angiography remains mandatory.

## Echocardiography in Transcatheter Aortic Valve Implantation

Transcatheter aortic valve implantation has become a treatment option for high-risk patients with AS. As discussed earlier, the choice of a management strategy in a specific patient should be based on a multidisciplinary approach. Echocardiography has a role both in the patient selection process and as a monitoring technique during valve implantation. The transcatheter valve can be implanted either retrogradely via a transfemoral access or surgically via the apex (see Chapter 5).

### PATIENT SELECTION

Several factors determine whether a patient is suitable for a transcatheter aortic valve implantation. Presently two valves, the CoreValve (Medtronic, Minneapolis) and the Edwards SAPIEN (Edwards LifeSciences, Irvine, Calif.) valves are commercially available. One of the most important factors is the sizing of the aortic annulus, which determines whether the available valve types are suitable and also affects the choice of prosthetic valve size. Although the aortic annulus can be visualized in transthoracic echocardiography, the use of TEE is recommended because it allows more accurate delineation of the annulus.[181] It further allows measurement of the distance from the aortic cusps to the coronary ostia. Furthermore, TEE permits a morphologic characterization of the thoracic aorta and thus the identification of aortic plaques. Nevertheless, computed tomography angiography of the aorta, which provides complementary information with regard to annulus size and aortic morphology, is routinely performed. The determination of aortic valve etiology is mandatory: A bicuspid aortic valve is a contraindication for transcatheter valve implantation because of the likelihood of noncircular deployment of the valve. However, it is not unlikely to miss the diagnosis of a bicuspid valve in the presence of a severely calcified valve, where an exact morphologic description is difficult. In the process of preinterventional patient evaluation, the basal interventricular septum should be assessed to detect a subaortic septal bulge that may interfere with an adequate valve deployment. Concomitant valve lesions are routinely assessed. In particular, the presence of concomitant mitral regurgitation may affect treatment decisions. When the mitral valve is morphologically normal, a reduction of regurgitation severity can be expected after aortic valve implantation and the resulting drop in LV afterload. However, when a structural lesion is present, regurgitation typically persists.

### VALVE IMPLANTATION

Intraprocedural TEE is complementary to fluoroscopy for the positioning of the balloon during valvuloplasty and also to confirm the position of the valve prosthesis before deployment. 3D TEE allows improved visualization of the prosthesis. Following prosthesis implantation, the valve position is confirmed and its function evaluated. In particular, the shape of stent expansion and the presence of aortic regurgitation, which is of prognostic relevance, can be assessed. Periinterventional TEE monitoring is particularly important for the identification of potential complications, such as incorrect valve positioning, pericardial effusion, cardiac tamponade, aortic dissection, or the rare event of annular rupture.

### KEY POINTS

- With an ageing population and widespread use of echocardiography, AS is increasingly diagnosed.
- Knowledge of the prognostic implications of echocardiographic findings in AS is essential for optimal management and should always be put in clinical context.
- Echocardiography is the method of choice for follow-up of patients with AS and allows:
  - The determination of the etiology of the stenosis (i.e., calcific, rheumatic, congenital)
  - The exclusion of other causes of obstruction to LV outflow (i.e., supravalvular AS, subvalvular AS, hypertrophic obstructive cardiomyopathy)
  - Identification of consequences of AS such as LV hypertrophy, impairment of LV systolic function, or presence of diastolic dysfunction as well as concomitant valve lesions
  - Quantification of the severity of the stenosis using flow-dependent (peak aortic jet velocity, mean gradient) and flow-independent (aortic valve area assessed by the continuity equation) variables
  - Measurement of hemodynamic progression
  - Risk stratification by integrating the information on stenosis severity, rate of hemodynamic progression and degree of aortic valve calcification
- Echocardiography plays a central role in management decisions, including surgical indications and scheduling control intervals.

# 24 Fluid Dynamics of Prosthetic Valves

AJIT P. YOGANATHAN, PhD | CHOON HWAI YAP, PhD

**Principles of Fluid Dynamics**
- Conservation of Mass
- Mechanical Energy
- Bernoulli's Equation
- The Control Volume Energy Analysis
- Mechanisms of Mechanical Energy Loss
- Mechanical Energy Conversion and Loss in a Stenosis

**Applications of Fluid Dynamics to Prosthetic Heart Valves**
- Pressure Drop
- Doppler Gradient
- Effective Orifice Area
- Regurgitant Volume
- Mechanical Energy Losses
- Novel Energy Loss Parameters
- In Vivo Evaluation of Prosthetic Valves

**Hemodynamics of Native Valves**

**Hemodynamics of Specific Prosthetic Valve Designs**
- Mechanical Valves
- Bioprostheses
- Transcatheter Valves

**Future Directions**

Doppler echocardiography has made noninvasive examination of prosthetic heart valve function a clinical reality. Unfortunately, there are still many imperfections in echocardiographic examinations due to acoustic shadowing, reflections caused by implanted valves, and limitations in ultrasound technology. Despite these limitations, a number of important parameters can be calculated or estimated to aid in the assessment of prosthetic heart valve function and performance. Once a valve has been implanted, its function is governed primarily by its hemodynamic characteristics. In order to understand the hemodynamic performance of prosthetic heart valves, it is necessary to have a solid background in the physical laws that govern their function. Therefore, the purpose of this chapter is to introduce cardiologists to the governing principles of fluid dynamics, relevant formulations used in prosthetic valve assessment, and fluid mechanical characteristics of specific prosthetic heart valves.

## Principles of Fluid Dynamics

### CONSERVATION OF MASS

The principle of conservation of mass is important in evaluating valve effective orifice area (EOA). Conservation of mass, or the continuity principle, is a mass balance over the boundaries of a volume of fluid. For example, this volume can be made to coincide with a section of an artery, with the left ventricle, or with the surface of a blood cell and may be made to move over time as well. Such a volume is called a *control volume*, and its boundaries are usually chosen to give information regarding an unknown flow rate, average velocity, or surface area flow into or out of the volume based on more easily measurable quantities. Examples of control volumes useful for determining aortic and mitral valve areas with conservation of mass are shown in Figure 24-1.

Conservation of mass within the control volume can be expressed in words as:

$$\text{Rate of mass accumulation} = \text{Rate of mass input} - \text{Rate of mass output} \quad (1)$$

In cardiovascular applications, we can assume that the density of blood is constant, because blood is composed mostly of water. Water is almost incompressible, and thermal expansion or contraction is insignificant because of the narrow range of body temperature. Because mass is the product of density and volume, mass conservation can be expressed as volume conservation:

$$\text{Rate of volume accumulation} = \text{Rate of volume input} - \text{Rate of volume output} \quad (2)$$

In mathematical form, this is

$$\frac{(V_f - V_i)}{t} = Q_{in} - Q_{out} \quad (3)$$

where $Q_{in}$ is the total flow rate into the control volume, $Q_{out}$ is the total flow rate out of the control volume, $V_i$ is the size of the control volume at the beginning of the observation, and $V_f$ is the size of the control volume after an observation at time $t$. There could be multiple sources of flow inlets and outlets, and thus

$$\frac{1}{t}(V_f - V_i) = (Q_{in(1)} + Q_{in(2)} + Q_{in(3)}) - (Q_{out(1)} + Q_{out(2)} + Q_{out(3)}) \quad (4)$$

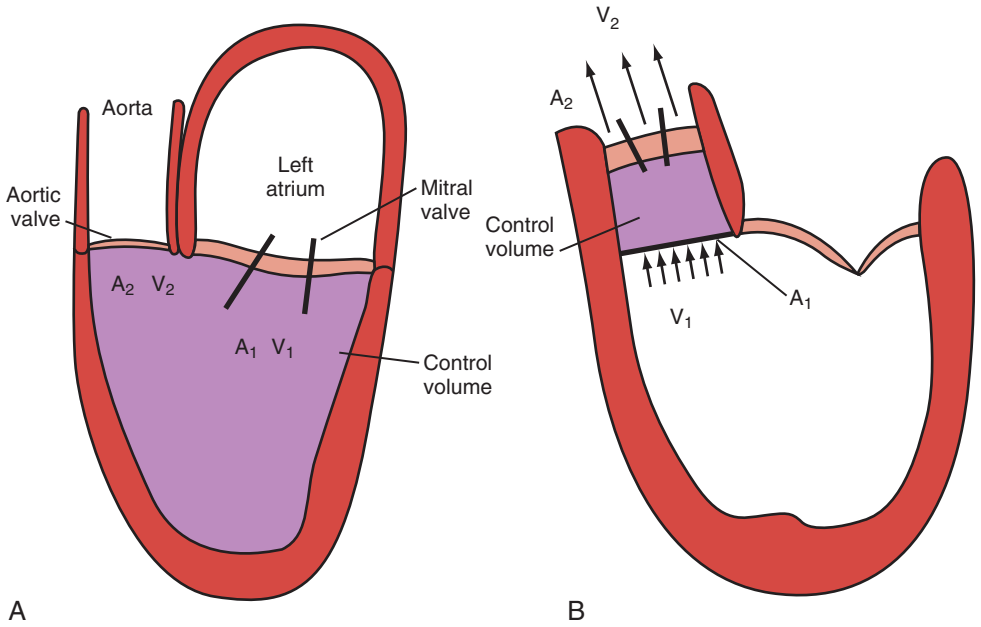

**Figure 24-1** Control volumes used for determining (**A**) mitral and (**B**) aortic valve area with conservation of mass. $V_1$ and $V_2$ represent average velocity of the blood flowing over areas $A_1$ and $A_2$.

If we further assume that the volume of the control volume does not change with time, the left side of Equation 3 is zero, and conservation of mass can be expressed as

$$Q_{in} = Q_{out} \tag{5}$$

This is approximately true in most blood vessels if we neglect expansion vessels under elevated pressure. Often, flow rate in circular, nonbranching vessels can be decomposed into an average axial velocity and a cross-sectional area (A). Equation 5 thus becomes:

$$\bar{v}_{in} A_{in} = \bar{v}_{out} A_{out} \tag{6}$$

Flow through a prosthetic aortic valve is an example of such a situation. The rate at which fluid mass moves toward the valve from upstream has to be equal to the rate at which fluid mass moves through the vena contracta or further downstream of the aorta. This principle is relied on to formulate the equations for calculating EOA using Doppler echocardiography.

## MECHANICAL ENERGY

Mechanical energy can be described as the ability to accelerate a mass of material over a certain distance. Energy per unit volume has the same dimensions as pressure. It is perhaps best to report energy in cardiovascular applications on a per-unit-volume basis, because the majority of the medical field is accustomed to working with the units of pressure. However, it is important to consider pressure as only one of several forms of mechanical energy.

Pressure ($p$) can be shown to be a form of mechanical energy per unit volume by recognizing that it represents a force ($F_p$) per unit area ($A$). If a force is applied to move a mass over a distance ($d$), it performs work, expending pressure energy ($E_p$). The area that the force acts on multiplied by the same distance represents a volume ($V$):

$$\frac{E_p}{V} = \frac{F_p d}{A d} = \frac{F_p}{A} = p \tag{7}$$

Pressure is not the only form of mechanical energy in the circulation. Acceleration due to gravity ($g$) creates another form of mechanical energy per unit volume. Gravity can accelerate a mass $m$ with a force $F_g$. If this force moves the mass over a vertical distance $h$, it too performs work and expends gravitational energy $E_g$. The energy per unit volume is obtained by substituting density $\rho$ for mass per unit volume.

$$\frac{E_g}{V} = \frac{F_g h}{V} = \frac{mgh}{V} = \rho g h \tag{8}$$

Finally, mechanical energy per unit volume exists in the circulation in the form of kinetic energy, or energy of movement. If a mass $m$ is moving at a velocity $v$, it contains kinetic energy equivalent to half the product of the mass and the square of the velocity:

$$\frac{E_k}{V} = \frac{\frac{1}{2} m v^2}{V} = \frac{1}{2} \rho v^2 \tag{9}$$

Again, the energy per unit volume is obtained by substituting density for mass per unit volume. Thus, there are three forms of mechanical energy in the circulation.

The primary source of mechanical energy in the circulation is the work performed by the left ventricle. Contraction of the ventricle creates an increase in pressure inside the ventricle. As Equation 7 implies, subsequent movement of a volume of fluid by this pressure results in the generation of mechanical energy. The energy generated by the ventricle is illustrated in Figure 24-2, which represents the pressure and volume within the ventricle during the course of one cardiac cycle. The curve between points *1* and *2* represents the period of diastolic filling, where the mitral valve is open and the ventricle fills. The mitral valve shuts at point *2*, and the period of isovolumic contraction begins. Between points *2* and *3*, the volume of blood in the ventricle remains constant, but the pressure rises considerably. The aortic valve opens at point *3*. This starts the period of systolic ejection, where blood is moved by the ventricle into the

aorta. At point *4*, the aortic valve closes and the period of isovolumic relaxation begins. During this period, the ventricular volume again remains constant, but the pressure falls. The fall in pressure returns the ventricle to its state at point *1*. The energy generated by the ventricle during one cardiac cycle is equivalent to the integral of the pressure-volume diagram (the shaded area in Fig. 24-2). The energy per unit volume generated by the ventricle is equivalent to the integral of the pressure-volume diagram divided by the stroke volume. This is roughly equivalent to the average increase in left ventricular pressure from diastole to systole. The ventricle thus creates energy in the form of pressure, but this energy is converted to gravitational and kinetic energy elsewhere in the circulation.

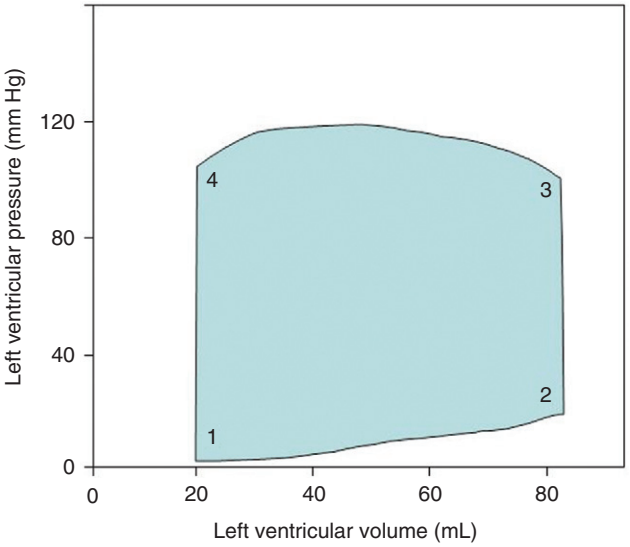

**Figure 24-2 Pressure-volume diagram for the left ventricle.** The shaded area represents the energy given to the flow by one stroke of the ventricle.

## BERNOULLI'S EQUATION

Pressure, gravitational, and kinetic energies in the circulation can be freely converted from one to another without energy loss. Bernoulli's equation for steady flow illustrates this. Bernoulli's equation for steady flow relates the relative amounts of pressure, gravitational, and kinetic energy per unit volume between two spatial locations along a path of a flow (locations 1 and 2, where location 2 is downstream of location 1), assuming that no energy is lost:

$$\frac{1}{2}\rho v_1^2 + \rho g h_1 + p_1 = \frac{1}{2}\rho v_2^2 + \rho g h_2 + p_2 \qquad (10)$$

Bernoulli's equation for steady flow states that the total mechanical energy per unit volume at locations 1 and 2 is the same but can exist in different forms. A decrease in pressure from location 1 to location 2 may be balanced by an increase in either fluid velocity or height without loss of energy. Therefore, a pressure drop is not mechanical energy loss if it is accompanied by an increase in either gravitational or kinetic energy. These energies can be converted back to pressure energy later.

Additional variables can be added to Bernoulli's equation for steady flow to account for the effects of unsteady flow and mechanical energy loss:

$$\frac{1}{2}\rho v_1^2 + \rho g h_1 + p_1 = \frac{1}{2}\rho v_2^2 + \rho g h_2 + p_2 + \int_1^2 \rho \frac{\partial v}{\partial t}\partial s + \Phi \qquad (11)$$

where $s$ represents the distance of the path between locations 1 and 2, and $\Phi$ represents loss of mechanical energy per unit volume. The added terms represents the contribution of acceleration of the fluid to the flow energy and the conversion of mechanical energy to heat, respectively, between locations 1 and 2. Rearranging Equation 11 to express energy loss in terms of the other parameters, we obtain

$$\Phi = (p_1 - p_2) + \frac{1}{2}\rho(v_1^2 - v_2^2) + \rho g(h_1 - h_2) - \int_1^2 \rho \frac{\partial v}{\partial t}\partial s \qquad (12)$$

## THE CONTROL VOLUME ENERGY ANALYSIS

A more detailed analysis of the energy of fluid flow through a valve can be conducted using the control volume approach. Bernoulli's equation describes energy conversion and loss along a streamline (line of fluid flow) and is a useful, simplified approach to analyze fluid energy in valves, while the control

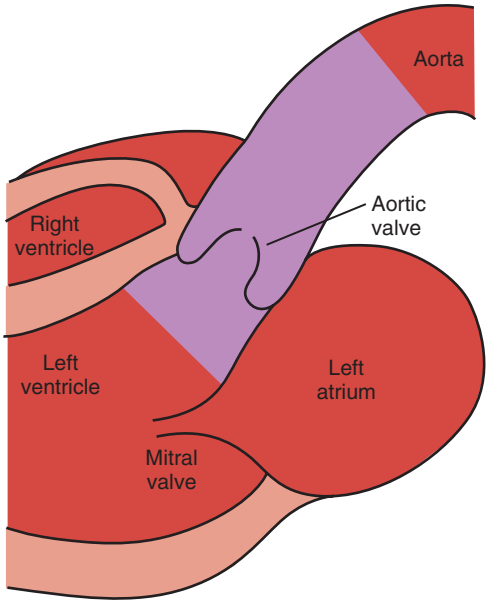

**Figure 24-3** Example of control volume for the analysis of energy loss in the aortic valve.

volume provides three-dimensional (3D) analysis of fluid energy at any time in the cardiac cycle. If we let the control volume be the blood volume around the valve, as shown in Figure 24-3, manipulation of the Navier-Stokes governing equations of fluid flow gives the following equation[1]:

$$\int S_{ij} T_{ij} dV = \int -P(u_i \cdot \hat{n}_i) dA - \int \rho u_i g_i dV - \frac{d}{dt}\int \frac{1}{2}\rho u_i^2 dV \qquad (13)$$

where $S$ is the shear stress, $T$ is the shear deformation, $P$ is pressure, $u$ is velocity, $A$ is the surface of the control volume, $\hat{n}$ is the normal direction at the surface of the control volume, $g$ is the gravitational force, and $V$ is the control volume. The subscripts $i$ and $j$ refer to any of the three Cartesian coordinate

axes, in accordance to Einstein's notation. Equation 13 can be described in words as

$$\begin{array}{c}\text{Energy}\\\text{dissipation}\end{array} = \begin{array}{c}\text{Energy supplied}\\\text{by pressure}\\\text{gradient}\end{array} - \begin{array}{c}\text{Energy}\\\text{converted to}\\\text{gravitational}\\\text{potential energy}\end{array} - \begin{array}{c}\text{Energy}\\\text{converted into}\\\text{kinetic energy}\end{array} \quad (14)$$

Pressure gradient across the valve, which is supplied by the heart muscles, is partially converted into kinetic energy, used to accelerate fluid, partially used to counter effects of gravity, and the remaining is lost as heat and sound.

## MECHANISMS OF MECHANICAL ENERGY LOSS

Mechanical energy can be converted to heat and sound through friction between blood moving at different velocities and between blood and the vessel walls. Heat and sound generated through friction is not readily converted back to mechanical energy, and this energy is said to be lost to the cause of blood circulation. These frictional losses take one of two forms: viscous losses and turbulent losses. Additional energy can be effectively lost in the circulation due to valvular leakage. These forms of energy loss are described next.

### *Viscous Losses*

As a result of frictional forces, fluid immediately adjacent to a solid boundary moves with the same velocity as the boundary. In the case of a stationary vessel, this means that fluid immediately adjacent to the vessel wall does not move, no matter how fast the surrounding flow is moving. As one moves away from the solid boundary, the velocity may increase. This leads to differences in fluid velocity with respect to radial distance within the vessel (Fig. 24-4). Fluid viscosity, the tendency of the fluid components or molecules to "stick" to each other, creates friction between the fluid components in close proximity if they move at different velocities. This is the mechanism of viscous energy loss. Viscous losses typically increase with flow rate and decrease dramatically with increasing vessel radius. This is why vasodilators are effective in relieving left ventricular workload.

### *Turbulent Losses*

Turbulent losses usually do not occur in the circulation but can be greater in magnitude than viscous losses when they do. Turbulence is characterized by chaotic spatial and temporal fluctuations in the direction and magnitude of fluid velocity. It is a result of the inertia of the flow being too great for frictional forces to stabilize fluid movement or to dampen unsteady secondary motions. The chaotic spatial and temporal velocity fluctuations result in excessive mixing of fluid, where individual tiny pockets of fluid will experience very high shear stresses with other pockets of fluid everywhere in the flow. Consequently, there will be high overall frictional energy loss, which is the essence of turbulence energy loss.

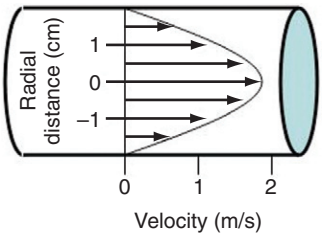

**Figure 24-4 Variations in velocity with respect to radial distance in a blood vessel.** These variations are a result of viscous forces.

In a straight vessel, fluid inertia disturbances may be initiated by small irregularities, or roughness, in the surface of the vessel. In laminar flow, these small inertial disturbances will quickly be damped out by viscous forces, and unsteady secondary flow and fluid mixing will be minimal. In turbulent flow, these inertial changes will be amplified because viscous forces are not strong enough to dampen them. The analogy is being tripped while one is walking versus running. It is harder to keep one's balance when tripped during running, because the inertia of the body's motion is difficult to control.

The tendency toward turbulence in a fluid flow depends on the ratio of inertial forces to frictional forces in the flow. The inertial force of a moving flow is the force required to bring the flow to rest, whereas the frictional force of such a flow is created by viscous shear stress acting on solid surfaces. In vessel flow, this ratio is approximated by the Reynolds number:

$$N_{Re} = \frac{D\bar{v}\rho}{\mu} \quad (15)$$

where $D$ is the inner diameter of the vessel, $v$ is the average velocity of the flow, $\rho$ is the fluid density, and $\mu$ is the fluid viscosity. A low Reynolds number will result in laminar flow; a high Reynolds number will result in turbulent flow. The point of transition between the two states, the critical Reynolds number, differs for different flow systems. For flow through a straight pipe, the critical Reynolds number is approximately 2000, and flow becomes fully turbulent at a Reynolds numbers of approximately 6000.[2] Flow through small, circular orifices creates a phenomenon known as a free jet. For steady free-jet flows, the critical Reynolds number is approximately 1000, with fully turbulent flow occurring at Reynolds numbers greater than 3000.[3,4] This transition point is lowered by sharp corners and bends in the flow, or rough solid surfaces. Further, for turbulence to occur, sufficient time must be allowed for the unsteadiness to amplify and grow. In pulsatile flows, however, if the frequency of pulses is too high, there may be insufficient time for turbulence to fully develop, making it harder to achieve turbulence. The critical Reynolds number thus increases.[5]

### *Valvular Regurgitation*

When valvular regurgitation occurs, the heart must compensate by expending more energy to pump additional blood through the valve during forward flow phase, such that the net of forward flow and regurgitation flow will still be sufficient for the body. Blood that leaks back through the valve will not contribute to circulation, and the energy used to pump it through the valve during forward flow phase can be viewed as being lost. In prosthetic valves, valvular regurgitation consists of the closing volume, paravalvular regurgitation, and perivalvular regurgitation. The closing volume is the amount of blood that will leak backwards through the valve at the end of forward flow before the valve can properly close (Fig. 24-5). Paravalvular regurgitation is the leakage of blood through the valve orifice. In the case of the bioprosthetic valve, calcification of the leaflets can lead to improper coaptation and thus paravalvular regurgitation. In mechanical valves, paravalvular regurgitation can occur through gaps in the closed valve. Perivalvular regurgitation occurs because of improper attachment of the prosthetic

valve with the heart tissues. For example, when prosthesis dehiscence occurs, blood will leak through the gap opened up by the dehiscence.

### MECHANICAL ENERGY CONVERSION AND LOSS IN A STENOSIS

To show how mechanical energy may be changed from one form to another or lost, we refer to an illustration depicting the changes in mechanical energy across an aortic stenosis. Figure 24-6 shows the overall energy conversion and losses, pressure energy, and kinetic energy as blood flow traverses the contraction, throat, and expansion sections of the stenosis.

The first section of the stenosis, from *1* to *2*, is a flow contraction. Because the continuity equation states that the velocity at *2* must be higher than that at *1*, kinetic energy increases from *1* to *2*. This increase in kinetic energy occurs at the expense of a large amount of pressure energy. A relatively small amount of total energy is actually lost in the flow contraction. Most of the lost energy in flow contraction is due to viscous losses. However, there may be a small amount of flow separation immediately following abrupt contractions. Flow separation occurs because the momentum of the flow causes it to continue to converge for a short period after the anatomic contraction (see Fig. 24-6). Such abrupt contractions have considerably more energy loss than gradual ones.

The second section of the stenosis, from *2* to *3*, represents a throat of constant cross-sectional area. In this section, the continuity equation states that the velocity at *2* and *3* are the same. Therefore, there is no loss in kinetic energy; the total energy lost in this section is completely pressure energy. It is worth noting that only in nonbranching vessels of constant cross-sectional area is pressure gradient equivalent to total energy loss per unit volume, and that usually only a small amount of total energy is lost in the stenosis throat. This energy loss is viscous in nature if the flow is laminar and completely turbulent in nature if the flow has enough momentum to enable its transition to turbulence.

Finally, in the expansion section of the stenosis, from *3* to *4*, a large amount of total energy is lost. All of this lost energy is kinetic in nature, which explains why the Doppler gradient correlates so strongly with total mechanical energy loss. However, the Doppler gradient does not completely specify total energy loss because a portion of the kinetic energy is converted into pressure. This is the cause of the *pressure recovery* phenomenon. The expansion section of the stenosis illustrates why pressure gradients can be misleading in the estimation of the lost driving force for flow. Although the pressure increased in the expansion section, the total energy loss was very large.

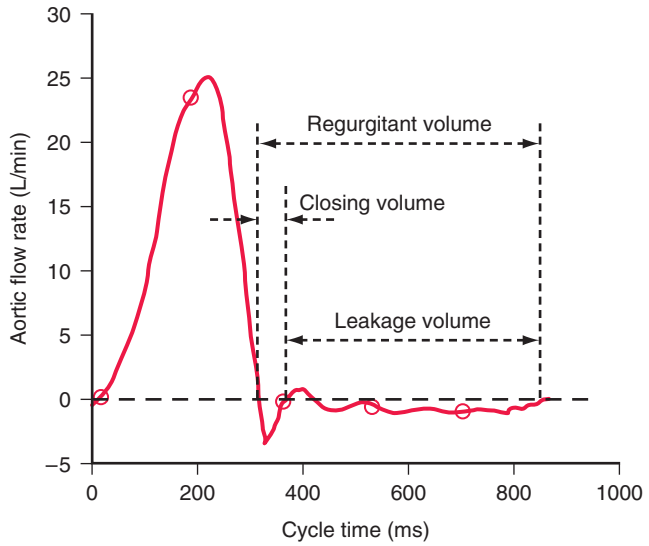

**Figure 24-5** Regurgitant, closing, and leakage volumes across an aortic valve.

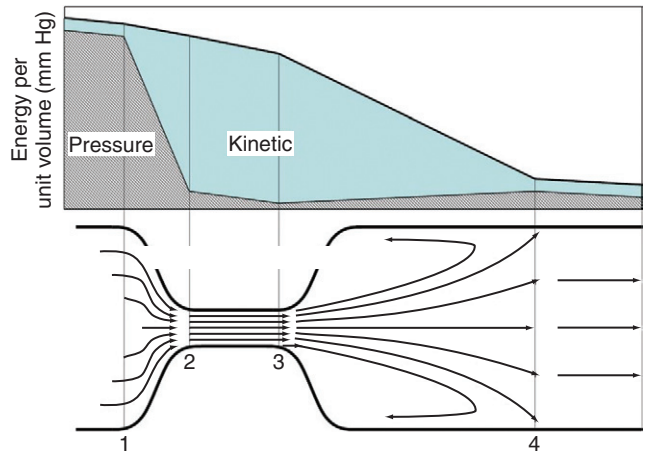

**Figure 24-6 Schematic of pressure and kinetic energy loss and conversion as flow traverses a stenosis.** The flow undergoes contraction from location *1* to location *2*. The throat of the stenosis lies between locations *2* and *3*, and the flow suddenly expands from location *3* to location *4*. *(From Yoganathan AP, He Z, Jones CS: Fluid mechanics of heart valves.* Annu Rev Biomed Eng *6:331-362, 2004.)*

## Applications of Fluid Dynamics to Prosthetic Heart Valves

### PRESSURE DROP

Pressure drop across a heart valve is commonly used to estimate the amount of energy lost by the flow in traversing the valve. Such pressure drops can be directly measured with invasive catheter techniques. Equation 16 shows that the pressure drop across a heart valve is equivalent to energy loss per unit volume if changes in the kinetic energy, gravitational energy, and local acceleration of the flow can be neglected. Because of the law of conservation of mass (see Equation 6), changes in kinetic energy are negligible if diameters of the vessels are the same at the locations of the upstream and downstream pressure measurements and if the downstream measurements are obtained at a location far enough from the valve to allow for pressure recovery. Changes in gravitational energy are negligible if the patient is supine, as there is little height difference between upstream and downstream measurement locations. If the patient is upright, every 5-cm difference in vertical height will result in approximately 3.9 mm Hg of pressure drop. Changes in local acceleration of the flow are negligible if measurements are obtained during peak flow rate across the valve (often called the peak gradient). This is because, at the peak flow rate, velocity is at the maximum turning point and is momentarily experiencing no acceleration. Effects of acceleration are also negligible if measurements are averaged over the forward flow portion of the valve cycle (often called the mean gradient). This is because fluid first accelerates and then decelerates back to the initial state over the forward flow phase; and thus, when the

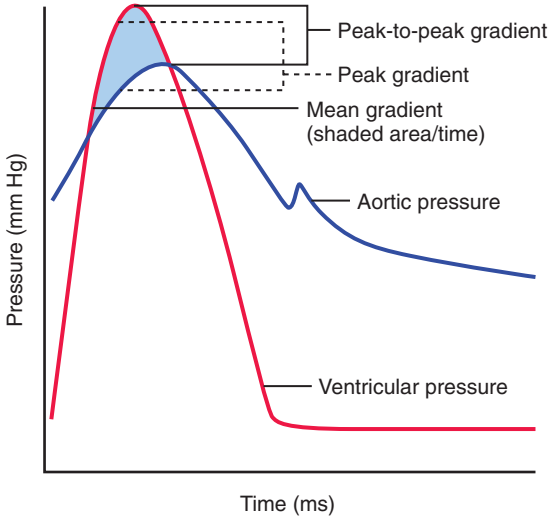

**Figure 24-7** Mean, peak, and peak-to-peak pressure differences across an aortic valve.

acceleration term is integrated over time, it becomes zero. However, it must be noted that *peak gradient* describes the energy loss during peak flow phase, whereas *mean gradient* describes the average energy loss over the entire forward flow period. Thus, peak gradient will always be higher than mean gradient. Pressure drop is also often reported in terms of a peak-to-peak gradient for convenience, as an approximation of the peak gradient. Differences between peak and peak-to-peak gradients are shown in Figure 24-7.

## DOPPLER GRADIENT

Although energy lost by the flow in traversing the valve can be estimated more directly with catheterization, such losses are now typically estimated noninvasively with the help of echocardiography. A simplified form of Equation 12 is used to estimate the amount of pressure converted to kinetic energy as the flow contracts from well upstream of the valve to the point of maximum flow contraction, by neglecting the small energy conversions to gravitational potential energy:

$$\Delta p = 4(v_{\max}{}^2 - v_{ups}{}^2) \tag{16}$$

where $\Delta p$ is the pressure drop ($p_1 - p_2$) during the flow contraction in mm Hg, $v_{ups}$ is the velocity upstream of the contraction during forward flow in cm/s, and $v_{\max}$ is the velocity at the point of maximum flow contraction during forward flow in cm/s. The constant 4 is used to account for the density of blood and unit conversions. This simplification assumes that mechanical energy loss and changes in gravitational energy and local acceleration are negligible as the flow contracts. Assumptions on changes in kinetic energy, effects of accelerations, the use of mean gradient versus peak gradient, and gravitational potential energy are the same as those discussed in the Pressure Drop section earlier.

The conversion from pressure to kinetic energy within the flow contraction of Figure 24-6 is therefore the quantity measured when estimating pressure gradient with Doppler echocardiography. Most of this converted energy will be lost after the expansion, because the kinetic energy upstream and that sufficiently downstream of the expansion are about the same according to Equation 6. However, because the Doppler gradient is measured between the upstream and the vena contracta point, it does not account for the pressure recovery, which occurs downstream of the vena contracta and may overestimate energy lost by the flow.

Another problem with the use of Doppler gradient is the placement of the transducer. If the transducer is placed obliquely with respect to the jet axis, the measured velocity will underestimate the true velocity of the jet,[6] and pressure gradient will be underestimated. Because the errors resulting from pressure recovery and oblique transducer placement tend to offset each other, Doppler ultrasound can at times match pressure measurements obtained from catheterization quite precisely. Nonetheless, there are instances when Doppler gradient gives significant errors.

Additional complications in the use of Doppler gradient to evaluate the total energy loss across mechanical prostheses arise because these valves have more than one orifice and because the resistance that each orifice offers to flow can be different. Velocity measurements made in the one orifice are therefore not representative of the gradient in either pressure or total energy as flow traverses the valve. The difference between Doppler and catheter gradients has been so notable for mechanical prostheses that empirically derived correction factors, dependent on valve design, have been suggested to the U.S. Food and Drug Administration (FDA).[7] Some studies claim that there is negligible difference between pressure gradients measured with catheter and Doppler, particularly with regard to mean gradients.[6] However, because of its potential problems, the use of Doppler to evaluate the performance of mechanical prostheses should be approached with caution. Often, Equation 16 is simplified further by assuming that upstream velocity is very small relative to the maximum velocity within the contraction:

$$\Delta p = 4v_{\max}{}^2 \tag{17}$$

In a very stenotic orifice, this equation will work well, because the velocity within the stenosis will indeed be much higher compared to the velocity upstream of the stenosis. This approximation should only be used in heavily calcified bioprosthetic valves.

## EFFECTIVE ORIFICE AREA

Evaluation of valve performance by pressure drop and Doppler gradient are heavily dependent on the flow rate across the valve. EOA does not represent the anatomic orifice area. Instead, it represents the cross-sectional area of the jet issuing from the valve at the point of its largest contraction (the vena contracta). The size of the EOA depends on the nature of the contraction as well as the size of the orifice itself. A sudden contraction will have a smaller EOA than a gradual contraction of the same orifice area. Although EOA has been considered to be an evaluation parameter of valve performance that is independent of cardiac output (CO) and heart rate (HR), in vivo[8,9] and in vitro[1] experiments have shown that it varies somewhat with flow rate. For bioprosthetic valves, higher flow causes the valve to open up a bigger valve orifice area by stretching the valve leaflets outward, allowing the jet flow area and thus EOA to be higher. For mechanical valves, changes in volumetric flow rate can lead to changes in the distribution of velocities across the diameter of the vena contracta,[10] leading to minor changes in the

computed EOA. However, the variation of EOA with flow is small, and so errors associated with the assumption of EOA invariance to flow rate are manageable.[11]

EOA can be estimated by applying the continuity equation (Equation 18) to echocardiography measurements of the upstream vessel area ($A_{ups}$), the temporal average of the velocity upstream of the contraction during forward flow, and the temporal average of the velocity at the point of maximum flow contraction during forward flow:

$$EOA = \frac{A_{ups} v_{ups}}{v_{\max}} \tag{18}$$

Pulsed-wave Doppler is used to measure the upstream velocity, whereas continuous-wave Doppler is used to measure the maximum velocity or the velocity within the vena contracta. If we assume *EOA* and $A_{ups}$ are constant over systole, we can use velocity-time integral (VTI) instead of velocities, which is the area under the curve of the velocity versus time plot. The upstream area is estimated with planimetry with B-mode echo. Thus, the clinically implemented equation is

$$EOA = \frac{A_{ups} VTI_{ups}}{VTI_{\max}} \tag{19}$$

The Gorlin formula can also be used to estimate EOA with catheter measurements. The Gorlin formula is a combination of Equation 6 and either Equation 16 or 17:

$$EOA = \frac{Q}{51.6\sqrt{\Delta p}} \tag{20}$$

where *EOA* is in $cm^2$, *Q* is the temporal average of the flow rate during forward flow in $cm^3$, and $\Delta p$ is the mean pressure drop across the valve during forward flow in mm Hg. The constant 51.6 in the denominator is used to account for the density of blood and unit conversions. It must be noted that the *EOA* differs from the aortic valve area initially described by Gorlin and Gorlin,[12] which is the geometric area of valve orifice traced by the free edge of the leaflets. The *EOA* is the area of flow slightly downstream of the aortic valve area, where flow contracted slightly. Thus, whereas a factor of 44.3 was used in the computation of aortic valve area, a factor of 51.6 should be used for *EOA*. *EOA* can be obtained through this method with either invasive cardiac catheterization or noninvasive echocardiographic examination. With the catheter approach, $\Delta p$ is directly measured with fluid-filled or sensor-mounted catheters, and *Q* is estimated by measuring the *CO* with the Fick method (thermodilution and dye dilution),[13] and the HR and systolic duration (*SD*):

$$Q = \frac{CO}{HR \cdot SD} \tag{21}$$

The catheter approach can be expected to overestimate the *EOA* because of the pressure recovery phenomenon. However, the catheter formulation, dubbed the energy loss coefficient, may be useful as a separate entity in evaluating the severity of aortic stenosis.

With the noninvasive echocardiography approach, *Q* is estimated by the upstream vessel area ($A_{ups}$) multiplied by the upstream velocity time integral ($VTI_{ups}$), and $\Delta p$ should be estimated by the Doppler gradient using Equation 16 or 17:

$$EOA = \frac{A_{ups} \cdot VTI_{ups}}{51.6\sqrt{\Delta p}} \tag{22}$$

Equation 16 or 17 will carry the same simplifying assumptions as those described in the sections on Doppler gradient and pressure Gradient and should be adapted for use with caution.

In the application of Equations 20 and 22, one subtlety should be kept in mind: all variables in the equations are averages during the systolic or diastolic forward flow period through the heart valve. Instantaneous values of pressure and flow rate cannot be used in these equations unless taken at peak flow rate. This is because the Gorlin formula is derived using Bernoulli's equation for steady flow and is, therefore, invalid in situations where there is a large net temporal acceleration or deceleration in the flow. For example, in the estimation of $\Delta p$ using the echocardiography method, one should use either the average of a few pressure gradients spaced equally over the forward flow phase or the time integration average of the pressure gradient data. For the estimation of *Q* in the echocardiography method, use of the velocity-time integral, which accounts for the velocities over the entire forward flow phase, is recommended.

Averages over the entire cycle may not be relevant either, especially if aortic regurgitation occurs concurrently.[14] Estimations of forward flow rate that do not involve echocardiography (Fick method, thermal and dye dilution) are averages over the entire cardiac cycle ($Q_{net}$). If no regurgitation is present, these methods can be used to estimate the average forward flow rate during systole. However, if aortic regurgitation is present, direct application of Gorlin's formula will result in an underestimation in *EOA*:

$$Q = \frac{Q_{net}}{(1 - RF)} \tag{23}$$

where *RF* represents the regurgitant fraction of the aortic valve.

In the in vitro setting, prosthetic valve *EOA* is measured with the Gorlin equation, because the direct measurement of pressures and flow is very easily achieved. Volumetric flow rate can be measured at high temporal resolution with commercial flow probes, and pressures can be measured through catheter-like tubes directly upstream and downstream of the valve, using commercial pressure gages. In vitro testing of prosthetic valves uses the following equation for calculating *EOA*[15]:

$$EOA = \frac{Q_{RMS}}{51.6\sqrt{\Delta p_{mean}}} \tag{24}$$

where *EOA* is in units of $cm^2$, $Q_{RMS}$ is the square root of the temporal mean of the square of volumetric flow rate in mL/s during the forward flow phase, and $\Delta p_{mean}$ is the temporal mean of the pressure drop across the valve during the forward flow phase in mm Hg.

A measure of a valve's resistance to forward flow that is based on *EOA* is the performance index. This is the ratio of EOA to the valve sewing ring area ($A_{sew}$):

$$PI = \frac{EOA}{A_{sew}} \tag{25}$$

It provides a measure of how well a valve design uses its total mounting area, the area the flow would experience without the valve. Although *EOA* is dependent on valve size, performance index effectively normalizes *EOA* for valve size.

## REGURGITANT VOLUME

Pressure drop, Doppler gradient, and *EOA* give quantitative estimates of the energy lost by the flow in traversing a valve during forward flow. Flow energy can also be lost due to leakage across the valve when the pressure gradient across the valve reverses. A small amount of flow leaks across the valve during valve closure. In addition, mechanical prosthetic valves are unable to form tight seals when closed, and regurgitant jets are present in these valves under normal conditions. Normal regurgitant flow is characterized by a closing volume during valve closure and leakage after closure. The regurgitant volume is the total volume of fluid through the valve per beat due to the retrograde flow. It is equal to the sum of the closing volume and the leakage volume. The closing volume is the volume of fluid flowing retrograde through the valve during valve closure. Any fluid volume accumulation after valve closure is due to leakage and is termed *leakage volume*.

Regurgitant volume of prosthetic valves is governed by valve type, size, and position. Bioprostheses have a small closing volume, but do not leak if functioning properly. Bileaflet mechanical designs tend to have greater regurgitant volume than tilting disk designs.[16] Larger valves leak more than smaller ones. Regurgitant volume is most problematic in positions where the pressure gradient during closure and leakage is high and where the duration of leakage is long. Energy losses due to regurgitant flow can exceed forward flow energy losses in large mitral prostheses.[16] Although prosthetic valves normally exhibit a very small amount of regurgitant flow, they can cause substantial regurgitation when they malfunction. To distinguish normal from abnormal valve function, it is important to differentiate between normal regurgitant volume and additional regurgitation due to disease. For in vitro evaluation of prosthetic valves, regurgitation volumes can be easily evaluated with commercial flow probes or velocimetry techniques such as particle image velocimetry or laser Doppler velocimetry. The energy loss due to regurgitation can be estimated using Equation 29, described later.

Most means of quantifying regurgitant volume use some form of a control volume and conservation of mass. For noninvasive quantification of regurgitation flow with echocardiography, perhaps the most commonly used method is the proximal isovelocity surface area method,[17-20] which is applicable for bioprosthetic valves. The principle of the proximal isovelocity surface area technique is based on the fact that a fluid entering a regurgitant orifice must accelerate to reach a peak velocity at the throat of the orifice. If the orifice is circular, this acceleration region should be axisymmetric about the center of the orifice. Thus, upstream of the regurgitant orifice, a series of hemispherical isovelocity contours can be defined within the flow field. Equation 5 states that for a control volume that does not change in size, the same amount of fluid that enters the volume must exit it as well. If the control volume is constructed to coincide with a hemispherical contour and the regurgitant orifice,

$$RV = 2\pi r^2 v_{ups} t \tag{26}$$

where $v_{ups}$ the temporal average of the velocity at a radial distance $r$ upstream of the regurgitant orifice during forward flow and $t$ represents the time during which regurgitation takes place during a single beat. The expression $2\pi r^2$ in this equation represents the surface area of the hemispherical shell surrounding the control volume.

## MECHANICAL ENERGY LOSSES

Pressure gradient and EOA parameters are indicative of the energy loss in valves. However, they are not direct measures of mechanical energy losses, which should be measured in joules per cycle or watts.

Direct measurement of mechanical energy losses is possible in vitro with both Equation 12 (the Bernoulli Equation analysis) and Equation 15 (the control volume analysis). When Equation 12 is integrated over one cardiac cycle, the final term on the right side of the equation becomes zero because of the periodicity or repetitive nature of the fluid flow. The gravitational potential energy term (the third term on the right side) is usually small and can be neglected. The remaining terms can be simplified to

$$\Phi_{cycle} = \int_{cycle} Q\left[\left(P_1 + \frac{1}{2}\rho v_1^2\right) - \left(P_2 + \frac{1}{2}\rho v_2^2\right)\right] dt \tag{27}$$

where $\Phi_{cycle}$ is the energy loss per cycle, $Q$ is the volumetric flow rate, and the subscripts *1* and *2* refer to upstream and downstream of the valve, respectively. Heinrich and colleagues[21] measured the energy loss per cardiac cycle for the St. Jude Medical bileaflet mechanical valve and the Medtronic Hall tilting disk mechanical valve and showed that there was no significant difference in the energy losses of these two valves. Energy loss was observed to increase with increased stroke volume and HR.

Equation 13 can be simplified to the following by assuming that energy conversion to gravitation potential energy is small:

$$\Phi_{inst} = Q \cdot (P_1 - P_2) - \frac{dKE}{dt} \tag{28}$$

where $\Phi_{inst}$ is the instantaneous energy loss, *KE* is the kinetic energy within the control volume, and the subscripts *1* and *2* refer to the control volume boundary upstream and downstream of the valve, respectively. By making suitable assumptions of the flow profile, Yap and co-workers[1] measured the instantaneous energy losses for a trileaflet valve and showed that most of the energy is lost during late systole, when there is adverse pressure gradient to decelerate forward flow and excessive mixing of fluid occurs from flow reversals. Energy loss was also observed to increase with stroke volume and HR.

To calculate energy loss as a result of valvular regurgitation, we assume that all the mechanical energy causing the regurgitation is lost:

$$\Phi_{regurg} = \int_{regurg} Q \cdot (P_1 - P_2) dt \tag{29}$$

where $\Phi_{regurg}$ is the total regurgitation energy loss over one cardiac cycle, $Q$ is the regurgitation volumetric flow rate, and the subscripts *1* and *2* refer to upstream and downstream of the regurgitation orifice, respectively (i.e., downstream and upstream of the valve, respectively). Azadani and associates[22] used this approach to estimate the regurgitation energy losses occurring in transcatheter valves and found that regurgitation energy loss can be as high as one third of the total energy loss associated with the valve.

Energy loss through valves during forward flow depends on the volumetric flow rate, the density of the fluid, the viscosity

of the fluid, the size of the valve (which can be represented by the body surface area), and the shape of the valve (for example, whether the valve is stenotic). Rigorous analysis with the Buckingham pi theorem indicates that energy loss can be nondimensionalized with density and the cube of flow rate and the square of body surface area.[23] When normalized by these scaling parameters, the energy loss is directly dependent on the Reynolds number and the shape of the valve:

$$\varepsilon \propto \rho \frac{Q^3}{BSA^2} \tag{30}$$

$$\frac{\varepsilon}{\rho \frac{Q^3}{BSA^2}} = f(N_{\mathrm{Re}}, S) \tag{31}$$

where $\varepsilon$ is energy dissipation, $\rho$ is density, $Q$ is flow rate, $BSA$ is body surface area, $N_{\mathrm{Re}}$ is the Reynolds number, and $S$ is the dimensionless shape factor.

Clinically, the direct measurement of energy loss is not widely used for assessing heart valves in vivo, even though energy efficiency parameters have the advantage of being a direct measure of the contribution of valve fluid dynamics to heart failure (heart failure can be interpreted as the failure of the heart to generate sufficient energy to overcome energy losses in the circulation). For example, Dasi and colleagues[23] discussed how end-stage aortic stenosis failure patients who have low flow and low gradients can have deceivingly normal EOAs, but with energy loss analysis, it becomes apparent that these patients have failing hearts. Atkins and co-workers[24] provided a review of mechanical energy loss analysis in heart valves.

## NOVEL ENERGY LOSS PARAMETERS

As Figure 24-6 implies, much more mechanical energy is lost in flow expansion than in flow contraction or in the throat regions of prosthetic valves. This is particularly true in tissue valves, because of the gradual nature of the flow contraction and the small throat region. The localization of energy loss to the flow expansion region simplifies the problem considerably by allowing energy losses occurring in aortic valve stenoses to be modeled by an abrupt expansion. The total energy loss per unit volume across an abrupt expansion can be derived using Equation 6, Equation 12, and a form of conservation of momentum[25]:

$$\Phi = 4v_{\max}{}^2 \left(1 - \left(\frac{EOA}{A_{aorta}}\right)\right)^2 \tag{32}$$

where $\Phi$ is in mm Hg and $v_{max}$ is the temporal average of the velocity at the point of maximum flow contraction, in cm/s. Equation 32, like recovered pressure, is thus a strong function of the EOA and the cross-sectional area of the aorta. As this area ratio approaches zero, the energy loss per unit volume in the expansion approaches the Doppler gradient. Thus, in cases of severe valvular stenosis, the Doppler gradient is equivalent to mechanical energy loss per unit volume. The advantage of using Equation 32 rather than pressure drop or Doppler gradient is that Equation 32 allows the estimation of energy lost by the flow in traversing the valve by noninvasive echocardiography while compensating for pressure recovery. In using this formulation in the aorta, the cross-sectional area of the expansion should be taken as the cross-sectional area of the aorta at the sinotubular junction, as the separated flow disappears after the flow has traversed the sinuses of Valsalva.

The energy loss in Equation 32, like pressure drop and Doppler gradient, is dependent on flow rate. It is desirable to have a parameter that is closely related to energy loss, but relatively independent of flow rate, for the evaluation of prosthesis function. Such a parameter can be derived by substituting Equation 32 for the Doppler gradient in Equation 20. This parameter has been dubbed the energy loss coefficient[26]:

$$ELCo = \frac{A_{aorta} EOA}{(A_{aorta} - EOA)} \tag{33}$$

where $EOA$ is measured by echocardiography, using either Equation 18 or Equation 20. The energy loss coefficient is equivalent to Equation 23 if $\Delta p$ in Equation 23 is measured with pressure transducers that are placed far enough downstream to account for energy recovery. The advantage of using the energy loss coefficient rather than $EOA$ is that the energy loss coefficient is based on recovered pressure.

## IN VIVO EVALUATION OF PROSTHETIC VALVES

The in vivo evaluation of prosthetic valves is done clinically when patients with prosthetic valve implants suffer from abnormal cardiac function. Prosthetic valve implants are all mildly stenotic, because prosthetic valves are usually implanted within aortic lumen space, which was previously space available for flow. In some cases, however, unusually high gradients despite normal prosthesis function are observed.[27] These are most likely cases of patient-prosthesis mismatch, where the implanted valve is too small to accommodate the CO required by the large size of the patient. Patients with hypertrophic hearts or calcific aortic stenosis are especially prone to patient-prosthesis mismatch, because it is difficult to insert the large prosthesis into constricted sites. Patient-prosthesis mismatch affects the patient's physical capacity as well as postoperative mortality.[28] To detect patient-prosthesis mismatch, the echocardiographic evaluation of the EOA of the prosthesis should be performed and compared to literature value of the EOA of the same model of prosthesis of the same size. If the EOA is lower than that reported in the literature, it is likely that there is prosthesis dysfunction. On the other hand, if the EOA is similar to that reported in the literature, and yet a high pressure gradient exists, patient-prosthesis mismatch is likely. In vitro investigation has shown that the indexed EOA is inversely related to mean pressure gradient, as shown in Figure 24-8. Further, in the case of a mismatch, where small indexed EOAs are present, exercising will lead to greater elevation in mean gradient than when the mismatch is not present.

# Hemodynamics of Native Valves

In order to effectively analyze flow through prosthetic heart valves in the mitral or aortic positions, it is important to

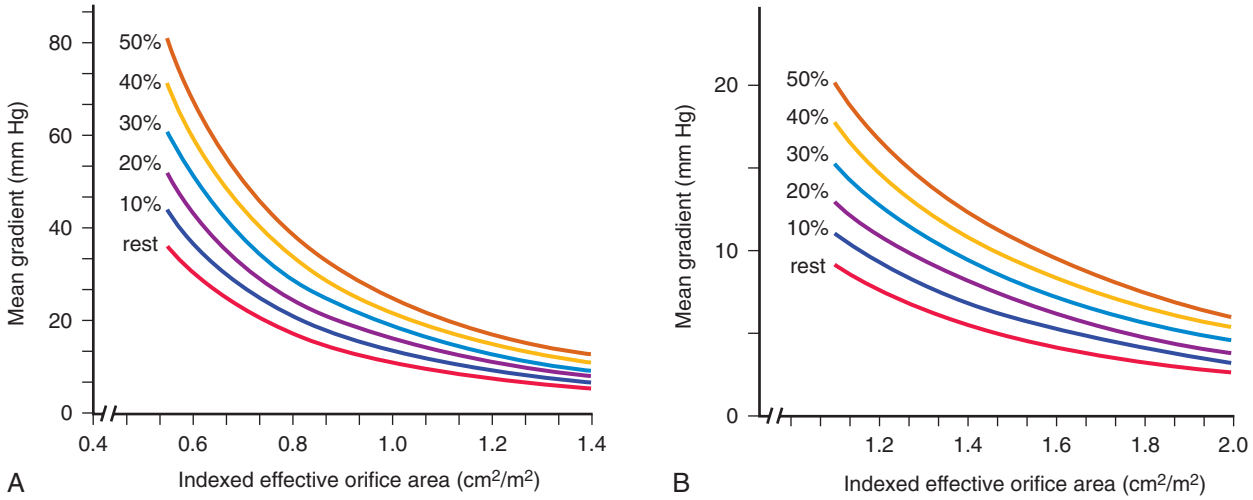

**Figure 24-8** Relationship between mean transprosthetic pressure gradients and indexed effective orifice area for (**A**) aortic bioprostheses and (**B**) mitral bioprostheses, studied in vitro in a physiologic pulse duplicator system assuming a normal cardiac index of 3.0 L/min/m$^2$ at rest, and 10% to 50% increase in stroke volume as may occur during exercise. *(Adapted from Dumesnil JG, Yoganathan AP: Valve prosthesis hemodynamics and the problem of high transprosthetic pressure gradients.* Eur J Cardiothorac Surg *6[Suppl 1]:S34-S37; discussion S38, 1992.)*

understand the conditions under which natural valves function. Figure 24-9 illustrates typical pressure and flow waveforms for healthy individuals at both the aortic and the mitral valves. During systole, the pressure difference required to drive the blood through the aortic valve is on the order of a few millimeters of mercury. Diastolic pressure differences across the aortic valve are much larger than systolic, the pressure usually being about 80 mm Hg. The valve closes near the end of the deceleration phase of systole with very little reverse flow. The blood flow through the mitral valve is biphasic during diastole, as shown in Figure 24-9. The first peak, the E-wave, is due to ventricular relaxation, whereas the second peak, the A-wave, is caused by contraction of the left atrium. This means that all valves in the mitral position open and close twice during each cardiac cycle. It is also evident that all cardiac valves are closed during both isovolumic contraction and isovolumic relaxation.

Measurements of the velocity profile just distal to the aortic valve have been performed with Doppler echocardiography in normal subjects.[26] The peak systolic velocity is 1.35 ± 0.35 m/s, and the velocity profile at the level of the aortic valve annulus is relatively flat. However, there is usually a slight skew toward the septal wall (less than 10% of the center-line velocity) caused by the orientation of the aortic valve relative to the long axis of the left ventricle. This skew in the velocity profile has been shown by many experimental techniques, including hot film anemometry,[29,30] Doppler ultrasound,[31] and magnetic resonance imaging.[32]

The flow patterns distal to the aortic valve also play an important role in proper valve function. During systole, vortices form behind each leaflet in the sinus region. In vitro studies have attempted to relate these vortices to effective valve closure.[33,34] It has been shown that the ventricular vortices are unnecessary for valve closure; however, they do ensure that the valve closes quickly, reducing leakage.[35]

The velocity profile at the mitral valve has been determined in detail in pigs and should be comparable to the velocity profile

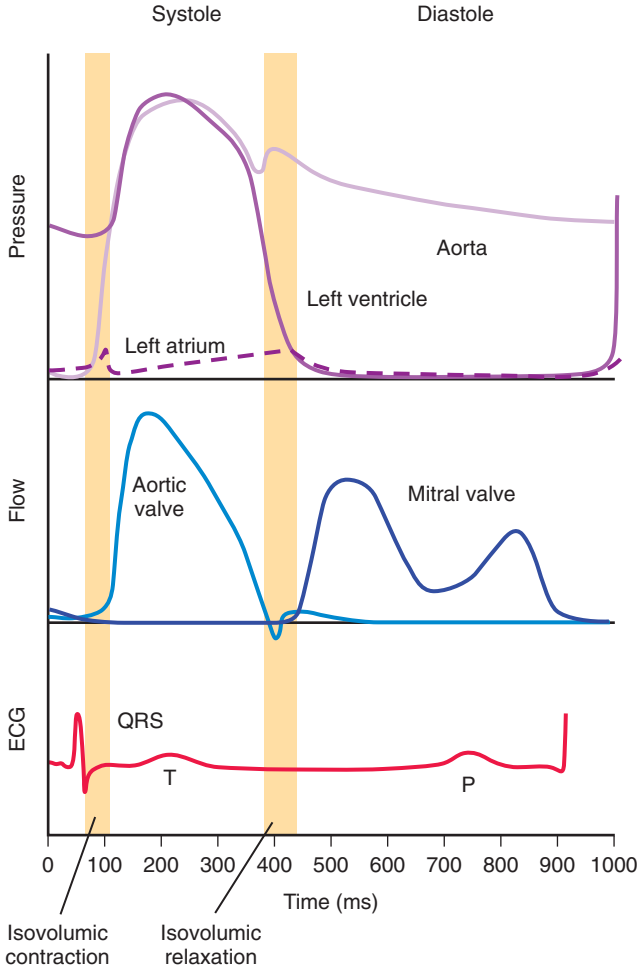

**Figure 24-9** Pressure and flow waveforms for the left heart.

in humans because of the similarity in cardiac anatomy.[36] Again, there is a slight skew to the profile, but there does not seem to be a preferred orientation. It is dependent on the particular geometry of the mitral valve, the diastolic flow patterns within the left ventricle, and the location at which the pulsed Doppler sample volume is placed. When the sample volume was placed at the mitral annulus, the peak early diastolic velocity was 63.6 ± 16.1 cm/s, whereas the late diastolic peak velocity was 53.7 ± 10.8 cm/s. When the sample volume was at the tip of the mitral valve leaflets, the peak early diastolic velocity was 82.9 ± 30.8 cm/s and the peak late diastolic velocity was 39.6 ± 14.2 cm/s.

Vortices develop in the left ventricle during diastole, as blood enters through the mitral valve. Bellhouse[28] proposed that the vortices helped to close the mitral valve at the end of diastole. Later work has shown that the vortices play a role in early closing of the mitral valve but late closure is dominated by left ventricular pressure.[37]

Because of the restrictive area of prosthetic valves, the peak velocities are usually higher, and the spatial velocity profiles are dramatically different from those in natural valves. The shear stresses in prosthetic valves will also be much larger because of the higher velocities and turbulence. The magnitude of the shear stress varies greatly depending on the type of prosthetic valve. It is important to note the differences and similarities between valve types in terms of shear stress magnitudes, peak velocities, and flow patterns so that an effective assessment of prosthetic valve function can be performed.

## Hemodynamics of Specific Prosthetic Valve Designs

Prosthetic heart valves have been successfully used in heart valve replacement over the past 40 years. Currently, heart valve prostheses can be classified into three primary categories: mechanical valves, biologic valves, and transcatheter valves. Mechanical valves are prosthetic valves manufactured from nonbiologic tissues. There are currently three basic designs or classifications of mechanical valves: ball and cage, tilting disk, and bileaflet. Biologic valves are prosthetic valves manufactured from animal tissues and can be further classified into three categories: stented, unstented, and homograft valves. Transcatheter valves are the newest addition to the prosthetic valve market. Although they are essentially biologic valves delivered through the catheter, these valves deserve a separate classification because of the novelty of their implantation mechanism. Figure 24-10 shows examples of each type of prosthesis.

Although significant progress has been made in the development of better prostheses through new materials and more physiologic valve designs, several problems associated with prosthetic valves have not been eliminated. Existing problems that can be related to the valve hemodynamics or local fluid mechanics are (1) thrombosis and thromboembolism, (2) hemolysis, (3) tissue overgrowth, (4) damage to endothelial lining, and (5) regurgitation. The presence of high shear stresses can lead to damage of formed blood elements, platelet activation, and initiation of biochemical processes affecting coagulation. Lethal damage to red cells can occur with fluid shear stresses as low as 800 dynes/cm$^2$.[38] However, these levels can be significantly lower, in the range of 10 to 100 dynes/cm$^2$, in the presence of foreign surfaces such as that presented by a valve prostheses.[39,40] In addition, platelet activation and damage have been shown to occur in shear stresses ranging from 100 to 500 dynes/cm$^2$.[41] The residence time of the cell in the damaging fluid environment is a significant factor in determining lethal stress levels that further complicates the mechanism for damage. Additionally, regions of flow separation and stagnation form local environments suitable for accumulation and growth of thrombi and fibrous/pannous tissue.[42]

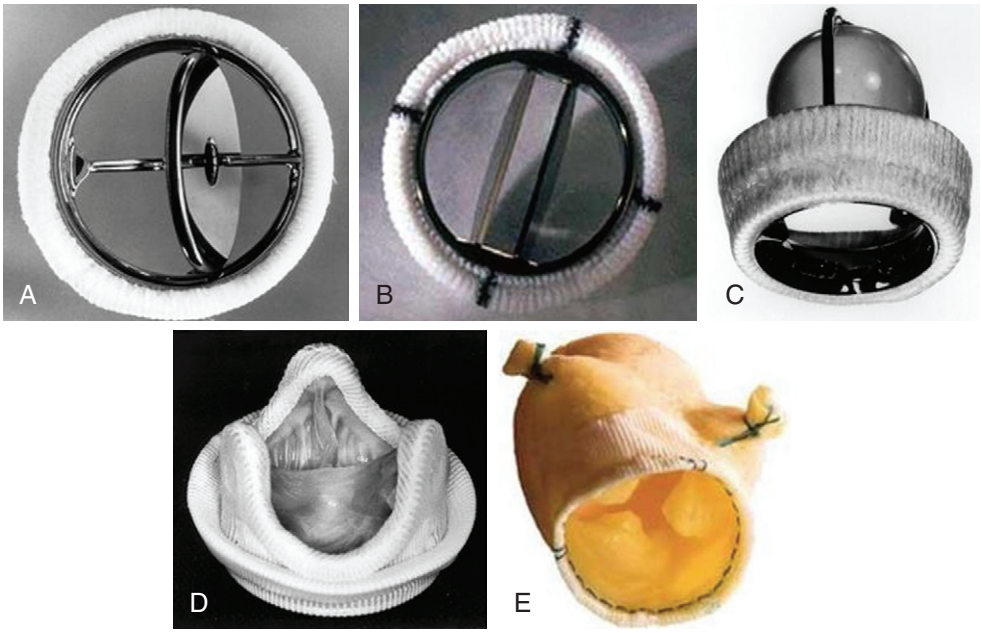

**Figure 24-10** **Major types of prosthetic heart valves. A,** Tilting disk; **B,** bileaflet; **C,** ball; **D,** stented bioprosthesis; **E,** stentless bioprosthesis.

The fluid mechanic performance of prosthetic heart valves is often assessed through in vitro testing to determine transvalvular pressure drops, regurgitant volumes (closure and leakage), distal and proximal velocity fields, and the locations and levels of turbulent stresses. The relationship between valve fluid mechanics and development of problematic function has been studied by numerous investigators over the past two decades. In vitro studies have concentrated on quantifying local fluid stress levels through flow measurement techniques such as laser Doppler anemometry, hot film anemometry, and ultrasound velocimetry. Table 24-1 summarizes the peak velocity and turbulent shear stress levels for many of the 27-mm aortic valves in clinical use. EOA and performance indices for such valves are provided in Tables 24-2 and 24-3.

The fluid mechanics of the various prosthetic valve designs are discussed in this section. Comparisons between the many

valve designs within each classification of prostheses are left to the many references dealing with the assessment of individual valves. Both antegrade and retrograde flow fields are described. All flow characteristics are referenced from in vitro experiments conducted in our laboratory unless otherwise specified. In most citations, the data are representative of 25- or 27-mm aortic prostheses tested under physiologic pulsatile flow conditions providing a CO of 5.0 to 6.0 L/min and an HR of 70 bpm. Exact test conditions (valve size, CO, HR, pressures) are noted for each citation.

## MECHANICAL VALVES

The three major mechanical valve designs or classes are the tilting disk, bileaflet, and ball and cage. These valves differ primarily in the type and function of the occluder. While these different designs influence the valvular fluid mechanics, all three designs share common flow structures such as well-defined jet flows, wakes with some degree of flow reversal, and turbulent shear layers (Figs. 24-11 to 24-16). The antegrade flow and regurgitant flow characteristics for each valve design are discussed in Table 24-4[43-54].

**TABLE 24-4 Mechanical Valve Types, Function, and Fluid Mechanics**

| *Valve* | *Characteristics* | *Antegrade Flow* | *Normal Regurgitant Flow* | *Orientation* |
|---|---|---|---|---|
| Tilting disk valve | Consists of a circular occluder disk, which is free to rotate about a pivot axis (see Fig. 24-10, *A*). Metal struts are used to secure the disk within the valve housing. Typically, disk opens to 60° to 80° with respect to the annulus. | Valve opens two orifices on either side of the disk. The jet through the major orifice jet is semicircular in cross section with peak systolic velocities of approximately 2 m/s in the aortic position. If a strut support obstructs the minor orifice (Björk-Shiley and Medtronic-Hall valves), the minor orifice will have two jets. If two struts are present, there will be three jets, or if no strut is present (Omni Carbon valve), there will be one jet. Minor orifice jet velocities are 30% to 40% of major orifice jet velocities. An example of forward flow velocity profiles downstream of the tilting disk valve is shown in Figure 24-11. | Normal regurgitation flow is low due to reduced closing volume and leakage flow. | In the mitral position, the preferred orientation for tilting disk valves in the mitral position is with the major orifice oriented toward the left ventricular free wall, as opposed to the septum,[43] so as to minimize intraventricular turbulence and velocity reversals. In the aortic position, the preferred orientation is positioning the major orifice to the right posterior aortic wall. This orientation is found to minimize in turbulent stress magnitude and energy loss.[44,45] |
| Bileaflet valve | Consists of two semicircular leaflets typically made of pyrolytic carbon that are hinged to the valve housing (see Fig. 24-10, *B*). The leaflets divide the flow into three regions, two lateral major orifices and a central minor orifice. Pressure drops and EOAs are comparable to tilting disk valves. Variations in opening angle of leaflets are 75° to 90° among different designs. | Three jets emanate from the orifice as illustrated in Figure 24-12 and 24-14. Greater flow emerges from the lateral orifices than from the central orifice in most valves. Shear stress fields downstream of the St. Jude Medical bileaflet valve are shown in Figure 24-14, *A*.[46] Much of the shear stress occurs directly downstream of the leaflets, due to uneven velocities between the central orifice and lateral orifice. Reynolds shear stress analysis shows that turbulence in the same region (see Fig. 24-14, *B*). | The bileaflet design shows slightly larger regurgitant volumes than the tilting disk valve. Leakage flow occurs primarily through the hinges of the leaflets (see Fig. 24-16, *B*) and persists over diastole. Some leakage occurs through the gap between the two leaflets. Studies suggest that hinge leakage flow are mainly responsible for thrombosis.[47] Regurgitation flow are 2-3 m/s with very high turbulence stresses exceeding 3000 dynes/cm$^2$.[48,49] (See Fig. 24-13) There are multiple hinge designs with varying flow features, summarized in Figure 24-15.[47,50-53] | For the mitral position. Two possible orientation are "anatomic position," with the gap between the leaflets perpendicular to the line between the aortic outflow and mitral inflow tracts, and the "anti-anatomic position," where the leaflet gap is parallel to the aorto-mitral line. In vivo studies showed that the antianatomic position resulted in diastolic flow that moves toward the ventricular outflow tract, whereas the anatomic position resulted in diastolic flow that moves back toward the valve.<br>In the aortic position, Travis and colleagues[44] found that orienting the open valve leaflets to the proximal flow direction minimizes energy loss, whereas Kleine and co-workers[45] found that turbulence created by the valve is minimal when one lateral orifice faces the right posterior wall of the aorta. |
| Ball and cage valve | Consists of a silicone ball mounted into a wire cage, as illustrated in Figure 24-11, *C*. The cage is constructed of three wire struts separated by 120°. The ball travels 1-2 cm within the cage during opening. | The flow fields of these valves consist of annular jets that emerge from around the occluder or poppet. A large wake in the central part of the flow field is generated. Peak systolic velocities are about 2 m/s (see Fig. 24-17). Large regions of flow separation are responsible for thrombogenicity of the valves,[54] and the ball obstruction of flow results in lower pressure drop and EOA. | The normal regurgitant flow of the ball and cage design is composed mainly of the closing volume flow. The seating of the ball valve is generally very good, with little or no leakage flow. | |

*EOA*, Effective orifice area.

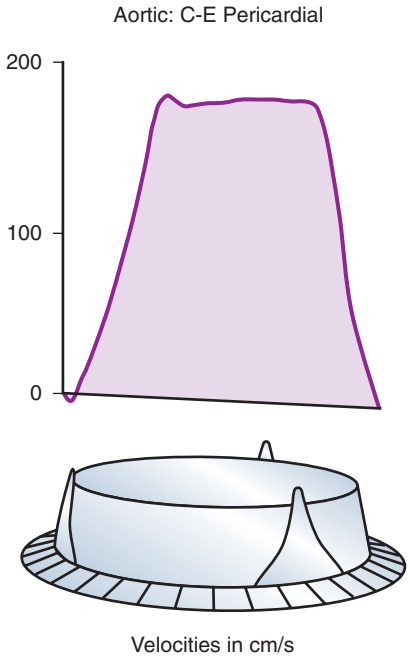

**Figure 24-17** Centerline velocity profile 17 mm downstream of a 27-mm Carpentier-Edwards pericardial valve at peak systole.

## BIOPROSTHESES

The three major tissue valve designs or classes are the stented xenograft, unstented xenograft, and homograft. These valves differ primarily in tissue type and structure. Tissue valves are less thrombogenic compared to mechanical valves and thus do not require anticoagulant treatment. However, these valves suffer from calcification of the leaflets and/or material fatigue leading to valve failure due to leaflet rupture or tearing. Calcification of the tissue is often a precursor to leaflet rupture and tearing, as these are often observed adjacent to calcified lesions. All bioprosthesis designs share the characteristics of flexible leaflets, a single orifice, and no leakage after valve closure (Fig. 24-17). The antegrade flow, regurgitant flow, and pressure drop characteristics for each valve type are summarized in Table 24-5.[55-57] The newest valve design, transcatheter valves, are discussed in more detail.

## TRANSCATHETER VALVES

The newest additions to the family of prosthetic valves are the transcatheter valves. Transcatheter valves are essentially bioprosthetic aortic valves mounted onto a collapsible stent, so that the valve can be collapsed onto a catheter and delivered through it in a minimally invasive manner Figure 24-18. These valves were introduced to target high risk-patient groups, such as old patients or those with diabetes, who are much less likely than others to survive an open-heart valve replacement treatment. The catheter delivery approach avoids cross-clamping and cardiopulmonary bypass and reduces procedure duration and thus risks. Although the outcome of transcatheter valve replacement has been shown to be poorer than that of traditional surgical

**TABLE 24-5 Bioprosthesis Valve Types, Function, and Fluid Mechanics**

| *Valve* | *Characteristics* | *Antegrade Flow* | *Normal Regurgitant Flow* | *Pressure Drops* |
|---|---|---|---|---|
| Stented xenograft | Most common valve: consist of three biologic leaflets made from the porcine aortic valve or bovine pericardium, mounted on a metal or polymeric stented ring. Various fixation methods are used. | All porcine stented valves are mildly stenotic in larger sizes and moderate to severely stenotic in small sizes. All valves have strong central jets (see Fig. 24-18). The newer generation valves have a flatter velocity profiles than earlier designs. | Regurgitant volumes are on the order of 1 mL/beat for most tissue valves. Regurgitation jets are normally nonexistent, and the presence of a jet indicates valve incompetence abnormality. | New generation of pericardial valves have pressure drops similar to those of tilting disk valves. |
| Unstented xenograft | Fashioned from porcine, bovine, and equine tissue and do not have rigid stents. Because of the complexity of the design, optimal performance is dependent on patient geometry and sizing of valve. | The flow accelerates uniformly through the valve, and downstream flow has a flat profile.[55] There is no appearance of a jet with steep velocity gradients, as is observed in stented bioprostheses. | Tests in our laboratory showed that unstented valves have comparable closing volumes to unfixed natural valves tested in the same flow loop. Good coaptation was observed with no leakage. The function of mitral heterografts is strongly dependent on the implantation technique. | The lack of stents and sewing cuffs allow larger valve sizes to be implanted for the same aorta size. Pressure drops are thus similar to those for mechanical prostheses.[55-57] |
| Homograft | Cryopreserved human valves; have been used for more than two decades in the aortic position. Aortic valve homografts are usually implanted as a complete aortic root, whereas mitral homografts are implanted with the leaflets, annulus, papillary muscles, and chordae tendineae intact. | Similar to those of the natural valves, although peak velocities are slightly higher because of the reduced EOAs resulting from the smaller area of the outflow tract. | Exhibit small closing volumes and little or no regurgitation due to leakage. Mitral homograft hemodynamics have the same dependency on implantation technique. For example, proper alignment of papillary muscles with valve annulus will eliminate regurgitation. | Has lower pressure drops and EOAs than mechanical and stented valves. |

*EOA*, Effective orifice area.

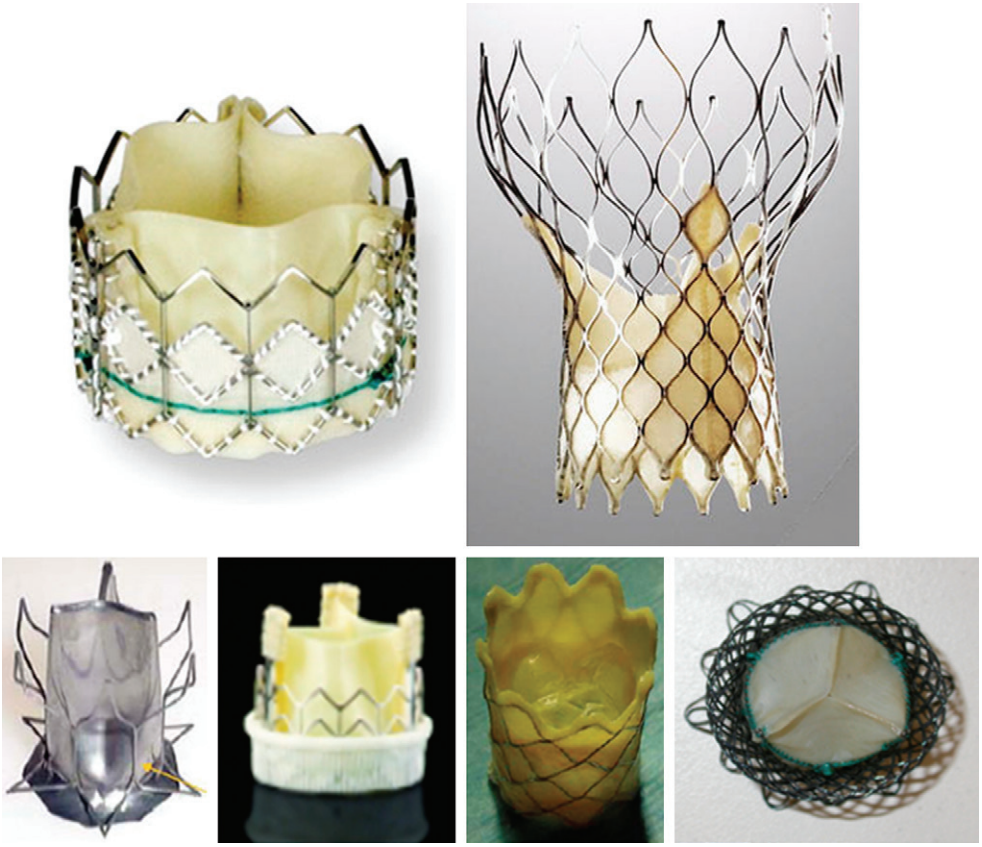

**Figure 24-18 Various designs of transcatheter valves.** *Top left*, Edwards Sapien valve; *top right*, Medtronic CoreValve. *Bottom*, Various other designs.

valve replacement, it appears to be better than other available options.[58]

Transcatheter valves can be delivered in a transfemoral or transapical manner. In the former, the catheter gains access to the diseased valve by entering through the femoral artery and backtracking through the aorta to the heart. In the latter, the catheter enters the left ventricle directly from the apex of the heart. Balloon valvuloplasty is first applied to the calcified aortic valve to open it up. The ventricle is then induced into a state of rapid pacing, and then the valve is deployed by expanding a second balloon from within the valve. There are multiple transcatheter valve designs, as shown in Figure 24-18. The leading designs are the Edwards Sapien valve and the Medtronic CoreValve. The Sapien valve is a trileaflet bovine pericardial valve mounted onto a stainless steel or cobalt-chromium frame. The CoreValve is a trileaflet porcine pericardial valve mounted in a Nitinol frame. The profile of the CoreValve stent is longer than that of the Sapien valve, because it extends slightly proximally and extends distally in a splayed-out manner to reach the aorta.

At the time of publication, no transcatheter valve design is currently approved by the FDA for clinical use in the United States. Other than their fluid dynamic performance, there are significant concerns in the biomechanics community about the long-term durability of transcatheter devices in comparison to surgically implanted prosthetic valves.

### *Antegrade Flow Fields*

Bench-testing of the transcatheter valve showed that they have EOA of about 1.8 $cm^2$ and mean pressure gradient of 8.3 mm Hg, which is comparable to stented bioprostheses.[22] Clinically, the EOAs of valves were shown to be between 1.5 and 1.8 $cm^2$, and pressure gradients were about 10 mm Hg.[59,60]

### *Normal Regurgitant Flow*

Unlike bioprosthetic valves, regurgitation in the transcatheter valve is very common. Mild to moderate regurgitation occurs in more than 50% of cases; severe regurgitation occurs in 5%.[59-62] Regurgitation in the transcatheter valve is mostly paravalvular, occurring between the valve and the native tissues rather than through the valve orifice. Because the implanted valve is merely pressed onto native tissues because of pressure exerted by the stents, a complete seal cannot be achieved in most cases, especially when the native aortic valve is heavily calcified and presents a very uneven surface for the transcatheter valve to fit onto. Perivalvular leakage can exert high shear stress on regurgitating blood and cause clots, which may explain the high incidence of vascular complication (10% to 15% of cases).[60,63]

## Future Directions

We foresee that future directions in prosthetic valve research will follow several courses: improved transcatheter valve technologies (delivery device designs as well as well valve designs); development of polymeric prostheses; tissue engineering bioprosthetic valves; invention of novel tissue fixation techniques; improving designs of mechanical valves; improving in vitro, computational, and animal testing protocols; and development of noninvasive diagnostic capabilities. Although transcatheter

valves enable noninvasive valve replacement, there are still concerns relating to durability and valve leakage. Currently, transcatheter valves are meant for use only in inoperable patients, because it cannot yet be shown that they provide better outcome in regular patients. Future improvements to the transcatheter valve may extend their application to regular patients. Polymeric prostheses may offer patients a durable alternative to mechanical and bioprostheses with little tendency for calcification or thromboembolic complications. The goal of tissue engineering research is to grow living human aortic valves in the laboratory, preferably using the patient's own tissue. Potential advantages involve total acceptance of the living tissue, with hemodynamic and cellular function similar to the normal human aortic valve, resulting in a lifetime equal to that of native valves. Tissue xenografts are currently fixed in glutaraldehyde, which stiffens the compliance of the valve material and hinders hemodynamic performance. Other fixative techniques may improve hemodynamic performance or increase the functional lifetime of xenografts. For mechanical valves, the focus will be on reducing their thrombogenic properties. This could possibly be accomplished by development of biocompatible surface coatings and materials, or by changing valve geometry to improve closure and leakage flow through these valves. A first step in this research should be in improved understanding of blood element damage, thromboembolic events, and thrombus formation. In vitro evaluation techniques and in vivo diagnostic techniques for bulk flow hemodynamics will focus more closely on mechanical energy loss, and more attention will be devoted to the small-scale, local hemodynamics that may give rise to thromboembolic complications.

## ACKNOWLEDGMENTS

The work reported on prosthetic heat valves was from our Cardiovascular Fluid Mechanics laboratory at Georgia Tech and has been supported by grants from the FDA, American Heart Association, the heart valve industry, and generous gifts from Tom and Shirley Gurley and the Lilla Boz Foundation.

## KEY POINTS

- Application of conservation of mass to a control volume allows the calculation of unknown flow rates, average velocities, or surface areas into or out of the volume based on measurable quantities.
- Mechanical energy per unit volume is a measure of the work available to drive flow.
- Pressure is one of several forms of mechanical energy, but there are others (kinetic and gravitational). These forms can be freely converted from one to another without loss. Pressure loss and mechanical energy loss per unit volume are not equivalent, as pressure can be recovered from a fall in either gravitational or kinetic energy.
- Effective means of reducing mechanical energy loss in the circulation include ensuring that any expansions in flow occur gradually, ensuring that bends and corners in the flow path are not sudden or sharp, and increasing vessel radius.
- The Doppler gradient measures the conversion of pressure to kinetic energy in flow across a valvular prosthesis. It does not measure mechanical energy loss, although it can be closely related to it.
- The EOA of a valvular prosthesis represents the cross-sectional area of a flow at its smallest contraction. It is equal to or smaller than the anatomic orifice area.
- Mechanical energy losses occur due to regurgitant flow as well as forward flow. Losses due to regurgitant flow can be greater than losses due to forward flow in large, mitral mechanical prostheses.

- Evaluation of Transcatheter Valve Implantation

**Conclusion**

## Prosthetic Valve Complications and Dysfunction

Many prosthesis-related complications can be prevented or their impact minimized through optimal prosthesis selection in the individual patient, careful medical management, and close follow-up of prosthetic valve function after implantation. Doppler echocardiography is the method of choice for the evaluation of prosthetic valve function. This evaluation follows the same basic principles used for the evaluation of native valves with some important particularities and caveats specific to the prosthetic valves. These particularities are described in this chapter.

### PATIENT PROSTHESIS MISMATCH

Patient prosthesis mismatch (PPM) is not an intrinsic dysfunction of the prosthesis, per se. This problem indeed occurs when the effective orifice area (EOA) of a normally functioning prosthesis is too small in relation to the patient's body size (and thus cardiac output requirements), resulting in abnormally high postoperative gradients (see Clinical Case 25-1 at ExpertConsult.com). The most widely accepted and validated parameter for identifying PPM is the indexed EOA, that is, the EOA of the prosthesis divided by the patient's body surface area.[1-5] Table 25-1 shows the cutoff values of indexed EOA generally used to identify PPM and quantify its severity. Moderate PPM may be quite frequent both in the aortic (20% to 70%) and mitral (30% to 70%) positions, whereas the prevalence of severe PPM ranges from 2% to 10% in both positions.[4-7] PPM is associated with worse hemodynamics; less regression of left ventricular (LV) hypertrophy and pulmonary hypertension; worse functional class, exercise capacity, and quality of life; more cardiac events; and lower survival.[6-17] The impact of PPM, and especially severe PPM, on outcomes is more important in younger patients as well in those with poor LV function or severe LV hypertrophy.[8,16] Moreover, as opposed to most other risk factors, PPM can largely be prevented by using a prospective strategy at the time of operation.[18,19] Transthoracic echocardiography (TTE) is essential to make the differential diagnosis between PPM and intrinsic prosthetic valve dysfunction.

### PROSTHETIC VALVE THROMBOSIS AND PANNUS

Obstruction of prosthetic valves may be caused by thrombus formation (Fig. 25-1, *A*), pannus ingrowth (see Fig. 25-1, *B*) or a combination of both (see Clinical Case 25-2 at ExpertConsult.com). Pannus ingrowth alone may be encountered in both bioprostheses and mechanical valves. It may present as a slowly progressive obstruction due to a subvalvular annulus, in which case it may be difficult to visualize and thus to distinguish from progressive structural valve deterioration. Valve thrombosis is most often encountered in patients with mechanical valves and inadequate antithrombotic therapy. Thrombosis may also be seen in bioprosthetic valves, where it most often occurs in the early postoperative period. Pannus and

| Aortic position | >0.85 (0.8-0.9) | ≤0.85 (0.8-0.9) | ≤0.65 (0.6-0.7) |
| Mitral position | >1.2 (1.2-1.3) | ≤1.2 (1.2-1.3) | ≤0.9 (0.9) |

Numbers in parentheses represent the range of threshold values that have been used in the literature.

thrombosis may be present alone or in combination and cause acute or subacute valve obstruction. The incidence of obstructive valve thrombosis varies between 0.3% and 1.3% per patient-year in patients with mechanical valves.[20,21]

Pannus is usually encountered in patients with a normal anticoagulation profile and with subacute or chronic symptoms.[20] Valve thrombosis should be suspected in any patient with any type of prosthetic valve who presents with a recent increase in dyspnea or fatigue.[22] Suspicion should be higher if there has been a period of interrupted or subtherapeutic anticoagulation in the recent past. In such cases, echocardiography should be done promptly and include transesophageal echocardiography (TEE), particularly if the prosthesis is in the mitral position.

## STRUCTURAL VALVE DETERIORATION

Mechanical prostheses have an excellent durability, and structural valve deterioration is extremely rare with contemporary valves, although mechanical failure (e.g., strut fracture, leaflet escape, occluder dysfunction due to lipid adsorption) has occurred with some models in the past (see Fig. 25-1, *C*).

The rate of structural valve deterioration in bioprosthetic valves (see Fig. 25-1, *D*) increases over time, particularly after the initial 7 to 8 years after implantation. Structural valve deterioration is often characterized by calcific degeneration of valve leaflets. However, this process may also occur with no or minimal leaflet calcification in approximately 30% of the cases. Structural valve deterioration is, by far, the most frequent cause of bioprosthetic valve failure. With conventional stented bioprostheses, the freedom of structural valve failure is 70% to 90% at 10 years and 50% to 80% at 15 years.[21,23-26] Risk factors previously found to be associated with bioprosthetic structural valve deterioration include younger age, mitral valve position, renal insufficiency, and hyperparathyroidism.[23-25,27] Structural valve deterioration can result in prosthetic valve stenosis, regurgitation, or both. A meticulous baseline Doppler-echocardiographic evaluation of prosthetic valve morphology and function within the first year after prosthesis implantation and a regular follow-up thereafter are essential to early detection of structural valve deterioration.

## INFECTIVE ENDOCARDITIS

Prosthetic valve endocarditis is the most severe form of infective endocarditis and occurs in 1% to 6% of patients with valve prostheses accounting for 10% to 30% of all cases of infective endocarditis.[28] Prosthetic valve endocarditis is an extremely serious condition with high mortality rates (30% to 50%).[21,22] Echocardiography and particularly TEE plays a

key role in the diagnostic and prognostic assessment of prosthetic valve endocarditis. The diagnosis relies predominantly on the combination of positive blood cultures and echocardiographic evidence of prosthetic infection, including vegetations, paraprosthetic abscesses, or a new paravalvular regurgitation.[29]

## PARAVALVULAR REGURGITATION

Paravalvular regurgitation is typically due to infection, suture dehiscence, or fibrosis and calcification of the native annulus leading to inadequate contact between the sewing ring and annulus. Dehiscence of the prosthesis in the late postoperative period may be related to operative technical factors but is most often caused by endocarditis, in which case emergency surgical treatment is generally required.

Long-term prognosis is generally benign in patients with mild paravalvular regurgitation identified by perioperative echocardiography, with progression of regurgitation requiring reoperation in fewer than 1% of patients at follow-up beyond 1 to 2 years.[30] Hence, closer clinical and Doppler-echocardiographic follow-up appears justified in these patients, with surgical intervention warranted only for those who develop symptoms, hemolysis, and/or progressive LV dysfunction.[31] Paravalvular regurgitation is more common following transcatheter aortic valve implantation. Recent studies indeed report incidence of regurgitation of 30% to 80% with 5% to 14% being moderate or severe (Fig. 25-2, *C*).[32-34]

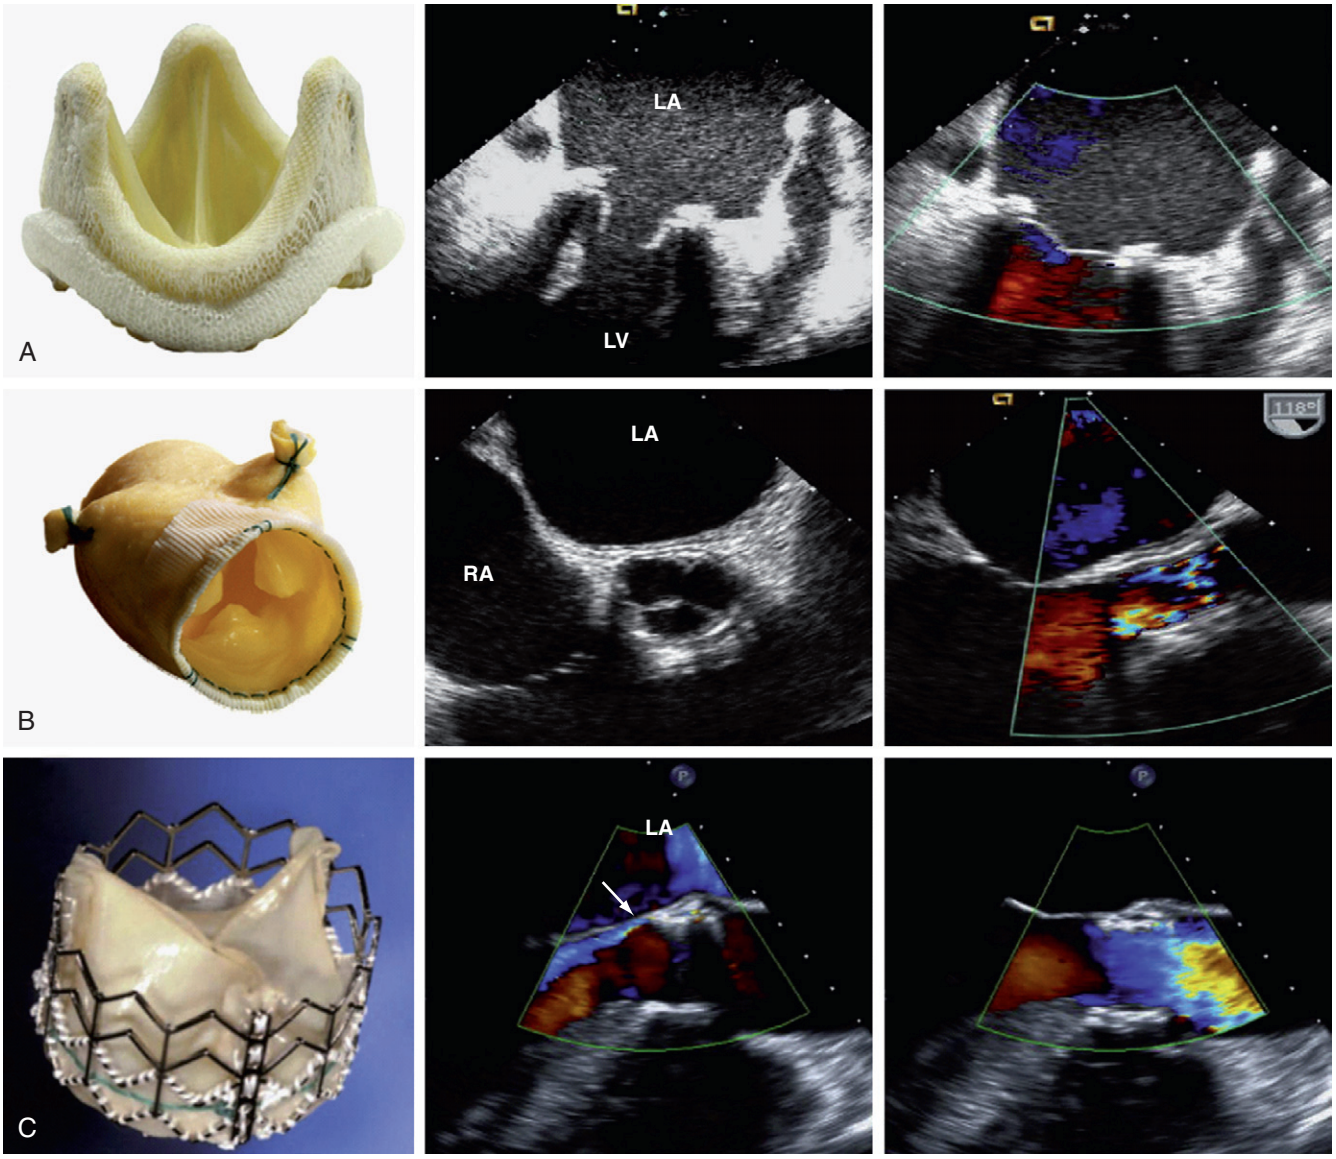

**Figure 25-2 Examples of stented (A), stentless (B), and percutaneous (C) biologic valves and their echocardiographic features in diastole (*middle*) and in systole (*right*) as seen by TEE.** The stentless valve is inserted by the root inclusion technique. ## Basic Principles and Parameters for the Doppler-Echocardiographic Evaluation of Prosthetic Valve Function

Doppler echocardiography is the method of choice to evaluate prosthetic valve function. This evaluation follows the same principles used for the evaluation of native valves with some important caveats described later. A complete echocardiography includes two-dimensional (2D) imaging of the prosthetic valve, evaluation of valve leaflet/occluder morphology and mobility, measurement of the transprosthetic gradients and EOA, estimation of the degree of regurgitation, evaluation of LV size and systolic function, and calculation of systolic pulmonary arterial pressure.

### TIMING OF ECHOCARDIOGRAPHIC FOLLOW-UP

Ideally, a baseline postoperative TTE study should be performed at the first visit, 2 to 4 weeks after hospital discharge, when the chest wound has healed, ventricular function has improved, and anemia with its associated hyperdynamic state has resolved.[35] However, if the patient is being transferred and/or may not return, it may be best to perform the study before hospital discharge, although image quality and reliability of measurements are often suboptimal. Routine follow-up clinical visits should be conducted annually after valve implantation, with earlier reevaluations and echocardiography if there is a change in clinical status. Routine echocardiography after a first postoperative study is not indicated for normally functioning prostheses unless there are other indications for echocardiography (e.g., follow-up of LV dysfunction) or clinical symptoms suggestive of valvular dysfunction or other cardiac pathology.[35] Annual echocardiography is recommended in patients with bioprosthetic valves after the first 5 years. In patients with mechanical valves, routine annual echocardiography is not indicated in the absence of a change in clinical status.

### CLINICAL DATA

The reason for the echocardiographic study and the patient's symptoms should be clearly documented. Furthermore, because the interpretation of Doppler-echocardiographic findings depends on the type and size of the replacement valve, this information and the date of surgery should be incorporated in the report. The exact type and model of prosthesis should clearly be recorded because the design and hemodynamic performance may differ substantially from one model generation to the other (e.g., St. Jude Standard vs. HP vs. Regent models). Blood pressure and heart rate should be measured. The heart rate of the cardiac cycles used for Doppler measurements is particularly important in mitral and tricuspid prosthetic valves, because the mean gradient is highly dependent on the duration of the diastolic filling period. Finally, the patient's height, weight, and body surface area should be recorded to assess whether PPM is present and to interpret the cardiac chamber size.

### RECOGNITION AND QUANTITATION OF PROSTHETIC VALVE STENOSIS

The appearance of a new murmur with new congestive heart failure symptoms in a patient with a prosthetic aortic valve should prompt an urgent TTE study and, if indicated, TEE.

*SD*, Standard deviation.

*Abnormal mechanical valves: occluder that is immobile or with restricted mobility, thrombus or pannus; abnormal biologic valves: leaflet thickening/calcification, thrombus or pannus.

†These parameters are more affected by low or high flow states including low LV output and concomitant aortic regurgitation.

‡This parameter is dependent on the size of the LV outflow tract.

§These parameters are affected by LV function and chronotropy.

However, the initial suspicion of prosthetic valve stenosis may be the incidental finding of abnormally high flow velocities and gradients detected during a routine examination. Tables 25-2 and 25-3 present the Doppler-echocardiographic criteria for the recognition and quantitation of prosthetic valve stenosis.

#### *Leaflet Morphology and Mobility*

Echocardiographic imaging should identify the sewing ring, the valve occluder, and the surrounding area. Echocardiographic imaging of the ball or disk of mechanical valves is often difficult to obtain because of reverberations and shadowing caused by the valve components. Figures 25-2 and 25-3 show the echocardiographic features of normally functioning bioprosthetic and mechanical valves, respectively. The leaflets of tissue valves normally appear thin, with unrestricted motion and no evidence of prolapse. Stentless, homograft, or autograft valves may be indistinguishable from native valves.

TEE can provide improved image quality and thereby improved detection of cusp calcification and thickening; valvular vegetations due to endocarditis, thrombus, or pannus; and reduced leaflet/disk/ball mobility.[36] In the case of mechanical prostheses, evaluation of occluder mobility can be attempted with some degree of success, but in our experience, valve cinefluoroscopy is definitely the best, most economical, and least invasive technique that can be used for this purpose (see Chapter 5).

Prosthetic valve stenosis is generally associated with abnormal valve morphology and/or mobility (see Tables 25-2 and

*SD*, Standard deviation.

*Abnormal mechanical valves: occluder that is immobile or with restricted mobility, thrombus or pannus; abnormal biologic valves: leaflet thickening/calcification, thrombus or pannus.

†The criteria proposed for these parameters are valid for near normal or normal diastolic volume (i.e., stroke volume: 50-90 mL) and heart rate (50-80 bpm).

‡These parameters are more affected by flow and chronotropy.

§These parameters are also abnormal in presence of significant mitral prosthesis regurgitation. This parameter is dependent on the size of the LV outflow tract.

‖These parameters are not valid when more than mild concomitant aortic or mitral regurgitation is present.

¶This parameter is influenced by chronotropy, LA compliance, and LV compliance.

25-3). In the cases of mechanical valves, the mobility of the occluder is usually reduced or absent (Fig. 25-4; also see Clinical Case 25-2). Thrombus, pannus, or vegetation are often visualized at the level of the prosthesis ring or hinge mechanism. In the case of bioprosthetic valves, prosthetic valve stenosis is most often associated with thickening, calcification, and reduced mobility of the leaflets (see Fig. 25-4 and Clinical Case 25-3). However, obstruction of the bioprosthesis may also be caused by thrombus, pannus, or vegetation.

### *Quantitative Parameters*

Quantitative parameters of prosthetic valve function include flow velocity, pressure gradients, EOA, and Doppler velocity index (DVI).

#### Transprosthetic Velocity and Gradient

The principles of interrogation and recording of flow velocity through prosthetic valves are similar to those used in evaluating native valve stenosis. This includes pulsed-wave (PW) and continuous-wave (CW) Doppler as well as color Doppler, using several windows for optimal recording and minimizing angulation between the Doppler beam and flow direction. CW Doppler evaluation of aortic prostheses must be performed from multiple transducer positions, including apical, right parasternal, right supraclavicular, and suprasternal notch. Measurements of prosthesis velocity and gradients are made from the transducer position yielding the highest velocities.[35]

One should however bear in mind that the fluid dynamics of the mechanical valves may differ substantially from those of the native valve (Figs. 25-3 and 25-5). The flow is eccentric in monoleaflet valves and composed of three separate jets in bileaflet valves. Because the direction of the transprosthetic jet may be eccentric, multiwindow examination should be carefully performed to detect the highest velocity signal in prosthetic aortic valves. Occasionally, an abnormally high jet gradient corresponding to a localized high velocity may be recorded by CW Doppler interrogation through the smaller central orifice of bileaflet mechanical prostheses in the aortic or mitral position (see Fig. 25-5).[37] This phenomenon may lead to an overestimation of gradient and a false suspicion of prosthesis dysfunction. In some rare cases, a double-envelope image may be observed with the superimposition of a high-velocity envelope corresponding to the flow through the central orifice and a lower-velocity envelope corresponding to the flow through the lateral orifices (Fig. 25-6).

Pressure gradient is calculated with the use of the simplified Bernoulli equation as follows: $\Delta P = 4 \times V_{Pr}^2$, where $V_{Pr}$ is the velocity of the peak transprosthetic flow jet in meters per second. In patients with aortic prostheses and high–flow-rate or narrow LV outflow tract (LVOT), the velocity proximal to the prosthesis may be increased and therefore not negligible. If proximal velocity ($V_{LVOT}$) is greater than 1.5 m/s, estimation of the pressure gradient is more accurately determined by including $V_{LVOT}$ in the equation: $\Delta P = 4 \times (V_{PrAv}^2 - V_{LVOT}^2)$.

Prosthetic valve stenosis is usually associated with increased transprosthetic peak flow velocity or mean gradient (at least 3 m/s or at least 20 mm Hg for aortic prostheses, and at least 1.9 m/s or at least 6 mm Hg for mitral prostheses) (see Tables 25-2 and 25-3). However, it is important to keep in mind that high velocity or gradient alone is not proof of intrinsic prosthetic obstruction and may be secondary to PPM, high-flow conditions, prosthetic valve regurgitation, or localized high central jet velocity in bileaflet mechanical valves (see Interpretation of High Transprosthetic Gradients for data interpretation and differential diagnosis). Significant prosthetic valve regurgitation may cause the flow rate across the prosthesis to increase, resulting in increased velocities and gradients.

The main limitation of transprosthetic velocity and gradients is that they are highly flow dependent. For instance, patients in a low cardiac-output state can exhibit normal transvalvular velocity and gradients despite the presence of significant prosthetic valve stenosis. Hence, other qualitative and quantitative indices that are less flow dependent should also be used to adequately assess prosthetic valve function.

#### Transprosthetic Jet Contour and Acceleration Time

The contour of the velocity through the prosthesis is a qualitative index that may be used to assess prosthetic aortic valve function in conjunction with the other quantitative indices. In a normal valve, the contour of the CW flow velocity generally has a triangular shape, with early peaking of the velocity and a short acceleration time, that is, the time from the onset of flow to maximal velocity (acceleration time less than 80 ms) (Fig. 25-7). With prosthetic valve obstruction, a more rounded velocity contour is seen, with the velocity peaking almost in midejection, prolonged acceleration time (greater than 100 ms) and ejection time, as well as the ratio of acceleration time to ejection time (greater than 0.4) (Fig. 25-7, and see Tables 25-2 and

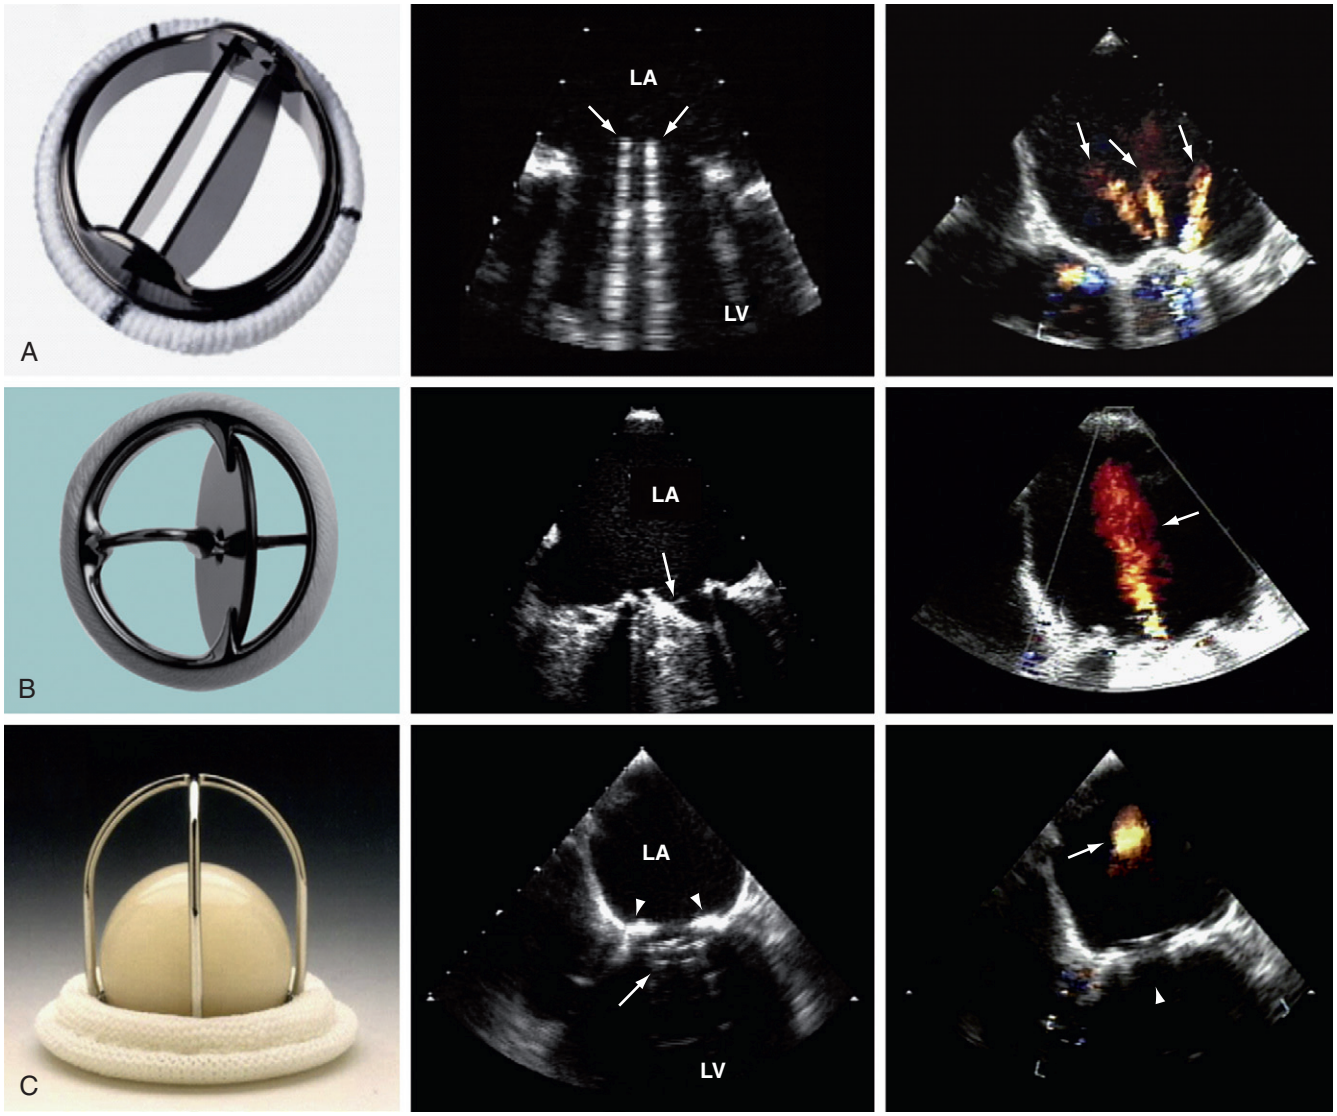

**Figure 25-3 Examples of bileaflet (A), monoleaflet (B), and caged-ball (C) mechanical valves and their transesophageal echocardiographic characteristics taken in the mitral position in diastole (*middle*) and in systole (*right*).** The *arrows* in diastole point to the occluder mechanism of the valve and in systole to the characteristic physiologic regurgitation observed with each valve. *(Reproduced with permission of the American Society of Echocardiography from Zoghbi WA, Chambers JB, Dumesnil JG, et al: Recommendations for evaluation of prosthetic valves with echocardiography and Doppler ultrasound: a report from the American Society of Echocardiography's Guidelines and Standards Committee and the Task Force on Prosthetic Valves.* J Am Soc Echocardiogr *22[9]:975-1014, 2009.)*

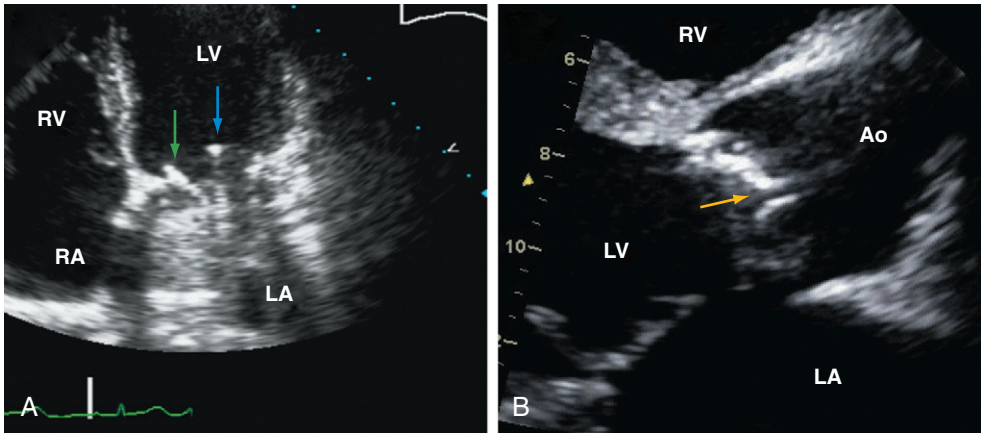

**Figure 25-4 Evaluation of prosthetic valve leaflet morphology and mobility. A,** Mitral bileaflet mechanical prosthesis in diastole with a fixed leaflet (*green arrow*); the other leaflet is still mobile (*blue arrow*). **B,** Thickening and reduced mobility of aortic bioprosthetic valve cusps (*yellow arrow*, systole). *Ao*, Aorta. (Image in panel **B** *courtesy Dr. John Chambers, Guy's and St. Thomas Hospitals, London.)*

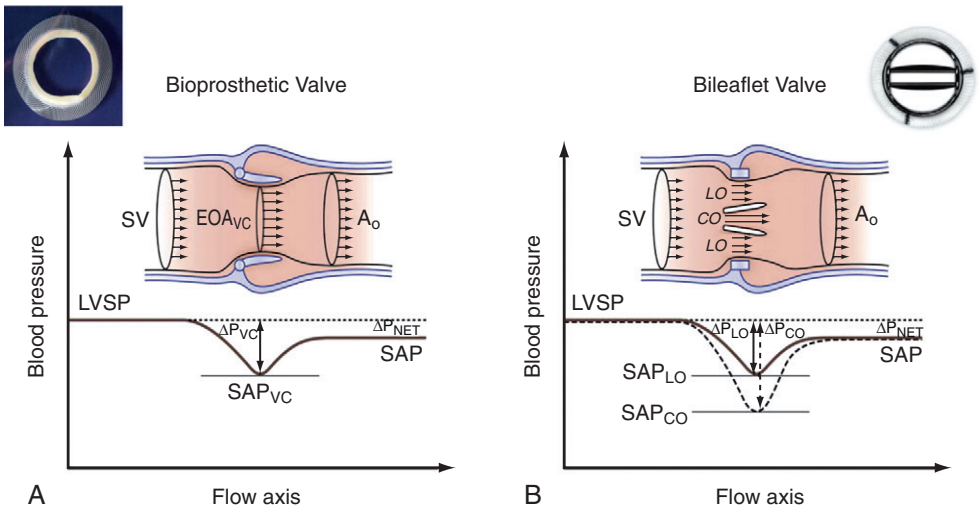

**Figure 25-5 Schematic representation of velocity and pressure changes from the LV outflow tract to the ascending aorta ($A_o$) in the presence of a stented bioprosthesis (A) and a bileaflet mechanical valve (B) illustrating the phenomena of pressure recovery and localized high gradient.** Because of pressure recovery, velocities are lower and systolic arterial pressure (*SAP*) is higher at the distal aorta than at the level of the vena contracta (*VC*). This is further exaggerated in the case of a bileaflet valve, in which the velocity is locally higher in the central orifice (*CO*) and thus pressure drop is higher at that level. Doppler gradients are estimated from maximal velocity at the level of the vena contracta and represent the maximal pressure drop, whereas invasive estimation of gradients usually reflect net pressure difference (*ΔP*) between LV systolic pressure (*LVSP*) and ascending aorta. *EOA*, Effective orifice area; *LO*, lateral orifice; *SAP*, systolic arterial pressure; *SV*, stroke volume in LV outflow tract; *VC*, vena contracta. *(Adapted with permission of the American Society of Echocardiography from Zoghbi WA, Chambers JB, Dumesnil JG, et al: Recommendations for evaluation of prosthetic valves with echocardiography and Doppler ultrasound: a report from the American Society of Echocardiography's Guidelines and Standards Committee and the Task Force on Prosthetic Valves.* J Am Soc Echocardiogr *22[9]:975-1014, 2009.)*

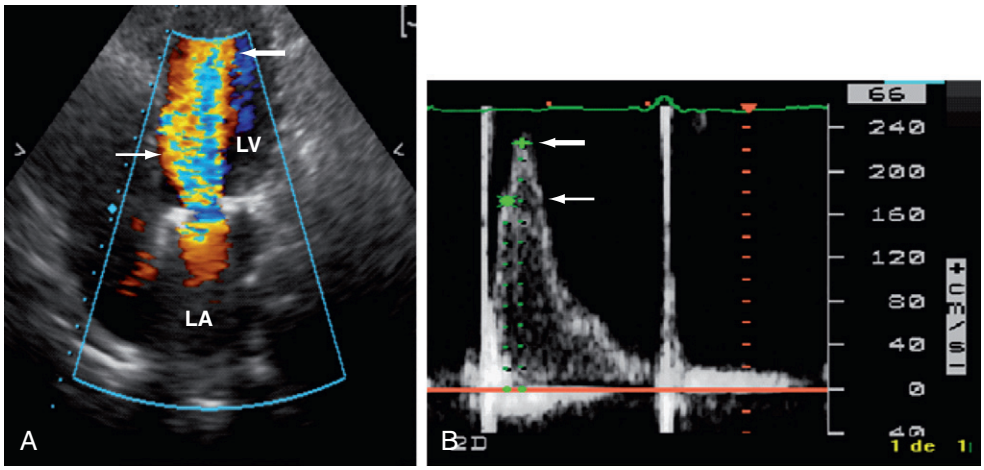

**Figure 25-6 Localized high gradient within the central orifice of a mitral bileaflet mechanical valve. A,** Visualization of lateral (*narrow arrow*) and central (*wide arrow*) jets on color Doppler image. **B,** Two Doppler envelopes are superimposed. The highest one, which presumably reflects the velocity within the central orifice, yields a value of peak gradient of 21 mm Hg, whereas the smallest one (lateral orifices) provides a gradient of 12 mm Hg. *(Adapted with permission of the American Heart Association from Pibarot P, Dumesnil JG: Prosthetic heart valves: selection of the optimal prosthesis and long-term management.* Circulation *119[7]:1034-1048, 2009.)*

25-3).[35] The advantage of these indices is that they are independent of Doppler beam angulation in relation to flow direction. The main limitation is that they are also influenced by LV systolic function and chronotropy. For example, a patient with a normally functioning aortic prosthesis and concomitant depressed myocardial contractility may nonetheless exhibit a rounded velocity contour with late velocity peaking, just as we have also witnessed in patients with severe PPM.

## Effective Orifice Area

The EOA of prosthetic aortic valves is calculated with the continuity equation, similar to native aortic valve area[38,39]:

$$EOA = (CSA_{LVOT} \times VTI_{LVOT})/VTI_{PrAv}$$

where $CSA_{LVOT}$ is the cross-sectional area of the LVOT, $VTI_{LVOT}$ the velocity-time integral obtained by PW Doppler in the LVOT,

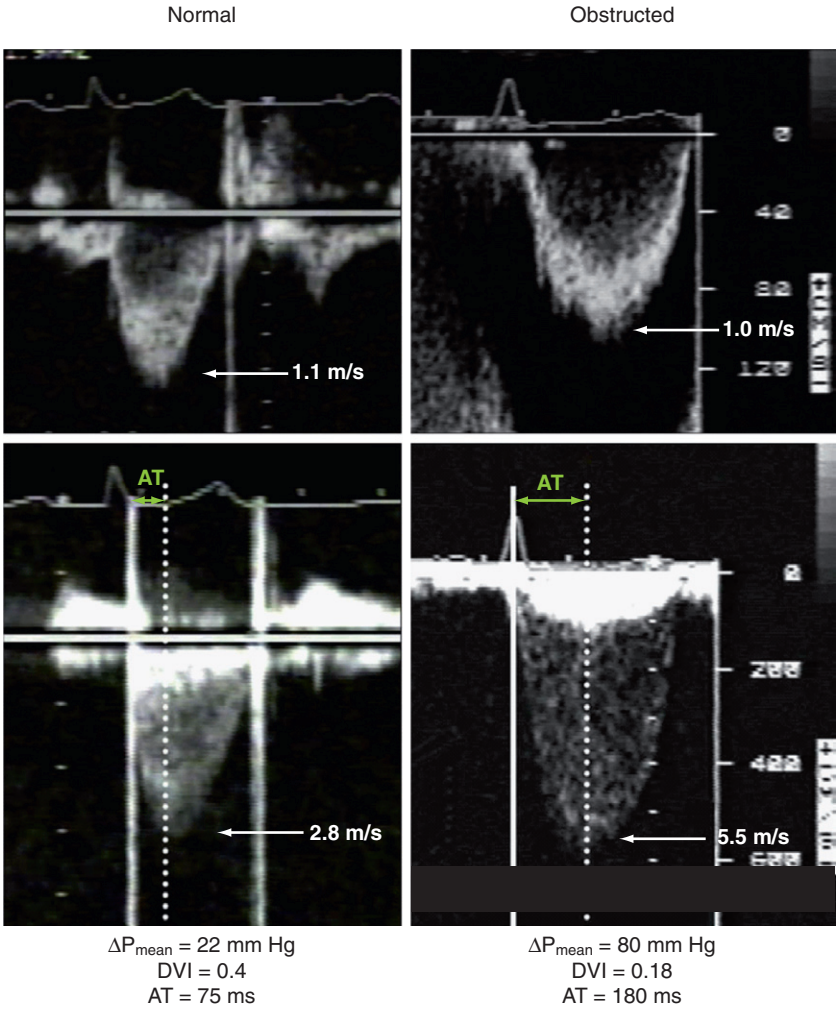

**Figure 25-7 Doppler recordings of a normal and obstructed prosthetic valve in the aortic position.** With obstruction, the velocity of the jet is increased along with changes in the contour of the jet velocity to that of a round, late-peaking profile. The acceleration time (*AT*) is increased. AT (in milliseconds) is measured as the duration from the onset of aortic ejection (*solid line*) to the maximal jet velocity (*dotted line*). Mean gradient ($\Delta P_{mean}$) is increased and the Doppler velocity index (*DVI*) is decreased with prosthetic obstruction. *(Reproduced with permission of the American Society of Echocardiography from Zoghbi WA, Chambers JB, Dumesnil JG, et al: Recommendations for evaluation of prosthetic valves with echocardiography and Doppler ultrasound: a report from the American Society of Echocardiography's Guidelines and Standards Committee and the Task Force on Prosthetic Valves.* J Am Soc Echocardiogr *22[9]:975-1014, 2009.)*

and $VTI_{PrAv}$ the velocity-time integral obtained by CW Doppler though the aortic prosthesis. When measuring the EOA of prosthetic aortic valves, a few specific caveats should be taken into consideration:

1. The cross-sectional area of the LVOT is derived from the diameter measurement just underneath the prosthesis from the parasternal long-axis zoomed view assuming a circular geometry (Fig. 25-8, *A*, *B*). This measurement is often difficult because of the reverberations and artifacts caused by the prosthesis stent or ring. Particular care should be taken not to mistake the inner border of the prosthesis stent/ring for the inner edge of the LVOT. One can use modified views (lower parasternal location) to keep the artifact from the prosthetic valve away from the LVOT. It is important to emphasize that the substitution of the LVOT diameter by the labeled prosthesis size in the continuity equation is not a valid method to determine the EOA of aortic prostheses.[40]
2. For the recording of LVOT velocity signal, care should be exercised in locating the PW Doppler sample volume adjacent to the prosthesis while avoiding the region of subvalvular acceleration (this usually requires a position 0.5 to 1 cm below the sewing ring (toward the apex). Color Doppler may be useful to guide the positioning of the PW Doppler sample. The Doppler waveform should be smooth, with minimal spectral broadening and a well-defined peak (see Fig. 25-8, *C*). An effort should be made to measure the LVOT VTI and LVOT diameter at about the same location.
3. The VTI across the prosthesis is obtained from the same signals that are used for measurement of prosthesis peak velocity and gradient (see Fig. 25-8, *D*).
4. The continuity equation method is also valid in presence of concomitant prosthetic aortic valve regurgitation because both the numerator and the denominator of the equation are increased in a similar proportion.

The EOA of mitral prostheses is calculated by the continuity equation using the stroke volume measured in the LVOT:

$$EOA = (CSA_{LVOT} \times VTI_{LVOT})/VTI_{PrMv}$$

where $VTI_{PrMv}$ is the velocity-time integral obtained by CW Doppler though the mitral prosthesis (Fig. 25-9). A few specific, important caveats should be taken into consideration for the estimation of EOA of prosthetic mitral valves:

1. The continuity equation method cannot be applied when there is more than mild concomitant mitral or aortic regurgitation.
2. The pressure half-time (PHT) method (similar to that used for native mitral valve stenosis) is not valid to estimate the valve EOA of mitral prostheses.[2,41] The PHT is highly influenced by chronotropy, left atrial (LA) compliance, and LV

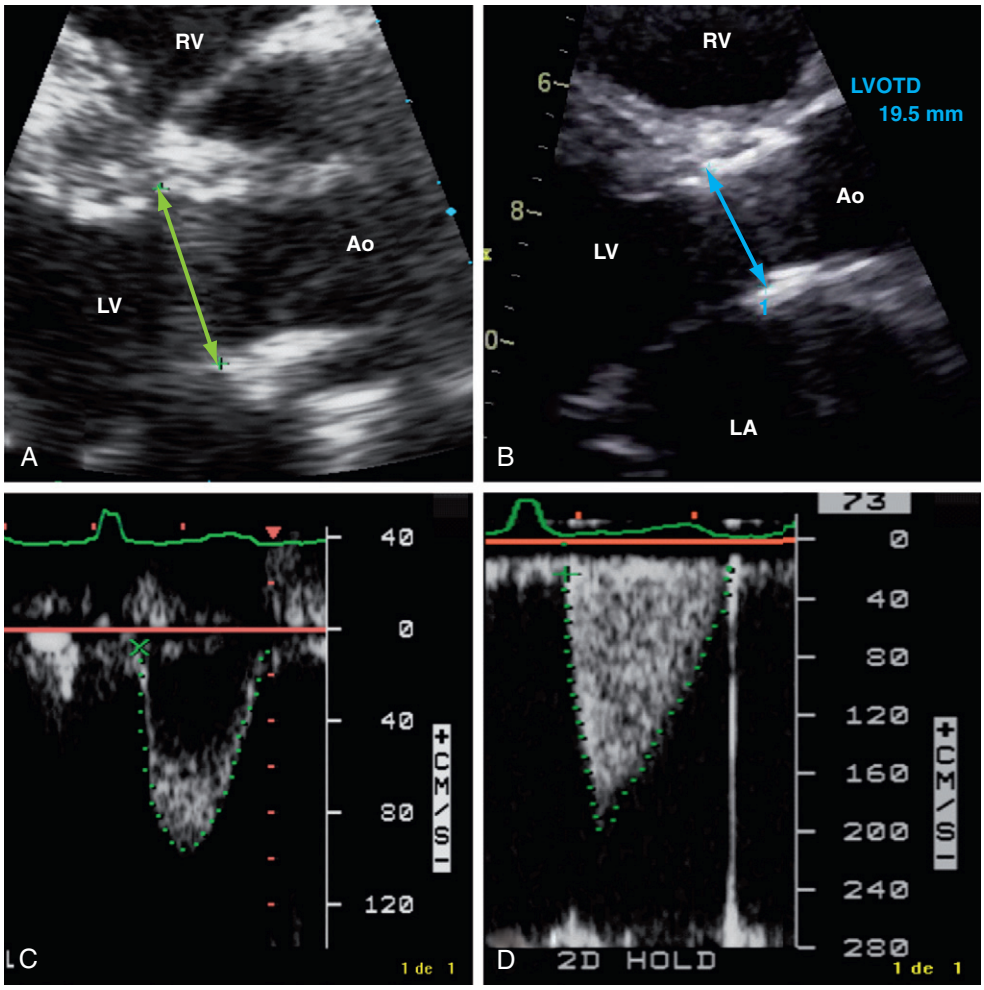

**Figure 25-8 Calculation of the effective orifice area of prosthetic valves in the aortic position using the continuity equation method.** The diameter of the LV outflow tract is measured just below the insertion of the prosthetic aortic valve (**A,** stented bioprosthesis; **B,** transcatheter bioprosthesis) from the junction of sewing ring and ventricular septum to the junction of the sewing ring and the base of the anterior mitral leaflet. Pulsed Doppler velocity recording is obtained in the LV outflow tract from the apical window (**C**). CW Doppler recording of the transprosthetic flow jet velocity is acquired from the apical five-chamber (**D**). *Ao*, Aorta.

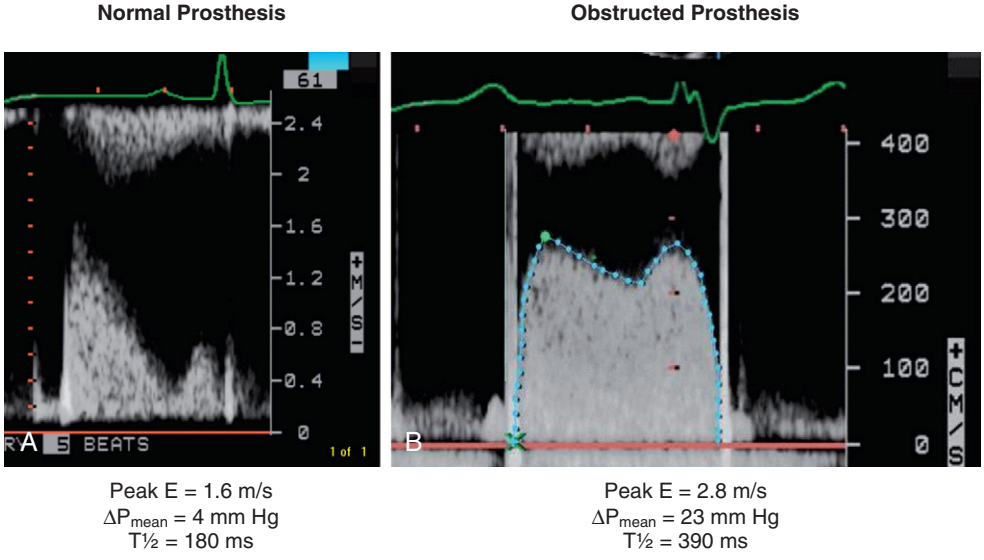

**Figure 25-9 Doppler findings with prosthetic mitral stenosis.** CW Doppler velocity recordings in a normal (**A**) and an obstructed (**B**) prosthetic valve in the mitral position. The peak E velocity, gradients, and pressure half-time ($T_{½}$) are elevated in the obstructed prosthetic valve.

compliance. Hence, patients with tachycardia or reduced atrioventricular compliance may exhibit a normal PHT despite the presence of significant prosthetic valve stenosis. Nonetheless, the pressure half time may be useful if it is significantly delayed (greater than 120 ms; see Table 25-3 and Fig. 25-9, *B*) or shows significant lengthening from one follow-up visit to the other despite similar heart rates.

Valve EOAs between 0.8 and 1.2 $cm^2$ and between 1.0 and 2.0 $cm^2$ suggest the presence of possible stenosis for aortic and mitral prostheses, respectively (see Tables 25-2 and 25-3), whereas values less than 0.8 $cm^2$ (aortic) and less than 1.0 $cm^2$ (mitral) indicate the presence of significant stenosis. These cutoff values proposed in the ASE guidelines,[35] however, have important limitation given that they overlap substantially with the normal reference values of EOA of several prosthesis models. In our experience, the recognition of prosthetic valve stenosis is better achieved by comparing the measured EOA to the normal reference value of EOA for the model and size of prosthesis implanted in the patient rather than applying fixed cutoff values to all patients regardless of the characteristics of their prosthesis.[42] Tables 25-4 and 25-5 show the normal reference values of EOA for the most commonly used prosthetic valves in the aortic and mitral position, respectively. If the measured EOA is less than the reference EOA minus one standard deviation, one should suspect possible stenosis. If the measured EOA is less than the reference minus two standard deviations, there is a high likelihood of significant stenosis (see Tables 25-2 and 25-3).

Given that its estimation requires the inclusion of several parameters in the continuity equation, the main limitation of the EOA is the susceptibility to measurement errors. In addition, although they are much less flow dependent than transprosthetic velocity or gradient, the anatomic and effective orifice areas may nonetheless vary, to some extent, with flow. The EOA may thus be "pseudoseverized" in the presence of low flow state (see Special Considerations for Low–Flow-State Conditions).

## Doppler Velocity Index

The DVI is a dimensionless ratio of the proximal velocity in the LVOT to the flow velocity through the aortic prosthesis: DVI = $V_{LVOT}/V_{PrAv}$. Time-velocity time integrals may also be used in place of peak velocities to calculate DVI = $VTI_{LVOT}/VTI_{PrAv}$. In the case of prosthetic mitral valves, the DVI is calculated by

*The ON-X valve has just one size for 27- to 29-mm and 31- to 33-mm prostheses. In addition, the strut and leaflets are identical for all sizes (25- to 33-mm); only the size of the sewing cuff is different.

dividing the VTI of the transprosthetic flow by that of LVOT flow: DVI = $VTI_{PrMv}/VTI_{LVOT}$. These parameters can be helpful to screen for valve obstruction, particularly when the cross-sectional area of the LVOT cannot be obtained.[43]

The DVI is reduced (less than or equal to 0.3) in presence of prosthetic aortic valve stenosis (see Table 25-2), whereas it is increased (greater than or equal to 2.2 m/s) in presence of prosthetic mitral valve stenosis (see Table 25-3). In presence of significant prosthetic valve stenosis, the DVI is generally less than 0.25 in the case of aortic prostheses and greater than 2.5 in the case of mitral prostheses.

The main limitations of the DVI are that it does not distinguish obstruction due to PPM from obstruction due to intrinsic dysfunction, and it is dependent on the size of the LVOT. For a given stroke volume and prosthetic valve EOA, the DVI will indeed be lower in a patient with a small LVOT than in a patient with a large LVOT. Hence, the cutoff values presented earlier (see Tables 25-2 and 25-3) may yield to overestimation or underestimation of prosthetic valve stenosis in the subsets of patients who are at the smaller or larger end of the LVOT size spectrum, respectively. Nonetheless, the observation of significant changes (decrease in case of aortic prostheses and increase in the case of mitral prostheses) in the DVI during serial echocardiographic follow-up is useful to detect the occurrence of prosthetic valve dysfunction.

#### Energy Loss Index and Influence of Pressure Recovery

Doppler echocardiography estimates the maximum pressure drop through the prosthesis from the maximum velocity recorded at the tip of the valve leaflets. However, several studies have reported that Doppler may overestimate the gradient across mechanical or bioprosthetic aortic valves when compared to catheter measurement.[44,45] As blood flow velocity decelerates between the aortic valve and the ascending aorta, part of the kinetic energy is reconverted back to static energy (i.e., pressure) because of the phenomenon called pressure recovery, and hence the net gradient between the LV and the ascending aorta (i.e., the gradient measured by catheter) is less than the maximum pressure gradient measured by Doppler (see Fig. 25-5, *A*).[45-49] The extent of pressure recovery is determined by the ratio between the valve EOA and the cross-sectional area of the downstream chamber, that is, the ascending aorta in the case of prosthetic aortic valves. Hence, pressure recovery generally becomes clinically relevant in patients with smaller aortas—those with an diameter at the sinotubular junction that is 30 mm or less.[47,48] In these patients, it thus becomes appropriate to account for pressure recovery by using the simple formula proposed by Garcia and collleagues[46] to calculate the energy loss coefficient: ELC = $(EOA \times A_A/A_A - EOA)$, where $A_A$ is the cross-sectional area of the aorta measured about 1 cm downstream of the sinotubular junction. The energy loss coefficient should be indexed for body surface area (i.e., energy loss index) to account for the change in cardiac output related to body size. An energy loss index less than 0.55 to 0.6 $cm^2/m^2$ suggests a significant prosthetic valve stenosis or PPM.[46] Not accounting for pressure recovery in patients with small aortas (i.e., smaller than 30 mm) may cause overestimation of prosthetic valve stenosis and/or PPM by Doppler echocardiography and lead to unwarranted investigations or interventions. The pressure recovery is generally negligible in the case of mitral prostheses because the downstream chamber (i.e., the LV) is large relative to the EOA of the prosthesis.

Hence, significant pressure recovery may occur downstream of aortic valves regardless of their type (native, bioprosthetic, or mechanical). This phenomenon should not, however, be confused with the phenomenon of localized high gradient that is specific to bileaflet mechanical valves (see Figs. 25-5, *B*, and 25-6). A localized high gradient may indeed be recorded through the central orifice of bileaflet mechanical valves, and this phenomenon may yield to substantial overestimation of gradient regardless of the position (aortic or mitral) of the prosthesis. The prevalence and magnitude of this phenomenon is not fully understood but is probably related to prosthetic valve size and design (ratio of the size of the central orifice to that of lateral orifices) and flow conditions.[42,49]

## RECOGNITION AND QUANTITATION OF PROSTHETIC VALVE REGURGITATION

The approach to detecting and grading prosthesis regurgitation is similar to that of native valves and involves multiple color Doppler views and measurements of several Doppler-echocardiographic indices.[50] However, care is needed to separate physiologic from pathologic prosthesis regurgitation. Mechanical prostheses indeed have a normal regurgitant volume known as leakage backflow. This "built-in" regurgitation theoretically prevents blood stasis and thrombus formation using a washing effect. As opposed to the pathologic regurgitant jets, the normal leakage backflow jets are characterized by being short in duration, narrow, and symmetric (see Fig. 25-3). In the case of pathologic regurgitation, it is also important to localize the origin of the regurgitant jet(s) in order to distinguish paravalvular from transvalvular regurgitation.

### *Prosthetic Aortic Valve Regurgitation*

#### Imaging Considerations

TTE generally provides a good visualization of the LV outflow tract and of both transvalvular and paravalvular prosthetic aortic regurgitation. Acoustic shadowing and occulting of regurgitant jets is less an issue for aortic prostheses than for mitral prostheses (Fig. 25-10).[35] The optimal views for the detection of prosthetic aortic valve regurgitant jets include the parasternal long-axis and short-axis views, the apical long-axis view, and the five-chamber view. Off-axis views may be helpful in determining the origin of the jets. Meticulous color flow Doppler interrogation should be performed in the parasternal long-axis view to localize and define the extent of a paravalvular leak. However, regurgitant jets may be occulted by acoustic shadowing, especially in the noncoronary sinus region.

TEE may be useful to identify the origin (paravalvular vs. transvalvular) of the regurgitant jets in technically difficult TTE studies and to identify the mechanism of regurgitation and the associated complications, such as flail bioprosthetic cusp; presence of pannus, thrombus, vegetations, or masses interacting with occluder closure; abscess formation; or prosthesis dehiscence (Figs. 25-11 and 25-12).[36] The long-axis view is useful for measuring LVOT diameter and jet width. Acoustic shadowing in the anterior region may limit the performance of TEE for evaluation of prosthetic aortic regurgitation at the midesophageal level. Importantly, the presence of a concomitant mitral prosthesis will cause significant shadowing and obscure the LVOT. In such cases it is crucial to evaluate the prosthesis from transgastric transducer positions.

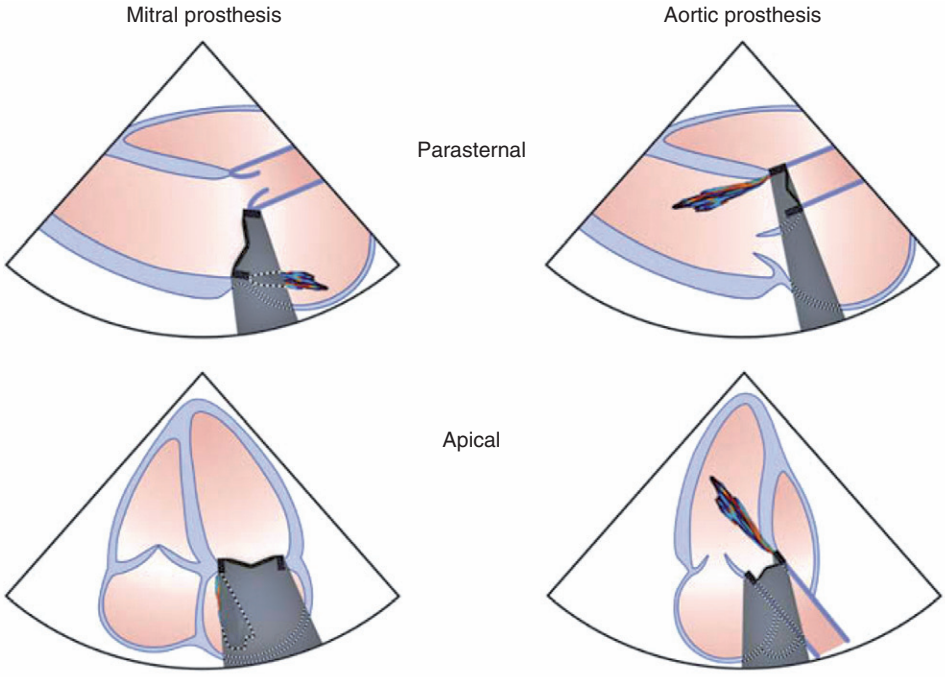

**Figure 25-10 Effect of position of mechanical prosthetic valve and of echocardiographic imaging view on shadowing and masking of regurgitation jet by Doppler.** Greater effect from TTE imaging is seen on prostheses in the mitral position compared to the aortic position. *(Reproduced with permission of the American Society of Echocardiography from Zoghbi WA, Chambers JB, Dumesnil JG, et al: Recommendations for evaluation of prosthetic valves with echocardiography and Doppler ultrasound: a report from the American Society of Echocardiography's Guidelines and Standards Committee and the Task Force on Prosthetic Valves.* J Am Soc Echocardiogr *22[9]:975-1014, 2009.)*

### Parameters of the Severity of Prosthetic Aortic Valve Regurgitation

The same principles and methods used for grading severity of native aortic valve regurgitation[50] can be used for prosthetic aortic regurgitation. It must be remembered, however, that there are very limited data on the application and validation of quantitative parameters such as the width of the regurgitant jet or of the vena contracta, the effective regurgitant orifice area, and the regurgitant volume in the context of prosthetic valves.[51,52] Given that all parameters of aortic regurgitation have important limitations and may be subject to measurement errors, a comprehensive, multiparametric approach is highly recommended (Table 25-6).

**Color Doppler parameters.** The ratios of regurgitant jet diameter to LVOT diameter from the parasternal long-axis view and of jet area to LVOT area from the parasternal short-axis view just below the prosthesis can be used to estimate the severity of central regurgitation. A ratio of jet diameter to LVOT diameter greater than 25% suggests moderate regurgitation and >65%, severe regurgitation (see Table 25-6). However, using this approach, regurgitation severity may be overestimated in the case of eccentric or crescent-shaped jets and underestimated in the case of jets impinging the wall of the LVOT or of anterior mitral valve (see Fig. 25-11, *B*, *D*). In contrast to native valves, the width of the vena contracta may be difficult to accurately measure in the long-axis view because of the shadowing caused by the prosthesis ring or stent.

For semiquantitative evaluation of the severity of paravalvular regurgitation, careful imaging of the neck of the jet in a short-axis view, at the level of the prosthesis sewing ring (surgically implanted prostheses) or stent (transcatheter bioprostheses), allows determination of the circumferential extent of regurgitation in the case of paravalvular regurgitation. A regurgitant jet occupying less than 10% of the sewing ring or stent circumference suggests mild, 10% to 20% suggests moderate, and more than 20% suggests severe regurgitation (see Table 25-6 and Fig. 25-12, *A*, *B*).[33,35] Rocking of the prosthesis is usually associated with greater than 40% dehiscence.[53]

The entrainment of the regurgitant (paravalvular or transvalvular) jet in the LVOT may lead to rapid broadening of the jet just after the vena contracta and thus to overestimation of regurgitant severity when using color Doppler parameters. Moreover, the estimation of regurgitation severity becomes more complex and less reliable when multiple jets are present. TEE may be helpful to better identify the origin (paravalvular vs. transvalvular) of the regurgitant jets and to better estimate the circumferential extent of paravalvular regurgitation.

**Spectral Doppler parameters.** Spectral Doppler parameters are useful to assess prosthetic aortic valve regurgitation because they are less sensitive to the prosthesis position and the associated shadowing and artifacts. The pressure half-time of the CW regurgitant jet signal is useful when the value is less than 200 ms, suggesting severe regurgitation, or greater than 500 ms, consistent with mild regurgitation (see Table 25-6). However,

**TABLE 25-6 Doppler-Echocardiographic Criteria for Severity of Prosthetic Aortic Valve Regurgitation (Central and Paravalvular)**

*Abnormal mechanical valves: immobile occluder, dehiscence or rocking (paravalvular regurgitation); abnormal biologic valves: leaflet thickening/calcification or prolapse, dehiscence or rocking (paravalvular regurgitation).

†Parameter applicable to central jets and is less accurate in eccentric jets.

‡This parameter is influenced by LV compliance.

§Applies only to paravalvular regurgitation.

‖Applies to chronic, late postoperative prosthetic aortic valve regurgitation in the absence of other etiologies.

intermediate values of pressure half-time (200 to 500 ms) are less specific because they are influenced by other variables such as heart rate and LV compliance. Proper care should also be given to obtaining a good-quality Doppler spectral envelope, which may not always be possible and might lead to gross over- or underestimations of in the case of frankly eccentric jets. The presence of holodiastolic flow reversal in the descending thoracic aorta is indicative of at least moderate AR; severe AR is suspected when the VTI of the reverse flow approximates that of the forward flow and when the end-diastolic velocity is greater than 18 cm/s.[54]

Regurgitant volume can be calculated as the difference between stroke volume at the LVOT (or 2D-derived total LV stroke volume) and the transmitral or pulmonary flow. Cutoff values for severity are similar to those for native aortic valve regurgitation.[50] The quantitative method based on proximal isovelocity surface area is difficult to apply to aortic prostheses. The ratio of the stroke volume measured in the LVOT to the stroke volume measured in the RV outflow tract (RVOT) may be helpful to assess aortic regurgitation severity (see Table 25-6). Given that the RVOT diameter is often difficult to measure, the ratio of the LVOT VTI to the RVOT VTI can be used alternatively, provided no dilation of LVOT or RVOT exist.

### Integrative, Multiparametric Approach for the Evaluation of Prosthetic Aortic Valve Regurgitation

Assessment of severity of prosthetic aortic valve regurgitation is generally much more complex than in native valves because of the high prevalence of paravalvular regurgitation and eccentric jets (see Figs. 25-11 and 25-12). The process of grading regurgitation severity should be comprehensive, integrative, and based on a multiparametric approach that includes the qualitative and semiquantitative parameters shown in Table 25-6. If the regurgitation is classified as mild or less using these parameters, no further measurement is needed. On the other hand, if there are parameters suggestive of more than mild AR and the quality of the data enables quantitation, it is recommended to measure quantitative parameters of regurgitation, including the vena contracta width, and the regurgitant volume and fraction. When the different parameters are concordant, it is easy to confirm the severity of the regurgitation. However, when there are discordances among the different parameters, one must look carefully for physiologic or technical reasons to explain these discrepancies and to rely on the parameters that have the best quality in terms of image/signal and that are the more accurate and reliable in the context of prosthetic valves. Importantly, one must also examine the indirect signs of prosthetic valve dysfunction (see later discussion under Indirect Signs and Consequences of Prosthetic Valve Regurgitation). Hence, in presence of severe chronic prosthetic valve regurgitation, one would expect to see a dilated LV.

## *Prosthetic Mitral Valve Regurgitation*

### Imaging Considerations

Assessment of prosthetic mitral regurgitation by TTE is problematic because the LA is largely occulted by the acoustic shadowing due to the metallic components of the prosthesis (see Fig. 25-10 and Clinical Case 25-2).[35] This problem is more frequent in mechanical valves than in bioprosthetic valves. In contrast, TEE provides excellent visualization of the LA and mitral regurgitant jet, but acoustic shadowing limits visualization of the LV. Thus, a comprehensive assessment of prosthetic mitral valve function often requires both TTE and TEE when valve dysfunction is suspected.

At TTE examination, the presence of "occult" mitral prosthesis regurgitation should be suspected when the following signs are present: presence of flow convergence on the LV side of the prosthesis during systole; increased mitral peak E wave velocity (greater than 2 m/s) and/or mean gradient (greater than 6 mm Hg); DVI greater than 2.2; unexplained or new worsening of pulmonary arterial hypertension; and a dilated and hyperkinetic LV (Table 25-7).[43] TEE should be systematically performed when there is a clinical or TTE suspicion of pathologic mitral regurgitation.[36] TEE is indeed superior to TTE in detecting prosthetic mitral regurgitation and determining its localization and mechanism.[55,56] On color Doppler, paravalvular leaks have a typical appearance of a jet that passes from the LV into the LA outside the prosthesis ring and often projects into the atrium in an eccentric direction (see Figs. 25-11 and 25-12).

**TABLE 25-7 Doppler-Echocardiographic Criteria for Severity of Prosthetic Mitral Valve Regurgitation (Central and Paravalvular)**

| | *Mild* | *Moderate* | *Severe* |
|---|---|---|---|
| **Valve Structure and Motion** | | | |
| Mechanical or bioprosthesis | Usually normal | Usually abnormal* | Usually abnormal* |
| **Doppler Parameters (Qualitative or Semiquantitative)** | | | |
| Color flow jet area | Small, central jet (usually <4 $cm^2$ or <20% of LA area) | Variable | Large central jet (usually >8 $cm^2$ or >40% of LA area) or variable size wall impinging jet swirling in LA |
| Flow convergence | None or minimal | Intermediate | Large |
| Jet density: CW Doppler | Incomplete or faint | Dense | Dense |
| Jet contour: CW Doppler† | Parabolic | Usually parabolic | Early peaking, triangular |

*Abnormal mechanical valves: immobile occluder, dehiscence or rocking (paravalvular regurgitation); abnormal biologic valves: leaflet thickening/calcification or prolapse, dehiscence or rocking (paravalvular regurgitation)

†This parameter is influenced by LV compliance.

‡Parameter applicable to central jets and is less accurate in eccentric jets.

§Applies to chronic, late postoperative prosthetic aortic valve regurgitation in the absence of other etiologies.

Multiple-plane examination is essential to determine the origin and extent of the regurgitant jet(s).

## Parameters of the Severity of Prosthetic Mitral Valve Regurgitation

Assessment of severity of prosthetic mitral regurgitation is complex because all quantitative parameters have important limitations and cannot be applied consistently in all patients. Hence, it is recommended to use a comprehensive approach that integrates the different findings and parameters obtained by TTE and TEE (see Table 25-7).

The estimation of regurgitant jet area in the LA is often difficult due to the shadowing and artifacts created by the prosthesis. A small thin jet (jet area less than 4 $cm^2$, less than 20% of the LA) usually reflects mild mitral regurgitation but can be grossly underestimated and should not be used to exclude severe regurgitation, whereas a large, wide jet (8 $cm^2$ or larger, more than 40% of the LA) is most often consistent with severe regurgitation.[35] A width of the vena contracta of less than 3, 3 to 6, and greater than 6 mm denotes mild, moderate, and severe regurgitation, respectively (see Table 25-7).[52] Significant swirling of the jet within the atrium as well as the presence of retrograde systolic flow in one or more of the pulmonary veins is specific for significant mitral regurgitation. TEE is superior to TTE to record the pulmonary venous flow in presence of a mitral prosthesis. The density and contour of the regurgitant jet CW Doppler signal may also be helpful to corroborate regurgitation severity (see Table 25-7).

The radius of the proximal flow convergence (i.e., proximal isovelocity surface area method) can be used in combination with recordings of mitral regurgitation velocity by CW Doppler to estimate effective regurgitant orifice area.[50,57] However, because mitral prosthetic regurgitation is often characterized by eccentric and/or multiple jets, the proximal isovelocity surface area method is difficult to achieve and may grossly under- or overestimate regurgitation severity. Given these important limitations, the volumetric method is often preferred to the proximal isovelocity surface area method for quantitation of mitral prosthesis regurgitation.[35] The calculation of regurgitant stroke volume consists in subtracting the LVOT stroke volume from the total LV stroke volume derived by 2D echocardiography. Total LV stroke volume may be obtained by the Simpson method. However, this method often underestimates the LV volumes and the LV stroke volume. Hence, one can alternatively estimate the total stroke volume by multiplying the LV ejection fraction calculated by the Simpson method by the LV end-diastolic volume obtained by the Teichholz formula (i.e., Dumesnil's method in reverse).[58] Three-dimensional (3D) echocardiography may also enhance the accuracy of the estimation of total LV stroke volume, especially when combined with enhancement of endocardial border with a contrast agent.[59] A LV ejection fraction above 60% with normal-sized or enlarged LV, along with a reduction of LVOT stroke volume, should raise the possibility that the mitral regurgitation is significant. Again, in light of the important challenges and limitations posed by quantitation of prosthetic mitral regurgitation, one should always have a comprehensive, multiparametric, and integrative approach (see Table 25-7).

### *Indirect Signs and Consequences of Prosthetic Valve Regurgitation*

The size and function of the LV and atrial chambers as well as the level of systolic pulmonary arterial pressure can be used to corroborate severity of prosthesis dysfunction and especially of prosthetic valve regurgitation. In particular, these measurements can be compared to previous measurements and are often the first sign to alert attention when the regurgitation is difficult to visualize. Although LV dilation is expected in the presence of hemodynamically significant prosthetic aortic or mitral valve regurgitation, LV volumes may also reflect the preoperative state, especially in cases of early postoperative prosthetic regurgitation. However, if LV volumes fail to decrease after valve replacement for aortic or mitral regurgitation or tend to increase after valve replacement for aortic or mitral stenosis, and in particular if the LV is hyperdynamic, a hemodynamically significant leak should be suspected among other factors. On the other hand, in the context of chronic aortic or mitral prosthesis regurgitation, the absence of dilation of LV and atrial chambers during follow-up is rather suggestive of a nonsignificant leak.

## ROLE OF STRESS ECHOCARDIOGRAPHY

Because normally and abnormally functioning prostheses can produce similar gradients at rest by TTE, stress echocardiography may be valuable in confirming or excluding the presence of hemodynamically significant prosthetic valve stenosis or PPM, especially when there is discordance between the patient's symptomatic status and the prosthetic valve hemodynamics measured at rest.[60-66] As opposed to normally functioning and well-matched prostheses or to bileaflet mechanical valves with localized high gradient, the presence of valve stenosis or significant PPM is generally associated with a marked increase in gradients and pulmonary arterial pressure, the occurrence of symptoms, and an impaired exercise capacity on stress exercise echocardiography.[60] In light of studies performed in the context of native or prosthetic valves, an absolute increase in mean gradient of at least 20 mm Hg in the aortic position and at least 12 mm Hg in the mitral position suggests severe prosthesis dysfunction or PPM.[61-69] A peak stress systolic pulmonary arterial pressure of 60 mm Hg or greater is consistent with the presence of a hemodynamically significant mitral prosthesis stenosis or regurgitation or mitral PPM.[60,61,69] Exercise testing is also useful to unmask symptoms in a significant proportion of patients with prosthetic valve dysfunction or PPM who claim to be asymptomatic.

## SPECIFIC CONSIDERATIONS FOR PARTICULAR TYPES OF VALVE SUBSTITUTES

### *Stentless Aortic Valve Substitutes*

Stentless substitutes include stentless bioprostheses, aortic homografts, and pulmonary autografts (the Ross operation). These substitutes are more likely than stented valves to have minor transvalvular regurgitant jets. In the early postoperative period, the stentless bioprostheses, particularly if implanted by the subcoronary technique, may exhibit higher than expected gradients, which often regress within the next 3 months, most likely because of regression of the edema between the prosthesis and the aortic wall and/or remodeling of the LVOT. In the late postoperative follow-up, the stentless substitutes are more likely than stented bioprostheses or mechanical valves to develop "functional" central aortic insufficiency due to dilation of the aortic root. This aspect thus needs particular attention, and it is recommended to regularly (i.e., every 2 years) measure the dimensions of the aortic root (annulus, sinus, and sinotubular junction levels) and ascending aorta, especially the diameter at the sinotubular junction. If dilation of the aorta and/or aortic insufficiency develops, closer follow-up is recommended.

### *Transcatheter Aortic Valves*

#### Valve Sizing and Positioning

In patients undergoing transcatheter aortic valve implantation, intraoperative TEE is particularly helpful (1) to accurately measure the aortic annulus size that is crucial to select the valve size, (2) to complement fluoroscopic imaging for positioning of the valve before deployment, and (3) to rapidly identify complications. The size of the transcatheter prostheses is selected according to the pre- or intraprocedural measurement of the aortic annulus diameter by TEE using a midesophageal long-axis view. The same view is used for valve positioning. The objective is to align the ventricular end of the valve prosthesis stent with the hinge point of the anterior leaflet of the mitral valve (Fig. 25-13).[70,71] Real-time 3D TEE may further facilitate valve positioning. Some investigators primarily use TEE instead of fluoroscopy to guide valve positioning and implantation in order to reduce the amount of contrast agent and thereby preserve kidney function.[70]

#### Late Postoperative Follow-up

One could use the same principles as for surgical prostheses. In particular, for the measurement of valve EOA, the LVOT diameter and velocity should be measured just underneath the stent (see Fig. 25-8, *B*). However, if the ventricular end of the stent sits too low in the LVOT, which may occur more frequently with self-expandable prostheses (such as the CoreValve), it may be preferable to measure the LVOT diameter and velocity within the proximal portion of the stent at approximately 5 to 10 mm below the bioprosthetic valve leaflets. As with surgical prostheses, the observation of significant changes in gradient, DVI, and EOA during serial evaluations as well as the comparison of the valve EOA measured by Doppler echocardiography during follow-up to the normal reference value may be useful to identify and quantify prosthetic valve stenosis (see Table 25-2). However, in the case of transcatheter valves, the normal reference EOA does not depend only on the model and label size of the prosthesis. It also depends on the size of the patient's aortic annulus, as this is the main factor limiting the expansion of the valve at implantation. It is too early to determine what will be the durability of the transcatheter valves. Gurvitch and co-workers[72] reported a slight deterioration of EOAs and gradients at 3-year follow-up. The severity of paravalvular regurgitations appears to remain stable during follow-up.

### *Prosthetic Pulmonary and Tricuspid Valves*

#### Prosthetic Tricuspid Valve

The tricuspid prosthesis flow velocities vary not only with the duration of the cycle but also with respiration. A minimum of five cardiac cycles should thus be averaged for the estimation of the Doppler-echocardiographic indices, whether the patient is in sinus rhythm or in atrial fibrillation. Prosthetic tricuspid valve stenosis should be suspected when prosthetic valve leaflet morphology and mobility are abnormal, peak velocity is greater

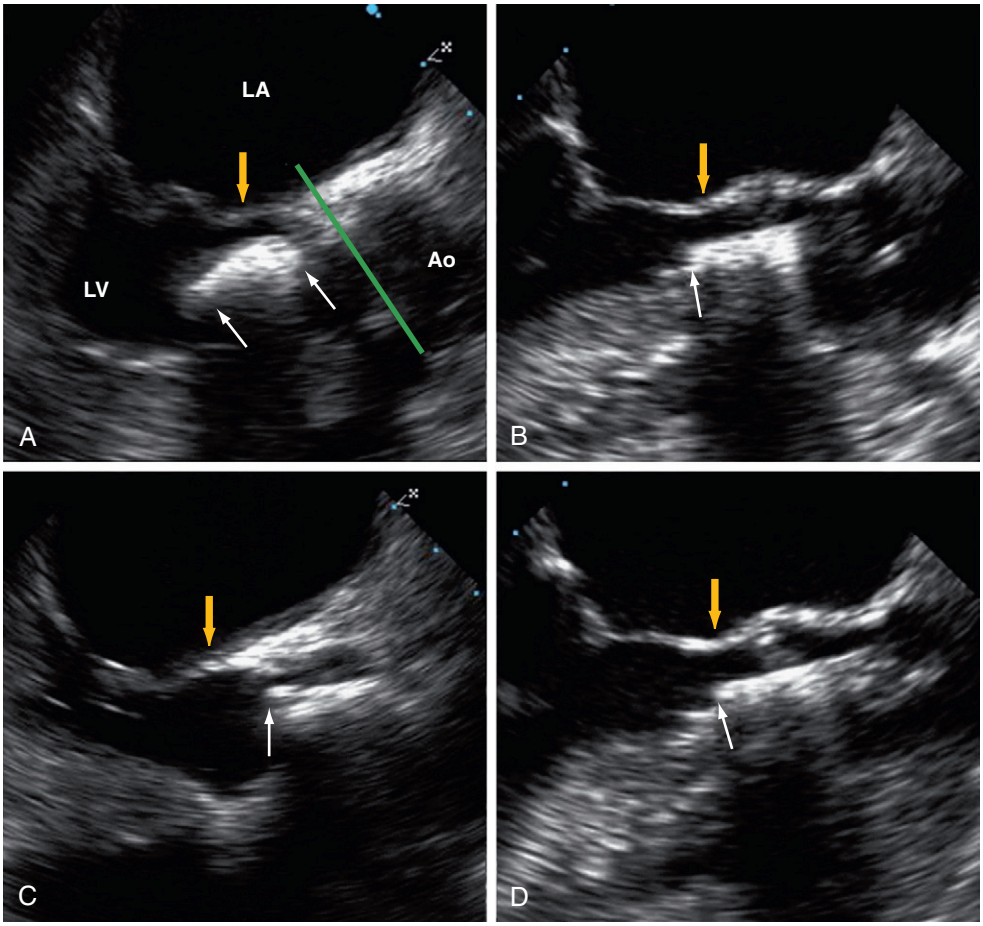

**Figure 25-13 Utility of TEE for positioning of transcatheter bioprosthetic aortic valves. A,** Prosthetic valve in the LV cavity showing the ventricular and aortic ends of the stent containing the valve (*white arrows*); *yellow arrow*, hinge point of the anterior mitral leaflet; *green line*, aortic annulus. **B,** "Too low" (ventricular) positioning of valve, (**C**) "too high" (aortic) positioning of valve, and (**D**) adequate positioning of valve, all using hinge point of anterior mitral leaflet (*yellow arrows*) as landmark for the ventricular end of the valve (*white arrows*). *Ao*, Aorta. *(Reproduced with permission of American College of Cardiology from Bagur R, Rodés-Cabau J, Doyle D, et al: Usefulness of TEE as the primary imaging technique to guide transcatheter transapical aortic valve implantation.* J Am Coll Cardiol *4[2]:115-124, 2011.)*

than 1.7 m/s, mean gradient is 6 mm Hg or greater, and/or pressure half-time is at least 230 ms.[35] The criteria for assessing severity of prosthetic tricuspid regurgitation are similar to those for native tricuspid valves.[35,50] TEE should be considered for all patients with clinical and/or TTE evidence of tricuspid prosthesis obstruction or regurgitation.

### Prosthetic Pulmonary Valve

Findings suspicious of prosthetic pulmonary valve stenosis include leaflet thickening or immobility, narrowing of forward color flow map, transvalvular peak velocity greater than 3 m/s for a prosthesis or greater than 2 m/s for a homograft, increase in peak velocity on serial studies, impaired RV function, or elevated RV systolic pressure. The severity of pulmonary prosthetic valve regurgitation is usually subjectively graded, using an integrative approach similar to native pulmonary regurgitation.[35,50]

## Interpretation of Doppler-Echocardiographic Data

### INTERPRETATION OF HIGH TRANSPROSTHETIC GRADIENTS

It is relatively frequent to measure a high gradient across a prosthetic valve and the differential diagnosis is much more complex than for native valves (see Clinical Cases 25-1, 25-2, and 25-3). Indeed, there are several potential causes of an elevated transprosthetic gradient. PPM is the most frequent cause of high gradient after valve replacement, the other potential causes being a central jet artifact in bileaflet prostheses, intrinsic valve dysfunction, high flow states, or technical errors.[35,42] Various algorithms aimed at better interpreting these high gradients have previously been proposed in the guidelines as well as by various authors including ourselves.[35,42,73] However, the acceptance of these algorithms by clinicians has varied, and they have been criticized for being either too complicated for routine clinical use or too simplistic to cover all possibilities. In a recent paper,[74] we thus proposed another alternative that is something of a compendium of previous algorithms and that can, we hope, answer both criticisms (Figs. 25-14 and 25-15).

#### *Prosthetic Aortic Valves*

After having excluded possible technical errors and given that PPM is the most frequent cause of high transprosthetic gradients after aortic valve replacement, the first step in the algorithm (see Fig. 25-14 and Clinical Case 25-1) would be to simply calculate the projected indexed EOA, that is, the ratio of EOA to body surface area, using the normal reference value of EOA for the type and size of prosthesis having been implanted (see Table 25-4). If the result is less than 0.85 $cm^2/m^2$, one can then surmise that PPM is present and that, depending on its degree of severity (see Table 25-1), it may be partially or totally responsible for the high gradient. In this context, it is important to keep in mind that both phenomena, PPM and intrinsic

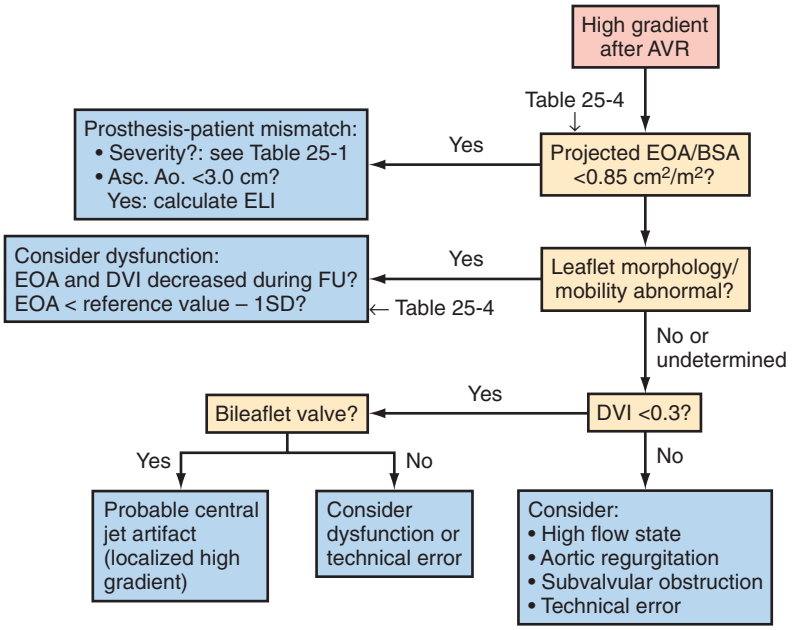

**Figure 25-14** Algorithm for interpreting abnormally high transprosthetic pressure gradients after aortic valve replacement (*AVR*). *BSA*, Body surface area; *DVI*, Doppler velocity index; *ELI*, energy loss index; *EOA*, effective orifice area; *FU*, follow-up; *SD*, standard deviation. *(Adapted from Dumesnil JG, Pibarot P: Prosthesis-patient mismatch: an update.* Curr Cardiol Rep *13[3]:250-257, 2011.)*

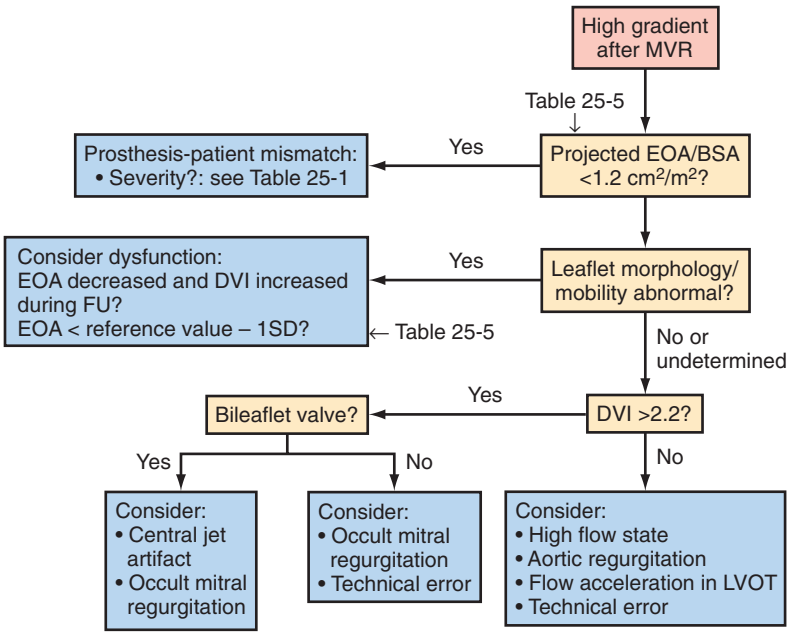

**Figure 25-15** Algorithm for interpreting abnormally high transprosthetic pressure gradients after mitral valve replacement (*MVR*). *BSA*, Body surface area; *DVI*, Doppler velocity index; *ELI*, energy loss index; *EOA*, effective orifice area; *FU*, follow-up; *SD*, standard deviation.

dysfunction, may coexist. To fully appreciate the clinical impact of the gradient, it should also be remembered that the net gradient is less in patients with a small aortic diameter (less than 3.0 cm) because of pressure recovery, and it might be useful in such cases to calculate the energy loss index.[46]

If PPM is not present or is not severe enough to totally explain the increased gradient, the next crucial step would be to thoroughly evaluate leaflet morphology and mobility. In the case of mechanical valves, TTE and even TEE often do not allow adequate visualization of leaflet(s) motion, and cinefluoroscopy should be performed in addition to echocardiography (see Fig. 25-14). If leaflet mobility is abnormal (see Fig. 25-4), dysfunction should be suspected. This can be corroborated if the EOA actually measured by echocardiography is much lower than the normal reference value for the same type and size of prosthesis (see Table 25-4) and/or has decreased progressively during follow-up. If, on the other hand, there is still uncertainty with regard to possible abnormal leaflet mobility, one can then proceed to calculate the DVI. If the DVI is less than 0.30 and the prosthesis is a bileaflet valve with normal leaflet mobility, the high gradient is in all likelihood due to a central jet artifact, that is, a localized high jet velocity through the central orifice (see Fig. 25-5). On the other hand, if the valve is not bileaflet, intrinsic dysfunction should be reconsidered as discussed previously, and the possibility of a technical error should also be envisioned. Finally, if the DVI is 0.30 or greater, possible etiologies for the high gradient include high flow states, aortic regurgitation, subvalvular obstruction, and, again, a technical error.

It should be noted that technical errors, particularly with regard to measurements in the LV outflow tract diameter, are frequent, and that this possibility should never be neglected.

### *Prosthetic Mitral Valves*

A similar algorithm can be used when confronted to a high gradient or velocity across a mitral prosthesis (see Fig. 25-15 and Clinical Cases 25-2 and 25-3). It should, however, be noted that the cutoff values of indexed EOA and DVI are different from those used for aortic prostheses. In the last step of the algorithm, if the leaflet mobility is considered to be normal or is undetermined and the DVI is less than 2.2, one should also suspect occult mitral transvalvular or paravalvular regurgitation, and TEE should be performed. This situation may also be related to the recording of a localized high gradient within the central orifice in the case of bileaflet mechanical valves (see Figs. 25-5 and 25-6).

## SPECIAL CONSIDERATIONS FOR LOW–FLOW-STATE CONDITIONS

It should be remembered that in patients with low flow states due to LV dysfunction, transprosthetic gradients may be only slightly or moderately elevated despite the presence of significant PPM or prosthesis dysfunction.[20,42] Gradients are indeed highly flow dependent and may thus be "pseudonormalized" in the presence of low flow states. The measurement of a low gradient in concomitance with a small EOA (less than 1.2 $cm^2$ and/or less than reference minus one standard deviation) should prompt further evaluation. As for the management of low-flow, low-gradient native aortic or mitral stenosis, dobutamine stress echocardiography (DSE) may be useful to differentiate a true from a pseudostenosis or mismatch in patients with prosthetic valves and low cardiac output. In the situation of pseudostenosis/PPM, the resting transprosthetic flow rate and thus the force applied on the leaflets are too low to completely open the valve. On DSE, these patients nonetheless have a substantial increase in valve EOA and no or minimal elevation in gradients with increasing flow rate. On the other hand, true stenosis or PPM is associated with no or minimal increase in EOA, a marked increase in gradient, and most often the occurrence of indirect signs (LV dysfunction, marked elevation in pulmonary arterial pressure, etc.) and symptoms. It should, however, be considered that DSE does not allow for the distinction between prosthesis stenosis and PPM. For this purpose, one should apply the algorithm presented in Figures 25-14 and 25-15 to the EOA and DVI values obtained after normalization of cardiac output on stress echocardiography.

## SPECIAL CONSIDERATIONS FOR PERIOPERATIVE EVALUATION

The most frequent causes of prosthesis dysfunction in the perioperative period are prosthetic valve thrombosis, entrapment of a valve leaflet by preserved chordae in mitral mechanical prosthesis, or entrapment or perforation/tear of a prosthetic valve leaflet by a suture. In transcatheter bioprostheses, suboptimal deployment, malpositioning, or migration of the prosthesis stent may cause prosthetic valve stenosis or regurgitation.

Small paravalvular regurgitant jets are frequently (10% to 25% of cases) seen on intraoperative TEE before cardiopulmonary bypass weaning[30,75] and may significantly decrease or resolve after the injection of protamine or in the days, weeks, or months after valve replacement as the healing process evolves. Moderate or severe paravalvular regurgitation is rare (1% to 2%) following aortic or mitral valve replacement and requires returning to cardiopulmonary bypass for immediate correction.

Because of LV remodeling, relative high output states, and the frequent occurrence of tachycardia, hemodynamic assessment of the prosthetic valve done in the immediate postoperative period cannot be considered as definitive. Moreover, the echocardiograms are technically challenging because of the location of the various incisions, and the quality of the images is often suboptimal. The main objective of a perioperative echocardiogram is to detect the presence of paravalvular or transvalvular regurgitation and obtain accurate measurements of peak and mean gradients as well as the EOA and DVI, when feasible and reliable. Several pitfalls may be encountered when performing these measurements in the immediate postoperative period: (1) Poor-quality images may yield to erroneous measurement of LVOT diameter; (2) LVOT flow velocity may be abnormally increased by high cardiac output or dynamic obstruction from temporary remodeling of the LVOT, hypovolemia, and/or perioperative use of inotropes; or (3) the presence of perivalvular edema or hematoma in a stentless bioprosthesis implanted with the subcoronary technique may result in a lower than expected EOA and higher gradient during the first few months after operation.

For these reasons, the recording of relatively high gradients in the immediate postoperative period should not be viewed with undue concern. The first step is to assess the presence and severity of PPM by calculating the projected indexed EOA (see Figs. 25-14 and 25-15). This step does not require any Doppler-echocardiographic measurement and can thus be done irrespective of the image quality and the patient's hemodynamic condition. If PPM is present, it may explain, in part or in totality, the high transprosthetic gradient. If PPM is absent, several of the aforementioned conditions and technical pitfalls must first be ruled out before concluding that prosthesis dysfunction has occurred. In particular, one must first determine if the gradient is not partially or principally related to a high flow velocity in the LVOT. Relief of the valvular obstruction in patients operated for aortic stenosis may result in some remodeling and temporary narrowing of the LVOT. The administration of inotropic agents during weaning from cardiopulmonary bypass may also contribute to this phenomenon. Therefore, unless the transvalvular gradients are very high or are associated with abnormality of leaflet motion, significant symptoms, or deterioration in LV function, a conservative approach with observation and repeat assessment 3 to 6 months later is advocated.

# Utility of Doppler Echocardiography for Management of Specific Prosthetic Valve–Related Complications

## PROSTHETIC VALVE THROMBOSIS

If prosthetic valve thrombosis is suspected, echocardiography should be performed promptly and include TEE (see Clinical Case 25-2).[20] A comprehensive TTE is performed first, with particular attention directed at evaluation of leaflet mobility and valve hemodynamic function and identification of thrombus and/or pannus. In the rare case of massive prosthetic valve thrombosis with hemodynamic instability, TEE will not be

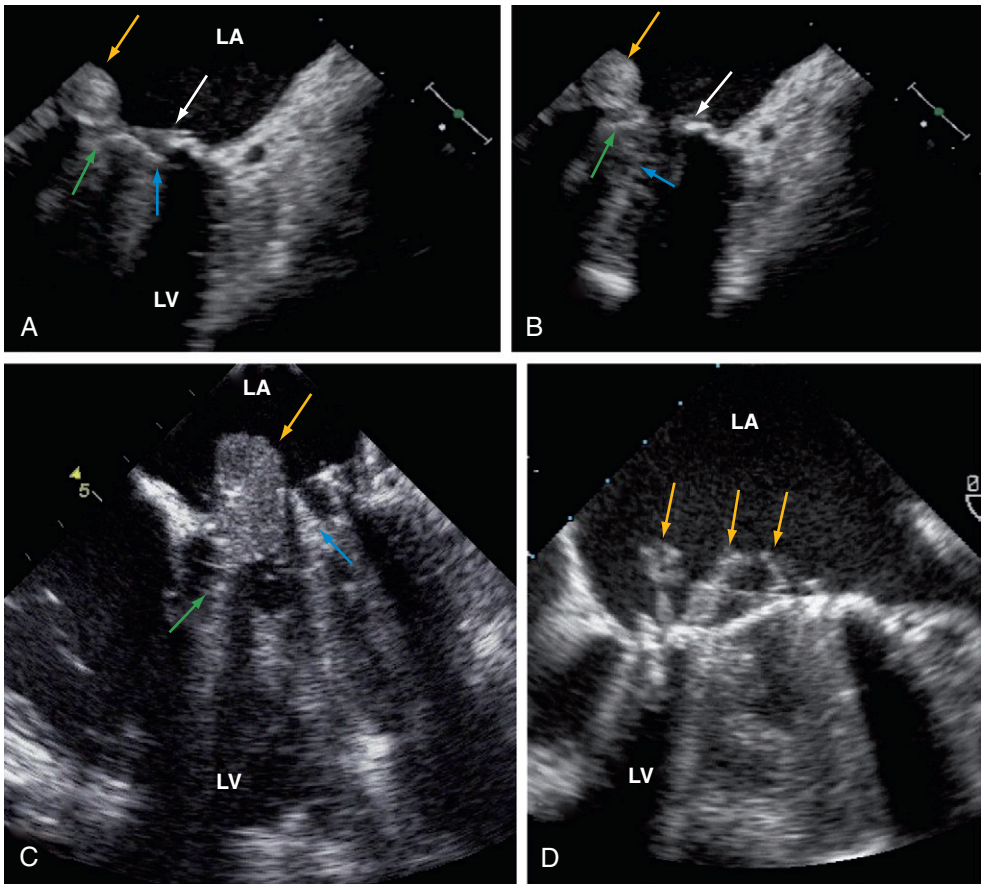

**Figure 25-16 Utility of TEE for diagnosis and treatment of prosthetic valve thrombosis.** Patient with obstructed mitral bileaflet mechanical valve in systole (**A**) and diastole (**B**). *Yellow arrow*: large thrombus; *white arrow*: pannus; *blue arrow*: mobile leaflet; *green arrow*: immobile leaflet. **C,** Mitral bileaflet mechanical valve obstructed by very large thrombus (*yellow arrow*). *Green arrow*: reverberation of immobile leaflet surrounded by thrombus; *blue arrow*: mobile leaflet with reverberation underneath. **D,** Multiple thrombi (*yellow arrows*) attached to mitral monoleaflet mechanical valve. needed, as this dramatic presentation constitutes a surgical emergency.[20] In most other cases, TEE will provide important incremental diagnostic information, which will also guide therapeutic management (Fig. 25-16; also see Clinical Case 25-2). TEE also has some limitations: aortic prostheses are more difficult to evaluate than mitral prostheses, and the ventricular side of a mitral prosthesis is more difficult to visualize than the atrial side.

Direct signs of prosthetic valve thrombosis include immobility or reduced leaflet mobility, and the presence of thrombus on either side of the prosthesis, with or without obstruction (see Fig. 25-4, *A*, and Fig. 25-16). It is important to differentiate thrombi from a fibrous pannus, which is usually annular in location and typically appears as a very dense immobile echo (see Fig. 25-16). Pannus formation is more frequent on aortic than on mitral prostheses and when observed on mitral prosthetic valves, they most often occur on the atrial side of the prosthesis (see Fig. 25-16, *A*, *B*). It is also important to differentiate small thrombi from strands or sutures. Strands are believed to be fibrin filaments, which appear as fine (1-mm), filamentous, mobile echoes of variable length (5 to 15 mm), most often observed on the atrial side of mitral prostheses.[20] Although the clinical relevance of these strands remains undetermined, there is no evidence that they are associated with an increased embolic risk.[20]

The most important factors to consider for therapeutic decision making (Fig. 25-17) are: (1) the presence of prosthetic valve obstruction; (2) the size and mobility of the thrombus; and (3) the clinical and hemodynamic condition of the patient.

In nonobstructive left-sided prosthetic valve thrombosis confirmed by TTE or TEE, first-line treatment consists of a short course of IV heparin with close echocardiographic follow-up plus adjustment of warfarin therapy and addition of aspirin (81 mg per day) (see Fig. 25-17).[20] However, if the medical treatment is unsuccessful, surgery should be considered in patients with large (length greater than 5 to 10 mm and/or area greater than 0.8 $cm^2$ as determined by TEE) or mobile thrombi. Thrombolysis with urokinase, streptokinase, or recombinant tissue plasminogen activator is recommended in other patients.[20,26,76] The presence of a large thrombus has been associated with a major increase in the risk of embolic complications following lytic treatment in the PRO-TEE registry.[77]

Urgent or emergent surgery (i.e., thrombectomy or valve replacement) is the treatment of choice in patients with obstructive valve thrombosis (see Fig. 25-17).[20] However, rescue thrombolysis should be considered in patients unlikely to survive surgery or when surgical treatment is unavailable and the patient cannot be transferred.[20,26,76] Thrombolysis may also be considered in patients with mild to moderate prosthetic valve

obstruction who are hemodynamically stable and have a small clot burden (see Fig. 25-17 and Clinical Case 25-2).

## PROSTHETIC VALVE ENDOCARDITIS

Prosthetic valve endocarditis represents one of the most frequent and severe form of infective endocarditis.[28] TEE is mandatory in prosthetic valve endocarditis because of its better sensitivity and specificity for the detection of vegetations, abscesses, and paravalvular lesions in this setting (Fig. 25-18).[36] When compared to native valve endocarditis, prosthetic valve endocarditis is characterized by a lower incidence of vegetations and higher incidence of abscesses and paravalvular complications. The sensitivity and specificity of both TTE and TEE are lower in prosthetic valve endocarditis than in native valve endocarditis.[28] Indeed, the components of the prosthetic valve may hinder the detection of vegetations and abscesses. Moreover, it may be difficult to differentiate a thrombus from a vegetation or bioprosthetic valve degeneration from infective lesions. Consequently, a negative echocardiogram is often observed in prosthetic valve endocarditis and does not rule out the diagnosis of infective endocarditis. If the initial TEE is negative but

suspicion for infective endocarditis remains, one should repeat within 7 to 10 days and/or use alternative imaging modality such as positron emission tomography or computed tomography (see Evaluation of Prosthetic Valve Endocarditis, later).

Infective endocarditis must be suspected in the presence of a new paraprosthetic regurgitation, even in the absence of a vegetation or abscess. TEE has a better sensitivity than TTE for this diagnosis, especially in mitral prosthetic valve endocarditis. Paravalvular complications are more frequent in aortic prosthetic valve endocarditis.[28] The anatomic involvement of infective endocarditis differs according to the type of prosthetic valve. In mechanical valves, the infection usually involves the junction between the sewing ring and the annulus, leading to paravalvular abscess, dehiscence, pseudoaneurysms, and fistula, whereas in bioprosthetic valve endocarditis, infection is more frequently located on the leaflets, leading to cusp tear, perforation, and vegetations (see Fig. 25-18).

Surgery should be considered in the following situations: failure of medical treatment; hemodynamically significant prosthesis regurgitation or obstruction, especially if associated with deterioration of LV function; large vegetations; paraprosthetic complications; and development of intracardiac fistulas.[22,26,29] Echocardiography is recommended for the perioperative and postoperative assessment of operated patients and for the follow-up of patients treated by medical therapy alone, because of the risk of late prosthetic dysfunction.[28]

### PARAVALVULAR REGURGITATION

Paravalvular regurgitation associated with development of symptoms, LV dysfunction, or hemolysis generally requires surgery. The paravalvular leaks can be repaired without valve replacement in approximately 50% of cases. Intraoperative TEE is mandatory to assess the results of leak correction. In patients with severe paravalvular mitral regurgitation refractory to aggressive medical therapy who are not candidates for surgical intervention, percutaneous implantation of an Amplatzer septal occluder device offers an alternative therapeutic option.[78] Contraindications to this alternative transcatheter procedure include very large paravalvular leak, valve rocking, more than two significant leaks, and active endocarditis. TEE is crucial to describe the location and extension of the paravalvular leak(s) and to guide and monitor the procedure.

## Limitations, Alternative Approaches, and Future Directions

### QUANTITATION OF PROSTHETIC VALVE REGURGITATION

One of the most difficult challenges in the Doppler-echocardiographic assessment of prosthetic valve function is the quantitation of prosthetic valve regurgitation, particularly when it is paravalvular, eccentric, and/or multijet. There is an urgent need for the development of new Doppler-echocardiographic methods that would allow accurate and reliable estimation of regurgitation severity, regardless of the location, direction, and number of regurgitant jet(s). The analysis of 3D color Doppler images and/or of the backscattered Doppler power signal may provide interesting avenues for future research in this regard.[79,80] Measurement of transprosthetic forward and backward flow by velocity-encoded cardiac magnetic resonance imaging may also be useful to quantitate prosthetic valve regurgitation, but the high cost and limited availability of this modality remains an important limitation.

### EVALUATION OF PROSTHETIC VALVE LEAFLET MOBILITY

One of the main limitations of TTE and to a lesser extent of TEE is the limited sensitivity for the detection of abnormalities of leaflet morphology and mobility, especially in the context of mechanical valves. The assessment of leaflet mobility is crucial to make the differential diagnosis between intrinsic valve dysfunction versus central localized high gradient in bileaflet mechanical valves (see Figs. 25-14 and 25-15). It is also helpful to differentiate prosthetic valve dysfunction versus PPM when the measurement of valve EOA is not feasible or not reliable. Cinefluoroscopy is a simple, fast, and noninvasive method that allows adequate visualization of leaflets and measurements of leaflets opening and closing angles in patients with mechanical valves (Table 25-8; also see Clinical Case 25-2). When a patient with a bileaflet mechanical valve presents with a high transprosthetic gradient that cannot be explained based from the findings of TTE, it is recommended to proceed to cinefluoroscopic examination of leaflet mobility. If it is normal, the high gradient is most likely due to localized high gradient across the central orifice (artifact), and prosthesis dysfunction can be excluded. If it is abnormal, the presence of prosthesis dysfunction is confirmed, and TEE should be performed to detect the presence of thrombus, pannus, vegetation, and/or occult regurgitation. Multislice computed tomography may also be used to evaluate leaflet mobility (Fig. 25-19, *A*).

### EVALUATION OF PROSTHETIC VALVE ENDOCARDITIS

Early diagnosis of prosthetic valve endocarditis is crucial to improve the success of therapy and the survival of patients. Unfortunately, some patients may have negative blood cultures and negative TTE and TEE despite presence of active prosthetic valve endocarditis, especially in the initial stages of the pathologic process. Enhanced uptake of fluorine-18-fluorodeoxyglucose in the region of the valve documented by positron emission tomography–computed tomography may help to confirm the presence of endocarditis and prompt the initiation of therapy (see Fig. 25-19, *B*).[81]

### EVALUATION OF TRANSCATHETER VALVE IMPLANTATION

It is expected that the number of these procedures will rise dramatically in the near future. TTE and TEE, including real-time 3D, will play a major role in patient selection, procedure

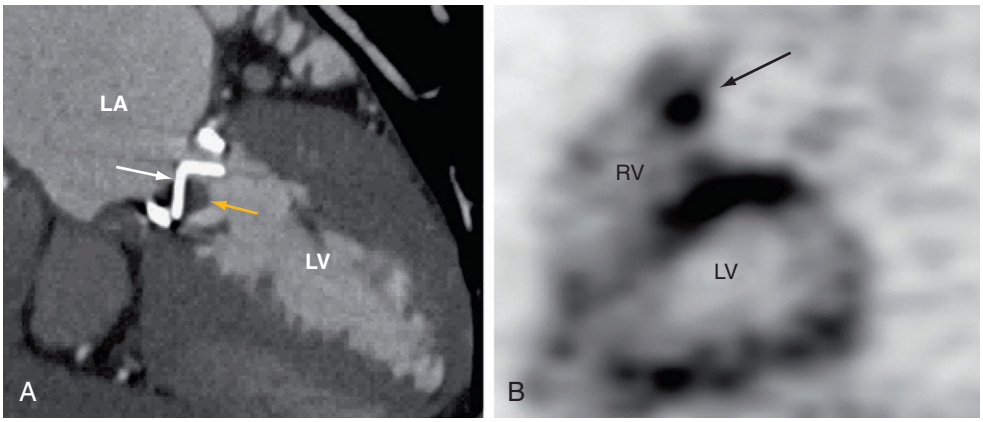

**Figure 25-19 Alternative imaging modalities to detect prosthetic valve dysfunction. guidance, and follow-up. Recently, transcatheter valves have also been implanted within failed bioprosthetic valves implanted surgically in the aortic, mitral, or pulmonary positions.[82] These emerging "valve-in-valve" procedures bring new challenges with regard to the role and use of Doppler echocardiography for selection of the appropriate size and model of transcatheter valve, and the assessment of prosthetic valve function in this particular context.

## Conclusion

Owing to its versatile, noninvasive, radiation-free nature and its low cost, Doppler echocardiography is undoubtedly the method of choice to identify and quantitate prosthetic valve dysfunction and assess its repercussions for cardiac function. However, the particular context of prosthetic valves poses some major challenges in terms of imaging and flow dynamics that push Doppler echocardiography to its limits. A comprehensive approach that integrates several direct and indirect parameters of valve function measured by TTE and TEE is key to appropriate assessment of prosthetic valve function, and other imaging modalities are often needed to complement or confirm the information obtained by Doppler echocardiography.

### KEY POINTS

- A comprehensive approach that integrates several direct and indirect Doppler-echocardiographic parameters of valve function is key to appropriately detect, quantitate, and manage prosthetic valve dysfunction
- Besides TTE, TEE provides important incremental information for the assessment and therapeutic management of prosthetic valve dysfunction and complications.
- Assessment of high transprosthetic gradient or velocity is much more complex than in native valves because there are several potential etiologies including PPM, prosthetic valve dysfunction, and localized high gradient.
- Assessment of severity of prosthetic valve regurgitation is generally much more complex than in native valves because of the high prevalence of paravalvular regurgitation and eccentric jets
- A high transprosthetic gradient or velocity does not necessarily imply prosthetic valve dysfunction. Conversely, a low gradient/velocity does not necessarily indicate absence of valve dysfunction.
- Evaluation of prosthetic leaflet morphology and mobility by TTE, TEE, or cinefluoroscopy is fundamental in making the differential diagnosis between prosthetic valve dysfunction and other potential causes of increased transprosthetic gradient.
- PPM is the most frequent cause of high gradient across prosthetic valves.
- TTE may underestimate the presence and severity of prosthetic mitral thrombosis and/or regurgitation because of reverberations and shadowing caused by the valve components. TEE is useful to unmask these "occult" abnormalities.

# 26 Doppler Echocardiography in Heart Failure and Cardiac Resynchronization

MARTIN ST. JOHN SUTTON, MD | THEODORE PLAPPERT, CVT

**Basic Principles**
- Definition of Heart Failure
- Prevalence of Heart Failure
- Etiology of Heart Failure

**Echocardiographic Diagnosis of Left Heart Failure**
- Acute Left Heart Failure
- Chronic Left Heart Failure
- Left Ventricular Remodeling to Heart Failure
- Systolic Versus Diastolic Heart Failure

**Echocardiographic Diagnosis of Right Heart Failure**
- Acute Right Ventricular Heart Failure
- Chronic Right Heart Failure
- Right Ventricular Remodeling to Heart Failure

**Echocardiography in Pharmacologic Therapy for Heart Failure**
- Pharmacologic Therapy

**Echocardiography for Mechanical Therapies in Heart Failure**
- Intraaortic Counterpulsation
- Ventricular Assist Devices
- Surgical Valve Repair or Replacement
- Cardiac Resynchronization Therapy
- New Techniques for Detection of Left Ventricular Dyssynchrony
- Heart Transplantation

**Summary**

## Basic Principles

### DEFINITION OF HEART FAILURE

Heart failure is a clinical syndrome characterized by easy fatigue, shortness of breath, exercise intolerance, fluid retention with lower extremity edema, and pulmonary congestion. Heart failure may be systolic as a result of abnormal myocardial excitation-contraction coupling or diastolic as a result of abnormal relaxation and increased myocardial passive stiffness. The symptomatic presentations of systolic and diastolic heart failure may be indistinguishable clinically, but the two etiologies can be determined with Doppler echocardiography by differences in left ventricular (LV) architecture and function. Differentiation between systolic and diastolic heart failure is important because the respective treatments and prognoses are different. Traditionally, diastolic heart failure has been regarded as a more benign form of heart failure than systolic heart failure. However, the annual mortality rate from diastolic heart failure is between 5% and 15%, and the hospitalization readmission rate for new onset heart failure is approximately 50% within the first 6 months.[1-4]

Systolic heart failure may be defined as the inability of the heart to supply the metabolic requirements of the body tissues. In systolic heart failure, myocardial shortening is impaired and results in a shift of the length-tension relationship to the right of the normal pressure-volume relationship (Fig. 26-1).[1,5]

Diastolic heart failure may be defined as the inability of the heart to receive blood from the body tissues at normal filling pressures.[4] In diastolic heart failure, the myocardial passive or resting length-tension relationship is displaced upwards and leftwards of the normal relationship (see Fig. 26-1). Thus, significant increases in LV diastolic pressure may occur with no detectable change in ventricular volume.[4,6] Myocardial relaxation is delayed or incomplete at the time of minimal LV diastolic pressure.[6]

The abnormal pressure-volume relations in systolic heart failure result in LV dilation and changes in both the composition and the material properties of the myocardium. This pattern of remodeling is known as "eccentric remodeling" and typifies systolic heart failure (Fig. 26-2). A chronically abnormal resting pressure-volume relationship is also associated with LV hypertrophy in which normal LV cavity size or volume is maintained, wall thickness is increased, and ejection performance is preserved. This latter form of "concentric remodeling" results in increased diastolic stiffness and incomplete or slowed relaxation that is characteristic of diastolic heart failure (see Fig. 26-2).

The purpose of this chapter is to show how Doppler echocardiography can be used in the clinical diagnosis of heart failure, to determine the etiology of heart failure and to distinguish systolic from diastolic heart failure. A second purpose of this chapter is to show how Doppler echocardiography can be used to assess of the efficacy of new treatments for heart failure and to guide the selection of novel pharmacologic agents or devices to optimize therapy.

### PREVALENCE OF HEART FAILURE

An estimated 30 million people worldwide are affected with chronic heart failure. Between five and six million patients with heart failure reside in the United States, and an additional 500,000 to 600,000 new cases are diagnosed each year.[7] This increase is the result of the greater availability of advanced diagnostic cardiac imaging capabilities. In a large proportion of these patients, the initial diagnosis of heart failure is made or confirmed by noninvasive imaging with Doppler echocardiography. Systolic heart failure is almost twice as common as diastolic heart failure and portends a much worse prognosis.[8]

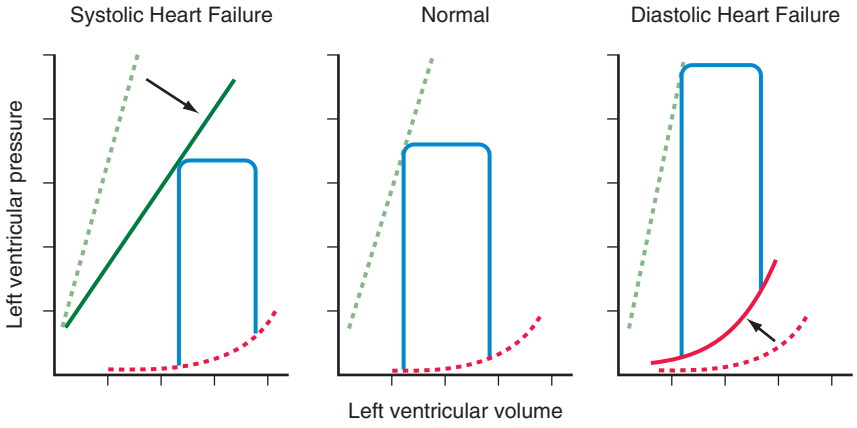

**Figure 26-1 LV pressure-volume loops in systolic heart failure (*left*), a normal control (*center*), and diastolic heart failure (*right*).** In systolic heart failure, a decrease is seen in the slope of the end-systolic pressure-volume relationship (decreased LV contractility); whereas in diastolic heart failure, the pressure-volume loop is shifted up and to the left (increased stiffness). *(From Aurigemma GP, Zile MR, Gaasch WH:* Circulation *113:296-304, 2006.)*

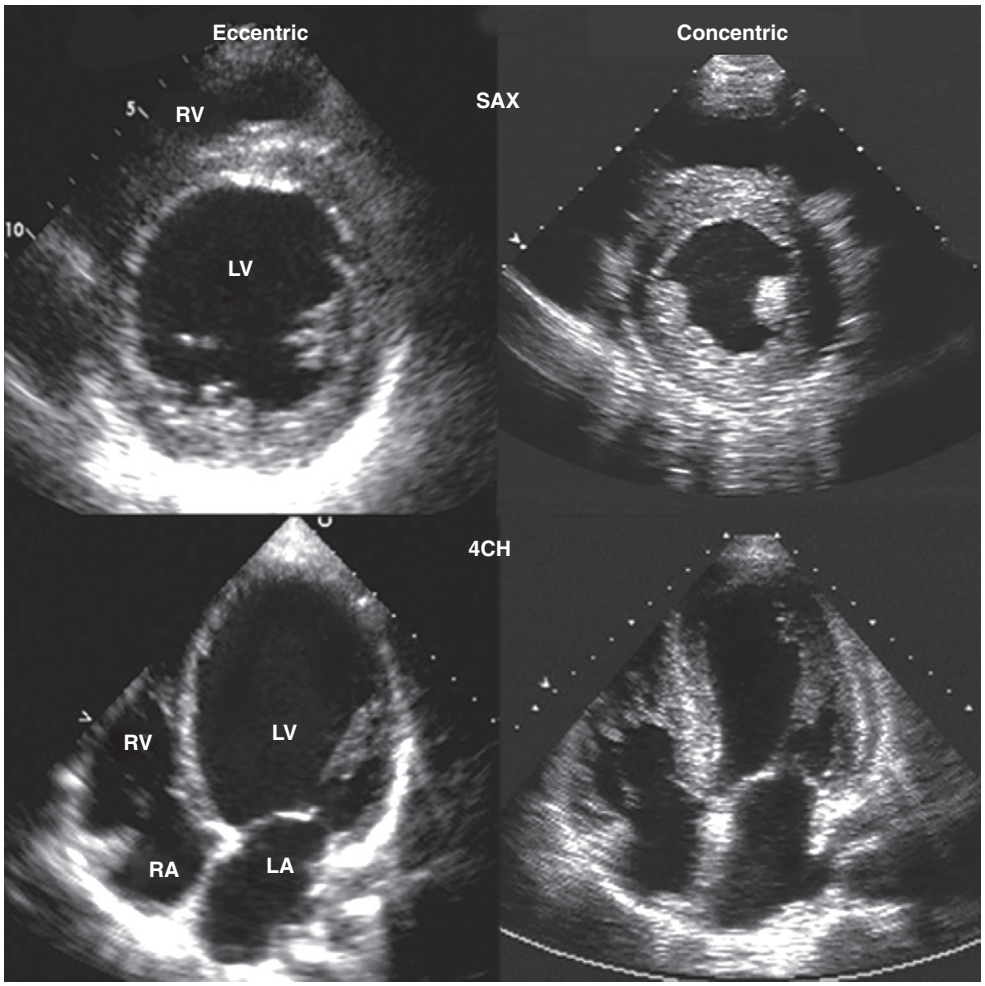

**Figure 26-2 LV short-axis (*top left*) and the apical four-chamber view (*bottom left*) of a patient with "eccentric" hypertrophy.** This is the result of a primary volume overload with a compensatory increase in wall thickness that fails to meet the increase in cavity radius. On the *right,* LV short axis *(top)* and apical four-chamber view *(bottom)* of a patient with "concentric" hypertrophy. This is the result of a primary pressure overload with an increase in wall thickness without significant increase in cavity radius. *SAX,* Short axis view; *4CH,* four-chamber view.

Heart failure increases with age so that currently 6% to 10% of persons older than 65 years have heart failure. Although the survival rate for women with heart failure has improved in the last two decades, the survival rate for men is unchanged in the same time period. The overall 5-year and 10-year survival rates in New York Heart Association Symptom Class III are 50% and 30%, respectively.

The total costs for the diagnostic related group for heart failure nationwide already exceeds 30 billion dollars per year. Included in this price tag are multiple hospital admissions, drugs, internal cardiac defibrillators, ventricular assist devices, cardiac resynchronization therapy (CRT), and heart transplants. These striking population statistics underscore the size of the problem of heart failure worldwide and the reason that

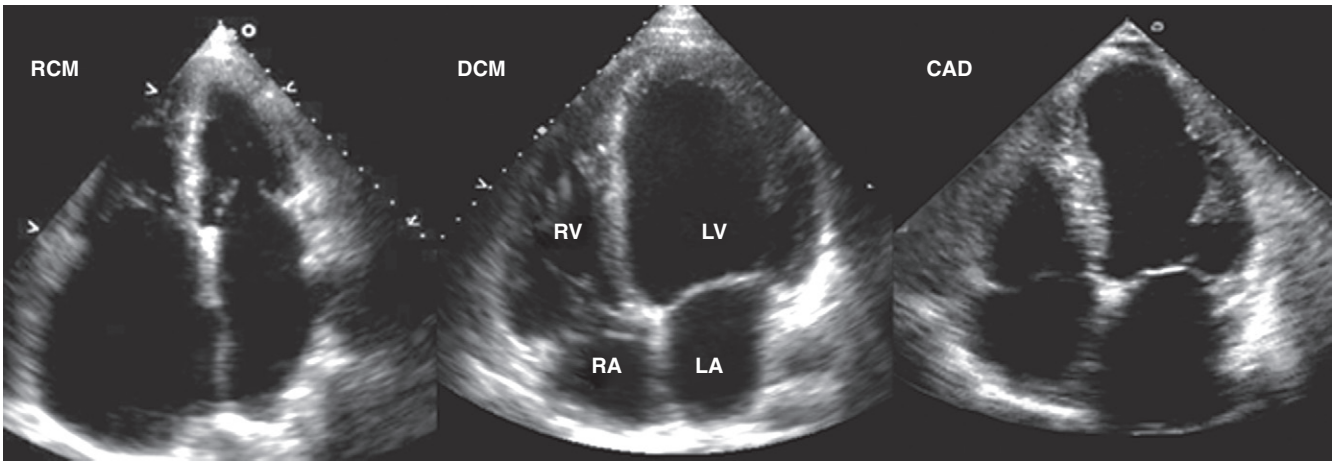

**Figure 26-3 Comparative imaging findings in restrictive cardiomyopathy (*RCM*), dilated cardiomyopathy (*DCM*) and coronary artery disease (*CAD*).** Apical four-chamber view of a patient with restrictive cardiomyopathy (*left*) that shows a small LV and biatrial dilation; apical four-chamber view of a dilated cardiomyopathy (*center*) with a dilated LV; and an apical four-chamber view of a patient with coronary artery disease (*right*) that shows apical dilation.

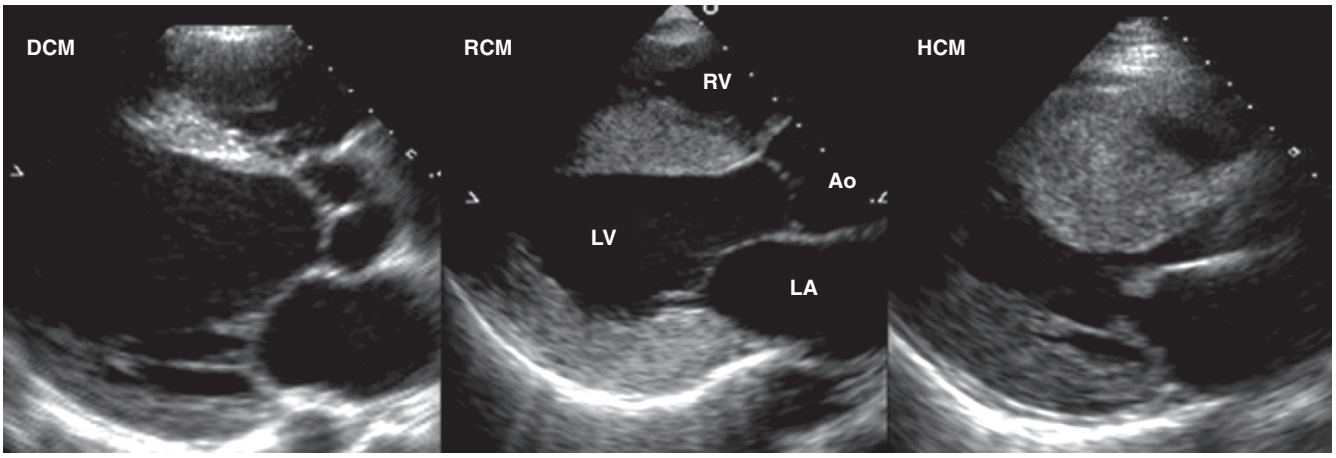

**Figure 26-4** Parasternal long-axis view of a patient with dilated cardiomyopathy shows an increase in internal diameter of the LV with normal wall thickness *(left);* parasternal long-axis view of a patient with amyloid restrictive cardiomyopathy (*center;* the walls are thick and highly reflective, and the LV diameter is normal); and parasternal long-axis view of a hypertrophic cardiomyopathy with asymmetric septal hypertrophy (*right;* the upper interventricular septum measures 4 cm with a small LV diameter). *Ao,* Aorta; *DCM,* dilated cardiomyopathy; *RCM,* restrictive cardiomyopathy; *HCM,* hypertrophic cardiomyopathy.

heart failure has become a high priority health care policy initiative.

### ETIOLOGY OF HEART FAILURE

Heart failure has many divergent causes, and their individual prevalence varies geographically. In the United States, Canada, and Europe, atherosclerotic coronary artery disease and myocardial infarction (MI) is the most common etiology, accounting for more than two thirds of all cases of chronic heart failure.[9] In West Africa, restrictive cardiomyopathy is the predominant etiology of heart failure. In Central and South America, heart failure is most frequently the result of an immunologic response to chronic infection with *Trypanosoma cruzi*. These three widely different etiologies of heart failure have their own individual structural and functional stigmata that can be easily recognized with Doppler echocardiography (Fig. 26-3). Other major causes of heart failure that can be diagnosed echocardiographically include chronic pressure overload from systemic hypertension; pressure or volume overload from valvular heart disease; and primary dilated, hypertrophic, and restrictive cardiomyopathies from genetically determined abnormalities of the sarcomeric contractile proteins or infiltrative diseases that change the extracellular matrix. Cardiac toxins are an infrequent cause of heart failure that include chronic excessive ingestion of alcohol and chemotherapeutic agents such as cytoxan and adriamycin, even in therapeutic doses for primary malignant solid and liquid tumors and as pretreatment for bone marrow transplant. Some of these conditions express consistent phenotypes that are pathognomonic and readily diagnosed with Doppler echocardiography (e.g., cardiac amyloid, hypertrophic cardiomyopathy, and dilated cardiomyopathy; Fig. 26-4).

## Echocardiographic Diagnosis of Left Heart Failure

### ACUTE LEFT HEART FAILURE

"The single most useful diagnostic test" in the evaluation of patients with heart failure is Doppler echocardiography for determination of whether abnormalities of the myocardium,

heart valves, or pericardium are present and which cardiac chambers are involved.[10] In patients with new-onset heart failure, the American College of Cardiology/American Heart Association practice guidelines recommend an initial Doppler echocardiographic algorithm to resolve three important issues.[10] The first issue is establishment of whether the LV ejection fraction is normal or decreased. The second issue is determination of whether LV structure is normal or abnormal and whether the LV is dilated, hypertrophied, or of normal size. The third issue is assessment of whether other structural abnormalities, such as valvular heart disease, pericardial disease, right ventricular (RV) abnormalities, or chronic pulmonary disease, could account for the clinical presentation of heart failure.

Common causes of acute onset of LV systolic heart failure include: (1) extensive acute MI; (2) acute LV volume overload from severe mitral regurgitation (MR) as a result of rupture of a papillary muscle after infarction (see Chapter 14); (3) severe ischemic MR with flash pulmonary edema from acute elevation of LV end-diastolic pressure; (4) postinfarction rupture of the interventricular septum (ventricular septal defect) with a large left-to-right shunt after infarction (see Chapter 14); (5) chordal rupture after MI or from endocarditis that causes a flail leaflet and severe MR; (6) acute severe MR as a result of rupture of a native valve or dehiscence of a prosthetic valve from vegetative endocarditis (see Chapter 25); (7) acute severe aortic regurgitation that results from avulsion of the aortic valve or dehiscence of a prosthetic aortic valve from endocarditis (see Chapter 22); (8) thrombotic encapsulation and occlusion of a mechanical aortic or mitral prosthetic valve as a result of inadequate oral anticoagulation status (see Chapter 25); (9) acute myocarditis; (10) exposure to oncologic cardiotoxic chemotherapeutic agents; and (11) acute destabilization of previously known or unknown chronic severe dilated cardiomyopathy. All of these conditions, except for the latter, present with either sudden massive increase in LV loading conditions, acute loss of contracting cardio-myocytes, or severe injury to the full complement of working myocardium.

Acute MI is diagnosed by history and confirmed with electrocardiographic changes and elevated cardiac enzymes. Echocardiography early after MI shows normal LV size with decreased global function and a variable sized regional wall motion abnormality in the territory of the occluded culprit coronary artery. Infarct size can be assessed with two-dimensional (2D) or three-dimensional (3D) echocardiography using a 17-segment model of the LV and scoring of regional wall motion in each segment from normal to akinetic. The average wall motion is calculated as a wall motion score index that correlates with the magnitude of the elevation of cardiac enzymes.

Sudden exacerbation of heart failure in the early periinfarction period may result from either rupture of the interventricular septum or acute severe MR from papillary muscle dysfunction or rupture. Although these two different lesions cannot be reliably distinguished clinically, Doppler echocardiography can unequivocally differentiate between the two lesions. These structural changes can be localized with color flow Doppler scan and their severity quantified as MR volume, the ratio of pulmonary blood flow to systemic blood flow (Qp/Qs), and the magnitude of shunt flow through the ventricular septal defect (see Chapter 14).

The remaining causes of acute heart failure listed previously are usually readily recognized with transthoracic Doppler echocardiography. Transesophageal echocardiography may be needed for diagnosis of vegetative endovascular infections that cause perforation or avulsion of native mitral or aortic valves (see Chapters 22 and 25) or dehiscence of a mechanical or biological aortic or mitral prosthesis. Transthoracic and transesophageal echocardiography are often necessary for diagnosis of acute severe MR associated with degenerative mitral valve disease as a result of rupture of redundant chordae that causes flail leaflets that fail to coapt normally and result in acute severe MR (see Chapter 18). The thickened yet highly mobile prolapsing myxomatous leaflets of degenerative mitral valve disease are easily recognized. Transesophageal echocardiography is invaluable for determining whether the valve can be repaired rather than replaced.

Acute left heart failure from use of high doses of oncologic agents results in severe global dysfunction that has a temporal cause-and-effect relationship to drug administration. In acute heart failure caused by adriamycin, transthoracic echocardiography shows that LV end-diastolic size is usually normal but the end-systolic size is increased so that resting sinus tachycardia is a prerequisite for maintaining resting cardiac output (Fig. 26-5).

## CHRONIC LEFT HEART FAILURE

The common causes of chronic left heart failure are coronary artery disease and MI, hypertensive heart disease, valvular disease, and cardiomyopathies. The different pathoetiologies in their late stages progress down a final common pathway to left-sided systolic heart failure characterized by structural and functional remodeling changes that lend themselves well to echocardiographic imaging. One finding that is almost universal in chronic systolic heart failure is the presence of LV dilation, which can be quantified echocardiographically either as cavity diameter at end-diastole and end-systole or as end-diastolic and end-systolic volumes with the modified Simpson's rule. The importance of LV volumes after infarction is their predictive value for adverse clinical outcome.[11] Increasing evidence shows that measurements of global longitudinal, radial, and circumferential myocardial strain with speckle tracking provide even greater predictive information regarding clinical outcomes after infarction and in dilated cardiomyopathies. Transthoracic 2D echocardiography has shown that progressive LV dilation occurs by a disproportionately greater increase in LV short-axis diameter than in LV long-axis diameter as exemplified by idiopathic dilated cardiomyopathy (Figs. 26-6 and 26-7). This pattern of remodeling confers on the LV a mechanically disadvantageous cavity shape that is more spherical compared with the configuration of the normal heart.[11] This change in LV shape is readily discernible with echocardiographic images of the LV in the apical two-chamber and apical four-chamber views (see Fig. 26-7). As the LV remodels to a larger volume, contractile function deteriorates because of inadequate hypertrophy that is unable to normalize end-systolic wall stress and leads to heart failure. In healthy subjects, the end-diastolic mass-to-volume relationship is virtually constant in normotensive hearts from early infancy through old age.

There are three important sequelae of the abnormal LV size and shape. First is the increase in loading conditions with the disproportionate LV mass-volume ratio associated with decreased contractile function. Second, LV dilation combined with the decreased contractile function results in low blood flow velocities within the LV, which predisposes to thrombus formation, especially in the apex of the LV cavity with regional wall motion abnormalities (Fig. 26-8). Thrombus may also occur in

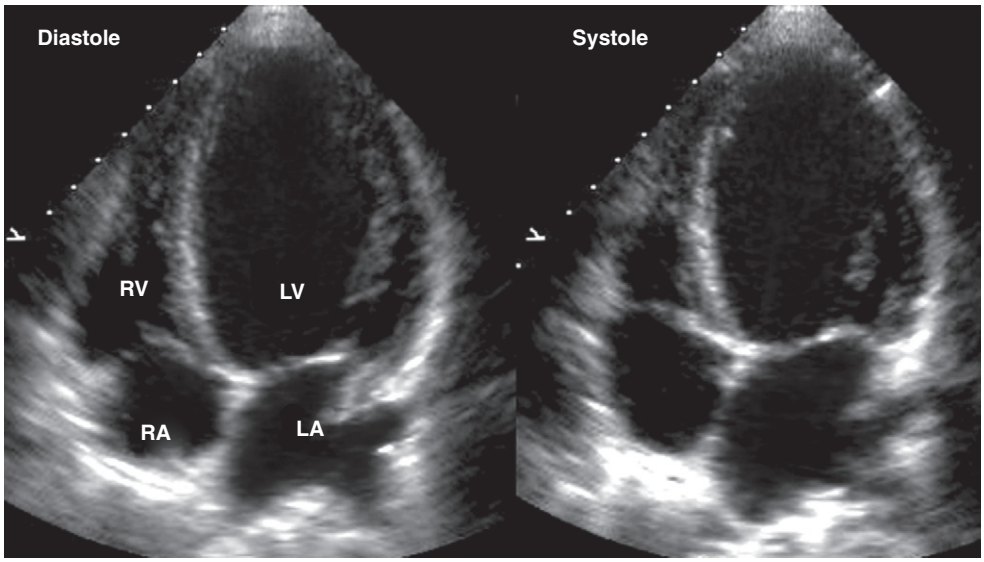

**Figure 26-5** Apical four-chamber view of a patient with adriamycin-induced cardiomyopathy that shows minimal LV dilation and little change in LV size from diastole (*left panel*) to systole (*right panel*), consistent with a very low stroke volume.

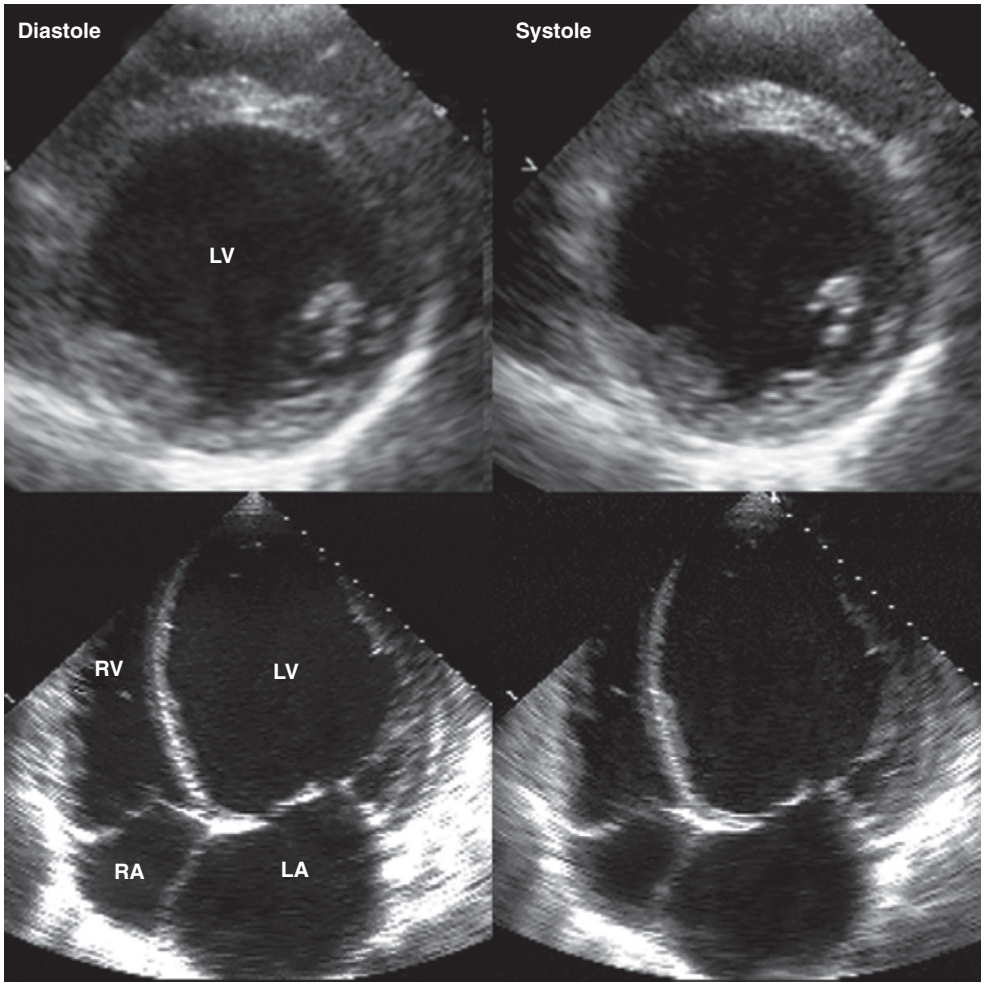

**Figure 26-6** Short-axis and four-chamber views of a dilated cardiomyopathy at end-diastole (*left*) and short-axis and four-chamber views of a dilated cardiomyopathy (*right*). Note the greater increase in the short-axis diameter as compared with the LV long-axis length in the four-chamber views.

the left atrial appendage as a result of low flow velocities. Both LV (see Fig. 26-8) and left atrial (LA) thrombus (Fig. 26-9) are potential sources of systemic embolism and especially stroke. Thrombus formation may be subtle and necessitate echocardiographic imaging with increased gain in orthogonal planes of the LV long axes with serial short-axis views with a high-frequency near-focus transducer. When doubt still remains as to the presence of LV thrombus, echocontrast studies are recommended to enhance endocardial definition (Fig. 26-10) so that the diagnosis of LV thrombus is unequivocal. The morphologic features of LV thrombus that correlate with increased embolic potential include mobility, large size, and convexity of the thrombus toward the LV cavity.

The third important consequence of LV dilation and change in LV shape is enlargement of the mitral annulus and distortion of the mitral valve and subvalve geometry. The spatial separation of the two papillary muscles caused by LV dilation increases the angle they subtend to the midpoint of the plane of the mitral annulus. This occurs without lengthening of the chordae and therefore reduces the area of leaflet coaptation that results in MR even though the mitral valve is intrinsically normal (Fig. 26-11). The anatomic relationships between the various components of the mitral valve apparatus are best appreciated with real-time 3D echocardiography in the short-axis and apical long-axis or four-chamber views (Fig. 26-12).

A different yet frequent cause of MR in heart failure relates to the presence of provocable ischemia in patients with advanced coronary artery disease. Serial quantitative Doppler echocardiographic studies of ischemic MR show its important adverse impact on survival.[12] MR is significantly more common and more severe in eccentric remodeling that occurs in systolic heart failure than in concentric remodeling in diastolic heart failure, in which LV cavity size is typically normal.

The severity of MR can be semiquantified with 2D transthoracic echocardiography as the ratio of color flow MR jet area averaged from orthogonal views and left atrial area. MR severity can be quantified as the effective regurgitant orifice area or regurgitant volume with proximal isovelocity surface area technique or with the diameter of the vena contracta (see Chapter 18). The significance of MR in systolic heart failure is that it results in an additional increase in load when loading conditions are already increased. Quantification of MR with proximal isovelocity surface area is advised.

After posteroinferior infarction, residual ischemia of the inferomedial papillary muscle may interfere with the timing and extent of shortening and cause MR. Hemodynamically important MR may escalate deterioration in contractile function. Ischemic MR may cause flash pulmonary edema triggered by transient increases in afterload associated with physical exertion. The poor prognosis of ischemic MR correlates closely with the severity of MR with Doppler echocardiography.[12] Rupture of a papillary muscle after MI may not be diagnosed initially but is usually suggested by the discrepancy between relatively normal LV size and function and the torrential MR. A search should be made to identify the papillary muscle heads and primary chordae that are disconnected from the muscle. This is a "must diagnose" because the severity of

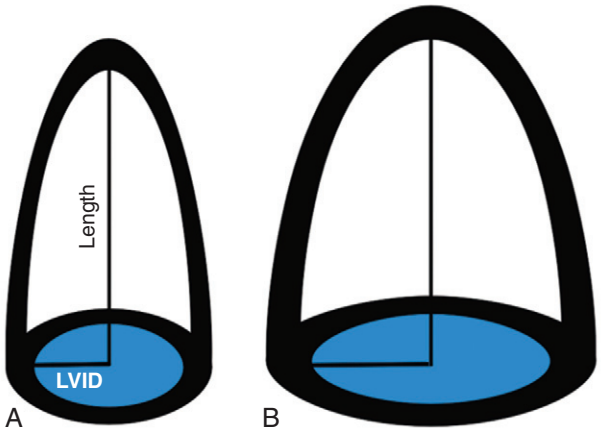

**Figure 26-7** Schematic representation of a normal LV shape (**A**) and a more spherical shape as a result of a greater increase of the minor diameter than in LV length (**B**) in dilated cardiomyopathy.

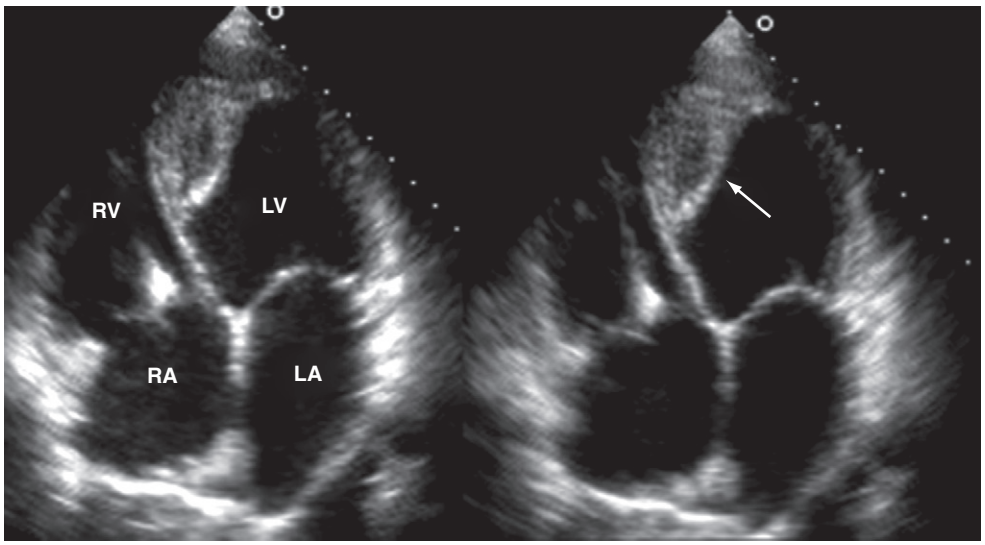

**Figure 26-8** **Echocardiographic appearance of LV thrombus.** Transthoracic apical four-chamber view that shows a large sessile LV cavity thrombus (*white arrow*) attached to the apical septum in an area of akinesis. A defibrillator electrode is present in the RV.

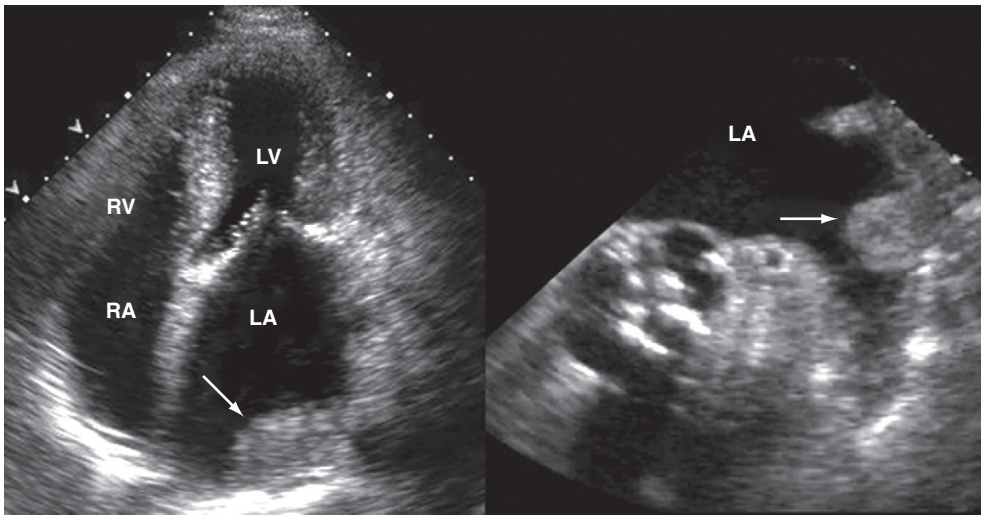

**Figure 26-9 Valvular heart disease with ventricular dysfunction**. Transthoracic echocardiogram of the four-chamber view of a patient with moderate LV dysfunction and heart failure symptoms with degenerative and calcific aortic and mitral valve disease (*left panel*). Note the large thrombus adherent to the roof of the markedly enlarged LA (*left panel*). A discrete immobile thrombus is visualized in the left atrial appendix that is a repository for the development of thrombus (*white arrow*). Calcification and narrowing of the aortic valve leaflets are also seen, consistent with at least mild aortic stenosis.

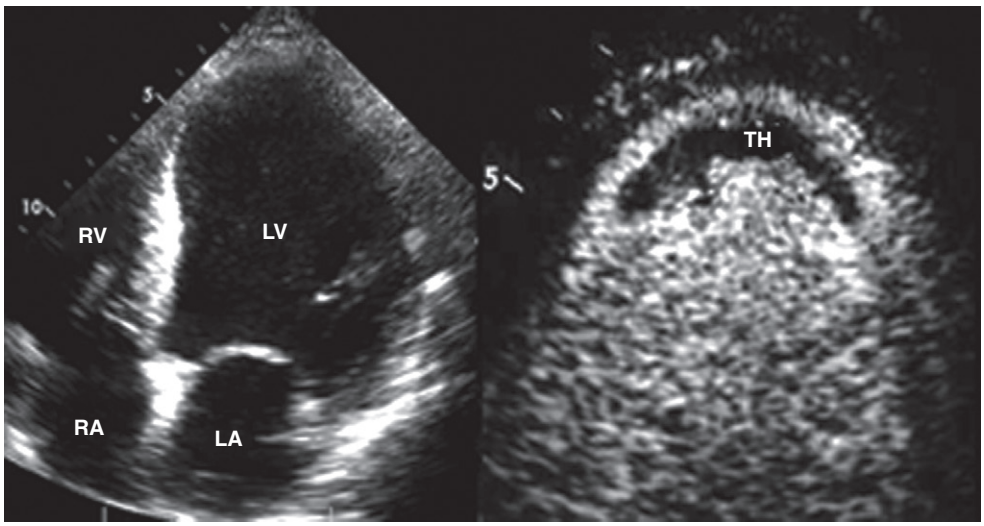

**Figure 26-10 Apical aneurysm.** Transthoracic 2D echocardiogram of an apical four-chamber view from a patient with ischemic cardiomyopathy that shows an apical aneurysm without any obvious thrombus present (*left panel*). However, when the endocardial definition is improved with intravenous contrast, a laminar thrombus becomes apparent (*right panel*). *TH*, Thrombus.

MR is poorly tolerated and irreversible cardiogenic shock may supervene.

## LEFT VENTRICULAR REMODELING TO HEART FAILURE

Left ventricular remodeling is a dynamic process that includes progressive LV dilation, distortion of LV shape, disruption of mitral valve geometry, development of MR, and deterioration in LV function. This type of remodeling is known as eccentric remodeling. These structural and functional changes and the transition to heart failure have been characterized by Doppler echocardiography.

Left ventricular remodeling is triggered by an imbalance between myocardial wall stress and the normal restraining forces exerted by the viscoelastic collagen matrix. Increased wall stress activates cell surface mechanoreceptors (integrins) that in turn activate myocardial matrix metalloproteinases that degrade the extracellular collagen matrix, thereby facilitating LV dilation. A new equilibrium is established between collagen degradation and collagen synthesis that stabilizes LV size and function. Progressive LV dilation leads to chronically elevated wall stress, which, if unchecked, results in heart failure. Thus, LV dilation begets increased wall stress that begets further LV dilation. LV dilation results in an increase in loading conditions that can be assessed as meridional and circumferential midwall stresses from echocardiographic measurements of LV cavity radius, length, and wall thickness. Cuff systolic blood pressure can be used to represent LV peak pressure.[13] A strong inverse relationship exists between end-systolic wall stress and ejection fraction, such that the greater the wall stress, the lower the LV ejection fraction. Increased myocardial wall stress is also a major stimulus for ventricular hypertrophy mediated by the angiotensin I receptor. When the hypertrophic response is

sufficient to normalize wall stress, the progressive deterioration in LV function is attenuated, LV geometry is stabilized, and function is preserved.

Insight into the structural and functional eccentric remodeling process and transition from stable LV function to systolic heart failure has been provided by Doppler echocardiography in a number of post-MI and heart failure clinical trials (SAVE and SOLVD).[11,14] Speckle tracking with 2D and 3D echocardiography provides a means of quantifying regional and global longitudinal, radial, and circumferential strain (Figs. 26-13 and 26-14) and also assessment of the temporal development of peak systolic velocities in opposing walls as a measure of dyssynchrony.

## SYSTOLIC VERSUS DIASTOLIC HEART FAILURE

The diagnostic criteria for diastolic heart failure are the combination of symptomatic heart failure and an LV ejection fraction of 50% or more to distinguish LV diastolic from systolic heart failure. Controversy exists with regard to nomenclature: "diastolic heart failure" versus "heart failure with preserved ejection fraction." There was concern initially as to whether Doppler indices provided sufficiently specific information about intrinsic passive diastolic properties of the myocardium and whether the information derived from LV filling dynamics equated with intrinsic myocardial diastolic dysfunction.[15] Other investigators have indicated that diastolic heart failure can be confidently diagnosed with the combined presence of impaired relaxation, decreased compliance, and increased LV filling pressures.[16]

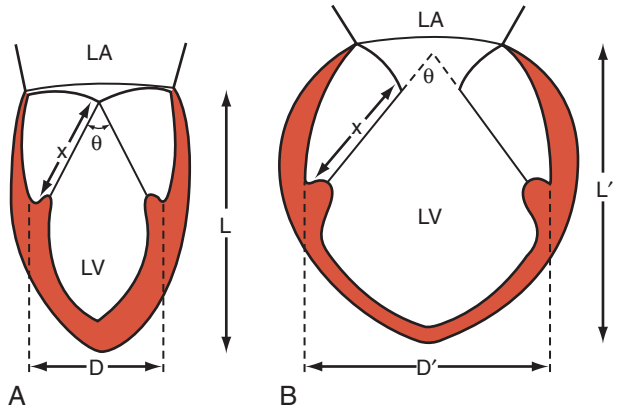

**Figure 26-11 Mechanism of functional mitral regurgitation.** Schematic that shows the LV architecture, the relations between the diameter and length of the LV and the geometry of the normal mitral valve (**A**), and the greater increase in LV diameter than the increase in LV length that confers an abnormal shape on the LV and also disrupts the mitral valve geometry that alters mitral leaflet coaptation area, leading to mitral regurgitation (**B**).

Diastolic heart failure has been less well characterized than systolic heart failure, until the last decade, when it became clear that LV diastolic dysfunction was responsible for 30% to 50% of all patients with heart failure and had an annual mortality rate of 5% to 15%. Patients with diastolic heart failure are similar to patients with systolic heart failure with regards to impaired quality of life, exercise capacity, demographic profiling, and neurohormonal activation. Neurohormonal activation in diastolic heart failure is similar to systolic failure with regard to norepinephrine levels, but plasma levels of brain natriuretic peptide and atrial natriuretic peptides are consistently greater in systolic heart failure.[17]

Diastolic dysfunction often precedes the onset of systolic dysfunction in hypertensive heart disease and in coronary artery disease. Factors that determine which patients have diastolic rather than systolic heart failure develop are largely unknown. Furthermore, diastolic heart failure may transition into systolic failure in its terminal stages, which confounds the arbitrary division between diastolic and systolic heart failure.

Diastolic heart failure occurs more commonly in elderly women, of whom more than 75% have a history of hypertension and approximately 40% have LV hypertrophy defined as a LV mass of more than 125 g/m$^2$.[2,16] The structural and functional concentric pattern of LV remodeling in diastolic heart failure is characterized echocardiographically by normal or near-normal LV end-diastolic volume, normal cavity shape, increased absolute and increased relative wall thicknesses (wall thickness/LV cavity radius), increased LV mass-volume ratio from a disproportionately greater increase in LV mass than volume, and preserved ejection fraction (more than 50%).[17] More specific Doppler echocardiographic findings in chronic diastolic heart failure include abnormal LV filling patterns (larger A wave velocity, a normal E wave deceleration time); prolonged

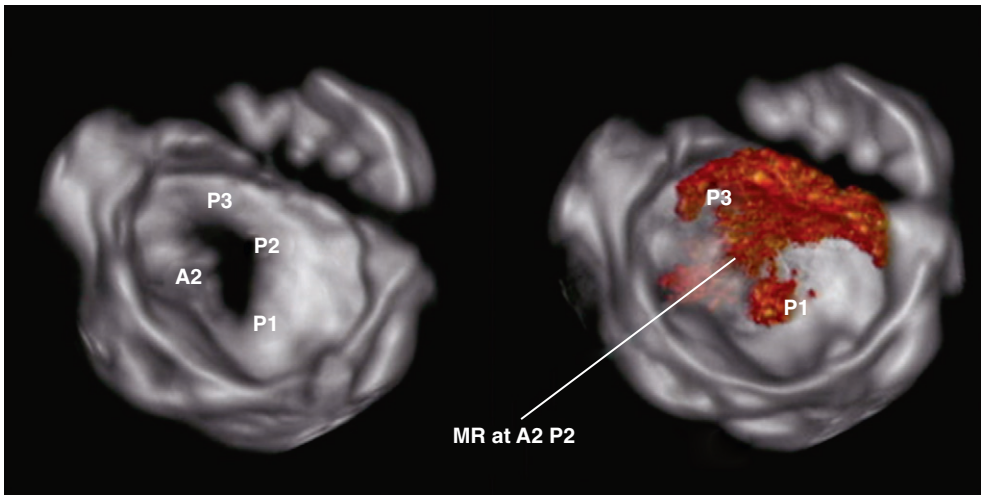

**Figure 26-12 Mitral valve prolapse.** Mitral valve visualized with 3D transesophageal echocardiography that shows prolapse of the P2 and A2 scallops (*left panel*) and the Doppler color flow jet of mitral regurgitant flow (*right panel*).

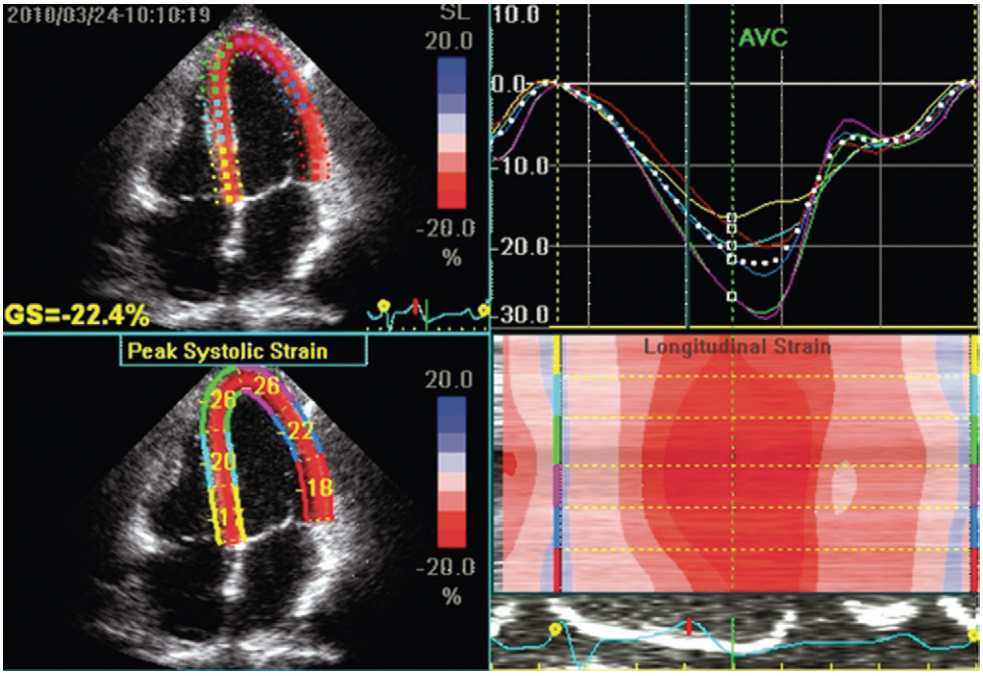

**Figure 26-13 Speckle tracking longitudinal strain.** Transthoracic echocardiogram in the apical four-chamber view with speckle tracking to quantify longitudinal strain with the average values in each myocardial segment (*right panels*). Continuous longitudinal myocardial strain recorded from four myocardial segments shows the high level of concordance between the segments that peak at the same time.

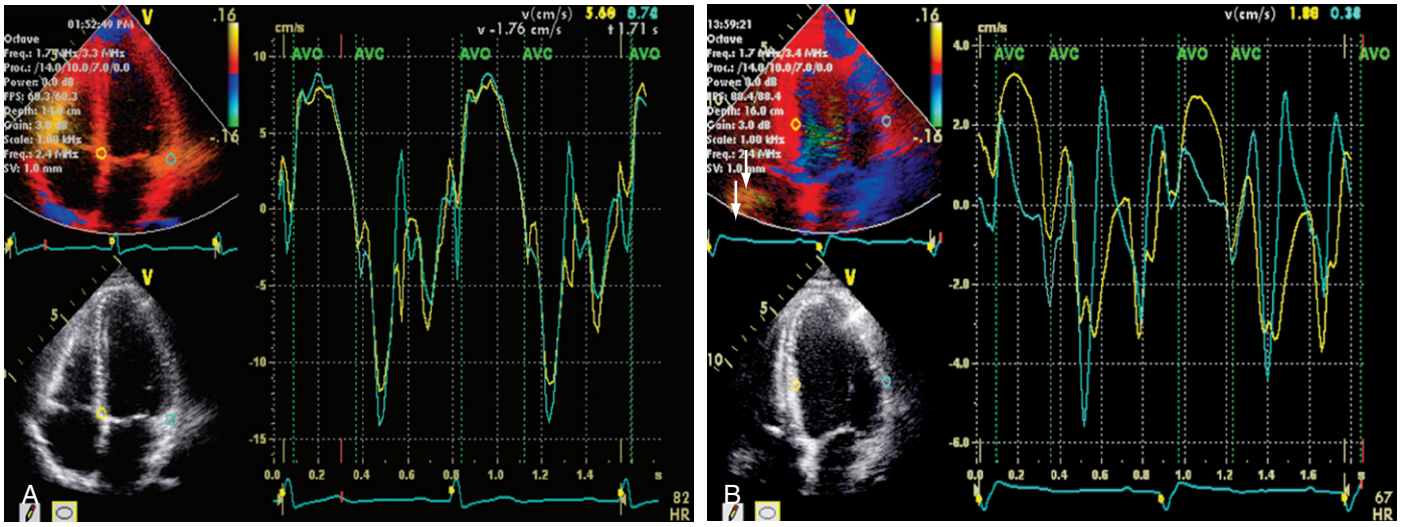

**Figure 26-14 Tissue Doppler myocardial velocity imaging. A,** Transthoracic echocardiogram of a normal LV with sample volumes placed in the proximal septum and in the lateral wall at the level of the mitral annulus (*left panel*) to obtain continuous myocardial velocities with tissue-Doppler imaging. Notice that the two tracings have similar magnitude throughout the whole cardiac cycle and track together in time such that the time interval between the onset of the QRS and acquisition of peak systolic myocardial velocity for the two sample volumes are virtually identical, occurring during ejection between aortic valve opening (*AVO*) and aortic valve closure (*AVC; right panel*). **B,** This recording has an identical format as the previous computer output but in an abnormal heart that shows the significant delay in the peak myocardial velocity in the lateral wall compared with the septum by more than 65 ms, a delay that defined the presence of ventricular dyssynchrony.

isovolumic relaxation time, which is the period between aortic valve closure and mitral valve opening; decreased propagation velocity in the LV inflow tract; and abnormal myocardial diastolic velocities with tissue-Doppler imaging (TDI); (see Chapter 11). TDI myocardial velocities and myocardial displacement reported in small cohorts of patients with diastolic heart failure are normal in more than 50%. Not all of the more specific Doppler echocardiographic parameters listed previously are abnormal in every patient with diastolic heart failure.

Detection of diastolic dysfunction is important because it is associated with a five-fold increase in mortality.[18] The earliest sign of diastolic dysfunction is impairment of relaxation from slowing of the rate of LV diastolic pressure decay. This early evidence for diastolic dysfunction can be detected noninvasively with prolongation of isovolumic relaxation time. Isovolumic relaxation time can be measured with the echocardiography transducer at the apex of the heart angled to record both aortic and mitral valve leaflet motion with Doppler scan and formerly with M-mode echograms recorded at a sweep speed of 200 cm/s.

Slow and prolonged myocardial relaxation are also detectable as altered mitral inflow velocities with a decreased peak velocity during passive filling (E wave), an increased E wave deceleration time, and an augmented peak velocity during active atrial systolic contraction (A wave) with a shortened duration. As the

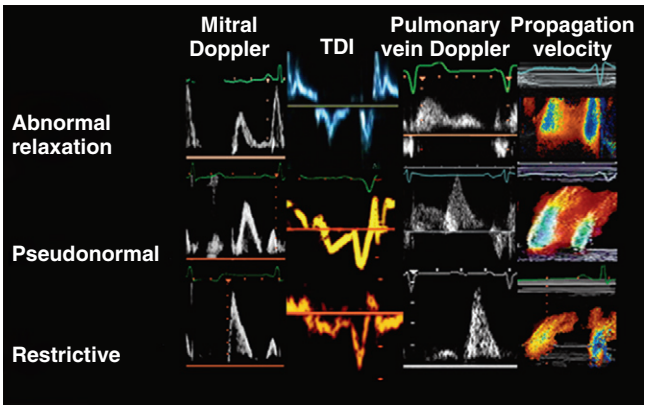

**Figure 26-15** Transmitral Doppler flow velocity, tissue Doppler imaging (TDI), pulmonary vein Doppler velocity and propagation velocity showing transition from abnormal relaxation through pseudo-normalization to restrictive physiology. *(From Zile MR, Brutsaert DL: Circulation 105:1387-1393, 2002.)*

duration of the peak A wave of the mitral inflow shortens, so the duration of the flow reversal in the pulmonary venous velocity profile increases until it finally exceeds the mitral peak A wave duration. Slowed or delayed LV relaxation can be diagnosed with TDI as reduced and delayed E′ velocity of the mitral annulus most frequently obtained from the septum and lateral wall.

The mitral diastolic flow propagation velocity recorded with color flow Doppler scan at the LV inflow correlates with tau (τ) and decreases progressively with increasing LV diastolic dysfunction. LV filling pressure or pulmonary capillary wedge pressure can be derived from the deceleration time of the E wave of the mitral inflow, and a value of less than 140 ms indicates a mitral inflow velocity profile consistent with restrictive physiology. Alternatively, LV diastolic pressure can be estimated from the ratio of E/E′ over a wide range of filling pressures and LV ejection fractions.[19] Chronic LV diastolic dysfunction may transition to heart failure, and in doing so, the mitral inflow, pulmonary venous, and TDI flow velocity profiles change from a pseudonormal pattern, which is reversible, to a restrictive physiology, which is irreversible (Fig. 26-15). Thus, diastolic heart failure can be diagnosed in symptomatic patients with normal LV size and ejection fraction and evidence for abnormal relaxation, diminished compliance, and increased LV diastolic filling pressure.[16]

Cardiac amyloid exemplifies the changes in cardiac architecture, LV diastolic function, and preservation of systolic function until late in the course of the disease. The LV cavity is typically normal size, and wall thickness is moderately to severely increased by deposition of noncontractile amyloid protein (immunoglobulin light chains) in the myocardial interstitium between the myofilaments. This protein deposition alters the material properties of the myocardium and causes increased chamber stiffness and abnormal mitral inflow velocity pattern consistent with restrictive physiology. The deceleration time is dramatically shortened, and the A wave of the mitral inflow is abbreviated and of low amplitude. The duration of the E wave deceleration time in cardiac amyloid is strongly predictive of clinical outcome.[20] In addition, the pulmonary venous velocity spectra show attenuation of the systolic wave. Marked reduction in the E′ wave of the mitral annulus is usually seen in the septum and in the lateral wall. These abnormal Doppler echocardiographic findings progress from the time of diagnosis to the restrictive physiology in the final stages of the disease (see Fig. 26-15).

Hypertrophic cardiomyopathy may present with classic symptoms of heart failure with supranormal systolic function and an ejection fraction of more than 70%. The LV cavity is small or normal with severe LV hypertrophy and asymmetric septal hypertrophy (see Chapter 27) or concentric hypertrophy typical of concentric remodeling. In cases with resting LV outflow tract obstruction, two echocardiographic features assist in diagnosis. Systolic anterior motion of the mitral valve narrows the LV outflow tract. The site of obstruction is shown by the onset of flow acceleration with color flow Doppler scan (see Chapter 27). Of note, diastolic septal thickness of more than 3.0 cm is associated with increased risk of sudden death and is one of the criteria for internal cardiac defibrillator placement. The second echocardiographic finding is the early systolic closure of the aortic valve that occurs at the end of ejection but may happen within the first half of systole. The peak and mean systolic LV outflow tract gradients should be measured at rest and after Valsalva's maneuver or isometric exercise (i.e., hand grip that usually increases the gradients to more than their resting values).

Ischemic cardiomyopathy can be detected with echocardiography because of: (1) the enlarged LV cavity; (2) the ejection fraction of less than 40%; (3) regional wall motion abnormalities; (4) loss of the normal uniform wall thickness; and (5) the near ubiquitous presence of MR.

## Echocardiographic Diagnosis of Right Heart Failure

### ACUTE RIGHT VENTRICULAR HEART FAILURE

Acute right heart failure and RV remodeling may occur over hours as compared with the time course of weeks to months in chronic RV failure. A sudden increase in RV afterload from a major pulmonary embolus causes acute RV dilation and usually severe reduction in systolic contractile function with hemodynamic compromise. This constellation of findings can be shown with Doppler echocardiography and the pathoetiologic mechanism ascertained (Fig. 26-16). Occasionally, mobile thrombus can be seen in transit through the right heart chambers or in the proximal pulmonary arteries (Fig. 26-17) with transthoracic or transesophageal echocardiography. RV function in major pulmonary embolism is severely depressed globally but usually recovers if reperfusion of the pulmonary circulation is reestablished and the increased load is rapidly attenuated with thrombolytic therapy, intravenous high-dose heparin, or acute surgical pulmonary arterial thrombectomy.

Acute RV dilation is associated with mild to moderate tricuspid regurgitation from disruption of the normal tricuspid valve geometry as a result of RV dilation. Pulmonary arterial systolic pressure can be estimated with the modified Bernoulli's formula ($4 \times$ peak [tricuspid regurgitation jet velocity]$^2$ + right atrial pressure). Right atrial pressure can be estimated from the degree of inferior vena cava collapse during normal respiration. The increase in pulmonary arterial systolic pressure is moderate rather than severe and characteristically does not exceed 55 mm Hg. Doppler echocardiography shows the time-dependent changes in RV remodeling in right heart systolic failure, the degree of secondary pulmonary hypertension, and often the pathoetiology of the RV failure.

Isolated RV infarction is a relatively rare cause of acute right heart failure that is important to recognize early and

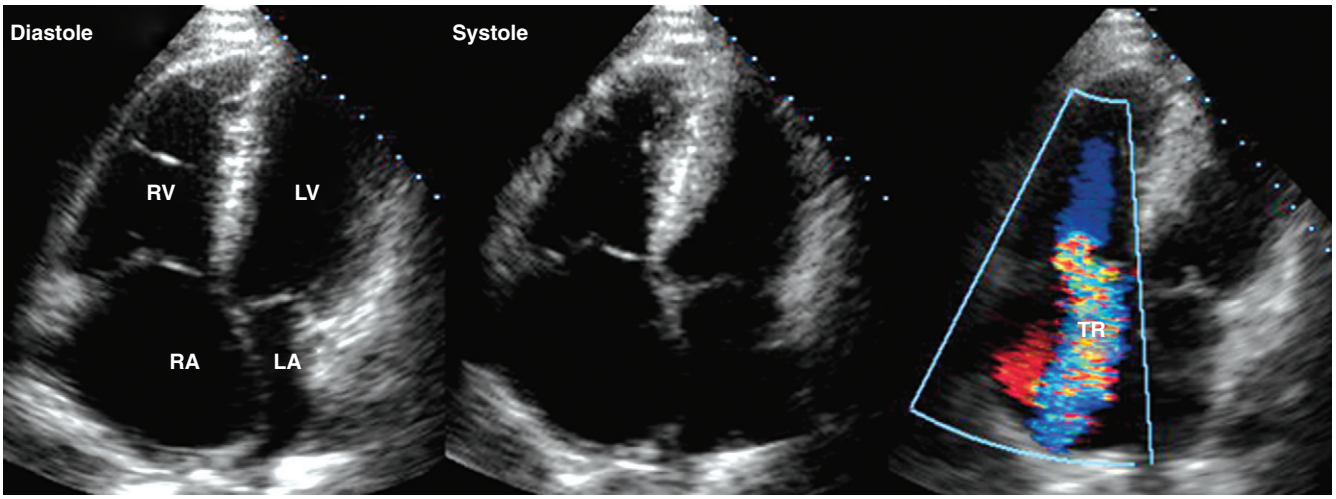

**Figure 26-16 Acute RV failure.** Transthoracic echocardiogram of the four-chamber view from a patient with acute RV strain at end-diastole (*left*) that shows a dilated overloaded RV. The RA is also dilated, and the interatrial septum bulges to the left at end systole (*center*). Color flow Doppler scan (*right*) shows severe tricuspid regurgitation (*TR*).

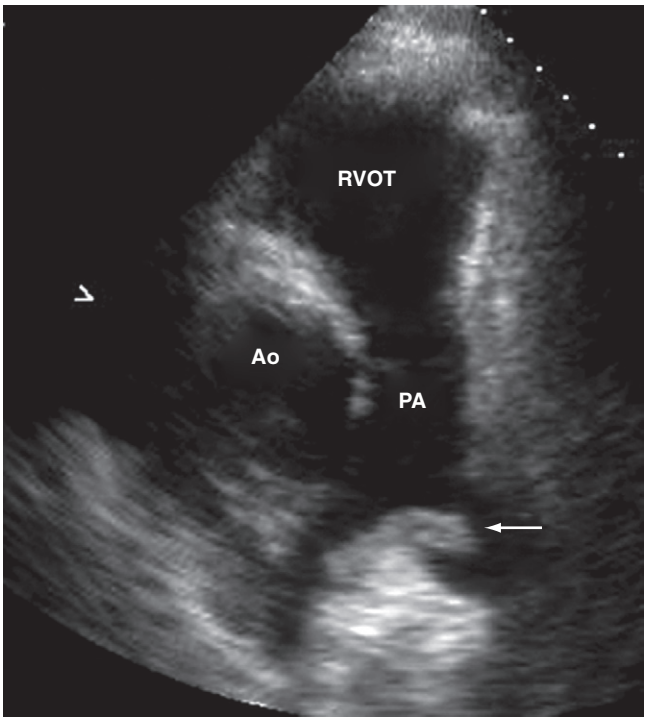

**Figure 26-17 Pulmonary embolus.** Transthoracic echocardiogram shows the main pulmonary artery in long-axis view and the bifurcation across which was a moderately large saddle embolus (*white arrow*).

begin treatment with intravenous fluid resuscitation and coronary reperfusion. The echocardiographic hallmark for diagnosis of RV infarction is unequivocal evidence of RV segmental wall motion abnormality. Usually, RV infarction is an extension of an inferoposterior LV MI as a result of proximal occlusion of a dominant right coronary artery (Fig. 26-18).

## CHRONIC RIGHT HEART FAILURE

In chronic systolic right heart failure, the RV dilates in response to chronically increased loading conditions when hypertrophy can no longer normalize the increase in wall stress. RV hypertrophy may be concentric or eccentric depending on whether the stimulus is pressure or volume overload. As the loading conditions increase, the interventricular septum bulges into the LV outflow tract and the RV shape changes to a more spherical configuration (see Chapter 33). RV diastolic pressure exceeds that in the LV and may result in abnormal LV diastolic filling and intracardiac shunting from right to left if a patent foramen ovale is present. Tricuspid regurgitation develops as the tricuspid subvalve geometry is disrupted by chamber dilation and accelerates the deterioration in RV function with progressive enlargement of the right atrium. As RV failure progresses, the RV continues to enlarge until it forms the apex of the heart. Echocardiographic measurements of RV end-systolic dimension and percent fractional area change in the apical four-chamber or subcostal four-chamber views are important predictors of adverse cardiovascular events.[21]

The configuration and internal architecture of the RV is not designed to generate chronically elevated systolic pressures. When RV systolic pressure exceeds 40 mm Hg, tricuspid regurgitation supervenes, which is associated with further RV dilation, such that a vicious cycle occurs that culminates in right heart failure. Echocardiography plays a key role not only in detection of right heart failure but also in differentiation of acute from chronic right heart failure in terms of LV cavity architecture and function.

Recently, echocardiographic measurements of the tricuspid annulus peak systolic excursion that reflect RV long-axis shortening have been shown to correlate with RV ejection function and predict clinical outcome.[22]

## RIGHT VENTRICULAR REMODELING TO HEART FAILURE

Until recently, few attempts were made to study RV remodeling because the unusual RV architecture cannot be represented by a simple or compound geometric algorithm that enables reproducible assessment of RV volumes and RV ejection fraction. Right ventricular remodeling is usually triggered by LV disease transmitted to the right heart chambers via the pulmonary venous circulation. The pulmonary arterioles react to chronic pressure and volume overload by developing medial hypertrophy that increases pulmonary vascular resistance and in turn

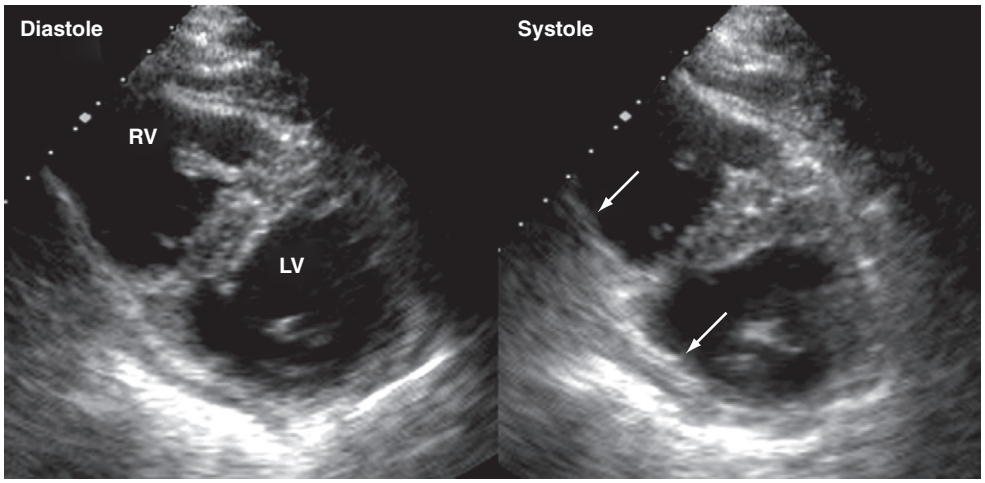

**Figure 26-18 RV infarction.** Parasternal LV short-axis view of a patient with a RV myocardial infarction in diastole (*left*) and in systole (*right*). Contiguous posterior infarction with RV involvement is seen (*white arrows*).

results in pulmonary arterial hypertension. Pulmonary hypertension induces RV hypertrophy that may temporarily normalize RV loading conditions and preserve near-normal RV cavity geometry and function for a prolonged period of time. However, unchecked RV afterload excess from chronic pulmonary hypertension causes progressive RV remodeling with dilation and hypertrophy in similar fashion to that which occurs in the LV (see Chapter 33).

## Echocardiography in Pharmacologic Therapy for Heart Failure

The primary aims in the treatment of chronic systolic heart failure are to provide symptomatic relief, improve quality of life, and ideally increase longevity. These aims may be achieved in part with prevention of progressive LV dilation, promotion of reverse remodeling, and improvement in ventricular function. Doppler echocardiography is the ideal method for tracking longitudinal changes in LV volume, shape, and function that result from treatment interventions. This technique has been used successfully in numerous prospective randomized chronic heart failure trials. New advanced technology with speckle tracking of the myocardium has provided a method for assessment of longitudinal, radial, and circumferential regional and global strain. Strain provides incremental information about myocardial function over and above that of LV volumes and LV ejection fraction.

### PHARMACOLOGIC THERAPY

Contemporary management of acute heart failure involves three fundamental principles. The first is aimed at maintenance of a normal blood pressure for organ perfusion with an increase in contractile performance (myocardial systolic shortening) with intravenous catecholamines in patients with hemodynamic compromise. The second medical strategy is reduction of LV loading conditions with vasodilator therapy. The third medical treatment strategy involves blocking neurohormonal activation with β-adrenergic receptor blockers plus angiotensin receptor blockers or angiotensin-converting enzyme inhibitors in combination with aldosterone antagonists.

Echocardiography has played a pivotal role in showing the efficacy of pharmacologic interventions and identifying individuals at increased risk for major complications in several randomized clinical trials. Echocardiography has clearly shown that serious adverse cardiovascular events, namely recurrent infarction, heart failure exacerbation, ventricular arrhythmias, and death, predominate in patients with progressive LV dilation.[23,24]

Serial echocardiography in patients with acute heart failure after MI provides unique information that is unattainable routinely with any other imaging technique and allows early risk stratification for optimization of individualized therapy. Numerous clinical post-MI and heart failure trials have shown that echocardiographic measurements of LV volumes, ejection fraction, and infarct size and RV systolic shortening predict clinical outcome (Fig. 26-19).[24-26] The prevalence of these adverse cardiovascular events increases directly with LV dilation assessed with echocardiography. Prevention of LV dilation and remodeling with angiotensin-converting enzyme inhibitors reduces the recurrence rate of heart failure. Echocardiographically determined LV volumes and percentage changes in systolic cavity area are powerful predictors of ventricular arrhythmias from the early postinfarction period through the 2-year follow-up (see Fig. 26-19).[21]

Serial echocardiographic measurements of LV size and function have shown the efficacy of angiotensin-converting enzyme inhibitors in infarct-related heart failure that is mediated through attenuating LV dilation by structural and functional reverse remodeling and blocking the neurohormonal activation.[23-26] Logistic regression analysis of baseline demographics for predictors of survival in post-MI and heart failure trials showed that echocardiographic LV end-systolic size was the most powerful predictor of survival after MI, even more than ejection fraction.[24] Similar randomized controlled trials of β-adrenergic receptor blocking agents in chronic systolic heart failure have used quantitative echocardiography to document efficacy.

## Echocardiography for Mechanical Therapies in Heart Failure

Surgical treatment has an important role in the management of acute heart failure and, similar to medical treatment, is based on two strategies. The first strategy is augmentation of cardiac output either with intraaortic balloon counterpulsation, LV or

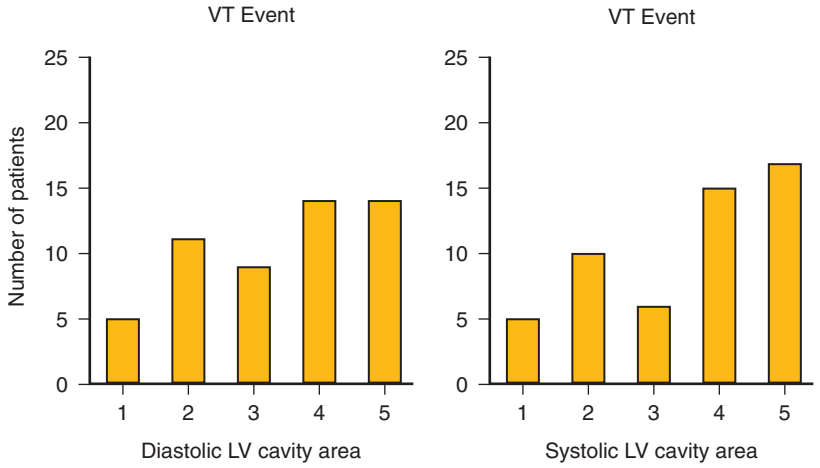

**Figure 26-19 Ventricular tachycardia after myocardial infarction.** A strong relationship is shown between LV size in diastole (*left*) and in systole (*right*) and ventricular tachycardia early after myocardial infarction. The same robust relationship was present at 2 years after myocardial infarction. *(From unpublished data.)*

RV assist device (Fig. 26-20), or acute heart transplantation. The second strategy is reduction of the acute elevation in LV loading conditions from MR with mitral valve repair or replacement and with aortic valve replacement for heart failure from acute or chronic severe valvular regurgitation.

## INTRAAORTIC COUNTERPULSATION

No randomized clinical trials with Doppler echocardiography have assessed the efficacy of intraaortic balloon counterpulsation in acute heart failure after MI where echocardiographic assessment was a primary or secondary endpoint. However, Doppler echocardiographic assessment of cardiac output is used routinely to measure the impact of intraaortic balloon counterpulsation on LV volumes, ejection fraction, and cardiac output. Forward stroke volume can be estimated as the product of the cross-sectional area of the flow stream and the time-velocity integral recorded from the LV outflow tract. Reliable Doppler echocardiographic measurements are critically important before and immediately after deployment of an intraaortic balloon counterpulsation and also during weaning from intraaortic balloon counterpulsation support, as the counterpulsation–to–native heart ratio is downgraded from 1:1 to 1:2 and 1:3. When cardiac output remains stable, withdrawal of intraaortic balloon counterpulsation can be achieved safely.

## VENTRICULAR ASSIST DEVICES

Placement of LV assist devices (LVAD) for severe acute heart failure or acute hemodynamic decompensation of chronic heart failure is becoming increasingly frequent.[27] Echocardiographic screening for significant aortic regurgitation and LV apical thrombus before insertion is important to avoid systemic embolization during insertion of the LV cannula. After insertion of a LVAD, which may provide pulsatile or nonpulsatile flow, the presettings of the LVAD pump are routinely evaluated with Doppler echocardiography over a range of flows. LV output is assessed by aligning the continuous wave Doppler scan parallel with the direction of blood flow through the sump drain at the LV apex. Stroke output is calculated as the product of the time-velocity integral and the cross-sectional area of the outlet cannula (see Fig. 26-20). Doppler echocardiographic assessment of LV outputs is reliable and correlates closely with LVAD flow rates. When divergence is found between the two estimates of flow, the Doppler flow is invariably lower; but if this occurs across a range of flow settings, it suggests partial obstruction of the LV outlet by thrombus either within or protruding into the LV apical cannula (Fig. 26-21).[28] Partial occlusion of the LV outlet cannula by either apical thrombus or myocardial trabeculations is identified by the presence of flow acceleration with color flow Doppler scan and a large systolic gradient across the LV apical outflow cannula (see Fig. 26-20). Recently, long-term or so-called destination LVAD therapy has been instituted for patients who need obligatory mechanical support and are not suitable candidates for orthotopic heart transplantation. These patients need regular corroboration between the pump flows and Doppler echocardiographic estimates of flow.

## SURGICAL VALVE REPAIR OR REPLACEMENT

Other surgical interventions for acute heart failure aim for reduction in systolic loading conditions, including mitral valve repair or replacement for acute severe MR after chordal rupture that results in a flail leaflet or papillary muscle rupture after MI. Similar reduction in afterload is the aim in patients with acute severe aortic regurgitation either from aortic valve endocarditis or from acute type A aortic dissection. In addition to establishing these individual diagnoses with either transthoracic or transesophageal assessment, baseline echocardiographic ejection fraction and LV size are the major determinants of survival and clinical outcome. Furthermore, Doppler echocardiography has been used to compare LV architecture (LV volume and mass) and function (ejection fraction) before and after surgery to determine whether any favorable structural changes have occurred that might explain the symptomatic improvement that occurs after successful surgery.

## CARDIAC RESYNCHRONIZATION THERAPY

Cardiac resynchronization therapy is a newly established therapy for patients with New York Heart Association symptom class II through IV heart failure, a prolonged QRS duration (more than 120 ms), and LV dyssynchrony. Prolonged QRS duration occurs in 30% to 50% of patients with heart failure and correlates directly with mortality.[29] The specific aim of CRT in heart failure is to alleviate symptoms and promote structural and functional reverse LV remodeling. This result is achieved with optimizing atrioventricular conduction,

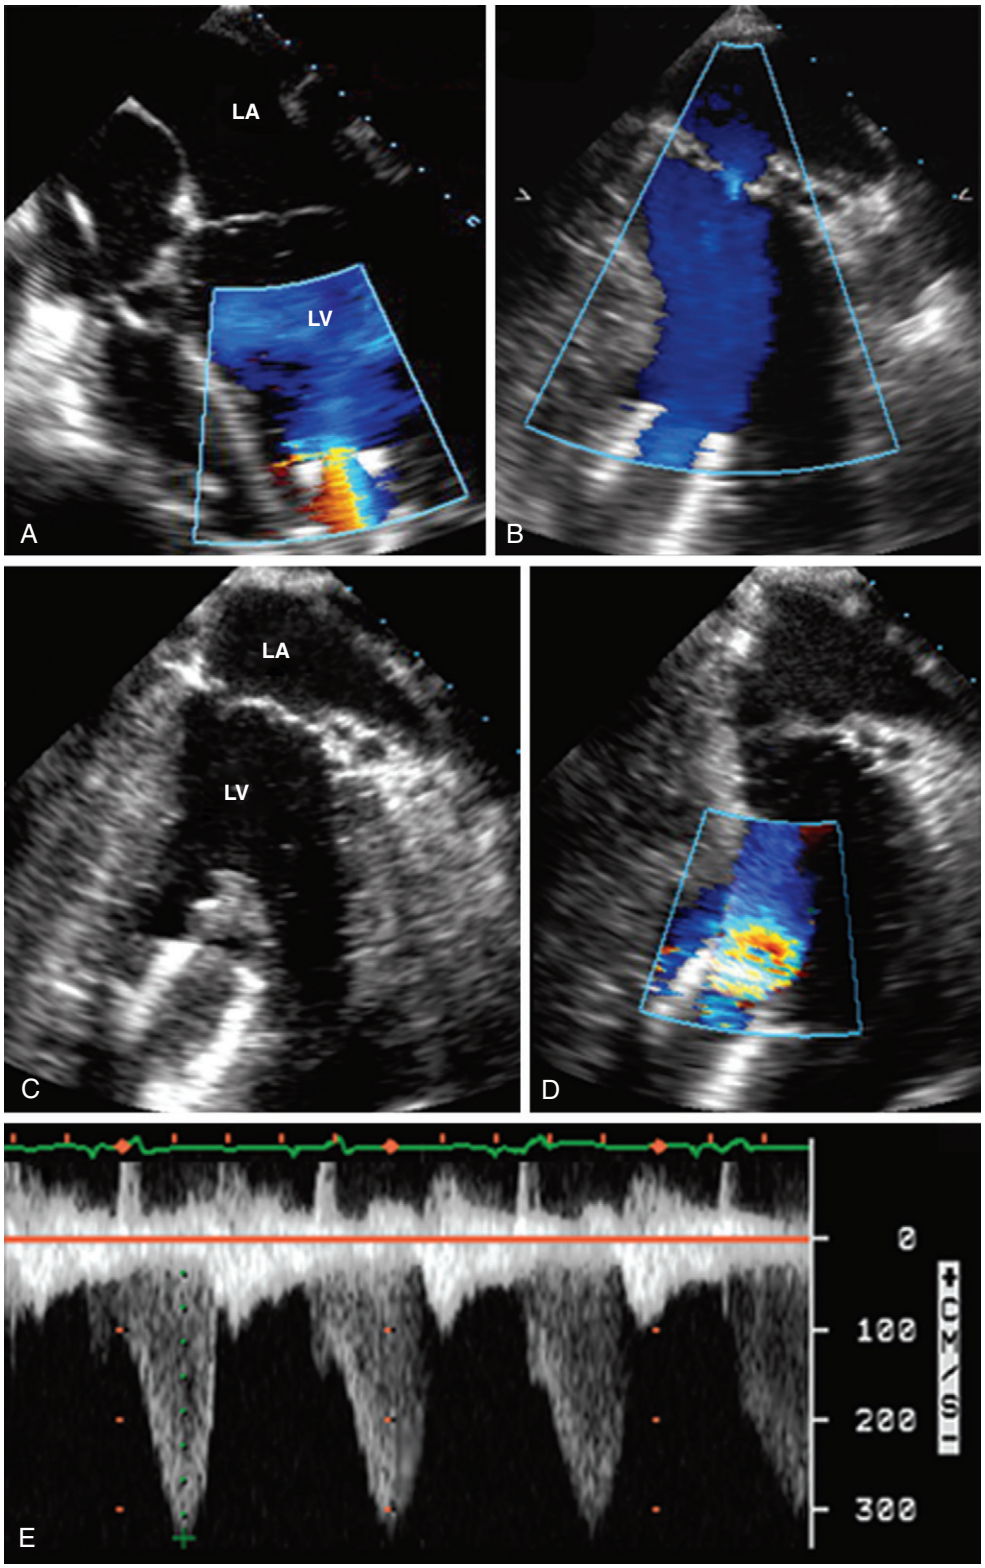

**Figure 26-20 Transesophageal echocardiogram of a patient with LV assist device.** The cannula is seen at the LV apex (**A** and **B**). A thrombus can be seen in the LV assist device cannula with color flow Doppler scan that shows obstruction (**C** and **D**). A systolic gradient was detected across the sump drain at the LV apex, corroborating the gradient obtained previously (**E**).

prolonging LV filling time, and synchronizing RV and LV contraction by minimizing interventricular and intraventricular mechanical delay.

Symptomatic benefit and improved exercise capacity have been consistent findings in CRT trials in most patients (65%)[30-36] already undergoing optimal medical heart failure therapy. Doppler echocardiography has played a crucial role in elucidating the mechanism of structural and functional LV reverse remodeling with CRT. Doppler echocardiography has also been used in an attempt to identify the 60% to 70% of

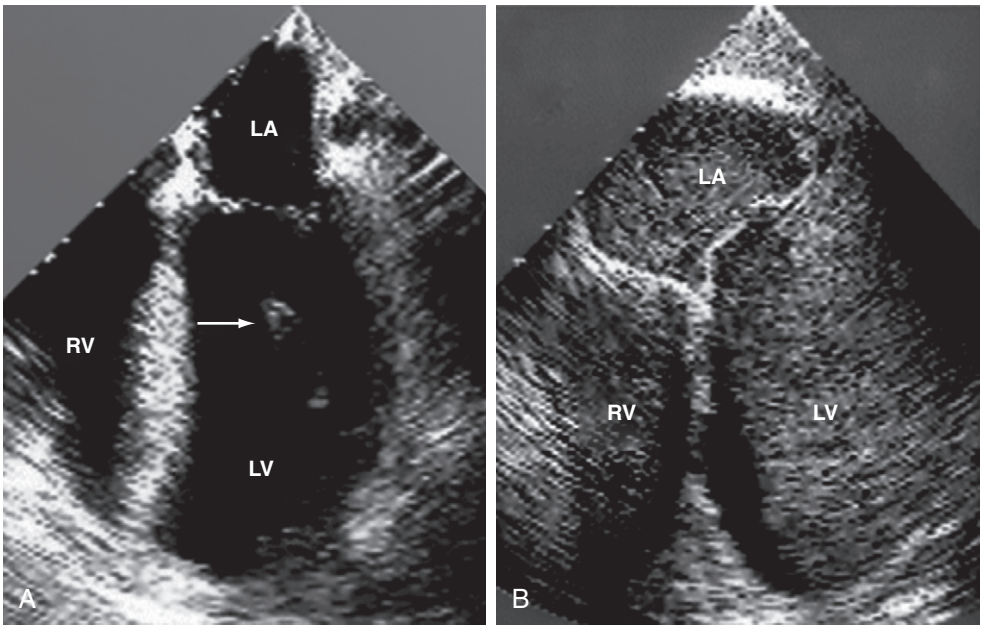

**Figure 26-21 Refractory right heart failure occurred 3 days after LV assist device placement.** At baseline, post device deployment was unremarkable except for a small mobile thrombus (**A**). On day 3, an emergency echocardiogram was performed that showed almost complete cardiac thrombosis from which the patient sustained a stroke and died soon after (**B**).

patients that are likely to respond to CRT before device implantation. The PROSPECT trial used advanced Doppler echocardiographic technology with the specific aim of discovering which Doppler echocardiographic parameter reliably identified patients with heart failure who have an optimal response to CRT before device implantation.[37] This trial failed to show that any single Doppler echocardiographic measurement predicted response to CRT. This negative PROSPECT trial resulted in a major loss of confidence in Doppler echocardiography by electrophysiologists. However, a number of recent studies have shown that the major reasons for the lack of response in 30% of patients with heart failure have been attributed to inappropriate LV lead position, the absence of dyssynchrony, or both of these factors. Of note, nonresponders to CRT, when treated aggressively with programmed medical therapy, achieved the same degree of symptomatic improvement and reverse remodeling as did the positive responders.[38] Internal cardiac defibrillator together with CRT affords additional survival benefit[35,39,40] by protecting against sudden death from ventricular arrhythmias.

Recently, large CRT trials[37-41] have used serial Doppler echocardiography to characterize LV structural and functional reverse remodeling and have shown for how long reverse remodeling is sustained. Most of these trials used echocardiographic assessment of LV end-diastolic and end-systolic diameters or LV volumes as secondary endpoints and showed that CRT results in significant decrease as early as 1 month[42,43] compared with control. Further reduction in LV volumes occurs by 6 months (Fig. 26-22), and these changes are sustained for at least 18 months[39-41] and potentially as long as 44 months when data are available from MADIT-CRT, RAFT, and REVERSE extension trials. The reduction in LV volumes with CRT results in a decrease in LV wall stress, which is a powerful stimulus for regression of LV mass. The decrease in LV mass was significant by 6 months but occurred at a slower rate than the reduction in LV volume.

Serial echocardiographic studies have shown that the sustained reductions in LV volume and mass with CRT result in alterations in LV architecture and restoration of mitral annular and subvalve geometry towards normal. Changes in the geometry of the mitral valve apparatus are associated with decreased MR. The severity of MR decreased significantly by 3 months and was maintained at 6 and 12 months (see Fig. 26-22). The favorable changes in LV load and architecture, together with the decrease in MR, are associated with progressive increase in LV ejection fraction at 3 and 6 months from baseline (see Fig. 26-22). Continuous CRT is required to sustain reverse LV remodeling.[44]

### *Changes in Diastolic Ventricular Function with Cardiac Resynchronization Therapy*

Cardiac resynchronization therapy studies have been conducted almost exclusively in patients with advanced systolic heart failure, but Doppler echocardiography has shown concomitant improvements in diastolic function.[43] CRT prolongs the duration of LV filling, separates the rapid filling phase from atrial systolic contraction, shortens interventricular mechanical delay, and coordinates regional and global ventricular contraction and relaxation. The prolonged LV diastolic filling time induced by CRT is not associated with changes in transmitral peak flow velocities during passive filling (E wave), during atrial contraction (peak A wave), the E/A ratio, or isovolumic relaxation time. The E wave deceleration time and the myocardial performance index improve by 3 months and improve further by 12 months.[43] However, patients with restrictive LV filling characterized by a short deceleration time and peak E wave velocity of more than 1.0 m/s exhibit little or no response to CRT.

Historically, exercise capacity in systolic heart failure has not correlated with changes in LV volume or ejection fraction. However, in the MIRACLE trial, the symptomatic benefits associated with CRT occurred predominantly in those patients with the greatest structural and functional LV remodeling.[30]

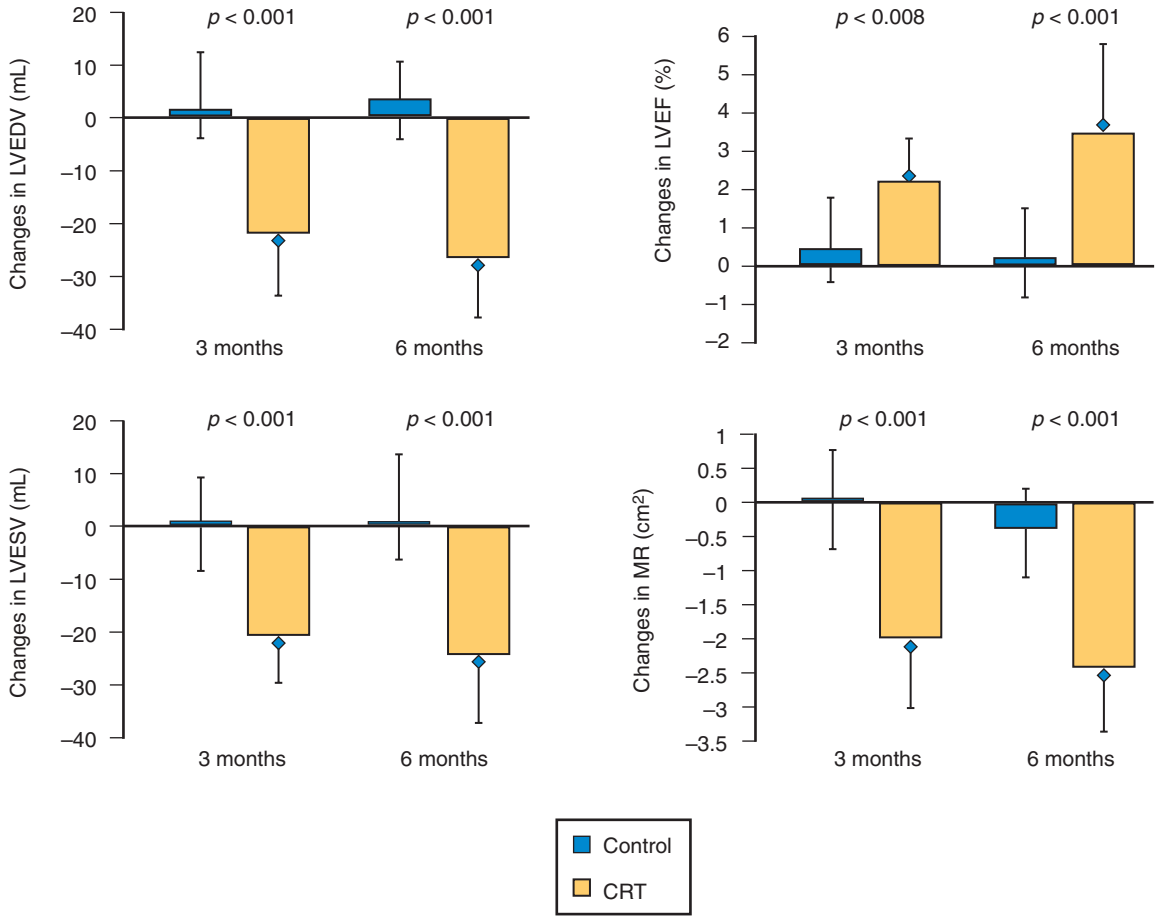

**Figure 26-22 Median changes in LV end-diastolic and end-systolic ventricular volumes, ejection fraction, and severity of mitral regurgitation.** All improved with cardiac resynchronization therapy as compared with optimized heart failure treatment at 3 and 6 months. *(With permission from St. John Sutton MG, Lee D, Rouleau JL, et al: Left ventricular remodeling and ventricular arrhythmias after myocardial infarction.* Circulation *107:2577-2582, 2003.)*

### *Responders and Nonresponders to Resynchronization Therapy*

The proportion of patients with New York Heart Association III/IV heart failure who respond to CRT (60% to 65%) by exhibiting LV reverse remodeling measured with Doppler echocardiography and symptomatic improvement is similar in patients with ischemic and nonischemic heart failure. Reduction in LV volumes and severity of MR and increase in LV ejection fraction are consistently two to three times greater in nonischemic than ischemic heart failure.[44,45] However, in spite of the two-fold to three-fold difference in LV volume reduction in the nonischemic cases at 6 months, both ischemic and nonischemic heart failure have similar improvement in symptoms and exercise capacity.

### *Predictors of Optimal Response to Resynchronization Therapy*

Between 60% and 70% of all patients for CRT exhibit reverse LV remodeling shown with echocardiography. The reasons for this short fall are not clear even 10 years after use was approved by the U.S. Food and Drug Administration. No baseline clinical demographics distinguish responders from nonresponders to CRT or predict an optimal response before device implantation. A number of possible mechanisms have been proposed. One theory is suboptimal placement of the RV or LV electrodes, especially in ischemic heart failure when myocardial scar may be subjacent to the LV electrode or when electrode placement is constrained by the anatomy of the coronary sinus. Prolonged QRS duration has been used as a surrogate for LV dyssynchrony even though the coefficient of correlation is weak ($r = 0.26$).[46-48] The presence of LV mechanical dyssynchrony is a prerequisite for optimal response to CRT, without which there is no substrate for improvement. However, prolonged QRS, and not ventricular dyssynchrony, is a guideline for use of CRT.

## NEW TECHNIQUES FOR DETECTION OF LEFT VENTRICULAR DYSSYNCHRONY

New advanced noninvasive imaging technology has recently been introduced for detection and semiquantification of regional (spatial) and temporal LV mechanical dyssynchrony or incoordinate contraction for identification of responders to CRT before device placement. Baseline clinical demographics, QRS duration, and echocardiographic measures of LV size or end-systolic volume, which are normally powerful predictors of clinical outcome, do not reliably predict response to CRT. What appears to be fundamental for a positive response to CRT is the presence of regional and global LV dyssynchrony that is associated with delayed electrical activation (prolonged QRS).

In the healthy heart, electrical activation results in synchronous long-axis and short-axis contraction. The concentric

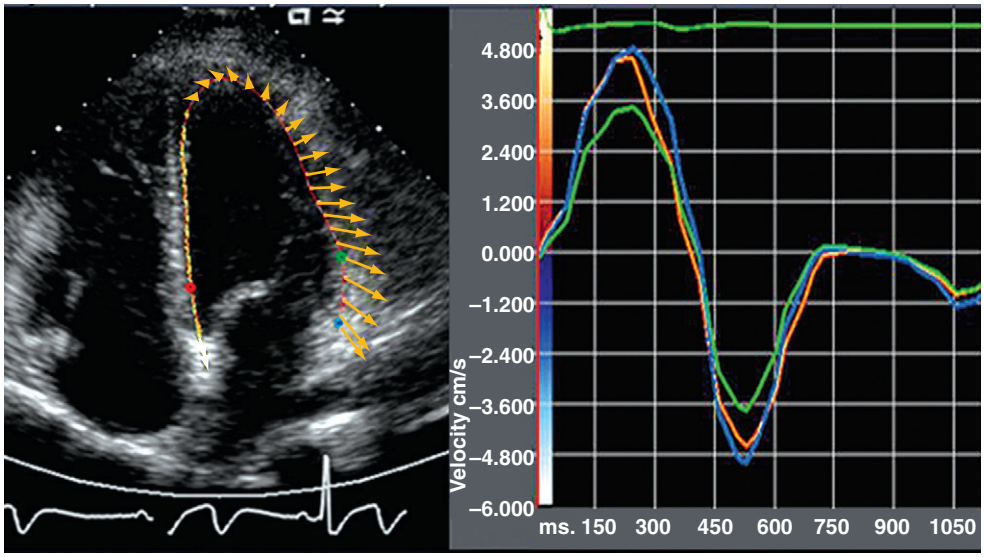

**Figure 26-23 Myocardial tracking in the four-chamber view from a healthy subject.** The continuous velocities of all LV segments should be aligned in time at the acme, the zero crossing point, and the nadir, indicating that the opposing walls in healthy subjects are completely synchronous.

inward wall motion can be appreciated visually in 2D and 3D echocardiograms of LV short-axis and LV apical four-chamber and two-chamber echocardiograms. Alternatively, myocardium can be tracked with velocity vector imaging or speckle tracking techniques (Fig. 26-23). LV dyssynchrony is the result of premature regional contraction before ejection or delayed regional contraction that stretches already contracting myocardium and thereby disrupts the normal coordinated sequence of activation and contraction that results in reduction in ejection fraction. The time interval between maximal posterior excursion of the septum and peak anterior excursion of the posterior LV wall with M-mode echocardiography LV wall has been used to identify dyssynchrony defined as a time delay of more than 130 ms.[49] This method is restricted to two opposing walls of the LV, and measurement of this time delay may not be possible when the septum is infarcted and does not thicken or move posteriorly. Several Doppler echocardiographic methodologies have been advocated for the diagnosis of dyssynchrony.

One of the most frequently used TDI methods for detection of LV dyssynchrony is measurement of the time interval from the onset of the QRS to the peak myocardial longitudinal systolic velocities in the basal and middle wall segments of opposing walls from the apical four-chamber, apical two-chamber, and apical long-axis views with color-coded or pulsed TDI (see Fig. 26-14). A delay in the time from the QRS to the peak velocity between segments in opposing walls of more than 65 ms is evidence for LV dyssynchrony and moreover predicts a favorable response to CRT. A more comprehensive assessment of LV dyssynchrony is the mechanical dyssynchrony index, which requires measurement of all six basal and middle segments in the three apical views and computation of the standard deviation of the time to peak systolic myocardial velocity that occurs during LV ejection. LV dyssynchrony can be detected throughout the LV as regional variation in the relative timing of contraction and automated time to peak velocities registered on the 2D echocardiographic images as color-coded overlays. This technique is commercially available and known as tissue synchronization imaging. These parameters are more robust estimates of LV dyssynchrony than measurement of the QRS duration, which has been used erroneously as a surrogate for dyssynchrony.

Regional deformation or strain defined as change in length through the cardiac cycle expressed as a ratio of resting length can be computed in the LV short axis (radial strain) and in the LV long axis (longitudinal strain) with speckle tracking techniques (Figs. 26-24 and 26-25). This can be used to detect LV dyssynchrony as delay in time to peak strain. These values can be displayed in simple graphics that enable dyssynchrony to be recognized. The topographic representation of dyssynchrony (see Figs. 26-14, 26-24, and 26-25) in terms of longitudinal and radial strain can be displayed in the format of a polar map. Speckle tracking of the myocardium and velocity vector imaging of the myocardium enable recording from multiple regions of myocardium simultaneously and analysis of timing of peak myocardial velocities (see Fig. 26-23). Strain rate imaging has thus far been disappointing as a measure of dyssynchrony on account of its limited reproducibility.

Real-time 3D echocardiography with the conventional 16-segment or 17-segment models of the LV can show LV dyssynchrony as regional variation in the timing of acquisition of minimal systolic and maximal diastolic volumes for each of the segments (Fig. 26-26). In addition, after resynchronization therapy, restoration of coordinated contraction occurs with minimal differences in the timing of onset of contraction and peak shortening among the 16 or 17 segments. Myocardial velocity information from real-time 3D echocardiography can also be displayed in a polar map format of the 16 or 17 LV segments, which when color-coded for time, provides a velocity map in real time that enables dyssynchrony to be easily identified visually (Fig. 26-27).

## HEART TRANSPLANTATION

Orthotopic heart transplantation is performed in patients with chronic and occasionally acute heart failure, which is refractory to medical therapy in approximately 2000 patients annually in

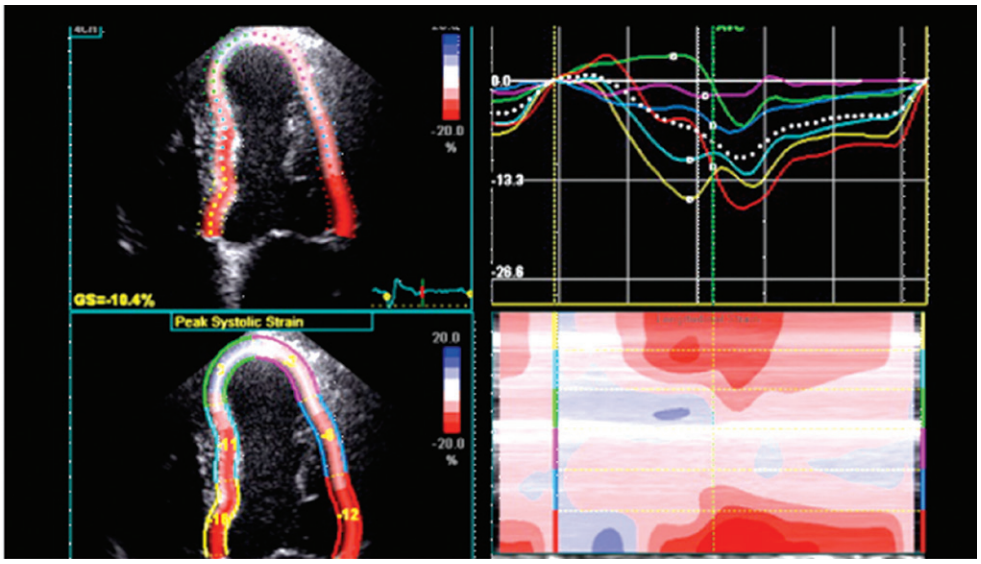

**Figure 26-24 Speckle tracking in the apical four-chamber view to measure global longitudinal strain and regional longitudinal strain from four myocardial segments from a patient with ischemic cardiomyopathy.** The two important findings are: first, the close time relations in acquisition of peak longitudinal strain from each segment is lost, suggesting the presence of ventricular dyssynchrony; and second, the magnitude of peak longitudinal by all segments is low and corroborated by the continuous recording of global strain. Compare with the normal tracing shown in Figure 26-13.

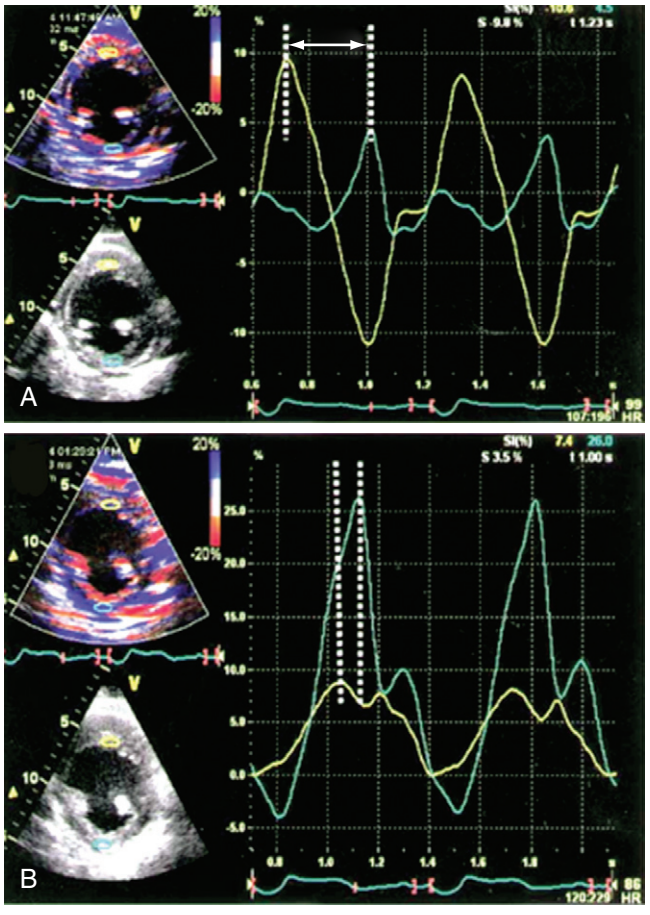

**Figure 26-25 A,** Radial strain imaging in a patient with ventricular dyssynchrony and a favorable response to cardiac resynchronization therapy. At baseline, the anterior septum had early peak strain development coincident with aortic valve opening (*AVO*), and the posterior wall development of peak radial strain occurred late coincident with aortic valve closure (*white arrows*) consistent with severe dyssynchrony. **B,** Time-strain plots after cardiac resynchronization therapy showed immediate improvement in the close time relations between peak strain developed by the same two myocardial walls, indicating immediate improvement in dyssynchrony. *(From Dohi K, Suffoletto MS, Schwartzman D, et al: Utility of echocardiographic radial strain imaging to quantify left ventricular dyssynchrony and predict acute response to cardiac resynchronization therapy.* Am J Cardiol *96:112-116, 2005.)*

the United States. This number of heart transplants has not increased in the last 5 years nationwide because of the scarcity of donors, the logistics and expense of organ procurement, and the subsequent immunosuppression therapy. Doppler echocardiography plays an important role in heart transplantation. The first role is in assessment of the donor heart for global and regional function and exclusion of all pathology. Second, after transplantation, Doppler echocardiography is used in the early postoperative period in all patients, especially those in whom early complications develop from rejection or severe pump failure and who need LVAD placement. The dramatic temporal and spatial changes in LV and RV structure and function in the transplanted heart have been well characterized with Doppler echocardiography[50] and are described in the chapter on heart transplantation (see Chapter 30).

## Summary

Recent advances in Doppler echocardiographic imaging have provided new insights into patient selection for novel heart failure therapies. LV volumes and ejection fraction can be computed and have proved to be powerful predictors of clinical outcomes in heart failure. The introduction of speckle tracking enables temporal and spatial quantification of regional and global myocardial strain that can be displayed as a polar map, and allows instantaneous visual recognition of the topography of abnormal longitudinal and radial strain distribution throughout the LV. CRT is now recognized as effective treatment in patients deemed refractory to traditional heart failure, although no significant benefit of CRT occurs in 30% of patients.

Current ongoing randomized CRT trials suggest that nonresponders to CRT with or without prolonged QRS duration have little or no ventricular dyssynchrony and have the worst prognosis.

Similar to surgical interventions and devices, pharmacologic agents are needed to do more than provide symptomatic relief by preventing development of heart failure and reversing rather than just attenuating the remodeling process. The efficacy and monitoring of new therapies are assessed by 2D and 3D echocardiographic imaging and quantitative Doppler echocardiography.

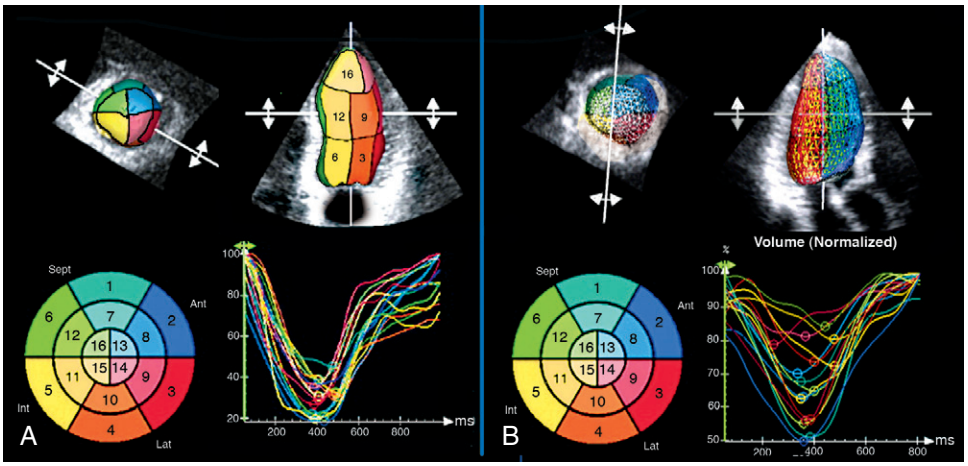

**Figure 26-26** **A,** Real-time 3D echocardiogram recordings from the apex enable the heart to be segmented with either a 16-segment or 17-segment model with continuous time-volume curves from each myocardial segment. In a normal heart, the minimal/end-systolic volumes from each segment occur at the same time (*bottom right*). **B,** By comparison with the normal heart in **A,** major differences in time of minimal/end-systolic volume for each segment (*bottom right*) are consistent with major dyssynchrony that is likely to improve with cardiac resynchronization therapy.

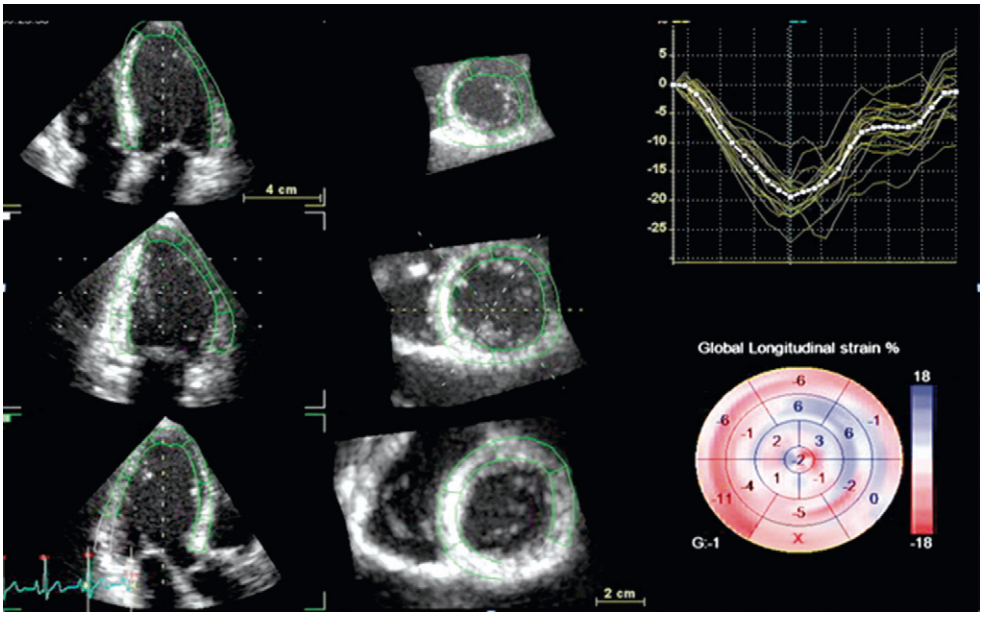

**Figure 26-27** Real-time 3D echocardiogram with speckle tracking provides instantaneous time-longitudinal strain plots for each segment and for global strain. The timing of peak strain enables dyssynchrony to be recognized and enables identification of patients likely to benefit from cardiac resynchronization therapy.

## KEY POINTS

- Echocardiography is the single most useful diagnostic test in evaluation of patients with heart failure.
- In chronic systolic heart failure, LV remodeling leads to a change in cavity shape because of the greater increase in the short-axis diameter than in LV long-axis diameter. As a result, the LV loses its ellipsoidal shape and becomes more spherical. LV shape is a predictor of clinical outcome.
- The four important sequelae to the abnormal LV size and shape are:
  - Increase in LV loading conditions.
  - Decrease in contractile function.
  - Predisposition to thrombus formation.
  - Mitral regurgitation from enlargement of the mitral annulus and distortion of the mitral valve and subvalvular geometry.
- Echocardiography plays a vital role in the diagnosis of right-sided heart failure and differentiation of acute from chronic right-sided heart failure in terms of RV cavity architecture and function.
- CRT is an established therapy for patients with New York Heart Association II to IV heart failure, prolonged QRS duration (more than 130 ms), and LV dyssynchrony.
- CRT reverses LV remodeling by optimizing atrioventricular conduction, prolonging LV filling time, and synchronizing RV and LV contraction.
- CRT studies have been conducted almost exclusively in patients with advanced systolic heart failure, but Doppler echocardiography has consistently shown concomitant improvements in diastolic function.
- Only 60% to 65% of patients with heart failure and QRS duration of more than 130 ms respond to CRT therapy.
- LV mechanical dyssynchrony is a prerequisite for response to CRT. Prolonged QRS duration correlates poorly with dyssynchrony and may be absent despite prolonged QRS duration.
- Longitudinal and radial strain and the 3D echocardiographic regional volume estimations may prove more robust estimates of LV dyssynchrony than QRS duration.

- Outcomes Following Myectomy

**Comparison of Treatment Strategies for Obstructive Hypertrophic Cardiomyopathy**

Hypertrophic cardiomyopathy (HCM) has unique clinical, echocardiographic, and hemodynamic features.[1] Since the modern description of HCM five decades ago,[2,3] there have been significant advances in its diagnosis, the understanding of its complex pathophysiology, and the evolution of its management.[1] HCM is defined as a hypertrophied, nondilated left ventricle (LV) in the absence of another cardiac or systemic disease that is capable of producing the magnitude of wall thickening detected (Fig. 27-1).[4] Echocardiography has played a crucial role in determining the pathophysiology of HCM, quantitating its morphologic and hemodynamic severity, and assessing the acute and chronic responses to various therapies.[5]

Echocardiographic studies have also provided invaluable insight into the epidemiology,[6] inheritance,[7] and prognosis of HCM.[8,9] The ability to perform serial noninvasive studies makes echocardiography the modality of choice in the screening,[7,10] diagnosis,[4] and serial monitoring of patients with this condition. In recent years the role of echocardiography in this disorder has extended to intraprocedural decision making, with the use of intraoperative transesophageal echocardiography (TEE) during surgical myectomy[11] and the application of myocardial contrast echocardiography in the guidance of septal ethanol ablation.[12,13]

## Epidemiology

HCM was initially thought to be a rare disorder affecting young adults.[3] However, modern studies using echocardiography in the evaluation of subjects suggest a much higher prevalence of this condition. The Coronary Artery Risk Development in Adults (CARDIA) study, a prospective study of 4111 apparently healthy young adults from a general population, detected HCM by echocardiographic examination in 0.17% of subjects.[6] There was a similar prevalence of HCM in a large study of 33,735 young athletes undergoing preparticipation medical screening in Italy, with a total of 22 cases (0.07%) identified from this cohort.[10] The reported incidence of HCM has ranged from an incidence of 0.4 per 100,000 person-years from 1980 to 1981 in Western Denmark[14] to 2.5 per 100,000 person-years between the years 1975 and 1984 in Olmsted County, Minnesota.[15]

Recent studies of the incidence of HCM in children have reported an annual incidence of 0.42 per 100,000 in the United States[16] and 0.32 per 100,000 children in Australia.[17]

## Molecular Genetics

HCM is a genetic disorder with an autosomal dominant pattern of inheritance. This condition is thought to arise from a genetic defect involving one of the genes encoding proteins of the cardiac sarcomeric apparatus.[18,19] The initial genetic defect was described in the late 1980s, and since then more than 400 different mutations have been associated with HCM. Mutations in the genes encoding β-myosin heavy chain (*MYH7*) and myosin binding protein C (*MYBPC3*) account for 80% to 85% of cases with identified mutations in most series, with mutations in troponin T (*TNNT2*), troponin I (*TNNI3*), and α-tropomyosin (*TPM1*) comprising 10% to 15% of additional cases. These genes, along with the myosin light chains (*MYL2* and *MYL3*) and α-cardiac actin (*ACTC*), are the eight genes most commonly involved in HCM. Rarer genetic causes include mutations in α-myosin heavy chain (*MYH6*), titin (*TTN*), and cardiac troponin C (*TNNC1*). More recently, mutations in genes encoding the cardiac Z-disk proteins have been implicated in the pathogenesis of HCM.[20]

The extent to which the underlying genotype influences the phenotype of this condition remains unclear. Some studies have suggested that patients with *MYH7* mutations have a greater degree and an earlier onset of hypertrophy than those patients with non-*MYH7* defects.[21,22] No significant differences were found in the degree of hypertrophy among patients with different mutations of the *MYH7* gene.[23,24] In contrast, mutations of the *MYBPC* gene have been associated with delayed penetrance.[21,25] However, one large study found no difference in the degree and onset of hypertrophy when comparing patients with mutations involving the thick filament, thin filament, or *MYBPC* genes.[26]

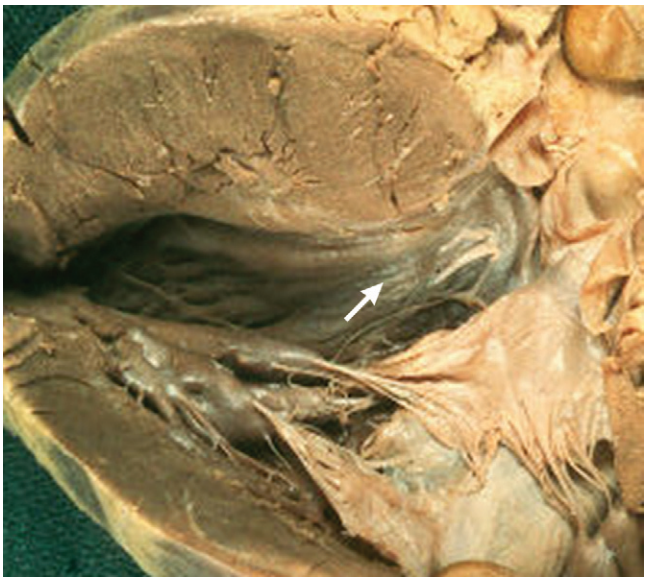

**Figure 27-1 Gross pathologic specimen of the heart from a patient with hypertrophic cardiomyopathy and LV outflow tract obstruction who died suddenly.** Note the asymmetric hypertrophy with a markedly thickened interventricular septum and narrow outflow tract between the basal septum and anterior mitral valve leaflet, which is thickened and fibrosed from repeated mitral leaflet-septal contact (*arrow*).

## Diagnosis

### DIAGNOSTIC CRITERIA

The diagnosis of HCM is based on the demonstration of LV hypertrophy in the absence of other causes, such as systemic hypertension or aortic stenosis (Fig. 27-2).[4] M-mode echocardiography assumed an early role in the diagnosis of HCM.[27,28] The echocardiographic finding of asymmetric septal hypertrophy, defined as a septal/posterior wall thickness ratio of 1.3 or greater, is strongly associated with HCM.[29] The septum is typically at least 15 mm in thickness.[1,29,30] Other findings associated with obstructive HCM, such as systolic anterior motion (SAM), have been detected in other conditions and are not considered

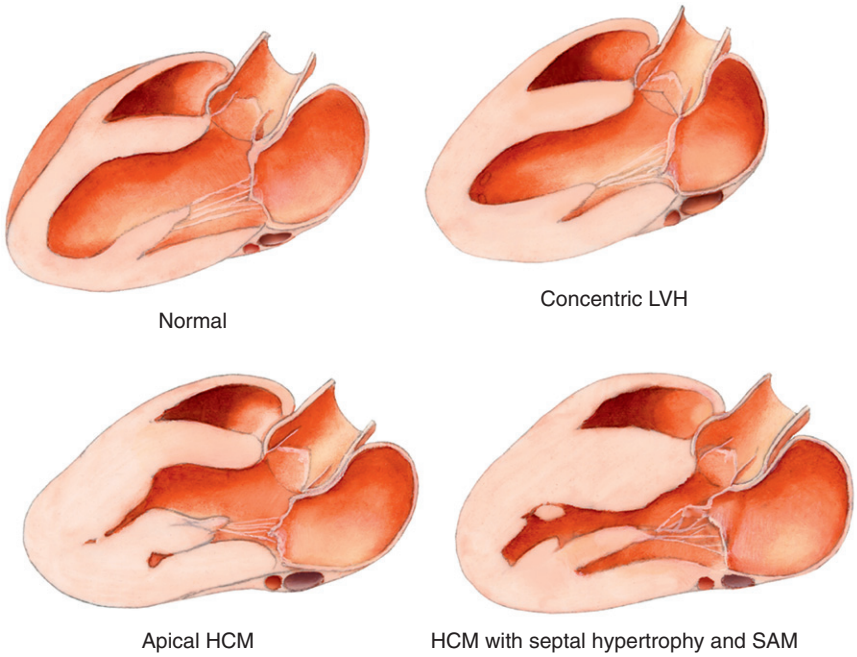

**Figure 27-2 Patterns of ventricular hypertrophy in hypertrophic cardiomyopathy patients.** Diagrammatic representation of the various forms of left ventricular hypertrophy (*LVH*), as viewed in a parasternal long-axis view. *Upper left*: Normal wall thickness in a normal subject. *Upper right*: Concentric pattern of LVH with similar increases in the wall thickness of the interventricular septum and the LV free wall. This is the predominant form of hypertrophy in patients with systemic hypertension or valvular aortic stenosis. *Lower left*: In contrast, patients with apical hypertrophic cardiomyopathy (*HCM*) have hypertrophy predominantly of the apical segments. Note that the basal interventricular septum is spared from hypertrophy and the distal LV cavity is small. Patients with apical HCM have near obliteration of the distal LV cavity during systole. *Lower right*: The more common form of HCM involves asymmetric hypertrophy of the interventricular septum. The LV free wall is normal or minimally thickened. Patients with the obstructive form of HCM typically have a narrow LV outflow tract, an anteriorly displaced mitral apparatus, and systolic anterior motion (*SAM*) of the anterior mitral leaflet.

pathognomonic for HCM.[31] The diagnosis of HCM is made in children when LV wall measurements are more than two standard deviations above the mean (corrected for age and body surface area).[32] Approximately 25% of patients have obstructive HCM, which has traditionally been defined as a left ventricular outflow tract (LVOT) gradient of at least 30 mm Hg at rest.[8]

### FAMILY SCREENING FOR HYPERTROPHIC CARDIOMYOPATHY

The first-degree relatives of patients with HCM should be screened for this condition.[1,33] Screening methods for family members include a history and physical examination, 12-lead electrocardiography, and echocardiography. Echocardiography is the most widely accepted screening test for HCM. Genetic testing is becoming more widely available, typically in academic centers.[1] Screening for HCM is recommended by at least 12 years of age (or earlier if a child is symptomatic, engaged in competitive sports, or has a malignant family history of premature death attributed to HCM).[33] Serial evaluations are then performed every 12 to 18 months until physical maturity is achieved (generally between ages 18 and 21). Because HCM may present in late adulthood, screening is generally recommended at 5-year intervals during adulthood.[33]

Genetic studies of patients with HCM have demonstrated that genotype-positive relatives of patients with HCM may have minimal or no hypertrophy evident on echocardiography.[21,24,25,33] Recent studies have shown that tissue Doppler imaging may identify genotype-positive patients before the onset of LV hypertrophy.[34,35] Reduced systolic and diastolic tissue Doppler velocities have a high sensitivity and high specificity in identifying mutation carriers (Table 27-1). Moreover, serial echocardiographic assessments of genotype-positive and initially phenotype-negative patients showed further reductions in tissue Doppler velocities and the development of overt hypertrophy during 2-year follow-up.[36]

## Differential Diagnosis

### MIMICS OF HYPERTROPHIC CARDIOMYOPATHY

There are multiple potential other causes for the echocardiographic abnormalities seen in HCM, often termed phenocopies (Box 27-1).[37,38] HCM caused by a genetic defect of the cardiac sarcomeric proteins needs to be distinguished from one of the congenital malformations/syndromes (e.g., Noonan or LEOPARD syndrome). Disproportionate hypertrophy of the ventricular septum may occur with right ventricular (RV) hypertrophy and D-transposition of the great arteries.[39] Other nongenetic causes of LV hypertrophy include athlete's heart (see later discussion), systemic hypertension, and aortic stenosis. Hypertrophy secondary to these disorders is usually concentric but may also be associated with a degree of focal septal hypertrophy and/or SAM.[30] Increased wall thickness not attributable to myocyte hypertrophy may be secondary to metabolic disorders (storage disorders—see later discussion), hypothyroidism,[40] or infiltrative cardiomyopathies (Fig. 27-3).[41] The increased wall thickness of patients with metabolic disorders or infiltrative cardiomyopathies typically occurs in a concentric pattern but may occasionally manifest as disproportionate septal thickening.

**TABLE 27-1 Test Characteristics of Tissue Doppler Findings for Diagnosis of Hypertrophic Cardiomyopathy**

| *Tissue Doppler Parameter* | *Sensitivity* | *Specificity* |
|---|---|---|

| E′ (septal) <13 cm/s[35] | 100% | 90% |
| Average E′ (from 4 corners) ≤13.5 cm/s[34] | 75% | 86% |
| Average E′ <15 cm/s + LVEF ≥ 68%[34] | 44% | 100% |

*E′*, Tissue Doppler early diastolic velocity; *LVEF*, left ventricular ejection fraction; *S′*, tissue Doppler systolic velocity.

### STORAGE DISEASES

Storage diseases should be considered in the workup of patients with unexplained increased LV wall thickness. Fabry disease was detected in 7 of 230 patients with LV hypertrophy (3% prevalence), with all of these patients having a concentric pattern of hypertrophy.[42] In male patients with a diagnosis of HCM, Fabry disease was detected in 6% of patients diagnosed at 40 years of age or older and in 1% diagnosed at 40 years of age or younger. The pattern of hypertrophy was concentric in 5 patients and asymmetric in 1 patient.[43] Approximately 50% to 60% of patients with Fabry disease present with cardiac symptoms, with one third dying from cardiac causes.[44] Most patients with cardiomyopathy exhibit concentric hypertrophy with preserved global ejection fraction and only mildly impaired diastolic function.[45] Characteristic of Fabry disease is the development of replacement fibrosis in the basal posterolateral wall, which in the late stage of the disease results in the coexistence of myocardial hypertrophy, myocardial thinning, and the presence of wall motion abnormalities in the fibrotic segments.[46]

Glycogen storage diseases may also mimic HCM. Mutations of the AMP-protein kinase $\gamma_2$ (*PRKAG2*) gene cause a glycogen storage cardiomyopathy, mutations of the lysosome-associated

membrane protein 2 (*LAMP2*) gene cause Danon disease, and mutations of the acid α-1,4-glucosidase gene cause Pompe disease.[47] In a cohort of 75 patients with unexplained hypertrophy, 40 patients (53%) were identified with sarcomeric protein gene mutations, 1 patient (1%) had a *PRKAG2* defect, and 2 patients (3%) had *LAMP2* mutations.[47] In another cohort of 24 patients with increased wall thickness and ventricular preexcitation, mutations of the *PRKAG2* and *LAMP2* genes were detected in 7 (29%) and 4 (17%) patients, respectively. None of these patients had the genetic defects causing Fabry or Pompe disease.[47]

## ATHLETE'S HEART

It is crucial to accurately diagnose HCM in individuals with LV hypertrophy participating in competitive sports given the potential risk of sudden cardiac death. HCM remains the most common cause of sudden death in young adults undertaking competitive sports. The diagnosis can be difficult in athletes with an advanced degree of physiologic hypertrophy. In dynamic exercise, the load on the heart is predominantly a volume overload, leading to dilatation of the LV cavity (and an increased LV end-diastolic dimension), associated with a proportional increase in wall thickness (eccentric hypertrophy). In static exercise, a pressure load can result in LV hypertrophy without an increase in LV cavity size (concentric hypertrophy). Although there is some variation in the study data, the largest study of elite athletes showed that only 2% develop an interventricular septal thickness greater than 13 mm,[48] with a wall thickness of 14 to 16 mm appearing to be the upper limit of physiologic hypertrophy. The distinction between athlete's heart and pathologic hypertrophy may be less of an issue in women because the LV wall thickness of elite female athletes is in the range of 6 to 12 mm, which does not exceed normal age-adjusted limits for wall thickness.[49] The pattern of hypertrophy tends to be symmetric, and true asymmetric LV hypertrophy is encountered only rarely in athletes.[50] The chamber size can also provide an invaluable clue. Outside the setting of "end-stage" HCM, the LV end-diastolic dimension is typically normal or reduced, whereas in athletes this dimension commonly exceeds 55 mm. About 5% of elite athletes have a diastolic dimension greater than 60 mm, well above the upper limit of normal. Power athletes such as weight lifters can develop thickening of the septum and posterior walls without an increase in cavity size. In these cases it is important to calculate true LV mass index to avoid making a spurious diagnosis of LV hypertrophy, because these athletes are often very large. LV systolic function is normal to supranormal in athletes, both at rest and on exercise. LV diastolic function is on average normal at rest, but is enhanced on exercise, favoring adequate filling of the ventricle at high heart rates. Tissue Doppler velocity imaging is extremely helpful in differentiating the two conditions. Whereas HCM patients demonstrate a reduction in both systolic and diastolic tissue Doppler velocities, athletes have normal or supranormal systolic and

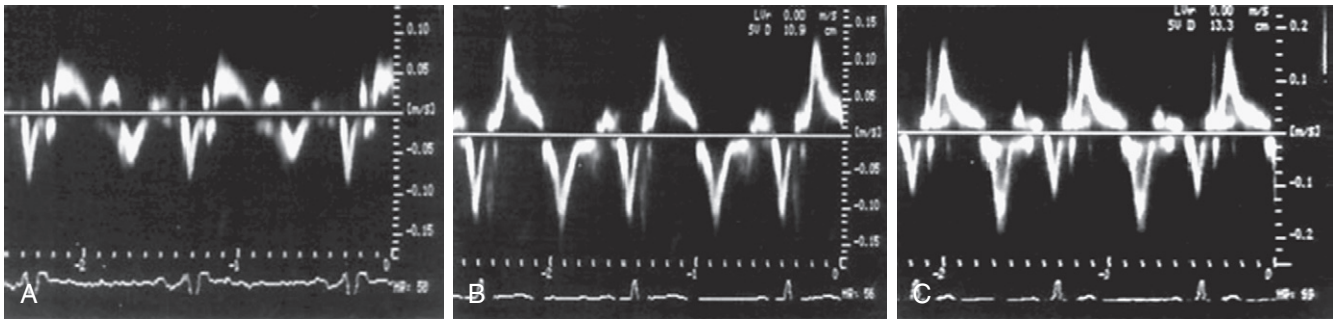

**Figure 27-4** Tissue Doppler velocity traces in a patients with hypertrophic cardiomyopathy (**A**), an athlete (**B**), and a healthy control (**C**). Note the significant reduction in both systolic and early diastolic velocities in the patient with hypertrophic cardiomyopathy in contrast to both the athlete and the healthy control.

**TABLE 27-2 Differentiation of Athlete's Heart from Hypertrophic Cardiomyopathy**

| | *Hypertrophic Cardiomyopathy* | *Athlete's Heart* |
|---|---|---|
| Unusual pattern of LVH | + | – |
| LV cavity ≤45 mm | + | – |
| LV cavity ≥55 mm | – | + |
| Abnormal LV filling | + | – |
| Female gender | + | – |
| Family history of HCM | + | – |
| Decreased wall thickness with deconditioning | – | + |

*HCM*, Hypertrophic cardiomyopathy; *LVH*, left ventricular hypertrophy.

diastolic function (Fig. 27-4).[51] A reflection of the diastolic dysfunction seen in HCM is left atrial (LA) enlargement. If LA size is normal, then LA pressure and LV end-diastolic pressure are very likely to be normal, making a diagnosis of athlete's heart more likely. The diagnosis of HCM is favored in the presence of the following: (1) a family history of HCM, (2) bizarre electrocardiographic patterns, (3) asymmetric hypertrophy (or other unusual patterns of hypertrophy), (4) an LV cavity size less than 45 mm, (5) LA enlargement, and (6) an abnormal LV filling profile (Table 27-2).[52] In some cases it may be necessary for the athlete to decondition. If regression of LV hypertrophy occurs, this is more suggestive of a diagnosis of athlete's heart rather than HCM.

### SEPTAL HYPERTROPHY IN THE ELDERLY

It may be difficult to distinguish between elderly patients with HCM and those with hypertensive heart disease. Elderly subjects may develop a sigmoid-shaped septum as an age-related phenomenon.[53] Terms that have been used to describe this finding are sigmoid septum, septal bulge, or discrete upper septal hypertrophy. It is controversial whether this finding should be considered a subtype of HCM or whether it represents a benign anatomic variant.[54,55] Other findings on echocardiographic examination that are more compatible with a septal bulge rather than HCM of the elderly include focal hypertrophy limited to less than a 3-cm length of the basal anterior septum, protrusion of the focal hypertrophy into the LVOT, a normal LV end-diastolic diameter, and the absence of characteristic echocardiographic findings of HCM.[55] Echocardiographic and clinical features of HCM in the elderly are discussed later in this chapter.

## Evaluation by Echocardiography

### LEFT VENTRICULAR HYPERTROPHY: SEVERITY, DISTRIBUTION, AND PATTERNS OF HYPERTROPHY

Two-dimensional (2D) echocardiography greatly increased the ability to detect the full extent, distribution, and severity of myocardial hypertrophy. Comprehensive echocardiographic assessment requires imaging of the LV from several transthoracic windows, including the parasternal long-axis view, serial parasternal short-axis views, and the apical windows. Measurements of the wall segments are obtained from cross-sectional parasternal short-axis views and are made at three levels: (1) basal (at the level of the mitral valve), (2) midventricular (at the level of the papillary muscles), and (3) apical.[5] The pattern of ventricular septal hypertrophy is variable and can be broadly divided into morphologic subtypes: reverse curvature, sigmoid, and neutral (Fig. 27-5). Reverse curvature morphology is characterized by a predominant midseptal convexity toward the LV cavity, with the cavity itself often having an overall crescent shape. In patients with sigmoid septal morphology the LV cavity is generally ovoid in shape, with the septum being concave to the LV cavity and a prominent basal septal bulge. Neutral septum HCM shows an overall straight septum that is neither predominantly convex nor concave toward the LV cavity.

Appropriate identification of these morphologic subtypes may be helpful because they appear to be closely related to the presence of an HCM-related genetic abnormality. In a recent study, the majority of patients (79%) with reverse curvature septum HCM harbored an identifiable HCM-associated mutation, compared with only a small proportion of patients with a sigmoid septum (8%).[56] Of those patients with apical hypertrophy, 30% were found to be genotype positive, with 41% of patients having a neutral septal morphology being genotype positive. These data have significant implications with respect to genetic counseling and the clinical application of genetic testing. Specifically, the possibility of echocardiography-guided genetic testing in HCM is evident.

### TECHNICAL FACTORS AND ECHOCARDIOGRAPHIC PITFALLS

There are important technical considerations in the echocardiographic assessment of HCM. The diagnosis of HCM is challenging, and diagnosis can only be 100% reliable when a genetic mutation has been identified. Echocardiographic assessment requires a comprehensive assessment in several imaging planes with careful attention to correct beam alignment in order to

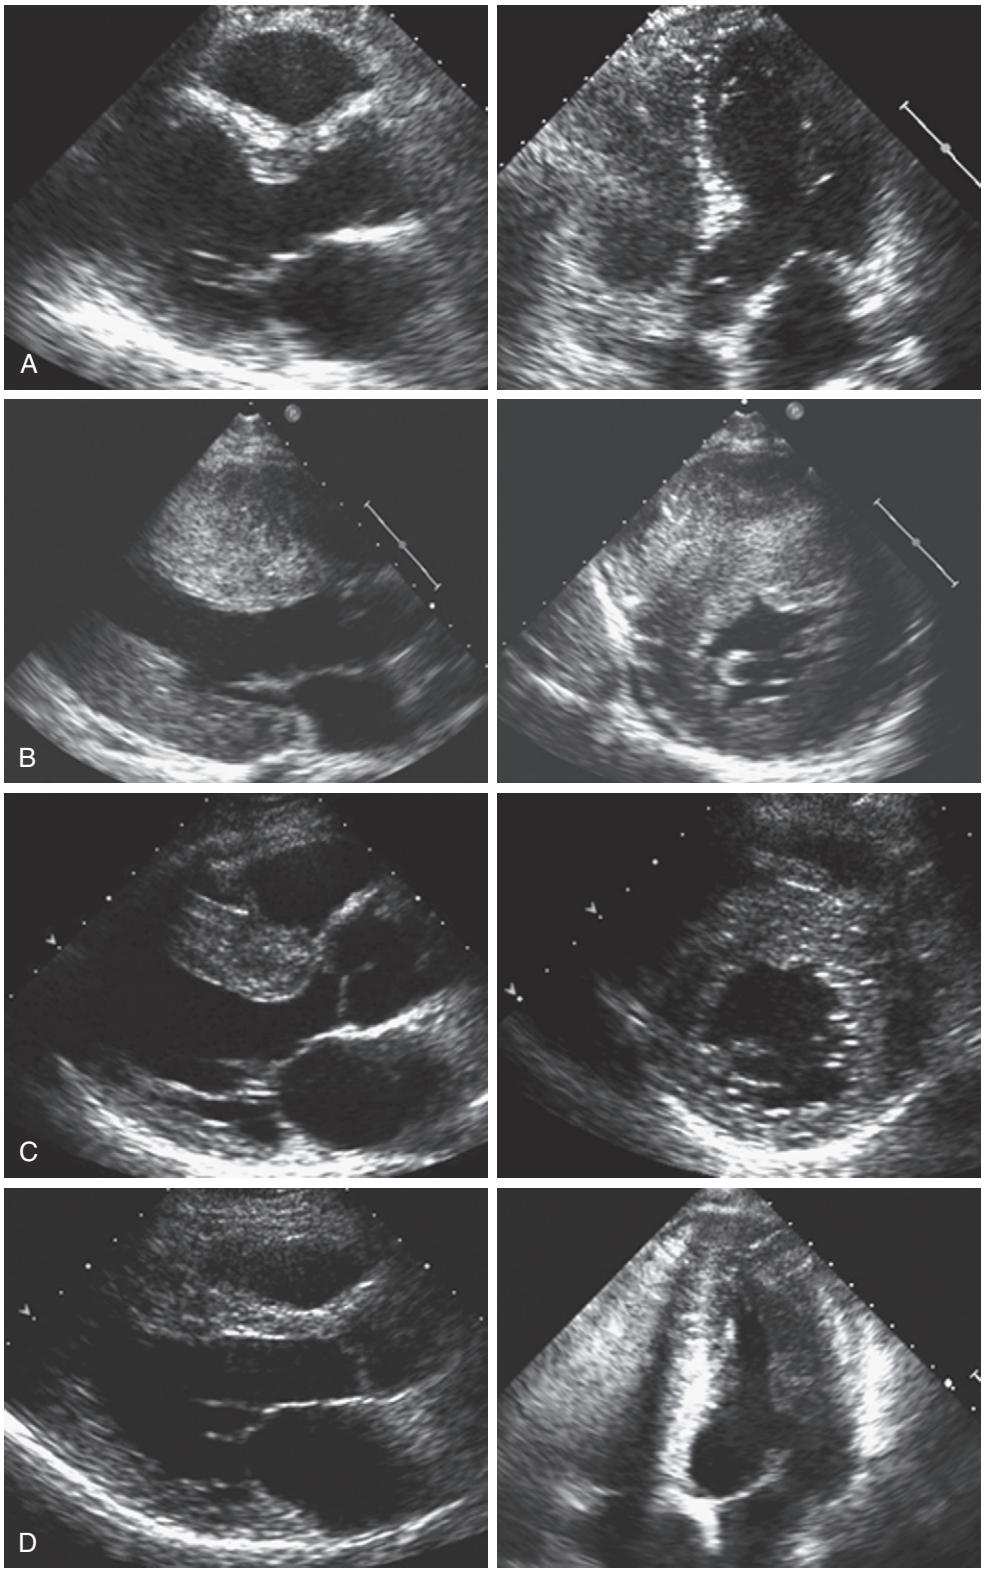

**Figure 27-5 Spectrum of morphologies in hypertrophic cardiomyopathy. A,** Sigmoid septum with hypertrophy confined to basal septum. **B,** Massive hypertrophy with reverse curvature pattern leading to crescent shape of LV cavity. **C,** Asymmetric septal hypertrophy with neutral septal morphology that is neither convex nor concave to LV cavity. **D,** Apical hypertrophy with hypertrophy confined to apex and normal wall thicknesses in basal segments.

minimize errors in the measurement of wall thickness and appropriate identification of hypertrophy with an unusual distribution.

### *Overdetection (False-Positive Diagnosis of Hypertrophic Cardiomyopathy)*

Oblique cuts of the LV can spuriously produce the appearance of asymmetric septal hypertrophy and overestimate wall thickness.[57] Similarly, the presence of an RV moderator band or an LV tendon may result in overestimation of septal thickness. Potential misdiagnosis may occur in hypertensive patients who have had an inferior myocardial infarction. In this setting, the septal/posterior wall ratio may exceed 1.3 simply because the septum is mildly hypertrophied and the posterior wall thinned as a result of prior infarction.

### *Underdetection (False-Negative Diagnosis of Hypertrophic Cardiomyopathy)*

2D echocardiographic studies have demonstrated that hypertrophy can be quite localized or eccentric in distribution.[58] More atypical forms of HCM, such as isolated lateral wall hypertrophy or asymmetric apical hypertrophy, may be missed from standard parasternal long-axis views, because the septum and anterior wall appear normal in thickness and there is no SAM of the mitral valve. The diagnosis of apical HCM by echocardiography may be missed in patients with difficult or suboptimal apical windows or if the apical segments are foreshortened. Wall thickness may be entirely normal, particularly in children and adolescents, in patients with specific gene mutations, and in end-stage HCM with a dilated impaired LV.

## Left Ventricular Outflow Tract Obstruction

### PATHOPHYSIOLOGY OF LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION

M-mode echocardiographic studies have demonstrated narrowing of the LVOT,[59] SAM of the mitral valve,[28,30] and midsystolic notching of the aortic valve[60] and established the important role of echocardiography in the assessment of LVOT obstruction in patients with HCM. Advances in 2D echocardiography and Doppler techniques would provide additional insights into the mechanisms responsible for dynamic outflow tract obstruction (Box 27-2). Morphologic features of HCM that contribute to LVOT obstruction include narrowing of the outflow tract by septal hypertrophy,[61] intrinsic abnormalities of the mitral leaflets,[62,63] anterior displacement of the mitral apparatus,[63,64] and anterior malposition of the papillary muscles.[65]

**Box 27-2**

**FACTORS CONTRIBUTING TO DYNAMIC LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTION**

Septal hypertrophy
Anterior displacement of the mitral apparatus
Anterior displacement of the papillary muscles

**Hydrodynamic Forces (Venturi and Drag Forces) Causing Systolic Anterior Motion**
Rapid early LV ejection
Elongated mitral leaflets

There tends to be a close relationship between the extent of LV hypertrophy and the presence of LVOT obstruction. The presence of resting outflow tract obstruction is associated with a higher hypertrophy point score.[66] The mitral leaflets in HCM are typically elongated[67] and coapt abnormally in the body of the leaflets rather than at the tips.[63,67] Patients with enlarged mitral valves have "typical" SAM and contact of the distal and central portions of the anterior mitral leaflet with the septum. In contrast, patients with normal-sized mitral valves have "atypical" SAM, involving greater portions of the body of the anterior mitral leaflet and related chordae tendinae, and with little bending of the anterior mitral leaflet.[68] The degree of anterior displacement of the mitral apparatus has been related to the degree of obstruction.[63,64] Furthermore, in HCM, the papillary muscle tips are displaced anteriorly and toward one another. This results in a decrease in the relative tension on the chordae tendinae to the body of the anterior mitral leaflet, producing relative chordal slack in the central and anterior leaflet portions.[67,69] Reduced chordal tension is more likely when the distance from the papillary muscle tips to the mitral leaflets is decreased by a combination of hypertrophy at the base of the papillary muscles and increased leaflet length.

### MITRAL LEAFLET SYSTOLIC ANTERIOR MOTION

Although the nature of the hydrodynamic forces on the anterior mitral leaflet remains controversial, it is believed that the anterior leaflet distal to the site of coaptation is subjected to Venturi and/or drag forces. Therefore, SAM occurs, and the tip of the anterior mitral valve leaflet typically develops a sharp anterior and superior angulation, leading to mitral leaflet-septal contact in early to midsystole (Fig. 27-6). There is a significant relationship between the development of SAM and the onset of the obstructive pressure gradient, which was demonstrated in patients undergoing simultaneous cardiac catheterization and M-mode echocardiographic studies (Fig. 27-7).[70] The presence of mitral leaflet-septal contact occurs almost simultaneously with the onset of the pressure gradient.

M-mode, 2D, and Doppler echocardiography are established noninvasive techniques in the assessment of the degree of LVOT obstruction in patients with HCM. An M-mode echocardiographic study classified the degree of SAM into three categories: (1) mild (SAM-septal distance greater than 10 mm), (2) moderate (SAM-septal distance less than 10 mm or brief mitral leaflet-septal contact), and (3) severe (prolonged SAM-septal contact, lasting more than 30% of echocardiographic systole).[30] There is a linear relationship between the time of onset of SAM and the severity of LVOT obstruction.[71]

### DOPPLER ASSESSMENT OF OUTFLOW TRACT OBSTRUCTION IN HYPERTROPHIC CARDIOMYOPATHY

Pulsed-wave (PW) and continuous-wave (CW) Doppler have been used to determine the pressure gradient across the LV outflow tract in patients with HCM. High–pulse-repetition frequency Doppler signals can be recorded sequentially from the LV apex to the outflow tract in order to establish the anatomic site of obstruction. Color flow mapping has been used to characterize the level of obstruction, either in the LVOT or in the midventricle.[72] It is important to identify those patients with midcavity obstruction, as this may be associated with apical aneurysm formation, which in turn carries a risk for systemic

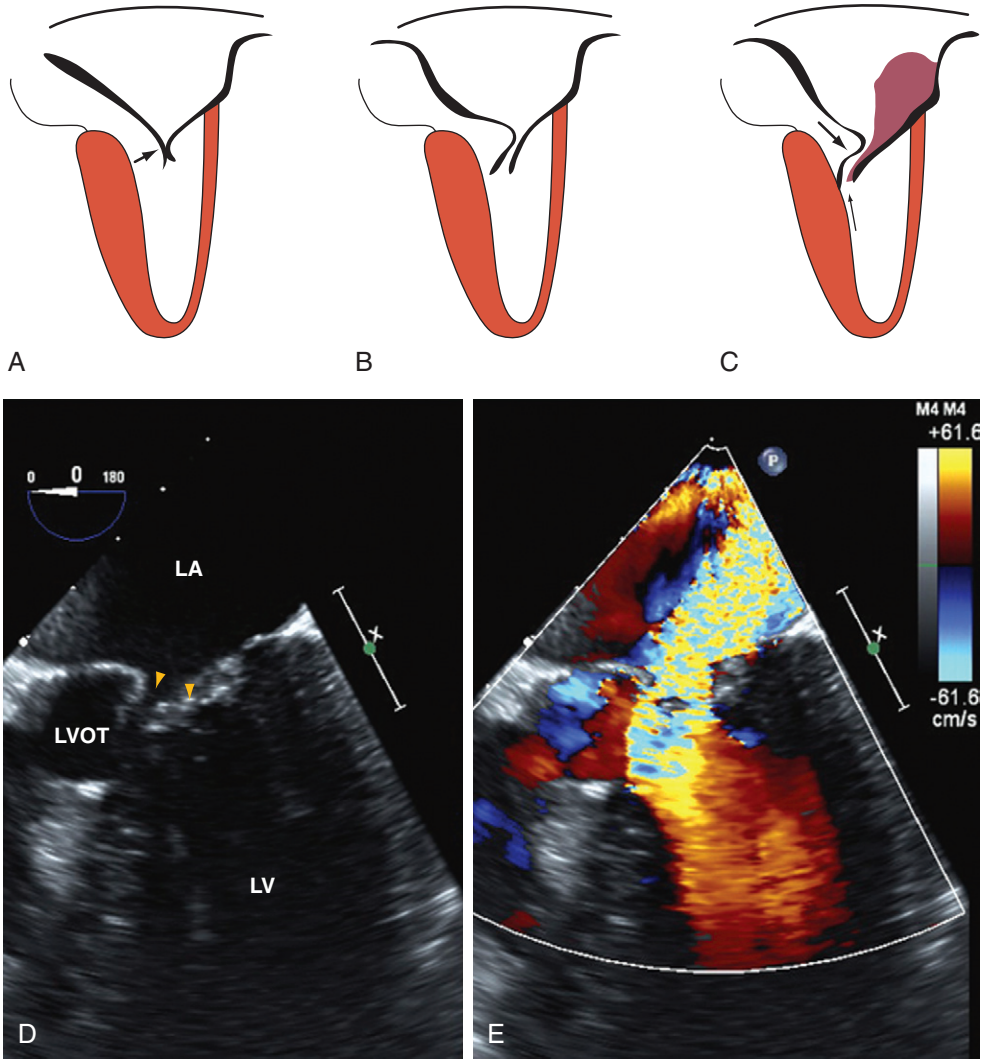

**Figure 27-6 Mechanism of dynamic outflow obstruction.** At the onset of systole (**A**), the coaptation point (*arrow*) is in the body of the mitral leaflets. During early systole (**B**) and midsystole (**C**), there is anterior and basal movement of the residual length of the anterior mitral leaflet (*thick arrow*) with septal contact and failure of leaflet coaptation. The resulting interleaflet gap (*thin arrow*) causes a posteriorly directed jet of mitral regurgitation into the LA cavity (*purple area*). Corresponding 2D transesophageal views (**D**) with color flow imaging (**E**) in a patient with obstructive hypertrophic cardiomyopathy show septal hypertrophy, anterior motion of anterior mitral valve leaflet, and color turbulence in left ventricular outflow tract (*LVOT*) with posteriorly directed mitral regurgitation. Failure of coaptation is demonstrated by *orange arrowheads*. *(Panels **A** to **C**, from Grigg LE, Wigle ED, Williams WG, et al: Transesophageal Doppler echocardiography in obstructive hypertrophic cardiomyopathy: clarification of pathophysiology and importance in intraoperative decision making.* J Am Coll Cardiol *20:42-52, 1992.)*

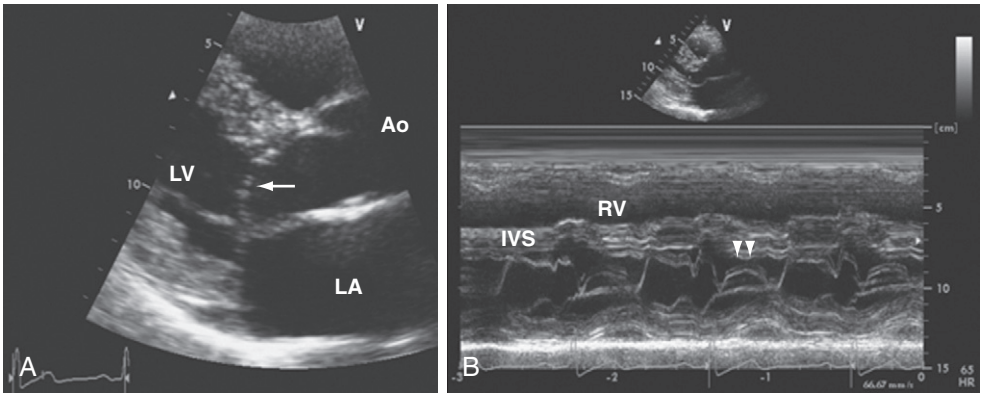

**Figure 27-7 2D and M-mode findings with dynamic outflow obstruction.** 2D parasternal long-axis (**A**) and M-mode (**B**) images obtained at level of mitral leaflet tips in patient with symptomatic obstructive hypertrophic cardiomyopathy. **A,** Anterior motion of the anterior mitral valve leaflet during systole (*arrow*). **B,** Corresponding finding marked by *arrowheads*. *Ao*, Aorta; *IVS*, interventricular septum.

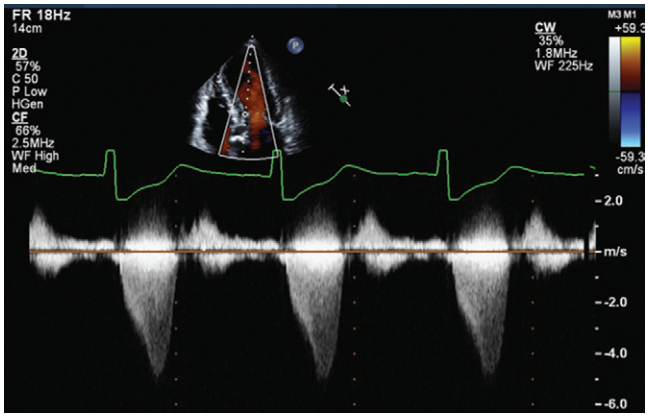

**Figure 27-8 CW Doppler recordings of left ventricular outflow tract (LVOT) in patient with symptomatic obstructive hypertrophic cardiomyopathy.** Evaluation revealed severe systolic anterior motion and posteriorly directed mitral regurgitation. Spectral profile has characteristic dagger shape. Peak velocity in LVOT is 4.3 m/s, corresponding to peak LVOT gradient of 74 mm Hg based on modified Bernoulli equation.

embolism and ventricular arrhythmias. In those patients with obstruction at the level of the outflow tract, the peak velocity increases as the sample volume approaches the site of mitral leaflet-septal contact. CW Doppler assessment from an apical approach with the beam directed across the outflow tract can be used to determine the peak velocity ($V_{max}$) at the site of obstruction. Patients with outflow tract obstruction have a characteristic spectral profile with an asymmetric leftward concave shape. This results from a relatively rapid initial rise in velocity followed by a more gradual increase in the outflow tract velocity to cause a peak in late systole (the typical dagger-shaped Doppler profile) (Fig. 27-8).[73] The peak gradient ($\Delta P$) can be estimated using the modified Bernoulli equation ($\Delta P = 4V^2$). There is an excellent correlation between the pressure gradient determined by CW Doppler measurements and that determined by high-fidelity micromanometer recordings during cardiac catheterization.[74]

## LATENT OBSTRUCTIVE HYPERTROPHIC CARDIOMYOPATHY

When categorizing patients with HCM, three distinct hemodynamic groups of patients should be distinguished: those with resting outflow tract obstruction (obstructive), those with provocable gradients but no obstruction at rest (latent obstruction), and those with no gradient either at rest or on provocation (nonobstructive). Dynamic LVOT obstruction is an important and frequent manifestation of HCM and can be a major cause of symptoms such as dyspnea, chest pain, presyncope, or syncope. Resting LVOT obstruction (LVOT gradient 30 mm Hg or greater) is present in around 25% to 30% of patients with HCM. However, a multicenter study using stress echocardiography has identified that with exercise, provocable outflow tract gradients are present in up to 70% of patients with HCM.[75] Resting LV outflow tract obstruction is associated with a higher risk of progressive heart failure and cardiovascular death, likely due to chronic elevation in LV intracavitary pressure and wall stress.[76] Outflow tract obstruction in HCM is by nature dynamic and affected by numerous hemodynamic changes that occur during daily life. This variability is dependent not only on heart rate, inotropic state, and systemic vascular resistance, but also on loading conditions. The echocardiographic features of patients with latent LVOT obstruction include a proximal septal bulge, a narrow LVOT diameter (2 cm or less), and a more oblique angle (35° or greater) between the ejection flow and the mitral valve.[77] Obstruction may be provoked by either physiologic or pharmacologic maneuvers that diminish LV preload (assumption of the upright posture, use of sublingual nitroglycerine, Valsalva maneuver), augment LV contractility (via dobutamine infusion or physiologically by upright exercise), or result in vasodilator stress (inhalation of amyl nitrate). The most commonly used methods for provoking latent obstruction include the Valsalva maneuver, the inhalation of amyl nitrate, intravenous inotropes, and exercise.

With the exception of exercise, these provocative maneuvers are considered to be nonphysiologic and unable to perfectly reproduce the conditions under which obstruction and symptoms occur during daily life. The ACC/ESC Clinical Expert Consensus Document on Hypertrophic Cardiomyopathy does not recommend the use of dobutamine to provoke outflow tract gradients, because it is capable of producing LVOT gradients even in normal hearts. The presence of an inducible gradient is of questionable clinical and physiologic significance in patients with HCM.[1] Amyl nitrite has been shown to be an effective tool for provoking latent obstruction, but there is a relatively poor correlation between the gradients induced by amyl nitrate and exercise. This difference may partly be explained by the routine discontinuation of beta blockers before exercise but not for Valsalva studies. In a study by Marwick and colleagues,[78] amyl nitrate appeared more effective in an older patient group (age greater than 65 years) with lesser degrees of septal hypertrophy and narrower LV outflow tracts. However, amyl nitrite is not widely available in all centers. Assumption of the upright posture has recently been shown to result in a 76% increase in gradients compared with the resting supine state, but was not as potent a maneuver as either Valsalva or exercise.[79] Upright exercise echocardiography has been shown to be the most potent provocative maneuver for the assessment of latent LVOT obstruction in several studies, as it combines both preload reduction and increased adrenergic drive. Exercise echocardiography can be performed safely in patients with HCM: major complications occurred in 1 of 263 patients undergoing treadmill exercise testing.[80]

## TECHNICAL ASPECTS OF DOPPLER EVALUATION IN HYPERTROPHIC CARDIOMYOPATHY

There are important technical considerations in the performance and interpretation of Doppler studies in patients with HCM. It was not possible to obtain a discernible signal from the LVOT in 16% of patients in one study comparing CW Doppler echocardiography to cardiac catheterization.[81] This inability to acquire a clear spectral display from the outflow tract may be secondary to inadequate transthoracic windows or distortion of LV geometry. In addition, it is imperative to distinguish the high-velocity systolic signal coming from the outflow tract from the signal of mitral regurgitation. The spectral profile of mitral regurgitation is characterized by an earlier onset, a more abrupt initial increase in velocity, and a higher peak velocity than that of an outflow tract signal. Systolic jets with a peak velocity of greater than 5.5 m/s (gradient greater than 120 mm Hg) are most likely secondary to mitral regurgitation rather than LVOT obstruction.[81] Further differentiation of

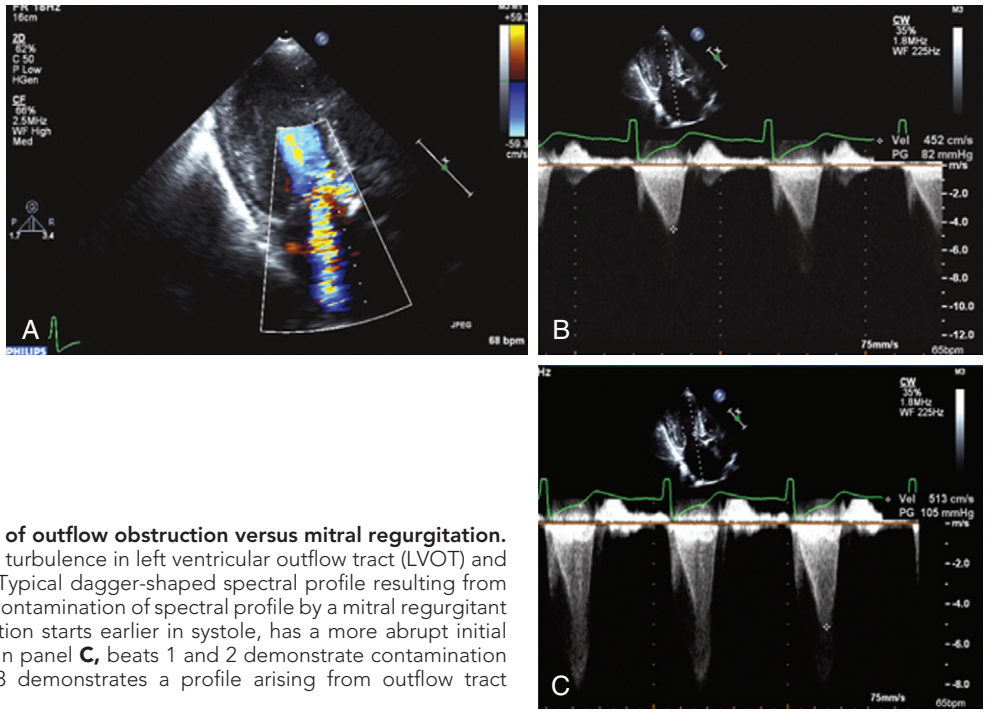

**Figure 27-9 CW Doppler characteristics of outflow obstruction versus mitral regurgitation.** **A,** Color Doppler imaging with evidence of turbulence in left ventricular outflow tract (LVOT) and fairly central jet of mitral regurgitation. **B,** Typical dagger-shaped spectral profile resulting from dynamic LVOT obstruction. **C,** Evidence of contamination of spectral profile by a mitral regurgitant jet. The spectral profile of mitral regurgitation starts earlier in systole, has a more abrupt initial rise in velocity and a higher peak velocity. In panel **C,** beats 1 and 2 demonstrate contamination from mitral regurgitation, whereas beat 3 demonstrates a profile arising from outflow tract obstruction alone.

these two jets can be accomplished by orienting the transducer more medially and anteriorly and away from the mitral regurgitant jet. Nevertheless, there may still be contamination of the high-velocity signal of outflow tract obstruction from the jet of mitral regurgitation (Fig. 27-9). This pitfall is particularly more common in patients with concomitant intrinsic mitral valve disease and a more centrally directed jet of mitral regurgitation. Despite optimal imaging, adjustments in instrument settings, and consideration of the differences in the timing and contour of these systolic jets, the distinction between these different Doppler signals may occasionally still be difficult.[82]

## Mitral Regurgitation in Hypertrophic Cardiomyopathy

Anterior mitral leaflet-septal contact and anterior displacement of the posterior leaflet results in failure of coaptation, creating a funnel-shaped gap in the leaflets through which mitral regurgitation develops, predominantly in mid- to late systole.[11] Patients with obstructive HCM and no independent mitral valve disease typically have a posteriorly directed jet of mitral regurgitation (Fig. 27-10).[11,83] Mitral regurgitation associated with obstructive HCM has been shown to be related to the degree of anterior leaflet SAM and to the length and mobility of the posterior leaflet, which determine the size of the interleaflet gap and the degree of midsystolic coaptation of the mitral leaflets.[84] These findings were corroborated by an intraoperative TEE study of 104 patients that demonstrated a significant correlation between the degree of mitral regurgitation, as assessed by color jet area and pulmonary venous flow pattern, and the degree of LVOT obstruction.[83] The presence of a nonposterior jet of mitral regurgitation suggests intrinsic mitral valve leaflet disease independent of SAM.

### INTRINSIC MITRAL VALVE ABNORMALITIES IN PATIENTS WITH HYPERTROPHIC CARDIOMYOPATHY

- Degenerative changes
  - Mitral annular calcification
- Leaflet trauma
- Myxomatous mitral valve leaflets
- Papillary muscle abnormalities
  - Hypertrophied papillary muscles
  - Direct insertion of the papillary muscle into the anterior mitral valve leaflet
- Restrictive chordal and leaflet abnormalities
  - Shortened/calcified chordae
  - Abnormal chordal insertions
  - Thickened/tethered leaflets

Adapted from Kaple RK, Murphy RT, DiPaola LM, et al: Mitral valve abnormalities in hypertrophic cardiomyopathy: echocardiographic features and surgical outcomes. *Ann Thorac Surg* 85:1527-1536, 2008.

Independent mitral valve lesions can be identified by echocardiography and are usually related to mitral valve prolapse, ruptured chordae, mitral annular calcification, anomalous insertion of a papillary muscle into the anterior mitral leaflet, or leaflet trauma (Box 27-3).[85] Repeated mitral leaflet-septal contact is associated with fibrosis and thickening of the anterior mitral leaflet (and with subaortic septal endocardial fibrosis and thickening, previously described as a septal "callus"). Myectomy alone is generally successful in relieving posteriorly directed mitral regurgitation, without the requirement for associated mitral valve replacement.[83]

Demonstration of posteriorly directed jet of mitral regurgitation secondary to systolic anterior motion of mitral valve causing dynamic outflow tract obstruction. *Ao*, Aorta.

## Subtypes of Hypertrophic Cardiomyopathy

### ASYMMETRIC APICAL HYPERTROPHIC CARDIOMYOPATHY

Asymmetric apical HCM was initially reported by Japanese investigators in the 1970s.[86,87] This unusual variant of HCM has subsequently been described in non-Asian populations.[88] The striking features of patients with apical hypertrophy include the presence of giant negative T waves (at least 10 mm) in the precordial electrocardiographic leads and an "ace of spades" configuration to the LV (Fig. 27-11). The diagnosis may be missed if acoustic windows are suboptimal and endocardial definition is poor. Contrast echocardiography may be useful in identifying cases of apical hypertrophy (Fig. 27-12). Echocardiography plays an important role in the assessment of the degree and extent of hypertrophy at the apex and the development of such complications as impaired diastolic filling, apical infarction, and aneurysm formation (Fig. 27-13) (which may result in ventricular tachycardia) and LA enlargement (which predisposes to atrial fibrillation). The long-term prognosis of patients with apical HCM is generally excellent (in the absence of apical aneurysm formation).[88]

### MIDVENTRICULAR OBSTRUCTION

The midventricular form of obstructive HCM, initially described in 1976,[89] is an uncommon variant of this condition. The features of this condition include an "hourglass"-shaped LV cavity, midventricular obliteration in systole, a distinct apical chamber, color turbulence at the midventricle, and a systolic pressure gradient at the midventricular level (Fig. 27-14).[72,90] The combination of color flow mapping, PW, and CW Doppler techniques is useful in localizing the level and severity of obstruction.

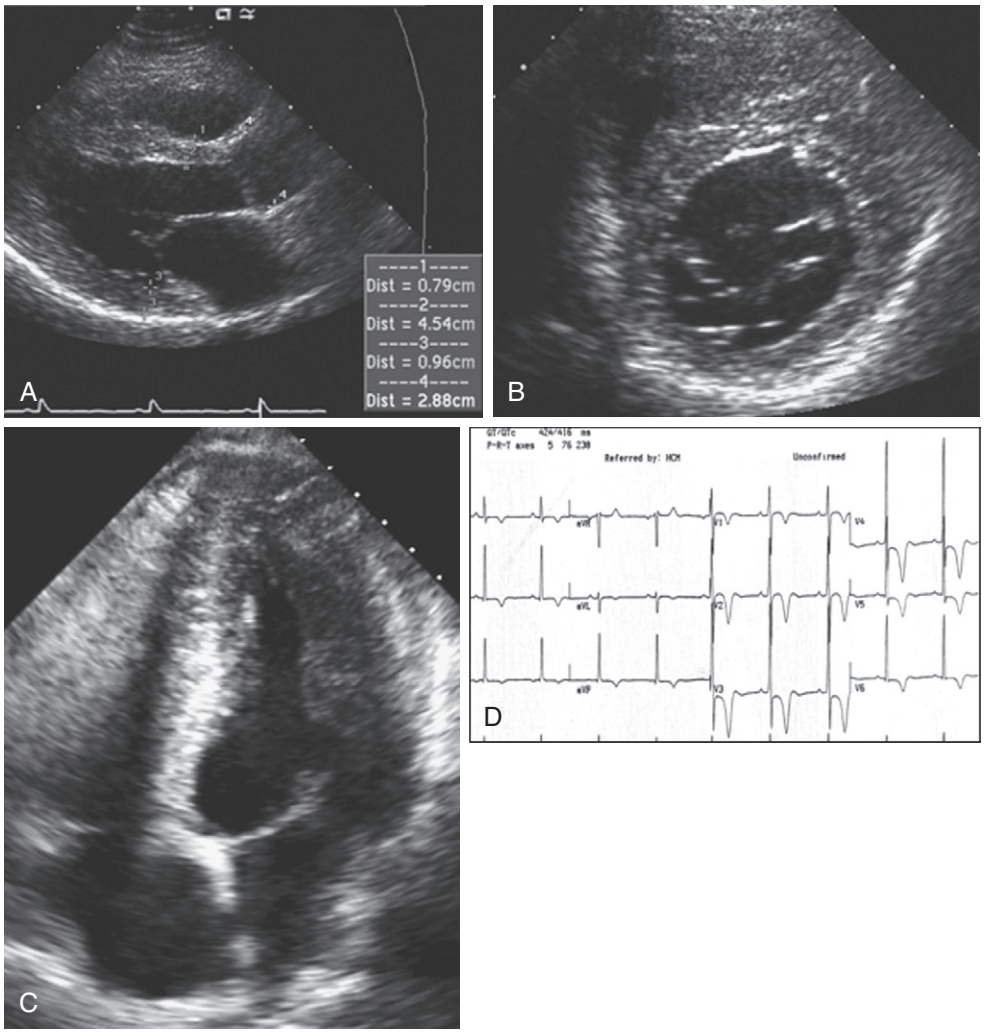

**Figure 27-11 Apical hypertrophic cardiomyopathy (HCM).** Parasternal long-axis view (**A**) and parasternal short-axis view at basal level (**B**). Wall thickness is normal in basal segments. Apical four-chamber view (**C**) shows hypertrophy of apical segments, resulting in typical "ace of spades" configuration of LV cavity. Corresponding electrocardiogram (**D**) demonstrates typical LV hypertrophy pattern seen in apical HCM, with giant negative T waves in chest leads.

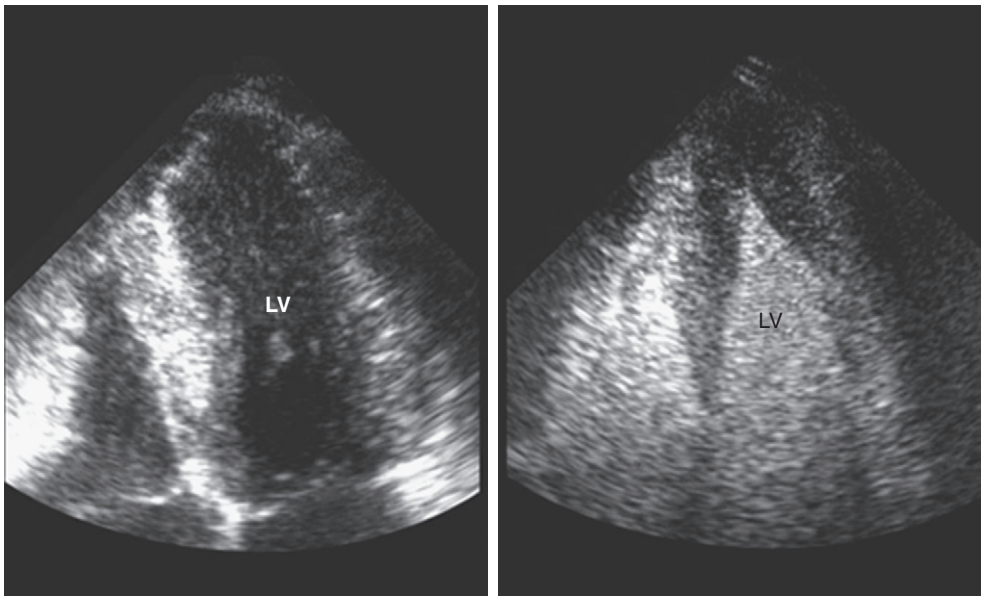

**Figure 27-12 Contrast echocardiography for diagnosis of apical hypertrophic cardiomyopathy.** In cases of suboptimal endocardial definition on TTE, injection of contrast agent may help to better visualize the apex. In addition, injection of contrast may be used to differentiate between apical hypertrophic cardiomyopathy and noncompaction of the LV.

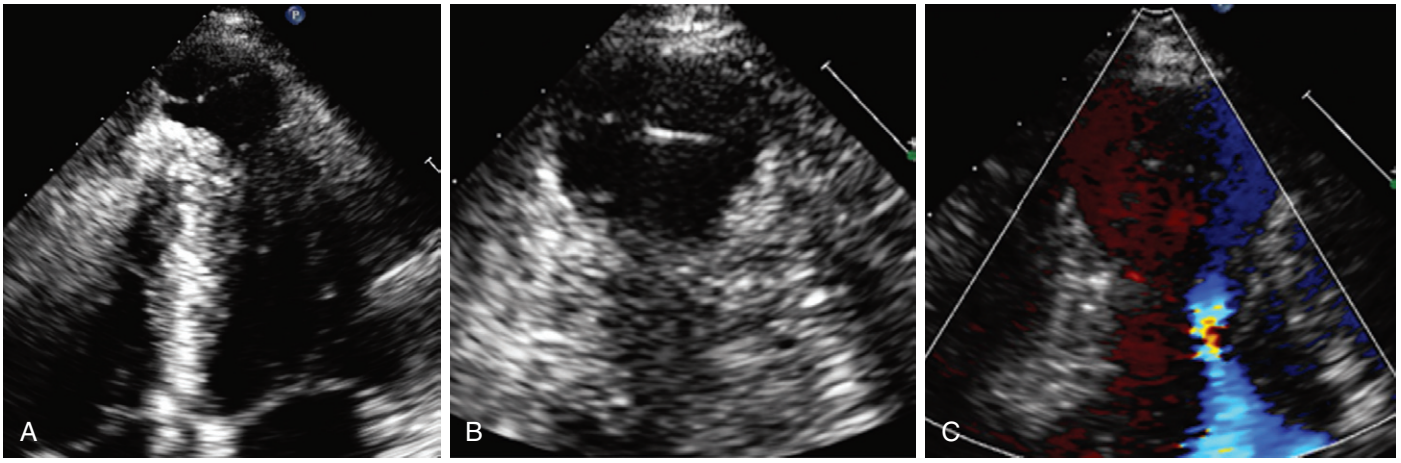

**Figure 27-13 Apical aneurysm in hypertrophic cardiomyopathy.** 2D echocardiographic images demonstrate apical aneurysm in a patient with apical hypertrophic cardiomyopathy. Note wall thinning in the apical segments (**A** and **B**). Color Doppler imaging may help assess for presence of thrombus in aneurysm (**C**). When using color Doppler, it is important to alter the Nyquist limit to account for low flow conditions in apical aneurysm.

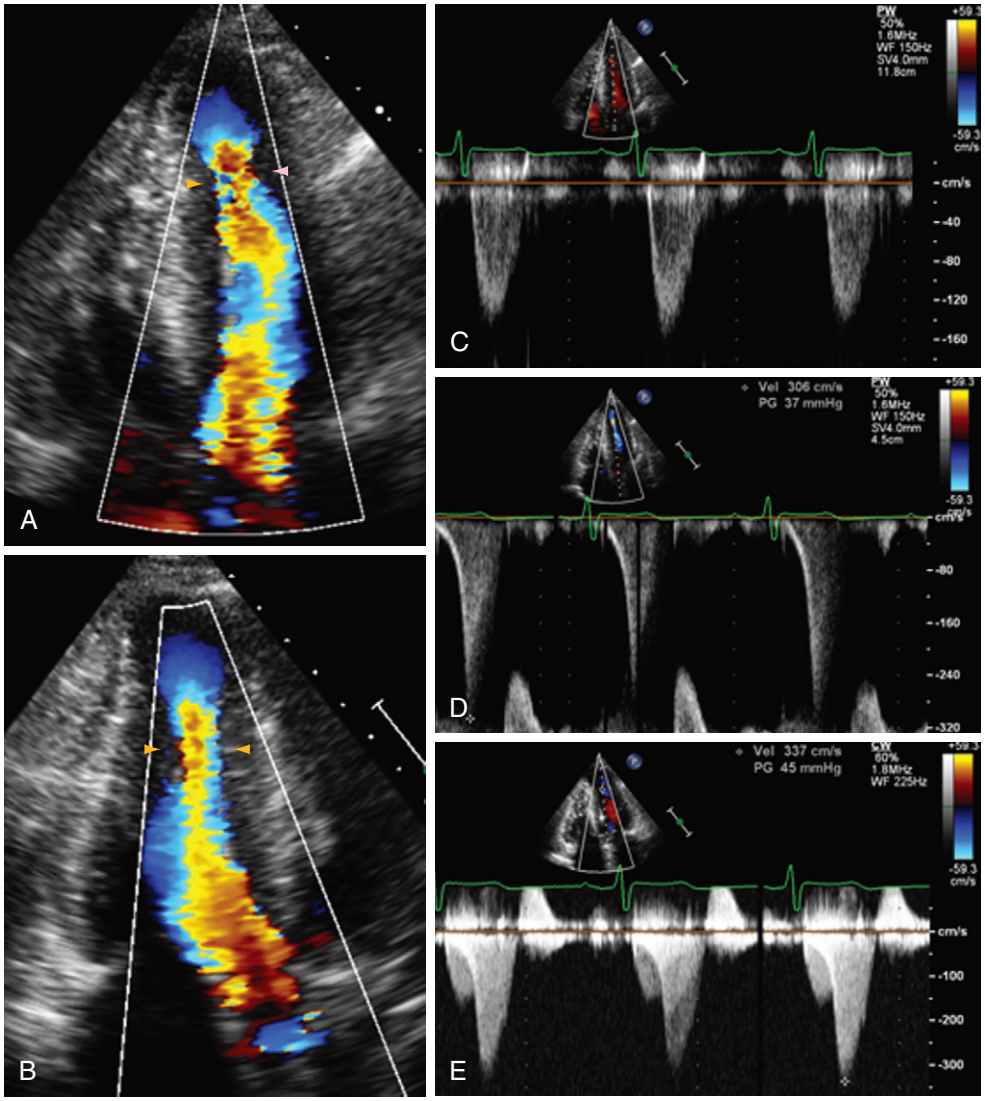

**Figure 27-14 Hypertrophic cardiomyopathy with midventricular obstruction.** 2D color Doppler echocardiographic images in apical five-chamber (**A**) and three-chamber (**B**) views demonstrate turbulent flow at level of midventricle (*yellow arrows*). PW Doppler traces demonstrate normal velocities in LV outflow tract (**C**), but evidence of obstruction at the midventricle (**D**). **E,** CW Doppler trace for assessment of peak velocity.

It is particularly important to identify those patients with mid-cavity obstruction, as this may be associated apical aneurysm formation, which is associated with systemic embolism, LV systolic dysfunction, and a risk of ventricular arrhythmias.[91]

### HYPERTROPHIC CARDIOMYOPATHY OF THE ELDERLY

HCM of the elderly is a subset of this condition with some distinguishing clinical and echocardiographic features.[92,93] The pattern of hypertrophy tends to be focal and localized to the basal anterior or posterior interventricular septum.[94] Elderly patients with HCM tend to have a milder degree of hypertrophy. The shape of the LV cavity in elderly patients is typically ovoid with normal septal curvature. In contrast, younger patients tend to have a crescent-shaped LV cavity and an abnormal convexity to the septum, characterized as a reversal of septal curvature.[95] Concomitant mitral annular calcification is a common feature of HCM in the elderly.[96]

The mechanisms leading to LVOT obstruction in HCM of the elderly are different from those seen in younger patients. Elderly patients have a relatively small heart and distorted geometry of the LVOT. Mitral annular calcification results in anterior displacement of the mitral apparatus, narrowing of the outflow tract, and less angulation of the mitral leaflets. Outflow tract obstruction, either at rest or with provocation, is associated with the majority of patients with HCM of the elderly.[95] Furthermore, the presence of mitral annular calcification distorts the mitral annulus and may lead to an independent jet of mitral regurgitation, which is often centrally directed and distinct from the posteriorly directed mitral regurgitant jet caused by SAM. However, in a recent study by Kubo and co-workers,[97] the authors demonstrated a significant correlation between the presence of reverse curvature morphology and genotype positivity (79%), compared with a low prevalence (8%) of mutations in those with sigmoid septal morphology. The previously mentioned echocardiographic features were described before the advent of genetic testing, and it is possible that LV hypertrophy of heterogeneous cause or age-related changes in morphology may have been included.

## Evaluation of Diastolic Function

### FACTORS CONTRIBUTING TO IMPAIRED DIASTOLIC FUNCTION IN HYPERTROPHIC CARDIOMYOPATHY

Diastolic filling of the LV is impaired in HCM and may result in dyspnea on exertion, elevated filling pressures, and progressive LA enlargement. Box 27-4 outlines the factors that contribute to diastolic filling in HCM. Impaired relaxation of the LV is secondary to increased contraction load, decreased relaxation loads, decreased inactivation, and increased nonuniformity. The early contraction load of outflow tract obstruction impairs and delays the onset of relaxation. The major relaxation loads, coronary and ventricular filling, are decreased. Calcium overload secondary to hypertrophy or ischemia leads to myofibril inactivation of actin-myosin cross-bridges. Relaxation is further impaired by the nonuniformity of load and inactivation in different segments of the LV. Chamber stiffness is directly proportional to the myocardial mass and the degree of myocardial fibrosis and is inversely proportional to the LV chamber volume.

**Box 27-4**

**FACTORS AFFECTING DIASTOLIC FUNCTION IN HYPERTROPHIC CARDIOMYOPATHY**

**Relaxation**

### TECHNIQUES FOR THE ASSESSMENT OF DIASTOLIC FUNCTION

Impaired LV relaxation is the predominant diastolic abnormality identified in patients with HCM, regardless of symptomatic status or the presence of LVOT obstruction.[98] The mitral inflow pattern typically demonstrates a prolonged isovolumic relaxation time, reduced early rapid filling (E), a prolonged deceleration time, and increased atrial filling (A). However, mitral inflow and pulmonary venous flow assessments correlate poorly with invasively measured filling pressures.[99,100] In addition, LV filling pressures can be assessed by calculating the E/E′ ratio (derived from the early diastolic tissue Doppler velocity from the lateral mitral annulus),[101] despite the correlation being only modest in the HCM patient population. There is a good correlation between LV filling pressures and the ratio of mitral inflow E velocity to flow propagation velocity ($V_P$).[101]

### TISSUE DOPPLER IMAGING

In addition to the assessment of LV filling pressures, tissue Doppler can provide important insights in the evaluation of patients with HCM. Reduced tissue Doppler early diastolic velocities have been detected in genotype-positive subjects without LV hypertrophy, suggesting that diastolic abnormalities may precede the onset of hypertrophy (see Diagnosis section).[34-36] Early diastolic velocities at the lateral and septal annulus are lower in patients with HCM compared to control subjects.[102] The E/E′ ratio was found to correlate inversely with peak oxygen consumption.[102] Patients with higher LA volumes had a higher E/E′ ratio, a higher incidence of diastolic filling abnormalities, and a higher incidence of serious cardiovascular events.[103] In addition, tissue Doppler has been used to monitor the response to invasive therapies. A significant increase in E′, suggestive of improved LV relaxation, was demonstrated in patients 6 months after septal ethanol ablation.[104] Similar improvements in diastolic function (as assessed by tissue Doppler and color M-mode Doppler) were demonstrated in patients undergoing septal ethanol ablation and myectomy.[105]

### ASYNCHRONOUS CONTRACTION AND RELAXATION IN HYPERTROPHIC CARDIOMYOPATHY

The inhomogeneity of relaxation seen in patients with HCM may result in LV intracavitary flow during isovolumic relaxation. Asynchronous relaxation in patients with asymmetric septal hypertrophy leads to earlier relaxation of the apex. Blood flow from the LV base to apex is detected during isovolumic relaxation and has been termed intracavitary "isovolumic relaxation time flow."[106] In contrast, patients with asymmetric apical HCM may have intracavitary apex-to-base flow, previously described as a paradoxical jet flow, with earlier relaxation of proximal LV segments.[107] Interventricular and intraventricular dyssynchrony are relatively common in HCM despite the absence of bundle branch block on the surface electrocardiogram. The degree of dyssynchrony appears to correlate with the degree of septal hypertrophy and the presence of LVOT obstruction.[108] A significant increase in LV dyssynchrony is seen in HCM patients compared with controls and patients with hypertensive heart disease, with no significant differences in dyssynchrony in those HCM patients with asymmetric septal hypertrophy versus those with apical HCM.[109]

## Strain Imaging in Hypertrophic Cardiomyopathy

Using gray-scale imaging, 2D deformation analysis allows spatial and temporal tracking of longitudinal, circumferential (representing systolic shortening), and radial (representing systolic thickening) myocardial deformation in order to quantify regional and global ventricular mechanics. Its ability to provide angle-independent measures of LV strain is advantageous. Studies in patients with HCM have demonstrated a reduction in longitudinal strain, an increase in circumferential strain, and a normal twist angle (despite a change in direction at the level of the midventricle), but a reduction in untwisting in diastole. Studies in the HCM population have shown evidence of reduced diastolic but preserved systolic strain in carriers of sarcomere mutations with no evidence of LV hypertrophy.[110] In overt disease, despite a preserved ejection fraction, there is a significant global reduction in longitudinal strain in association with a compensatory increase in circumferential strain.[111] These changes in systolic strain are mirrored by changes in the early diastolic strain rates in this patient group.[112] The longitudinal strain rate E/S ratio allows assessment of the relative extent of diastolic changes to systolic ones and has been shown to be reduced in HCM, most profoundly in those patients with obstruction.[112] Systolic contraction is dependent on twisting of the heart, with untwisting after systolic contraction being an important mechanism by which the heart recoils, in effect creating suction force that augments early diastolic filling. Although twist time is shortened in patients with HCM, the untwist time is prolonged, a finding that paralleled the severity of LV hypertrophy (Fig. 27-15).[113] Strain rate imaging has been shown to be useful in differentiating HCM from hypertensive LV hypertrophy, with the septum/posterior wall thickness ratio (greater than 1.3) and systolic strain ($\varepsilon_{sys}$) being the two parameters that were useful in distinguishing between these two disorders.[114] The combination of the septum/posterior wall thickness and $\varepsilon_{sys}$ discriminated HCM from hypertensive heart disease with a predictive accuracy of 96%.[114]

## Prognostication by Echocardiography

Echocardiography is increasingly providing important information regarding the long-term prognosis of patients with HCM. Spirito and colleagues[9] have demonstrated in a series of

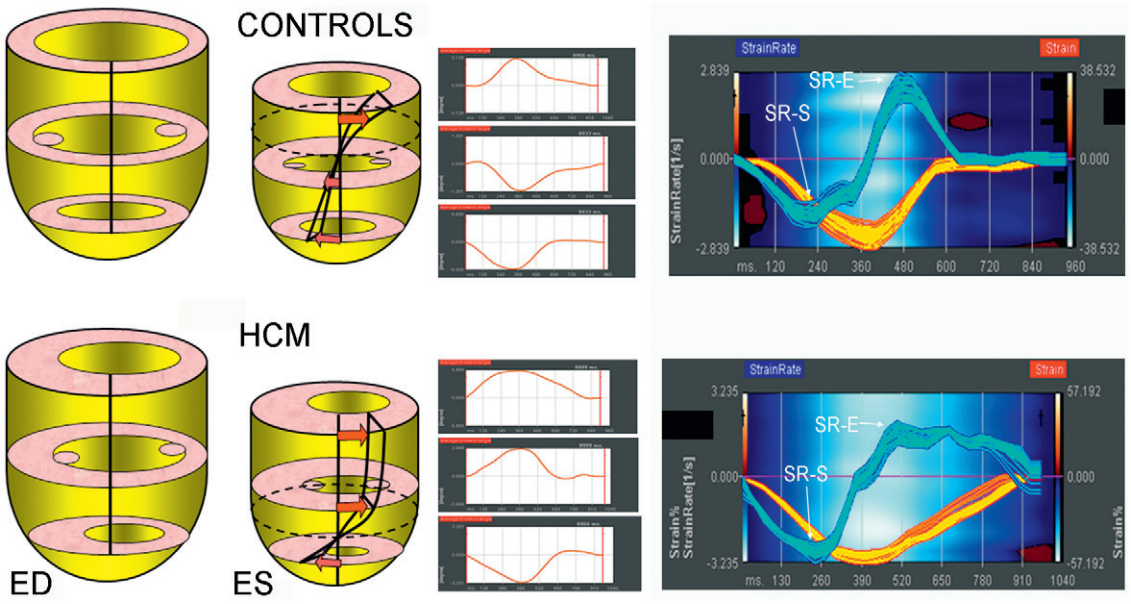

**Figure 27-15 LV rotation and twist, strain, and strain rate in hypertrophic cardiomyopathy (*HCM*) compared with controls.** Changes in rotation and twist of LV (*left*) in a patient with HCM. Principal difference is at midlevel, which rotates in opposite direction (clockwise) in patients with HCM compared with control subjects. Thus, in HCM, rotation of midventricle follows the base, in contrast with controls, where midventricle follows the apex. This may be consistent with the hypertrophied and rigid myocardium of HCM, which prevents a more gradual change of rotation from base to apex. Circumferential strain (*center panels*) and strain rate (*right*) show an increase in circumferential strain and systolic strain rate in patient with HCM. Reduction in diastolic strain rate in patient with HCM reflects underlying diastolic dysfunction. *ED*, Early diastole; *ES*, early systole; *SR-S*, strain rate in systole; *SR-E*, strain rate in early diastole.

about 500 patients that a wall thickness greater than 30 mm confers a long-term risk of sudden death of 20% at 10 years and 40% at 20 years. A further study of more than 600 patients again demonstrated the highest risk in patients with a wall thickness greater than 30 mm (with a relative risk of 1.31 for every further 5-mm increase in wall thickness).[115]

The presence of resting LVOT obstruction has also been associated with increased mortality.[8] In addition, McLeod and colleagues[116] have demonstrated a significantly lower rate of appropriate ICD discharges after septal myectomy compared with a nonoperated group with obstructive HCM. However, the positive predictive value of a resting LVOT gradient for the development of sudden cardiac death is particularly low (7%).[8] Finally, LA enlargement has been found to be a significant predictor of atrial fibrillation in patients with HCM[117] and of long-term survival in patients following surgical myectomy.[118]

## Medical Therapy

Medical management in HCM is optimized by monitoring the response to therapy with serial echocardiographic and Doppler studies. The three different classes of pharmacologic agents used for the treatment of obstructive HCM are beta blockers, disopyramide, and calcium channel blockers. The mechanism of benefit of these agents is thought to be a decrease in myocardial contractility, which results in decreased LV ejection velocity, the delayed onset of mitral leaflet SAM, and, consequently, decreased outflow tract obstruction and mitral regurgitation. In addition, beta blockers and calcium channel blockers relieve myocardial ischemia and reduce the heart rate, which prolongs diastole and relaxation and increases passive ventricular filling.[1] However, verapamil should be used with caution in patients with obstructive HCM because it can lead to vasodilatation and worsening outflow tract obstruction.[119] Disopyramide is a type IA antiarrhythmic agent with significant negative inotropic properties.[120] Cardiac symptoms and the magnitude of the LVOT gradient are significantly improved following the institution of disopyramide. In one multicenter study of 118 patients treated with disopyramide, two thirds of patients were maintained with disopyramide without the need for an invasive intervention.[121]

## Dual-Chamber Pacing

The interest in dual-chamber pacing in the reduction of outflow tract obstruction dates back to the 1960s, when it was noted that patients who developed a left bundle branch block after myectomy had a better clinical outcome than those patients with no interventricular delay. RV pacing results in a reduction in outflow tract obstruction via an alteration in the activation sequence of the interventricular septum, resulting in an increased outflow tract diameter and a reduction in SAM of the mitral valve. In addition, the resultant dyssynchrony results in a fall in LV contractility and stroke work.[122,123] Initial studies had suggested significant symptomatic improvement and LV mass regression with dual-chamber pacing.[124] However, the results of multiple subsequent studies have been less encouraging. Randomized crossover studies of dual-chamber pacing (treatment arm) versus atrial demand inhibited pacing (control arm) have shown an incomplete reduction in the LVOT gradient, no significant decrease in LV wall thickness, and no significant increase in peak myocardial oxygen consumption ($VO_2$) during follow-up.[125-127] The perceived decline in symptoms following pacemaker implantation may, in part, be due to a placebo effect.[127] These findings were corroborated by a nonrandomized study comparing dual-chamber pacing and septal myectomy, which showed a significantly greater improvement in the functional class, oxygen consumption, and LVOT gradient in the patients who underwent surgery.[128]

## Septal Ethanol Ablation

Septal ethanol ablation is an interventional technique that consists of the selective injection of ethanol into a septal perforator branch of the left anterior descending artery.[129] This leads to occlusion of the septal branch and localized infarction of the hypertrophied interventricular septum. The targeted infarction results in focal thinning of the septum, widening of the LVOT, and relief of LVOT obstruction.[130] The first clinical experience with septal ethanol ablation was reported in the 1990s. The selection of the appropriate septal branch to be injected was determined by the reduction in the LVOT gradient following transient occlusion of the targeted vessel by a balloon catheter. However, a key development in this technique was the use of intraprocedural echocardiography. Myocardial contrast echocardiography with transthoracic imaging has become essential for the guidance and monitoring of septal ethanol ablation.[12,13,131]

### MYOCARDIAL CONTRAST ECHOCARDIOGRAPHY DURING SEPTAL ETHANOL ABLATION

The intraarterial injection of an echo-enhancing agent allows for the specific localization of the vascular beds perfused by individual septal perforator branches of the left anterior descending artery. The vascular territory targeted by contrast echocardiography is the region of contact of the anterior mitral leaflet with the basal septum, which leads to LVOT obstruction. The site of leaflet-septal contact is typically adjacent to the zone of flow acceleration and color turbulence in the LVOT (Fig. 27-16).[12] Contrast agents that have been used during septal ethanol ablation have included sonicated human albumin (Albunex), Levovist, Optison, and most recently Definity. After the injection of the contrast agent, the segments of the interventricular septum supplied by the septal branch become opacified. The spatial extent of myocardial opacification can be determined from multiple transthoracic windows. The contrast effect of ethanol has the same distribution as that of the contrast agent, and intraarterial ethanol injection frequently results in increased echogenicity and reflectivity.

### IMPROVED OUTCOMES WITH CONTRAST ECHOCARDIOGRAPHY

Intraprocedural contrast echocardiography results in improved outcomes compared with the strategy of target vessel selection by probatory balloon occlusion.[12] The use of contrast echocardiography was associated with a shorter intervention time, a smaller amount of injected ethanol, a smaller infarct, and a significantly higher number of patients with more than 50% gradient reduction (92% versus 70%). The superiority of this echocardiographic approach persisted at 3-month follow-up, in terms of improvements in both the functional class and the magnitude of the LVOT gradient.[12]

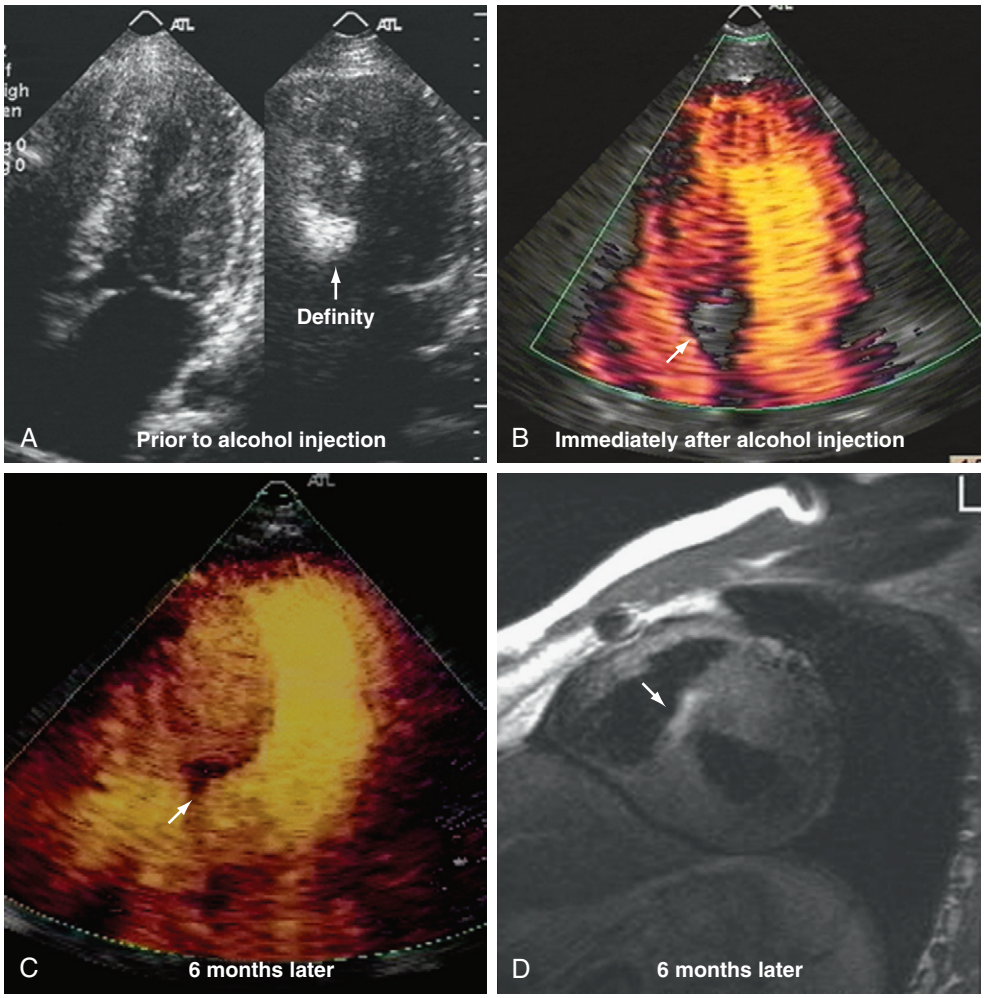

**Figure 27-16** **Intraprocedural myocardial contrast echocardiography during septal ethanol ablation. A,** Baseline echocardiogram prior to septal ethanol ablation (*left*). Following injection of echocardiographic contrast agent into first septal perforator of left anterior descending artery, contrast depot is identified in region of basal septum by transthoracic 2D apical imaging (*right*). **B,** Immediately after alcohol injection, venous injection of contrast demonstrates perfusion defect in basal septum (*arrow*). **C,** Repeat transthoracic apical view with contrast injection at 6 months postprocedure demonstrates thinning of basal septum and perfusion defect in basal septum (*arrow*). **D,** Corresponding cardiac magnetic resonance imaging at 6 months postprocedure demonstrating thinning of septum and evidence of scarring after gadolinium injection (*arrow*).

Contrast echocardiography is invaluable in detecting contrast opacification in regions remote from the site of mitral leaflet-septal contact. Echocardiographic guidance with a contrast agent can determine whether the selected septal branch supplies other territories such as the LV free wall or apex, RV free wall, or a papillary muscle (Fig. 27-17).[131,132] Contrast enhancement in nonseptal sites necessitates the selection of another vessel to be injected or abandonment of the procedure. Studies have shown that 7% to 11% of all procedures have been altered based on information obtained by contrast echocardiography.[131,133]

Furthermore, the size of the induced infarct, as determined by planimetry of the contrast-enhanced region, can provide incremental information regarding outcomes following septal ethanol ablation.[134] A septal infarction risk area of 3.5 $cm^2$ or greater has been associated with a higher risk of cardiovascular complications after the procedure (primarily pacemaker and defibrillator implantation), without necessarily improving the clinical and hemodynamic results of septal ethanol ablation.[134] In summary, myocardial contrast echocardiography optimizes septal ethanol ablation by permitting the targeted delivery of ethanol, by limiting the induced infarction to the culprit region of mitral leaflet-septal contact, and by minimizing procedural complications.

## CLINICAL RESULTS FOLLOWING SEPTAL ETHANOL ABLATION

Studies from multiple experienced centers have demonstrated that septal ethanol ablation can effectively reduce the LVOT gradient in patients with obstructive HCM.[135-138] Subsequent studies beyond 1 year following this procedure have shown ongoing symptomatic improvement.[139,140] Septal ethanol ablation results in an acute deterioration of basal septal function and a delay in LV ejection.[130] There is a gradual and continued decrease in the degree of LVOT obstruction,[135,138] with thinning of the infarcted septal segment and enlargement of the outflow tract.[141] Echocardiographic and Doppler studies are beneficial in the serial noninvasive follow-up of patients after septal ethanol ablation. Multiple studies have documented significant progressive reductions in basal septal thickness and the resting and provocable LVOT gradients.[135,138,142] These developments have been associated with favorable changes in the geometry of the LVOT.[130,141] In addition to the alleviation of LVOT

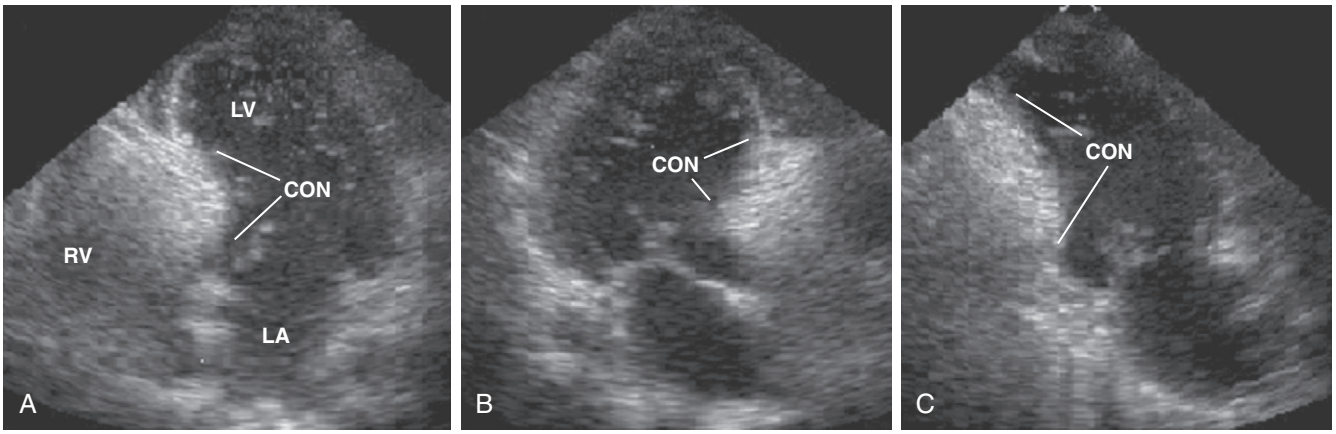

**Figure 27-17 Echocardiographic guidance of transcatheter septal ablation.** Intraprocedural myocardial contrast echocardiography during septal ethanol ablation is essential for guiding the targeted delivery of ethanol. After intraarterial injection of echocardiographic contrast (*CON*), transthoracic imaging from apical four-chamber view (**A**) and apical three-chamber view (**B**) shows opacification of basal and midposterior and anterior interventricular septum. However, apical two-chamber view (**C**) reveals contrast opacification of inferior wall. Selected vessel was not thought to be suitable for the injection of ethanol. No other septal perforator branches were identified; procedure was abandoned and patient referred for septal myectomy.

obstruction and septal remodeling, improvements in LV diastolic function have been demonstrated 6 months after this procedure.[104] These changes in diastolic function, as assessed by tissue and color M-mode Doppler, were sustained at 2 years of follow-up.[143] The long-term risk of late ventricular arrhythmias after induced infarction in patients with HCM remains unclear, although the majority of studies thus far have not demonstrated an increased risk of ventricular arrhythmias or of sudden death.[136,140,144]

## Surgical Myectomy

Septal myotomy or myectomy has been performed for the past four decades for the management of severe obstructive HCM refractory to maximally tolerated medical therapy. Septal myectomy acutely relieves outflow tract obstruction by widening of the LVOT, which leads to decreased SAM of the mitral valve and decreased dynamic outflow tract obstruction. Echocardiography is useful in the identification of patients suitable for surgical myectomy. The preoperative echocardiographic characteristics predictive of symptomatic benefit from surgical myectomy include asymmetric hypertrophy, severe SAM of the mitral leaflet(s), and a prolonged isovolumic relaxation time.[145] In addition, echocardiography plays an important role in detecting additional lesions requiring surgical management. Comprehensive preoperative echocardiographic imaging in patients referred for surgical myectomy includes the evaluation of independent mitral valve disease, concomitant aortic valve disease, and the assessment of additional levels of obstruction (midventricular or RV outflow tract).[11]

### INTRAOPERATIVE ECHOCARDIOGRAPHY

Surgical myectomy is performed from the transaortic approach and is technically challenging given the limited exposure and visualization of the hypertrophied septum. Before the introduction of intraoperative echocardiography, the extent and degree of septal hypertrophy was estimated by surgical palpation and by preoperative TTE studies. A key development in the surgical management of obstructive HCM has been the use of TEE imaging. Intraoperative echocardiography guides the surgical intervention(s), assesses immediate results, and excludes important complications.[11,146] Intraoperative TEE allows for detailed delineation of the depth, width and length of the required myectomy, the degree of SAM and LVOT obstruction, and the quantitation and mechanism(s) of mitral regurgitation.[11,83] Imaging from multiple transesophageal and transgastric views using a multiplane transducer allows for the careful assessment of the thickness of the anterior and posterior portions of the interventricular septum. The length of septal hypertrophy is measured from the base of the right coronary cusp of the aortic valve (Fig. 27-18). The targeted length of resection is 1 cm below the point of anterior mitral leaflet-septal contact. The LVOT gradient can be measured by transgastric imaging in the long-axis view with the CW Doppler beam aligned parallel to the LVOT. Following surgical excision of the basal septum, repeat echocardiographic imaging permits the instantaneous evaluation of the adequacy of the myectomy (Figs. 27-19 and 27-20).[11,146] Intraoperative echocardiography can determine if there is significant residual outflow tract obstruction (Fig. 27-21) or hemodynamically important residual mitral regurgitation. In addition, intraoperative echocardiography allows for the immediate detection of such operative complications as a ventricular septal defect[147] and LV dysfunction.[11] The value of intraoperative echocardiography was demonstrated in one study[148] showing that intraoperative TEE detected unexpected findings in 17% of cases before cardiopulmonary bypass and in 7% of cases after cardiopulmonary bypass. Intraoperative echocardiography prompted further surgical procedures in 4% of cases.

### OUTCOMES FOLLOWING MYECTOMY

Studies of the results of surgical myectomy from experienced tertiary referral centers have shown excellent early and long-term postoperative outcomes. Potential complications following myectomy include heart block, ventricular septal defect, aortic regurgitation, and arrhythmias. Aortic regurgitation is felt to be mainly secondary to the loss of aortic annular support after myectomy.[149] Echocardiographic studies performed at rest and with provocative maneuvers are important in the serial monitoring of patients following myectomy. Multiple studies

Meta-analyses include the five cohorts above (in addition to other cohorts).
$\Delta P_{LVOT}$, Left ventricular outflow tract gradient before (pre) and after (post) procedure; *PPM*, permanent pacemaker; *SEA*, septal ethanol ablation; *SM*, septal myectomy.

have documented a significant reduction or abolition of the resting outflow tract gradient in the majority of patients following myectomy, resulting in substantial and lasting symptomatic improvement.[150-154] In addition, a recent study comparing invasive versus conservative management has demonstrated that invasive treatment results in improved overall, but not HCM-related, survival.[155]

## Comparison of Treatment Strategies for Obstructive Hypertrophic Cardiomyopathy

Multiple therapeutic options are currently available in the management of patients with obstructive HCM. Pharmacologic agents have variable effects in reducing the outflow tract gradient and in improving diastolic function. Patients with drug-refractory symptoms are candidates for dual-chamber pacing, septal ethanol ablation, or surgical myectomy. The initial enthusiasm for dual-chamber pacing as a treatment modality for LVOT obstruction has declined considerably. In terms of the outcomes of septal ethanol ablation compared with myectomy, there have been several nonrandomized studies that have compared these two treatment strategies.[144,156,158-161] No significant differences in cardiac mortality during early and midterm follow-up were identified. Patients who underwent septal ethanol ablation were more likely to develop atrioventricular block and require permanent pacing.[156,157,159] All these studies showed similar improvements in the functional class and in the resting LVOT gradients following both procedures (Table 27-3).[156-160] The greatest difference in the resting gradients between the two treatment groups occurred at 3 months after the procedure, when patients with septal ethanol ablation were more likely to have a larger resting outflow tract gradient.[158] This divergence likely emerged because myectomy offers immediate relief of the LVOT gradient, whereas the effect on the gradient with septal ethanol ablation is more gradual, with the maximal reduction in the gradient occurring at more than 1 year after the procedure.[138,140] In addition, the long-term benefits of myectomy have been well demonstrated, whereas the long-term sequelae of septal ethanol ablation have yet to be determined. Conditions that favor the selection of myectomy over septal ethanol ablation include the presence of coexisting disease (e.g., coronary artery disease, intrinsic disease of the mitral valve or subvalvular apparatus), the presence of coronary anatomy not amenable to septal ethanol ablation, the requirement for an acute reduction in the LVOT gradient, or the presence of extreme septal hypertrophy.

Septal ethanol ablation and surgical myectomy are challenging techniques. Importantly, both procedures need to be performed at centers with both technical and echocardiographic expertise. Comprehensive preprocedural echocardiographic assessment is essential for identifying patients with additional lesions that require surgical correction. The success of both septal ethanol ablation and myectomy depends on experienced intraprocedural echocardiographic guidance, with myocardial contrast echocardiography during septal ethanol ablation and TEE during myectomy. Intraprocedural echocardiographic guidance is indispensable for the identification of the culprit septal segments requiring chemical or surgical reduction, the immediate assessment of the LVOT gradient in response to septal infarction or myectomy, and the monitoring of potential complications.

## KEY POINTS

- The diagnostic feature of HCM on echocardiography is the finding of asymmetric septal hypertrophy, defined as a septal/posterior wall ratio of 1.3 or greater. The maximal wall thickness is typically at least 15 mm.
- Because there may be delayed penetrance of HCM, which has an autosomal dominant pattern of inheritance, serial screening (every 5 years) throughout adulthood is advised for the first-degree relatives of patients.
- The differential diagnosis of HCM is broad. Alternate causes of increased LV wall thickness include other causes of LV hypertrophy (e.g., hypertensive heart disease, athlete's heart), storage diseases (e.g., Fabry, glycogen storage diseases), and infiltrative cardiomyopathies (e.g., amyloidosis).
- 2D echocardiography with imaging from several transthoracic windows is used to determine the extent, distribution, and severity of LV hypertrophy.
- The pathophysiology of LVOT obstruction involves narrowing of the LVOT (due to septal hypertrophy, intrinsic abnormalities of the mitral leaflets, or anterior displacement of the mitral apparatus) and hydrodynamic forces causing SAM.
- The LVOT gradient can be measured with CW Doppler, where the pressure gradient = $4 \times V^2$ (V = LVOT velocity). The Doppler spectral profile is typically a dagger-shaped configuration.
- Subtypes of HCM that can be distinguished by echocardiography are asymmetric apical HCM, midventricular obstruction, latent obstructive HCM, and HCM of the elderly.
- Diastolic function in patients with HCM can be assessed with tissue Doppler imaging and color M mode Doppler.
- Septal ethanol ablation should be performed with myocardial contrast echocardiographic guidance, which allows for the targeted delivery of ethanol to the basal septum, avoids infarction of nonseptal sites, and minimizes complications.
- Intraoperative TEE during surgical myectomy provides detailed visualization of the septum and the mitral apparatus in order to guide the surgical resection and permits immediate assessment of the degree of residual outflow tract obstruction and mitral regurgitation.

## Definition of Restrictive Cardiomyopathy

Restrictive cardiomyopathy is an idiopathic or systemic myocardial disorder characterized by a primary abnormality of diastolic function leading to diastolic heart failure in the presence of normal or mildly abnormal systolic function. A recent consensus statement proposed replacement of the terms *systolic* and *diastolic heart failure* with HFrEF (heart failure with reduced ejection fraction) and HFpEF (heart failure with preserved ejection fraction), respectively, because diastolic dysfunction is highly prevalent in systolic heart failure,[1] and there is evidence to suggest reduced systolic tissue velocities in diastolic heart failure.[2] Primary diastolic dysfunction in HFpEF leads to abnormal ventricular filling, resulting in an increase in ventricular end-diastolic pressures and dilated atria. Biventricular volumes are either reduced or normal, and systolic function impairment manifest as reduced ejection fraction is seen in the late stages of the disease.[3]

Patients commonly present with congestive failure with fatigue, exercise intolerance, right-sided or left-sided heart failure, and atrial fibrillation.[4] An elevated jugular venous pressure with an x and prominent y descent, y descent only (late-stage), and Kussmaul sign may be present, although pulsus paradoxus is always absent. Depending on the stage of disease, an S4 (early) or S3 (late) may be present. Restriction can be isolated to either ventricle or show biventricular involvement[5] (Table 28-1). The prognosis of restrictive cardiomyopathies is generally poor, except for those with reversible causes such as hemochromatosis. Doppler echocardiography plays a key role in the diagnosis and management of this disease entity.

## Imaging

Guidelines on the diagnosis of HFpEF[1,2] require objective evidence of diastolic left ventricular (LV) dysfunction in addition to clinical features of heart failure and LV ejection fraction greater than 50%.[6] Thus, imaging modalities play a pivotal role in 2 of the 3 diagnostic criteria of HFpEF.[7]

## Echocardiographic Features

Echocardiographic assessment for restrictive cardiomyopathy includes measurement of LV wall thickness, LV mass, LV volumes, LV ejection fraction, and a comprehensive evaluation of diastolic function[8-10] (Table 28-2). More recently specific pattern of late gadolinium enhancement on magnetic resonance imaging (MRI) has been shown in restrictive cardiomyopathy of varying etiology. A number of important observations relative to this topic have been made recently, including the assessment of LV mass and volumes by three-dimensional (3D) echocardiography and assessment of myocardial function by two dimensional strain.

Restrictive cardiomyopathy is characterized by concentric remodeling with marked increase in wall thickness relative to cavity size and preservation of LV volumes (Figs. 28-1 and 28-2). Echocardiographic LV mass assessment by M-mode (see Fig. 28-2) has been replaced by two-dimensional (2D) methods. More recently, 3D echocardiographic measurement of LV mass has been shown to be more reproducible than 2D and to closely approximate cardiac MRI.[11] (See Chapters 4 and 9.) Assessment of LV volumes using biplane Simpson's method is used to measure LV volumes in the four- and two-chamber views. However, there is an inherent variability in ejection fraction measurement of ±5%, and lack of endocardial border visualization occurs in up to 30% of patients, precluding precise evaluation of LV ejection fraction. Use of contrast imaging improves accuracy of volume measurements by both 2D and 3D echocardiography.[12] More recently, 3D echocardiography has been shown to have superior reproducibility and closer approximation to MRI than 2D echocardiography in the measurement of LV ejection fraction.[13,14]

Atrial enlargement is often significant (see Fig. 28-1) and is associated with the grade of diastolic dysfunction. Mild,

**TABLE 28-1 Classification of Restrictive Cardiomyopathy**

moderate, and severe diastolic dysfunction is often associated with left atrial (LA) volume index greater than 28 mL/m$^2$, greater than 35 mL/m$^2$, and greater than 40 mL/m$^2$, respectively. Simpson's biplane method or the area length method is used for assessment of LA volumes, and the two methods are closely correlated. More recently, 3D LA volumes have been shown to have less variability than 2D methods.[15]

## SPECKLE TRACKING

Speckle tracking technology is a newer echocardiographic method to evaluate segmental and global systolic LV function by tracking small myocardial regions of interest on 2D as well as 3D cineloops from frame to frame.[16] It allows assessment of subclinical LV and right ventricular (RV) systolic dysfunction even when the LV ejection fraction and segmental function appear preserved[17] and provides greater accuracy than LV ejection fraction in predicting events in patients with heart failure.[18] Radial, longitudinal, and circumferential myocardial deformation can be measured, because the technique is angle independent. (See Chapter 10.) It allows evaluation of basal clockwise and apical counterclockwise myocardial rotation and net LV twist. Longitudinal and radial systolic strains are reduced in diastolic heart failure, although LV twist is preserved.[19] Recent data suggest that in patients with elevated LV filling pressure and

**TABLE 28-2 Echocardiographic Features of Restrictive Cardiomyopathy**

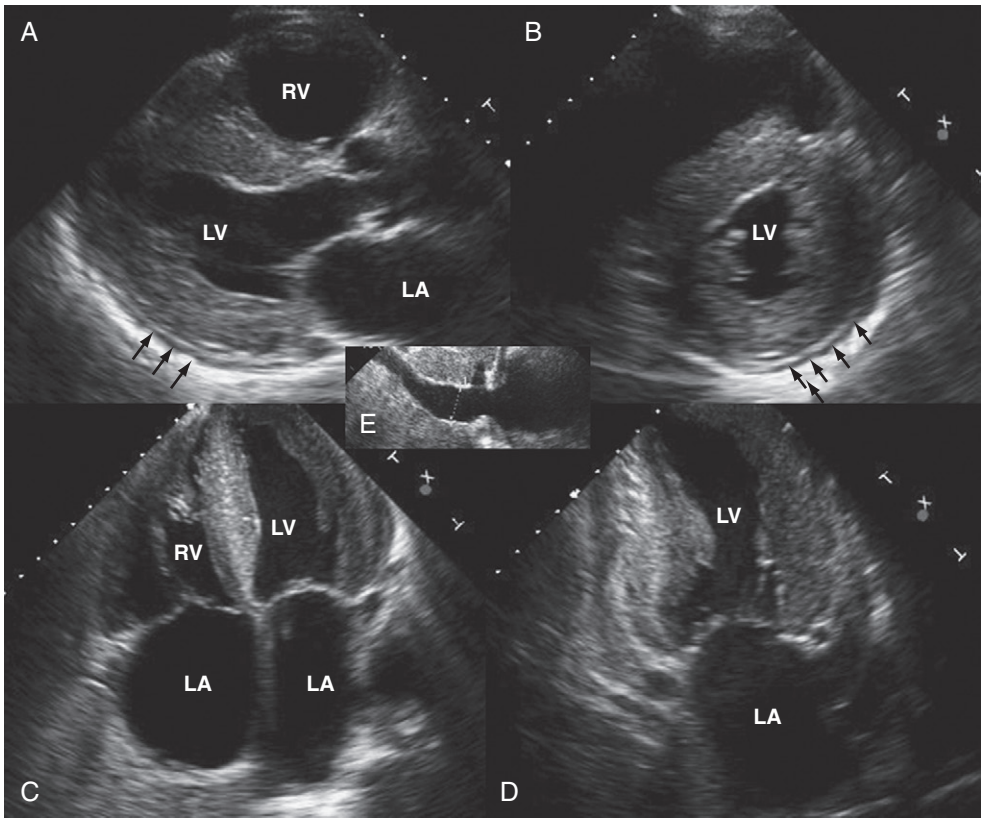

**Figure 28-1** **Cardiac amyloidosis. A,** Parasternal long-axis, (**B**) short-axis, (**C**) apical four-chamber, (**D**) apical two-chamber, and (**E**) subcostal views. Marked generalized hypertrophy is shown in all views. Note ground-glass appearance of myocardium, biatrial and RV enlargement, and small pericardial effusion (*arrows*) as well dilated inferior vena cava indicating elevated right atrial pressure.

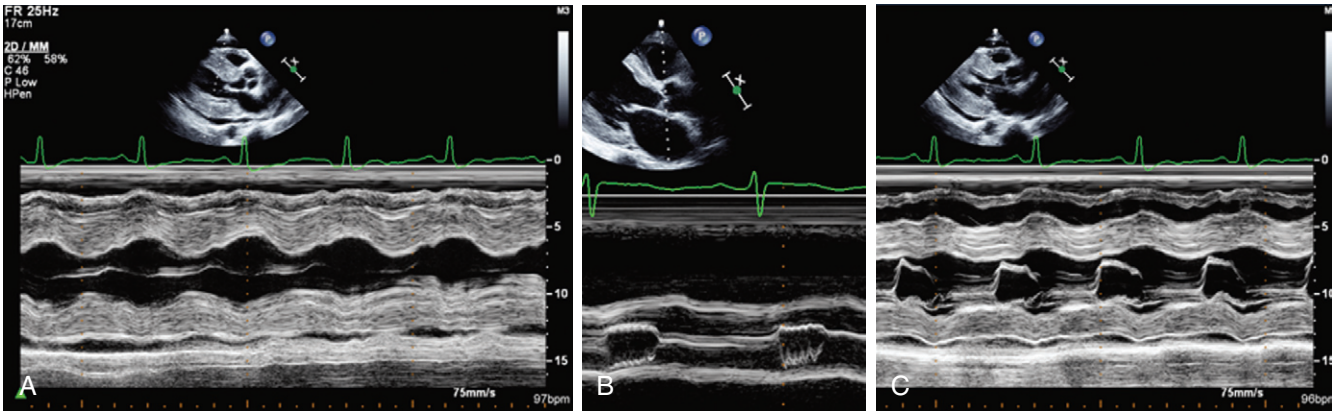

**Figure 28-2** **M-mode findings in senile cardiac amyloidosis. A,** Parasternal long-axis M-mode showing dilated RV and normal sized LV and marked increase in LV wall thickness. **B,** M-mode at aortic valve level showing deceased systolic opening time of aortic valve as well markedly reduced excursion of aortic root indicating reduced cardiac output and reduced atrial mechanical function. **C,** Reduced diastolic opening time of mitral valve consistent with reduced cardiac output.

preserved LV ejection fraction, significant abnormalities in myocardial mechanics are observed by speckle tracking with reduced longitudinal, radial, and circumferential strain rates, thus challenging the notion of HFpEF as an isolated diastolic dysfunction.[20] Other work has shown that although the deterioration of myocardial function begins in the longitudinal direction, patients with more advanced heart failure develop abnormalities in the radial and circumferential directions as well.[21]

## Doppler Features

Echocardiography is the gold standard for evaluation of diastolic LV and RV function.[22,23] (See Chapter 11.) Reports are, however, beginning to emerge of the feasibility of MRI and its modest correlation with Doppler echocardiography in evaluation of mitral inflow filling pattern in patients with cardiac amyloidosis.[24] However, the cardiac MRI technique remains time consuming and is not used clinically for assessment of diastolic function.

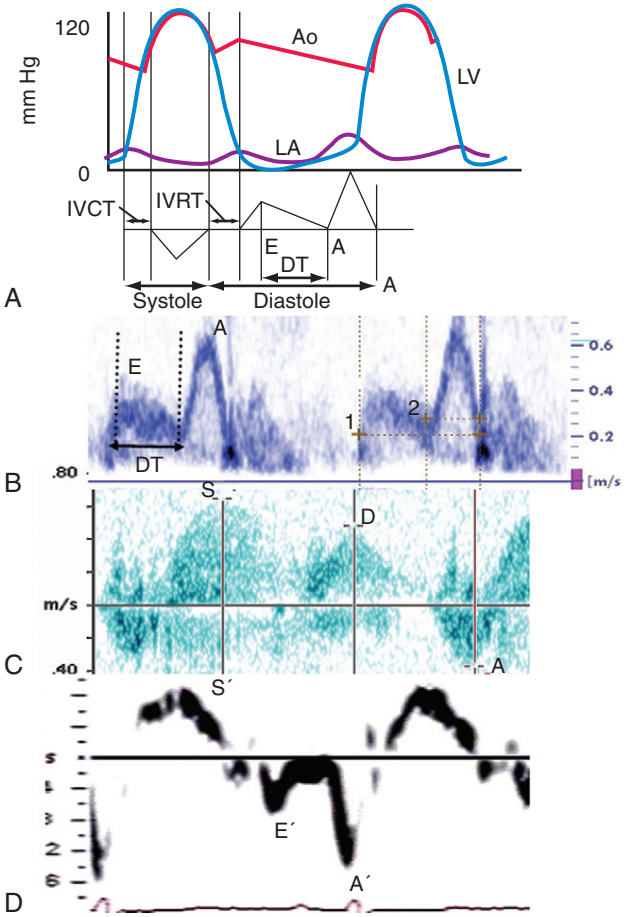

**Figure 28-3 Doppler findings with delayed LV relaxation.** LV, LA, and aortic (*Ao*) pressure tracings (**A**), mitral inflow PW Doppler (**B**), pulmonary vein PW Doppler (**C**), and mitral annular tissue Doppler (**D**) tracings are shown. Mitral inflow velocities were obtained by placing the PW Doppler sample volume between the tips of the mitral leaflets and Doppler tissue imaging by placing the PW Doppler sample volume at the lateral mitral annulus. *Large black horizontal arrows* depict duration of ventricular systole and ventricular diastole. Ventricular relaxation continues to occur in the latter third of diastole, causing E/A ratio less than 1 and prolonged mitral inflow deceleration time. Pulmonary vein flow pattern is systolic dominant, and there may be significant pulmonary vein atrial reversal. *D*, Diastolic; *DT*, deceleration time; *IVCT*, isovolumic contraction time; *IVRT*, isovolumic relaxation time; *S*, systolic.

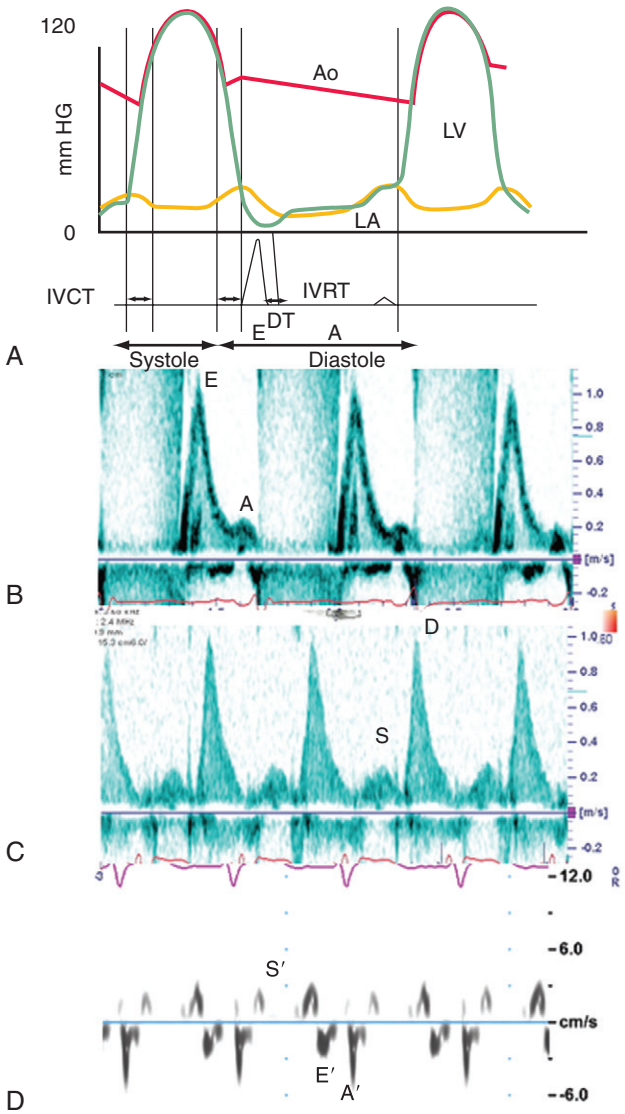

**Figure 28-4 Doppler findings with restrictive cardiomyopathy.** LV, LA, and aortic (*Ao*) pressure tracings (**A**), mitral inflow PW Doppler (**B**), pulmonary vein PW Doppler (**C**), and mitral annular tissue Doppler (**D**) show abnormal LV relaxation, abnormal LA and LV compliance, and elevated LA filling pressure. Mitral inflow velocities were obtained by placing the PW Doppler sample volume between the tips of the mitral leaflets and Doppler tissue imaging by placing the PW Doppler sample volume at the lateral mitral annulus. *Large black horizontal arrows* depict duration of LV systole and LV diastole. Early diastolic LV filling occurs due to the pressure gradient between LA and LV. Filling beyond first third of diastole is halted due to increase in LV diastolic pressure. Atrial contraction leads to a small filling A wave and marked pulmonary vein atrial reversal (unless in advanced stages when atrial pump failure occurs as shown in this example where no significant atrial reversal wave is seen despite a small mitral inflow A wave). Pulmonary vein PW Doppler shows marked S and D reversal with shortened pulmonary vein D-wave deceleration time. *D*, Diastolic; *DT*, deceleration time; *IVCT*, isovolumic contraction time; *IVRT*, isovolumic relaxation time; *S*, systolic.

### *Mitral Inflow Pulsed-Wave Doppler*

Diastolic features of restrictive cardiomyopathy show a spectrum of findings of increasing abnormality diastolic function, from normal diastolic function to abnormal relaxation (Fig. 28-3) and finally to a progressively abnormal chamber compliance leading to increase in LA and LV filling pressures (Figs. 28-4 and 28-5). In the early stages of the disease, mitral inflow filling pattern shows an abnormal relaxation pattern characterized by E/A ratio of less than 1, a prolonged mitral inflow E-wave deceleration time, and a prolonged isovolumic relaxation time (see Fig. 28-3). As the disease progresses and LA and LV diastolic compliance abnormality sets in, a pseudonormal phase is seen on mitral inflow that can reverse to an abnormal relaxation pattern on Valsalva maneuver.[25] With severe abnormalities of ventricular compliance, advanced diastolic dysfunction develops, characterized by a markedly increased E velocity. Deceleration time (DT) becomes short from rapid equalization of left atrioventricular pressure soon after early diastolic filling in a noncompliant ventricle (see Figs. 28-4 and 28-5). Because of poor LA function and limited late diastolic left atrioventricular pressure gradient from an elevated LV diastolic pressure, A-wave amplitude becomes small. Initially, this *restrictive mitral inflow pattern* is reversible on preload reduction with the Valsalva maneuver (Fig. 28-6) or nitroglycerin or diuretic administration. Finally, an irreversible restrictive pattern develops with no significant change with preload reduction (Fig. 28-7).

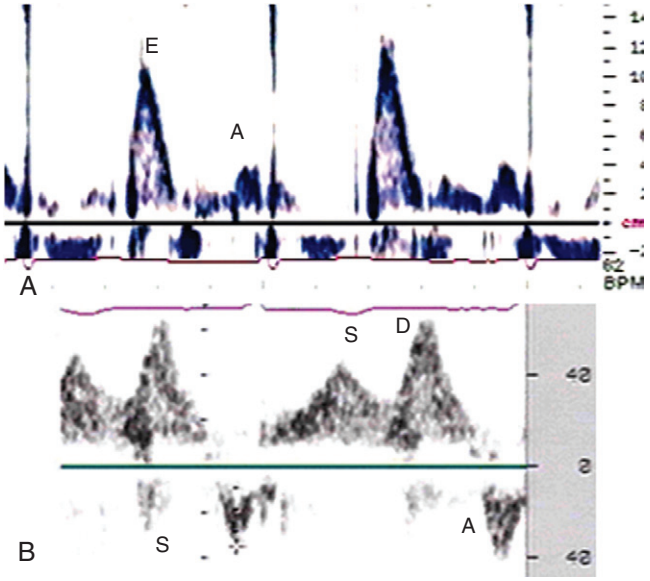

**Figure 28-5 Severely reduced LV diastolic compliance.** Restrictive mitral inflow (**A**) and pulmonary vein inflow (**B**) showing S and D reversal along with a prominent atrial reversal velocity and duration.

### *Pulmonary Vein Pulsed-Wave Doppler*

In the early stages of the disease, pulmonary vein flow may show a systolic dominant pattern with systolic-to-diastolic (D/S) ratio greater than 1 (see Fig. 28-3). Atrial reversal may be normal in early stages, and then as LA compliance abnormality sets in, progressively increasing A-wave velocity as well as duration develop (see Figs. 28-5 and 28-7). With progressively increasing compliance abnormality, decreased S and increased D waves on pulmonary vein Doppler occur (see Figs. 28-4, 28-5, and 28-7). The S wave becomes blunted due to decreased LA compliance, increased mean LA pressure,[26] and LV pressure.[27] Presence of significant mitral regurgitation may further blunt the S wave because of competing mitral regurgitation and pulmonary vein flow at the atrial inflow chamber.[28] In the presence of atrial fibrillation, marked blunting of pulmonary vein S wave with or without mitral regurgitation is the rule. The pulmonary-vein D wave that results from the pulmonary vein–LA pressure gradient created during atrioventricular filling in early LV diastole is dependent on the same factors that influence the early mitral velocity and its DT. Hence, in advanced stages of the disease a tall D wave with a shortened DT is seen (see Figs. 28-4 and

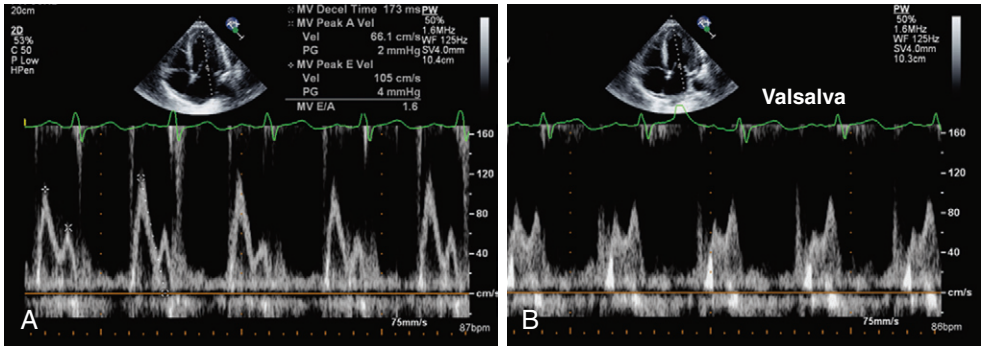

**Figure 28-6 Effect of Valsalva maneuver on mitral inflow filling pattern in a patient with restrictive cardiomyopathy.** Baseline E/A ratio is 1.6 (**A**) and reduced to 0.77 post Valsalva maneuver (**B**), indicating moderate diastolic dysfunction and reversible restrictive diastolic filling.

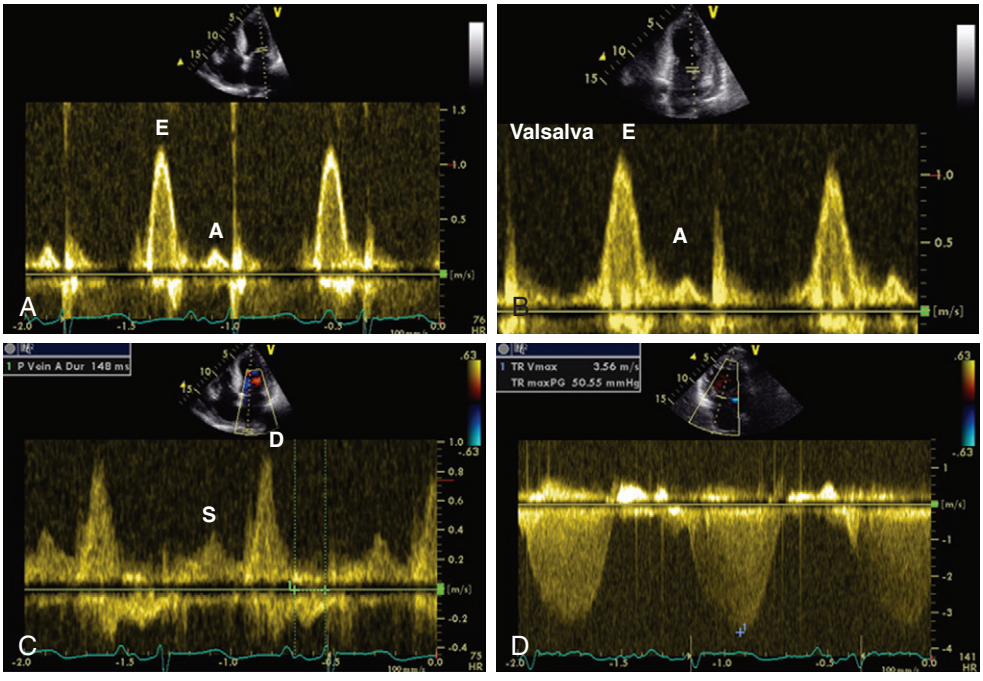

**Figure 28-7 Doppler characteristics of patients with restrictive cardiomyopathy. A,** Restrictive mitral inflow with increased E/A ratio and short mitral inflow E-wave deceleration time. **B,** No change in mitral inflow restrictive filling pattern with Valsalva maneuver, suggesting grade IV or advanced LV diastolic dysfunction. **C,** Restrictive pulmonary vein inflow with reversed S/D ratio and short pulmonary vein D-wave deceleration time. **D,** Increased pulmonary artery systolic pressure (RV-RA gradient of 3.56 m/s corresponding to a pressure gradient of 51 mm Hg in this case example).

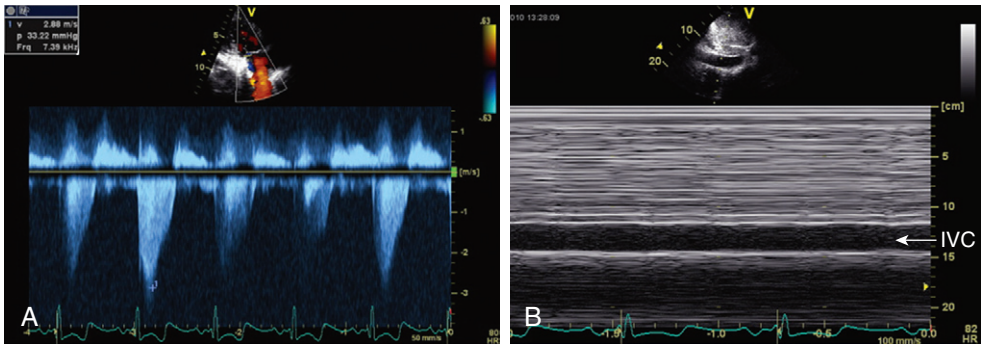

**Figure 28-8 Other Doppler features of restrictive cardiomyopathy. A,** V-shaped tricuspid regurgitation (TR) CW signal indicating elevated RA pressure. In addition, phasic change in tricuspid inflow and TR severity and gradient is noted. **B,** M-mode of the inferior vena cava (*IVC*) in the subcostal view showing dilated IVC without respiratory variation suggesting elevated RA pressure.

28-7). With abnormal LV relaxation and compliance, an increase in LV end-diastolic pressure leads to minimal atrioventricular filling on atrial contraction and a prominent and prolonged pulmonary vein A-wave reversal that becomes greater than the mitral inflow atrial duration. Finally, impairment of LA contraction due to mechanical atrial failure leads to a decrease in amplitude and duration of the pulmonary-vein A wave.[8]

Other pulsed-wave (PW) Doppler features include decreased tricuspid inflow DT on inspiration, D greater than S on the hepatic vein, and A-wave reversal in the hepatic vein on inspiration.

### *Color Doppler*

Moderate mitral and tricuspid valve regurgitation are often present. Because of a marked increase in LV end-diastolic pressure, diastolic mitral regurgitation may be seen, especially in the presence of first-degree heart block.

### *Continuous-Wave Doppler*

A characteristic V-shaped tricuspid regurgitation signal indicating elevated right atrial pressure may be seen (Fig. 28-8), along with mitral and tricuspid valve regurgitation on CW Doppler. Increased LV and RV *dP*/*dt* may be noted on CW Doppler signals.

### *Tissue Doppler*

#### Mitral Annulus

Unlike load dependence of mitral and pulmonary vein PW Doppler flow patterns, tissue Doppler imaging (TDI) of the septal and lateral mitral annulus allows more reliable and direct quantitation of myocardial relaxation.[29-31] With progressively increasing stages of the disease, the myocardial early motion wave shows a progressive decline in its amplitude so that the ratio of mitral inflow E wave to mitral annular E wave increases progressively (see Figs. 28-3 and 28-4). A markedly diminished velocity of diastolic motion is observed in patients with advanced restrictive cardiomyopathy (Fig. 28-9). In fact, decreased TDI velocities are used as a diagnostic method of differentiating between constrictive pericarditis (in which TDI velocities of mitral annulus are preserved) and restrictive cardiomyopathy when mitral annular E wave is less than 8 cm/s.[32] Systolic (S′) velocity of TDI of tricuspid annulus is a good measure of RV systolic function with a low-normal value of 10 cm/s.[33,34] A decrease in RV systolic and diastolic velocities is also often present and reflects a global impairment in myocardial relaxation (Fig. 28-10).

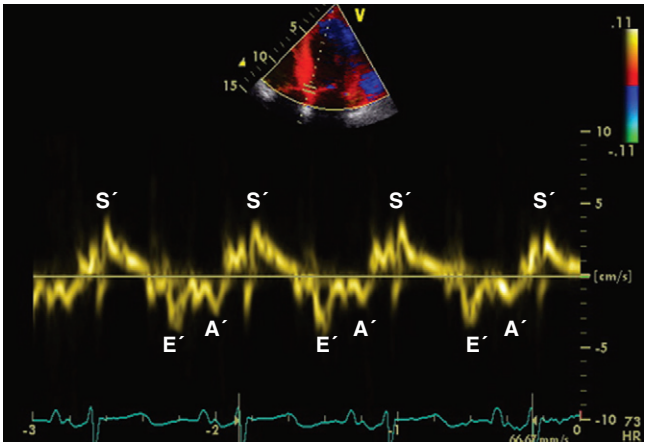

**Figure 28-9 Grade IV LV diastolic dysfunction.** Mitral septal annular tissue Doppler showing markedly reduced systolic (*S′*) as well as diastolic velocities (*E′* and *A′*).

#### Color M Mode

Patients with restrictive cardiomyopathy show a significantly slower slope of the first aliasing contour of velocity of propagation (Vp) on color M-mode. An E/Vp ratio greater than 1.5 can be used to assess elevated LV end-diastolic pressure[35] (Fig. 28-11).

## Cardiac Magnetic Resonance Imaging

Visual inspection of LV and RV architecture on MRI is able to identify patterns of regional or diffuse wall thinning and concentric or asymmetric hypertrophy. Pericardial thickness and calcification can be assessed to distinguish pericardial constriction from restrictive cardiomyopathy. Specific patterns of fibrosis and scarring are seen in different types of restrictive cardiomyopathies that may initially present with HFpEF.[36-39]

## Specific Restrictive Cardiomyopathies

Restrictive cardiomyopathies are associated with characteristic imaging features, although none is particularly sensitive or specific for the underlying etiology (see Table 28-1).[40] In most cases, careful consideration of the clinical context and endomyocardial biopsy may be required. Infiltrative processes and metabolic storage diseases including amyloidosis, hemochromatosis, sarcoidosis, Fabry disease, and glycogen storage diseases are the most frequent causes of restrictive cardiomyopathies. Less common forms of restrictive cardiomyopathies include

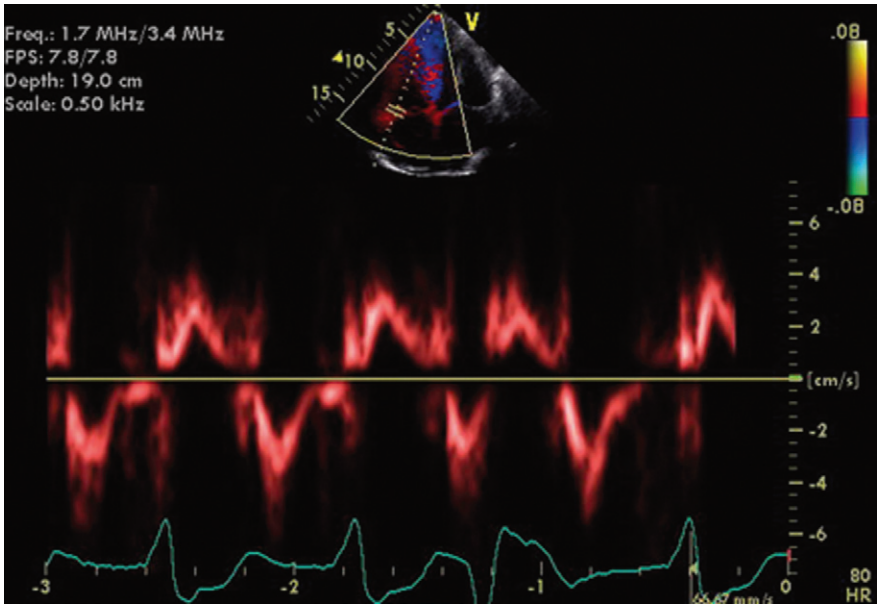

**Figure 28-10 Cardiac amyloidosis with atrial fibrillation.** Reduced systolic (S′) and diastolic (E′) tissue Doppler tricuspid annular velocities with the absence of A′ waves due to atrial fibrillation. Tissue Doppler PW sample volume is placed at the lateral tricuspid annulus in the four-chamber view.

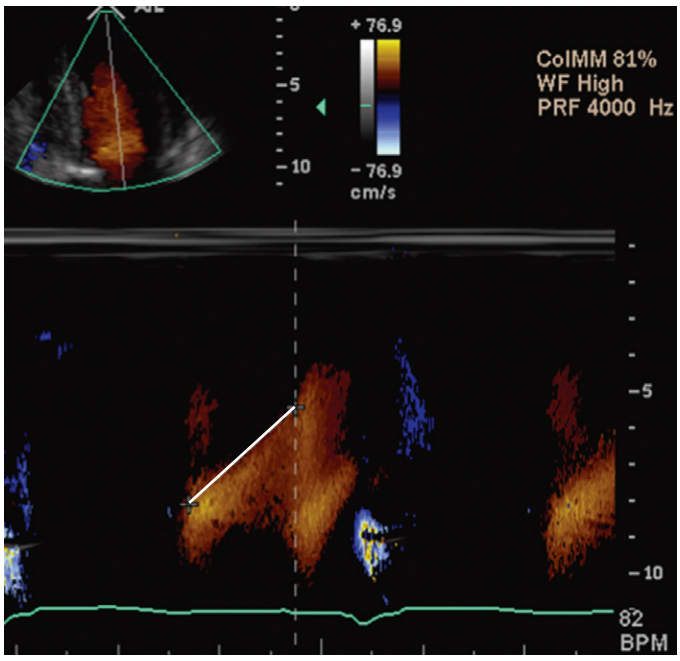

**Figure 28-11 Reduced E-wave propagation velocity with cardiac amyloidosis.** Markedly reduced velocity of E-wave propagation (Vp 13 cm/s) on color M-mode indicating markedly abnormal LV relaxation.

endocardial fibrosis associated with the hypereosinophilic syndrome (Loeffler cardiomyopathy), idiopathic restrictive cardiomyopathy scleroderma,[41,42] carcinoid syndrome,[43] and metastatic malignancy.[44]

## AMYLOIDOSIS

Amyloidosis is the most commonly encountered and recognized cause of restrictive cardiac disease. Four different types of amyloidosis have been described according to the underlying disease:

1. *Immunoglobulin amyloidosis:* Immunoglobulin amyloidosis constitutes about 85% of all newly diagnosed cases of amyloidosis. It includes primary amyloidosis, multiple myeloma, and other plasma cell dyscrasias such as B cell lymphoma and Waldenström macroglobulinemia.[45] The building block of the amyloid fibril is an immunoglobulin light-chain protein. Primary amyloidosis is a plasma cell disorder in which approximately 5% to 10% of bone marrow plasma cells have clonal dominance of a light chain isotype.[46] There is predominance of lambda versus kappa free light chains (3:1) in primary AL amyloidosis; in comparison, other plasma cell dyscrasias, such as multiple myeloma, usually have a lambda-to-kappa ratio of 1:2. Common presenting features include nephrotic syndrome, sensorimotor peripheral neuropathy, hepatomegaly, splenomegaly, and, less often, macroglossia.[47]
2. *Familial amyloidosis:* Familial amyloidosis, or hereditary amyloidosis, is less common than primary amyloidosis and is caused by an autosomal-dominant mutation, most frequently in the transthyretin gene.[48] Common features include peripheral neuropathy, renal impairment, autonomic dysfunction with mainly gastrointestinal symptoms, and cardiomyopathy.[49] Macroglossia does not occur, and renal involvement is less prevalent than it is in primary AL amyloidosis.
3. *Senile systemic amyloidosis:* Senile systemic amyloidosis affects approximately 25% of patients over the age of 80 and is derived from normal transthyretin.[50] This type of amyloidosis mainly involves the atria (91%) and less often is isolated in the aorta or involves the entire heart.[51] Senile cardiac amyloidosis is not always a benign condition and can result in heart failure, atrial fibrillation, and other conduction disturbances.[52] Isolated atrial involvement may occur.[53]
4. *Secondary amyloidosis:* Secondary amyloidosis is characterized by reactive amyloid fibrils, which are acute-phase reactants produced in response to systemic inflammation such as tuberculosis, leprosy, rheumatoid arthritis, familial

Mediterranean fever, inflammatory bowel syndrome, chronic lung diseases, and chronic infections.

### Cardiac Features

Restrictive cardiomyopathy is the main finding in cardiac amyloidosis. There is replacement of normal myocardial contractile elements by deposits of amyloid, leading to alterations in cellular metabolism, calcium transport, receptor regulation, and cellular edema. Injury can also occur from circulating light chains in the absence of amyloid fibril formation.[54] Amyloid myocardium becomes firm, rubbery, and noncompliant. Involvement of the cardiac conduction system can lead to fibrosis of sinoatrial and atrioventricular nodes as well as involvement of infra His fibers, leading to various types of heart block and arrhythmias.[55] Another cardiac manifestation can be cor pulmonale due to amyloid infiltration of pulmonary vasculature, causing significant pulmonary hypertension.[56] An infarction pattern in the absence of epicardial coronary disease is not uncommon as a result of amyloid deposition in the coronary microvasculature.[57]

Cardiac involvement is most common in immunoglobulin amyloidosis, occurring in about 50% of patients with congestive heart failure in about 25% of patients. Cardiac involvement is less common in other forms of primary amyloidosis and least common in secondary amyloidosis. Specific echocardiographic features occur in two third of patients[58] and in 91% of patients in a recent study and include thickening of the LV walls with low voltages on electrocardiography, increased myocardial reflectivity (the "speckled" or "granular" or "ground glass" pattern), biatrial enlargement, thickening of the interatrial septum, thickening of mitral and tricuspid valves, mitral and tricuspid regurgitation, presence of a small-to-moderate pericardial effusion and various abnormalities in diastolic filling and filling pressures depending on the stage of the disease (see Figs. 28-1 through 28-11), with restrictive filling pattern only in the advanced stages.[59] A marked reduction in tissue Doppler velocities, strain, and strain rate occurs in amyloidosis[60] even in early stages (see Fig. 28-9). Further studies are needed to define prognostic relevance of TDI and myocardial strain and strain rate[61] for earlier diagnosis of cardiac amyloid. Significant LV hypertrophy and wall motion abnormalities may be seen in patients with secondary amyloidosis.[62] Differential diagnosis of amyloidosis includes hypertrophic cardiomyopathy and other infiltrative cardiomyopathies. Decreased LV function strongly suggests absence of hypertrophic cardiomyopathy.

LA dysfunction preceding echocardiographic features of amyloidosis can be detected by atrial strain and rate. In 95 patients with amyloid LA ejection fraction was lower compared to controls ($40.4 \pm 13.6$ vs. $67.0 \pm 6\%$, $P = 0.01$). LA septal strain rate and strain were lower compared to controls ($0.8 \pm 0.5\ s^{-1}$ and $5.5 \pm 4\%$, respectively) compared with controls ($1.8 \pm 0.8\ s^{-1}$ and $14 \pm 4\%$, respectively, $P \leq 0.0001$).[63]

Endomyocardial biopsy remains the definitive diagnostic method for cardiac amyloidosis.[64] Transthoracic echocardiography has played a major role in the evaluation of amyloid deposition in the heart and is the procedure of choice for the noninvasive diagnosis of cardiac amyloid.[41] Increased myocardial echogenicity is useful for diagnosing cardiac amyloidosis. Especially in the presence of increased atrial thickness, specificity can reach 100%; however, this feature is evident only in the advanced stages of the disease. If the combined clinical[65] and echocardiographic picture suggests amyloidosis, then immunocharacterization of the underlying amyloid protein can be obtained less invasively from extracardiac tissue sites.[66] These sites include the tongue, subcutaneous fat pads, kidneys, bone marrow, gastric mucosa, and, less commonly, rectal mucosa.

### Other Diagnostic Approaches

A number of modalities besides echocardiography help arrive at a diagnosis of restrictive cardiomyopathy from amyloidosis. These are listed in Table 28-3.

Circulating free immunoglobulin light chains are found in over 98% of patients with primary amyloidosis and are used to determine prognosis and response to chemotherapy.[67] Serum levels of cardiac troponin (in response to myocardial injury) and pro–brain natriuretic peptide[68] (released in response to myocardial stress) are independent predictors of survival in patients with primary amyloidosis. Immunocharacterization of the underlying amyloid protein can be obtained by extracardiac tissue sites.[69] However, endomyocardial biopsy remains the definitive diagnostic method for cardiac amyloidosis. Nonbranching extracellular fibrils, interstitial eosinophilic amyloid deposits as homogenous waxy material on eosin hematoxylin staining, and apple-green birefringence Congo red staining under polarized light are the most common findings on pathology.[70] The characteristic fibrillar pattern of the amyloid deposits can be seen by electron microscopy and immunohistochemical staining can then be used to determine the type of amyloid deposit.[71] Combining a subcutaneous fat pad biopsy and Congo red staining of bone marrow has yielded a tissue diagnosis in 90% of patients with amyloidosis.[72] Electrocardiography shows a low voltage in up to 50% of patients with cardiac amyloidosis and, in conjunction with LV hypertrophy on echocardiography, should raise the suspicion for cardiac amyloidosis.[63]

Nuclear scintigraphy with $^{99}$Tc pyrophosphate[73] or indium-labeled serum amyloid protein can detect extensive cardiac involvement of cardiac amyloidosis.[74] Technetium pyrophosphate scan is positive in familial and senile amyloidosis (100% accuracy for diagnosis) and negative in primary amyloidosis (100% specificity).[74] Serum amyloid P component (SAP) is a normal circulating plasma protein that is deposited on amyloid fibrils because of its specific binding affinity for these fibrils. Scintigraphy after the injection of $^{123}$I-SAP can be used for diagnosing, locating, and monitoring the extent of systemic amyloidosis.[75]

The role of cardiac MRI has recently expanded in the diagnosis of cardiac amyloidosis. In patients with histologically verified cardiac amyloidosis, abnormal late gadolinium enhancement was found in 97% of patients and increased echocardiographic LV wall thickness in 91% patients.[76] Presence of late gadolinium enhancement on cardiac MRI in the absence of echocardiographic findings of cardiac amyloidosis is associated with worse clinical profile and disease severity.[77] Global subendocardial (Fig. 28-12, *A*) or transmural late gadolinium enhancement (see Fig. 28-12, *B*) along with reduced subendocardial to blood T1 difference on MRI has been reported to be very accurate in advanced stages of cardiac amyloidosis[39]; however, utility of cardiac MRI in early stages of the disease has not been evaluated (see Table 28-3).[77]

### Natural History

Onset of congestive heart failure is associated with poor prognosis, often with a survival less than 6 months. The prognosis varies according to the type of amyloidosis, the stage of the disease, and the age of the patient at the time of diagnosis. Primary amyloidosis has the worst prognosis, which

**TABLE 28-3 Other Approaches in the Diagnosis of Restrictive Cardiomyopathies**

| *Diagnostic Modalities* | *Findings* | *Limitations* |
|---|---|---|
| 2D/Doppler echocardiography | LV hypertrophy<br>Restrictive filling | Comorbidities of advanced age and coexisting hypertension renders LVH nonspecific. May be late findings with limited impact on guiding treatment or affecting prognosis. Nonreproducible measurements make regression difficult to follow.[80] Does not provide etiologic information in amyloidosis[60] |
| Systemic markers | Light chains, serum amyloid p component, troponin, and pro-BNP<br>In primary amyloidosis | |
| Biopsy<br>Tongue, subcutaneous fat pads, kidneys, bone marrow, gastric mucosa, rectal mucosa, and EMB | May reveal specific cause of restrictive cardiomyopathy<br>Eosinophilic interstitial deposits on H & E, apple-green birefringence on Congo red staining, and fibrillar protein on EM in cardiac amyloid | Procedural risk<br>Uncertainty about sampling error limits use in monitoring disease |
| Cardiac catheterization | Dip and plateau<br>RV systolic pressure usually >50 mm Hg<br>LVEDP often >5 mm Hg > RVEDP<br>RVEDP < one third of RV systolic pressure | |
| CT imaging | Pericardium of normal thickness | |
| MRI | High spatial resolution and tissue contrast definition. Pattern of late gadolinium enhancement is diffuse subendocardial or global transmural in over 83%. Suboptimal myocardial nulling (8%) and patchy focal LGE (6%) is less common in cardiac amyloidosis. LGE is subendocardial sparing and often involving basal inferolateral wall in Fabry disease, midwall within hypertrophied segments in patchy distribution most consistently at anterior and posterior junction of interventricular septum and right ventricular free wall in HCM. T2 noncontrast MRI valuable in quantitation of myocardial iron deposition in hemochromatosis. Subendocardial longitudinal relaxation time (T1) in amyloid patients is shorter than in controls. Prevalence of late gadolinium enhancement 50% in Fabry disease, 69% in cardiac amyloidosis and 80% in HCM | Risk of the development of nephrogenic systemic fibrosis from gadolinium, in patients with acute or chronic severe renal insufficiency (glomerular filtration rate <30 mL/min/1.73 $m^2$) and patients with renal dysfunction due to the hepatorenal syndrome |
| Nuclear scintigraphy with $^{99}$Tc pyrophosphate or indium-labeled systemic amyloid protein scan | Tc pyrophosphate scan differentiates between immunoglobulin light chain and transthyretin-related familial and senile amyloidosis. Strong uptake transthyretin-related amyloidosis with accuracy of 100%<br>Indium cardiac uptake in primary and multiorgan uptake in systemic amyloidosis | |

A,** 76-year-old woman with histologic diagnosis of amyloidosis of periumbilical adipose tissue. Late enhancement in short-axis image shows intense subendocardial enhancement involving all LV walls (*arrows*). **B,** Global transmural late gadolinium enhancement in a homogenous pattern in the LV and RV. Blood pool has characteristic dark appearance commonly seen in cardiac amyloidosis. (***A,*** *Adapted from Belloni E, De Cobelli F, Esposito A, et al: MRI of cardiomyopathy.* Am J Roentgenol *191:1702-1710, 2008.* ***B,*** *Adapted from Syed IS, Glockner JF, Feng D, et al: Role of cardiac magnetic resonance imaging in the detection of cardiac amyloidosis.* JACC Cardiovasc Imaging *3:155-164(B), 2010.)*

is exacerbated by multisystem involvement and cardiac involvement in particular.[48] A marked increase in wall thickness, specifically mean LV and RV wall thickness of greater than 15 mm and 7 mm, respectively,[78] reduced LV systolic function, shortened mitral inflow DT of less than 150 ms,[79] increased early diastolic filling velocity to atrial filling (E/A) ratio, and Doppler-derived myocardial performance index (MPI)[80] have all been proposed as predictors of cardiac death. One study[81] found that the myocardial integrated back scatter of the posterior wall was a better predictor of cardiac and overall death compared to Doppler features. Another poor prognostic marker is RV dilation.[82] Late gadolinium enhancement has been shown

to offer prognostic value in the assessment of amyloidosis.[83] Histologically, the worst prognosis is connected with the presence of nodular deposits, thick perimyocytic layers of amyloid, and small myocyte diameters in endomyocardial biopsy.[84] The overall median survival after diagnosis is less than 2 years in most. Syncope indicates a poor prognosis as well and is often a precursor of sudden cardiac death.[85]

In secondary amyloidosis, the underlying chronic disease affects the prognosis, and hereditary amyloidoses vary in prognosis according to the specific mutation.[86] Heart rate variability assessed by Holter monitoring was found to be a possible predictor of mortality in patients with both primary and secondary amyloidosis involving the heart.[87] Impaired LV systolic function is more common in primary than other forms of amyloidosis[88]; primary amyloidosis also carries a worse prognosis compared to secondary amyloidosis.

### *Outcome Data*

The use of high-dose melphalan with rescue autologous peripheral blood stem cell transplantation has resulted in reversal of the clinical manifestations of AL amyloidosis in a significant proportion of patients who survived the procedure.[89-91]

## HEMOCHROMATOSIS

The clinical presentation of primary (hereditary) hemochromatosis (an autosomal recessive disorder) includes liver disease in 75% of cases, weakness and lethargy in 74%, skin hyperpigmentation in 70%, diabetes mellitus in 48%, arthralgia in 44%, impotence in 45%, electrocardiographic abnormalities in 31%, and heart failure and conduction disturbances in 15%.[92] The primary clinical feature of secondary hemochromatosis is high-output cardiac failure from anemia and hemosiderosis. Reversible restrictive cardiomyopathy has been described as a rare clinical feature of hemochromatosis.[93,94] An early echocardiographic study[95] in patients with anemia who developed cardiac secondary hemochromatosis due to transfusion described LV hypertrophy as characteristic of this disorder; however, a subsequent echocardiographic study[96] that examined echocardiographic features of patients with primary (hereditary) hemochromatosis compared to normal subjects found that hypertrophy is not a feature of hemochromatosis cardiomyopathy. One study[97] found increased echocardiographic integrated myocardial backscatter ($33 \pm 13$ vs. $21 \pm 6$, p less than 0.001) in 38 patients with thalassemia receiving chronic blood transfusion compared to 20 control subjects despite comparable fractional shortening but increased LV mass. The same group subsequently showed the myocardial backscatter in this group of patients is not related to prognosis over a $122 \pm 36$ month follow-up.[98] Decreased S′ of mitral annulus was found in treated subjects with hemochromatosis and S′ = 10.88 cm/s achieved a 56% sensitivity and 74% specificity for separating hemochromatosis from controls. Negative predictive value of S′ was only slightly greater than 50%; thus, additional imaging with cardiac MRI is still needed in the presence of normal S′.[99] Most of the echocardiographic studies[100] report a dilated cardiomyopathy with hemochromatosis. One study[101] found increased wall thickness that was reversible after iron chelation therapy. Increased thickness may be an early feature of the disease with progression to dilated cardiomyopathy in later stages. Serum ferritin is highly correlated with the amount of iron deposition and can therefore be used as an index for intracardiac iron load[102]; however, ferritin can be elevated in inflammation and fever.[103] T2 relaxation time on cardiac MRI has a linear correlation with the total iron content in the heart.[104]

## HYPEREOSINOPHILIC SYNDROME AND ENDOMYOCARDIAL FIBROSIS

Idiopathic hypereosinophilic syndrome is a leukoproliferative disorder characterized by idiopathic sustained peripheral blood eosinophilia (greater than $1.5 \times 10^9$/L) and (multi-) organ dysfunction caused by infiltration of eosinophils. Cardiac dysfunction is the most common cause of morbidity and mortality. Endocardial fibrosis and myocardial inflammation cause heart failure and ventricular mural thrombus formation.

Dyspnea, ascites, peripheral edema, and right heart failure are common clinical manifestations of the disease in patients with RV or biventricular involvement. Increased endocardial thickness suggestive of fibrosis with restricted leaflet motion of the atrioventricular valve is seen in endomyocardial fibrosis.[105] This disease is characterized by fibrosis of the endocardium and of the myocardium of the inlet region and LV apex. Involvement of the papillary muscles leads to regurgitation of mitral and tricuspid valves. Progressive shrinkage of the LV cavity occurs.[106] Ventriculography may show a polylobulated LV silhouette with linear calcific shadows at the "amputated" apex giving an appearance of a clenched fist[107] or a hissing snake.[108]

Echocardiographic findings include Merlon sign (basal hypercontractility), which contrasts with the abnormal apex.[109] On M-mode echocardiography, the initial rapid motion is followed by a flat endocardial reflection (the square root sign is seen in the septum and posterior wall). On 2D echocardiography, inversion of the normal ventricular-to-atrial size ratio is seen with obliterated ventricles and dilated atria. The LA is dilated with left-sided endomyocardial fibrosis, and the RA is dilated with right-sided endomyocardial fibrosis.[107] Marked biatrial enlargement is seen when both sides of the heart are involved. The apex of the involved ventricle shows layered thrombus in the early stages (Fig. 28-13), which is later obliterated by fibrosis. Apical thrombus does not alter the movement of the underlying myocardium. Different grades of pericardial effusion are also found. Echocardiography seems to be the only noninvasive method that can detect endomyocardial disease in its early stages.[110] Peripheral eosinophilia along with increased cardiac troponin T without other known etiology, which decreases after treatment, has been proposed to be an early marker of disease even before echocardiographic manifestations appear.[111]

A restrictive pattern is typical of the late stage of the disease. There is minimal change in mitral and tricuspid velocities as found in healthy patients, which differentiates endomyocardial fibrosis from constrictive pericarditis. Furthermore, a restrictive pattern is observed on both atrioventricular valves when both sides are involved with a markedly short tricuspid inflow DT. Pulmonary veins often show D dominance and a broad reversal A wave (the latter presented a low velocity when the wall of the LA is diseased). Hepatic veins showed a markedly deep diastolic forward wave throughout the respiratory cycle and a marked reversal with inspiration. Fibrous thickening of the endocardium, made up of collagen without elastic fibers and sometimes organized thrombus, is seen on endomyocardial biopsy. Normal thickness of mitral and tricuspid valve leaflets despite severe regurgitation, involvement of papillary muscles, obliteration of LV apex, and normal-sized to small ventricle in the presence of

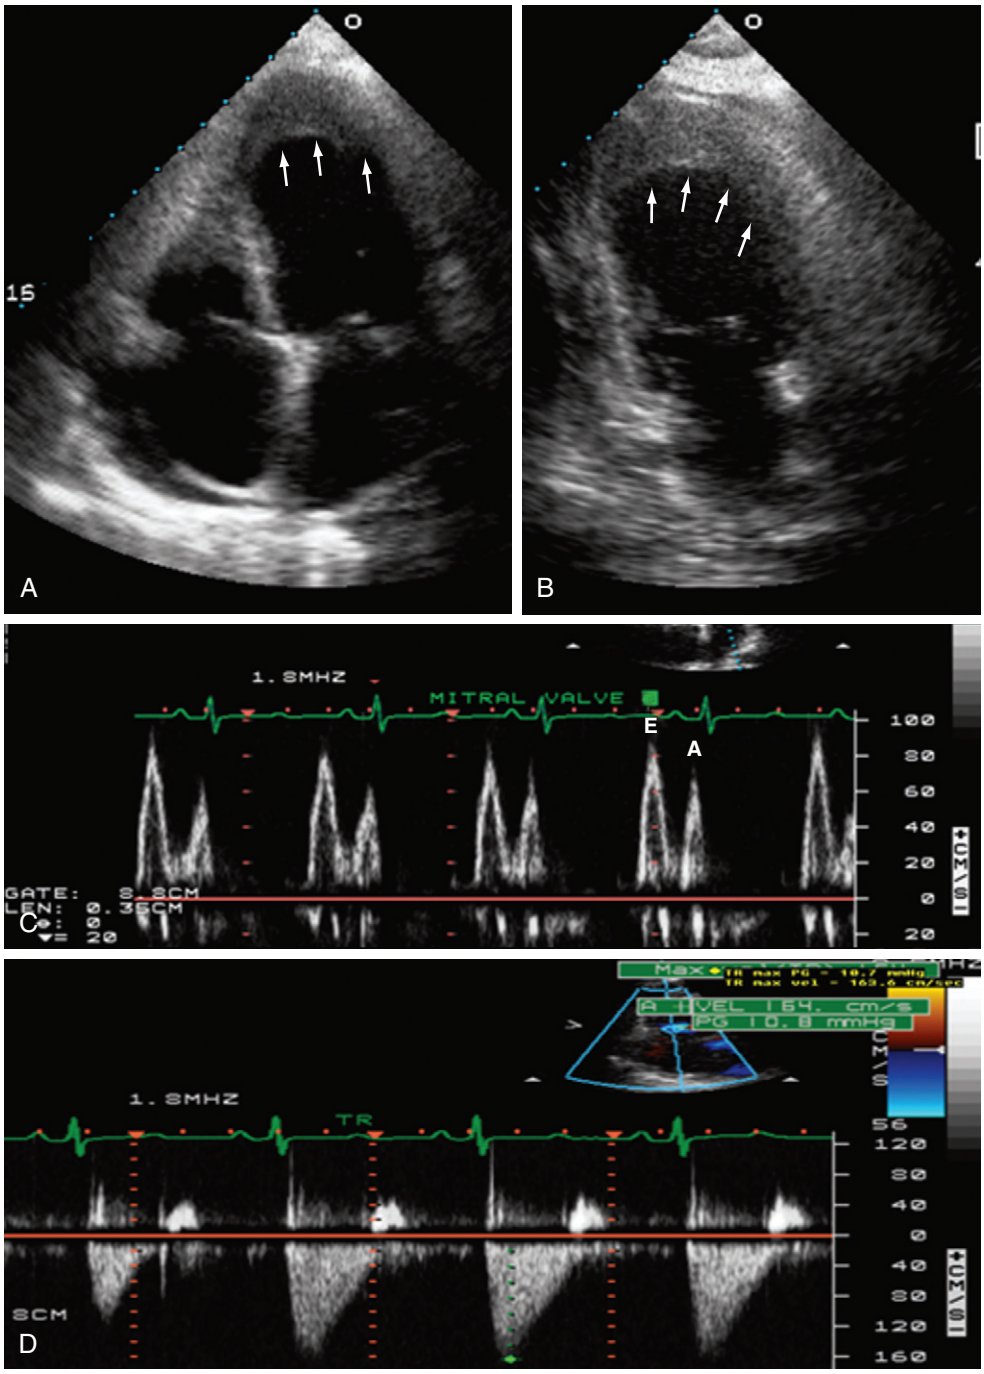

**Figure 28-13 Cardiac involvement in idiopathic hypereosinophilic syndrome.** TTE revealed the presence of deposits at the apex of the LV in apical four-channel and two-channel views (*white arrows*, **A** and **B**). **C,** Pseudonormal to restrictive filling pattern. **D,** Tricuspid regurgitation (TR) envelope by CW Doppler. V-shaped TR signal suggests markedly elevated RA pressure.

severe valvular regurgitation distinguish this condition from rheumatic heart disease.

Patients who present with right-sided endocardial fibrosis may have clinical features that can be confused with those of constrictive pericarditis. Presence of normal pericardial thickness, obliteration of RV apex, and markedly dilated RA distinguish it from constrictive pericarditis. Patients who develop an extensive LV apical thrombus after an acute myocardial infarction may mimic endomyocardial fibrosis; however, wall motion abnormalities in the classic distribution, history of myocardial infarction, and lack of eosinophilia aid in diagnosis (see Fig. 28-13). Obliteration of LV apex during both systole and diastole distinguishes endomyocardial fibrosis from apical hypertrophic cardiomyopathy where obliteration only occurs in systole. The presence of a normal-sized ventricle in the presence of gross cardiomegaly on chest radiography and normal-sized and normal LV systolic function distinguish it from dilated cardiomyopathy. Gigantic RA and apical obliteration of RV apex may suggest Ebstein anomaly; however, normal attachment of tricuspid leaflets and focal involvement of RV inflow and outflow regions distinguish right-sided endomyocardial fibrosis from Ebstein anomaly.

Asymptomatic patients are closely monitored with serum troponin level every 3 to 6 months and echocardiography and pulmonary function tests every 6 to 12 months. Early institution of alpha interferon, steroids, and hydroxyurea and favorable response to treatment may halt the fibrotic process and improve symptoms and prognosis in these patients. Imatinib mesylate (Novartis), a tyrosine kinase inhibitor, chemotherapeutic agents, and hematopoietic stem cell transplantation are used for resistant cases.[112] Valve replacement with bioprosthetic valves may be required in patients with severe regurgitant lesions. Risk of thrombosis with mechanical valves is very high in patients with hypereosinophilic syndrome despite therapeutic anticoagulation. Endocardiectomy may be required for patients with endomyocardial fibrosis, and thrombectomy may be required for individuals with thrombosis.

## SARCOIDOSIS

Sarcoidosis is a granulomatous disease of unknown etiology that has a predilection for certain ethnic groups such as African Americans. Pulmonary sarcoid is often the first manifestation of the disease.[113] Endomyocardial biopsy may assist in making a diagnosis with the finding of noncaseating granulomas. The histological diagnostic rate of cardiac sarcoidosis using endomyocardial biopsy has a low sensitivity of 19.2%[114] due to a patchy distribution of the pathology and predilection of granulomas for the cephalad portion of the septum that is less accessible to biopsy.

Cardiac involvement occurs in 25% of patients with systemic sarcoidosis but is clinically silent in the majority of patients.[115-117] In a comparative study[118] of cardiac sarcoidosis in Japanese, African Americans, and U.S. whites, the incidences of cardiac sarcoid granulomas were 67.8%, 21.2%, and 13.7%, respectively. A recent report in 69 patients, 30 with biopsy-proven sarcoid, without clinical evidence of heart disease found no differences in echocardiographic findings compared to 26 control subject except for a mildly reduced fractional shortening in patients with long-standing sarcoid.[119] In another study,[120] occult myocardial involvement was shown in patients with sarcoidosis without cardiac involvement. Of these 21 patients, 10 showed abnormal interventricular septal motion and abnormal LV ejection fraction during stress compared to control subjects. Diastolic dysfunction is not uncommon in patients with pulmonary sarcoid without any cardiac involvement.[121] Wall motion abnormalities, LV aneurysm, systolic dysfunction, dilated cardiomyopathy, conduction abnormalities, arrhythmias, and pericardial effusion are more common manifestations of cardiac sarcoidosis.[114] Sarcoid is an important diagnostic consideration in scar-related ventricular tachycardia.[122] Sudden death may be the first manifestation of cardiac sarcoidosis.[123] Sarcoid can be misdiagnosed as idiopathic or arrhythmogenic RV cardiomyopathy. Restrictive cardiomyopathy is more unusual, and diagnosis of sarcoid restrictive cardiomyopathy may be made only after characteristic findings of noncaseating granulomas on endomyocardial biopsy are documented.[124]

To date, no single cardiac investigation has been shown to reliably predict cardiac involvement. Valantine's group[125] reported that thinning, as well as wall motion abnormalities, at the base of the intraventricular septum characterizes the presence of cardiac sarcoidosis. The finding of reduced systolic thickening and excursions of the interventricular septum in about 10% of patients with cardiac sarcoid may be related to the frequent prevalence of sarcoid granulomas in the septum. Asymmetric septal hypertrophy, recorded in 10% of patients, may have had a similar origin.[126,127] Such abnormalities in the upper portion of the intraventricular septum may be considered a reliable diagnostic element of cardiac sarcoidosis, even though there is no further evidence of other organ involvement. One report found that more than 50% of patients with cardiac sarcoidosis had diastolic dysfunction and preserved systolic function.[128] One report described normal LV systolic function, marked biatrial enlargement, severe tricuspid regurgitation, and marked thickening of biatrial walls, appendages, and interatrial septum.[129] It may be considered that when thickening is present, the sarcoid lesions may be of a progressive nature, which is manifested with interstitial edema due to exudative or activated granuloma formation. In the advanced stages of disease, interstitial fibrosis may progress, and thus thinning of the ventricular wall may occur.

Because of low yield on endomyocardial biopsy,[115] the diagnosis is often made with a combination of electrocardiography, Holter monitoring, echocardiography, myocardial perfusion imaging, and, most recently, cardiac MRI.[130] Radionuclide scanning with thallium[131] or sestamibi[132] may show abnormal defects that reverse with dipyridamole.[133] In patients with normal coronaries and known cardiac sarcoid, presence of myocardial thallium defects may be used to guide response to therapy. One report found that Holter monitoring was associated with a sensitivity of 67% and a specificity of 80% for identification of cardiac involvement in patients with systemic sarcoidosis.[134] The plasma brain natriuretic peptide level is considered to be a useful noninvasive biomarker for identifying a possible cardiac involvement in sarcoidosis patients with a preserved LV ejection fraction.[135]

Unlike isolated pulmonary disease, cardiac involvement implies a poor prognosis. Patients with sarcoidosis are at increased risk of sudden death. Owing to the progress in antiarrhythmic drugs and pacemaker implantation, the primary cause of death in cardiac sarcoidosis has changed from sudden death to heart failure.

### *Outcome Data*

For symptomatic patients, medical therapy may include a trial of steroids and immunosuppressive therapy. An excellent response can be achieved with steroid therapy in the early acute inflammatory stage. Monoclonal antibodies against tumor necrosis factor may be employed in refractory cases. Heart block warrants a permanent pacemaker, whereas ventricular tachyarrhythmias are typically amiodarone unresponsive, requiring implantation of an implantable cardioverter-defibrillator. Heart transplantation is a suitable option for patients with end-stage disease.

## STORAGE DISORDERS[136]

### *Gaucher Disease*

Gaucher disease, the most common lysosomal storage disorder, is due to inherited deficiency of the lysosomal enzyme glucocerebrosidase.[137] Clinically, three phenotypes have been delineated on the basis of the presence and severity of central nervous system involvement[138]: type 1 (nonneuronopathic adult form), type 2 (acute neuronopathic form diagnosed classically in infants who are several months old), and type 3 (subacute neuronopathic juvenile form). Partial deficiency of acid beta-glucosidase is associated with parenchymal disease of the liver, spleen, and bone marrow with concomitant anemia and

thrombocytopenia in nonneuronopathic, type 1 Gaucher disease. Severe deficiency of glucocerebrosidase caused by severe mutations is additionally associated with neurological manifestations in the less common type 2 and type 3 subtypes.[139] The perinatal lethal form is very rare, and prominent features of the severe perinatal form are hepatosplenomegaly, associated with hydrops fetalis, generalized ichthyosis, and facial dysmorphy.[140]

Echocardiographic features of this disease in the nonneuropathic (adult) form include increase in LV mass with a septal muscular prominence, areas of apical akinesis, and pericardial changes.[141] Ascending aortic as well as aortic and mitral valve calcification has been described in a family.[142]

Enzyme replacement therapy in type 1 Gaucher disease regresses hepatosplenomegaly, anemia, thrombocytopenia, bone fractures, and bone crisis, whereas neurologic abnormalities and interstitial fibrosis do not respond to treatment.[143]

### *Glycogen Storage Disorder*

Pompe disease occurs due to an α-1,4-glucosidase deficiency, characterized by progressive deposition of glycogen in all tissues.[144] The disease has an autosomal recessive inheritance with a predicted frequency of 1 : 40,000. Pompe disease is associated with elevation of muscle enzymes creatine phosphokinase, lactate dehydrogenase, alanine aminotransferase, and aspartate aminotransferase in 90% to 95% of cases and is confirmed by measurement of α-glucosidase deficiency in leukocytes, fibroblasts, and/or in muscle tissue. The classic infantile form of the disease occurs in infants shortly after birth and is characterized by generalized hypotonia, failure to thrive, and cardiorespiratory failure. Muscular abnormalities and respiratory difficulties are the most common manifestations, followed by cardiac manifestations, pain, epilepsy, fatigue, feeding problems, underweight, macroglossia, abnormal speech, hepatosplenomegaly, abnormal mental development, and hyperparathyroidism.[145]

One review of 225 patients with adult-onset Pompe disease found echocardiographic evidence of hypertrophic cardiomyopathy in 5% of patients, cor pulmonale in 2%, and other cardiac abnormalities in another 4% of patients.[146] Cardiac hypertrophy was only found in subjects younger than 1 year. Echocardiographic features include severe thickening of the interventricular septum, free wall, and posterior LV wall[146] with a tumor-like appearance of the papillary muscles, a small LV cavity, and poor LV systolic function.[147] Case reports of apical hypertrophy causing artifacts on myocardial perfusion imaging and restrictive cardiomyopathy have been described.[148] Normal motion of the intraventricular septum and mitral valve leaflets and midsystolic closure of the aortic valve have been noted.[149] The combination of echocardiographic and electrocardiographic findings is helpful in the clinical diagnosis and recognition of the severity of cardiac involvement of this disease.

Patients with the infantile form of this disease usually die within the first year of life. The nonclassic or late-onset form of the disease may occur at any age in childhood or adulthood. It presents predominantly as a slowly progressive proximal myopathy (in 95% of patients), with or without respiratory difficulties (in 44%).[149,150]

Patients with later onset of disease have better prognosis.[146] Respiratory failure is the most common cause of death. Beneficial effects of recombinant human alpha glucosidase have been reported in patients with the classic infantile form[151] as well as in patients with the nonclassic or late-onset form of the disease.[152] Enzyme replacement therapy regresses cardiac hypertrophy and improves heart failure symptoms and skeletal muscle weakness and respiratory failure, whereas lower motor neuron disease is unresponsive to treatment.[153]

### *Fabry Disease*

Fabry disease is a rare X-linked recessive metabolic disorder caused by deficiency of the lysosomal enzyme α-galactosidase A.[154] Accordingly, hemizygous males have the most severe form of the disease and heterozygous females usually have a more benign presentation.[155] The enzymatic defect in this lysosomal storage disease leads to the accumulation of globotriaosylceramide in several organs including the skin, kidney, nervous system, cornea, and heart.

Cardiac involvement in Fabry disease may occur in conjunction with involvement of other organs or the disease may manifest only with cardiac involvement. Electrocardiographic features include a short PR interval, abnormalities of conduction, and LV hypertrophy.[156] Echocardiographic findings include aortic root dilatation, generalized asymmetric increase in myocardial wall thickness, myocardial dysfunction, ultimately dilated cardiac chambers, and valve dysfunction, especially of the mitral valve.[157] The increased ventricular wall thickness is the consequence of the deposition of globotriaosylceramide in cardiomyocytes and cellular hypertrophy. In female patients, the features are usually subclinical; however, more than half of heterozygous females may have cardiac hypertrophy on echocardiogram.[158] Endomyocardial biopsy and/or measurement of plasma α-galactosidase A activity are definitive diagnostic tests. Sarcoplasmic vacuolization is the classic finding on light microscopy of hematoxylin and eosin–stained tissue. On electron microscopy, concentric lamellar bodies are noted in the sarcoplasm of myocardial cells. In two recent studies, Fabry disease was diagnosed in 3% to 4% of men with concentric LV hypertrophy.[159,160] Asymmetric septal hypertrophy may be present in as many as 4% of patients with Fabry disease.

LV systolic function progressively deteriorates in untreated patients with Fabry disease. A large cross-sectional study[161] of a patient cohort from the Anderson Fabry disease clinical and genetic register showed that the median cumulative survival was 50 years (n = 51), which represents an approximately 20-year reduction of life span. Steep decline in survival occurs after age 35. Neuropathic pain (77%), sensorineural deafness (78%), renal failure (30%), cerebrovascular complications (24%), and low body mass index due to gastrointestinal complications were common.

Recently the availability of enzyme replacement therapy has been shown to result in clearing of vascular endothelial deposits of globotriaosylceramide.[162] Improvement in LV mass and systolic function has also been reported with enzyme replacement treatment.[163] A recent study[164] in 29 patients with mean age of 37 ± 13 years who were treated with 37-month enzyme replacement therapy demonstrated lack of progression of LV hypertrophy and some improvement in LV diastolic function with prolongation of mitral inflow E-wave DT and decreased E/E′ (lateral) ratio. Increased echogenicity in the posterobasal segment was present in 83% of patients, whereas binary appearance (increased echogenicity of the mid interventricular septum due to compartmentalization of glycosphingolipids) was found in only 20% of patients in this study. An earlier study[165] had found presence of binary appearance (Fig. 28-14) in 83% of patients with Fabry disease and had found its sensitivity and specificity at 94% and 100%, respectively, in detecting Fabry disease compared to patients with hypertrophic

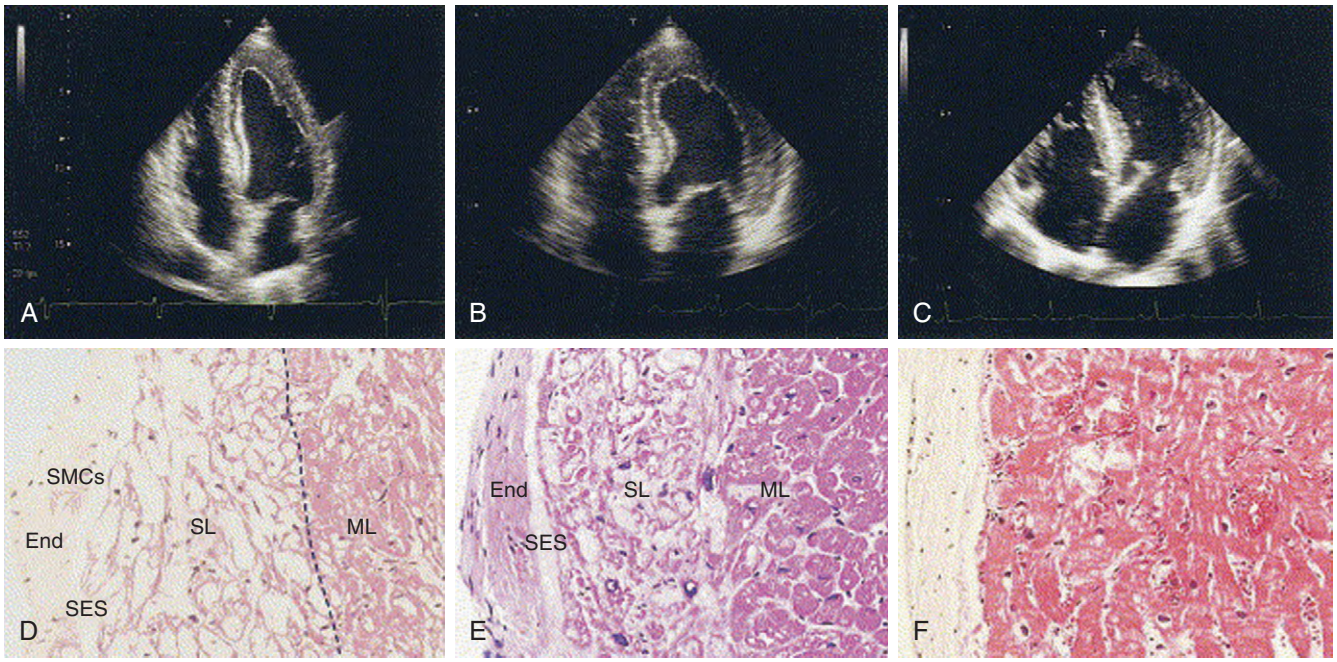

**Figure 28-14 Two-dimensional echocardiography in four-chamber apical view and LV endomyocardial biopsy from two patients with Fabry disease cardiomyopathy.** (**A, D** and **B, E,** respectively) and a patient with hypertrophic cardiomyopathy (**C, F**). Comparison of the three echocardiographic frames reveals the presence of a binary appearance of left ventricular endocardial border in the two Fabry patients (**A, B**). This echocardiographic finding reflects the glycosphingolipids compartmentalization involving a thickened endocardium (*End*) with enlarged and engulfed smooth muscle cells (*SMC*), a subendocardial empty space (*SES*), and a prominent involvement of subendocardial myocardial layer (*SL*), while the middle layer (*ML*) appears partially spared (**D, E**). The echocardiographic pattern is absent in hypertrophic cardiomyopathy (**C**), despite a similar thickening of the endocardium (**F**). *(From Pieroni M, Chimenti C, De Cobelli F, et al: Fabry's disease cardiomyopathy: echocardiographic detection of endomyocardial glycosphingolipid compartmentalization.* J Am Coll Cardiol *47:1663-1671, 2006.)*

cardiomyopathy and hypertensive and normal subjects. One study in patients with aortic stenosis, hypertrophic cardiomyopathy, and Fabry disease found a characteristic double peak sign on strain rate imaging in the 42 segments that showed late gadolinium enhancement. This pattern consisted of a sharp early first systolic peak (negative for longitudinal function and positive for radial function) followed by a rapid fall of strain rate close to the zero line and an additional second strain-rate peak during the isovolumic relaxation period (directed in the same direction as the first peak and at least 50% in magnitude compared with the first peak).[166]

## IDIOPATHIC RESTRICTIVE CARDIOMYOPATHY

Idiopathic restrictive cardiomyopathy occurs predominantly in elderly women. It is a rare entity distinguished from the other forms of restrictive cardiomyopathy by the presence of normal ventricular wall thickness. There have been a few reports of mutations in idiopathic restrictive cardiomyopathy, implicating the desmin and cardiac troponin I genes.[167] Linkage of genes to a region on chromosome 10 has been found in autosomal dominant restrictive cardiomyopathy in a family.[168] Idiopathic restrictive cardiomyopathy accounts for 2% to 5% of all cardiomyopathies in children.[169] Biatrial enlargement and no or minimal hypertrophy are evident, as in the idiopathic restrictive cardiomyopathy of the adult.

There is marked biatrial enlargement and presence of atrial fibrillation in the absence of valvular heart disease, hypertension, and ischemic heart disease. This disease is seen in individuals where other etiologies for cardiomyopathy have been excluded, such as connective tissue disease, carcinoid syndrome, amyloidosis, hemochromatosis, eosinophilic syndrome, malignancy, radiation exposure, cardiotoxic drug exposure, or history of alcohol abuse. Interstitial fibrosis is the predominant histologic finding. LV systolic function is preserved in more than two third of patients.[170] Compared to cardiac amyloidosis, long-axis function as measured by tissue Doppler imaging is often preserved in these patients.[171] Atrial fibrillation is common.[172] Endomyocardial biopsy shows mild to severe interstitial fibrosis and mild myocyte hypertrophy. The interstitial fibrosis found in this condition only rarely interferes with the shortening of myocardial fiber bundles but is sufficient to prevent ventricular dilation and thereby limit diastolic stretch.

The disease is characterized by increased mortality in adults, with 5- and 10-year survival rates of 64% and 37%, respectively.[172] LA dimension greater than 60 mm is associated with poor prognosis.[173] The disease carries a poor prognosis in children, with a median survival of 2 years.[173] The strongest predictor of survival in children with idiopathic restrictive cardiomyopathy is the extent of increase in LA-to-aortic ratio at presentation followed by pulmonary capillary wedge pressure and LV end-diastolic pressure. Symptoms at the time of presentation do not predict outcome.[174]

## DRUG-INDUCED RESTRICTIVE CARDIOMYOPATHY

Fibrous thickening of LV endocardium with features of restrictive cardiomyopathy occurs in anthracycline cardiotoxicity.[174] Ultrastructural abnormalities of the myocytes with myofibrillar loss and cytoplasmic vacuolation are seen in both anthracycline and chloroquine cardiotoxicity. Both restrictive features as well as concentric LV hypertrophy have been shown to be reversible

on chloroquine withdrawal.[175] Methysergide cardiotoxicity involves encasing of heart valves with fibrous tissue causing valvular regurgitation.

### POSTRADIATION CARDIOMYOPATHY

Radiation-induced heart disease, with its clinical manifestations, is becoming a growing problem. Its prevalence is increasing, keeping pace with the increased survival of many malignancies. The majority of patients with radiation induced heart disease are constituted by Hodgkin disease survivors, followed by non-Hodgkin disease, esophageal carcinoma, thymoma, lung cancer, breast cancer, and metastatic seminoma. Pericardial disease is the most well-known expression of radiation-induced heart disease, present clinically in 60% to 70% of patients receiving mediastinal irradiation.[176] The manifestations include acute pericarditis, pericardial effusion with or without tamponade, and constrictive pericarditis. Almost all patients who develop radiation-induced heart disease develop a pericardial effusion with relative sinus tachycardia 3 to 4 weeks postradiation, which may be transient. Six to 12 months after radiation, late damage is manifest as massive pericardial effusion followed by myocardial damage and coronary sclerosis depending on field and radiation dose. The mean time of presentation for constrictive pericarditis is 48 months. Follow-up of the irradiated patients by echocardiography, especially those who received more than 5000 rad to the heart area, is advisable.[177] Appropriate cardiac shielding and minimum possible radiation dose are preventive measures.

Late cardiac effects occur from mediastinal radiation.[178] Published observations on the effect of radiation of LV function differ. Gustavsson and colleagues[179] found a decrease of the LV shortening in 44% of patients and a decreased LV end-diastolic dimension in 28% of patients as well as evidence of diastolic dysfunction in 50% of patients. Others found decrease in LV systolic function in one third of patients and borderline value in another third;[180] still others[181] found no effect on LV function. The most conspicuous change is diffuse interstitial fibrosis seen chiefly in the RV, presumably because of the commonly used anterior radiation fields leading to congestive heart failure, and typically a restrictive cardiomyopathy. In an autopsy series, the endocardium was thickened from fibrous proliferation with some increase in elastic fibers mainly in the RV in 12 of 16 patients making the ventricular muscle less compliant and necessitating higher filling pressures to maintain stroke volume.[182] One series found cardiac involvement in 12 of 108 patients after irradiation for Hodgkin disease. Chronic pericardial disease and coronary artery disease were the most frequent manifestations.[183]

Coronary artery obstructive disease frequently involves ostial coronary segments and the left main coronary artery, and risk appears greater in those with known risk factors for coronary artery disease.[184] All patients undergoing chest irradiation require serial cardiac evaluation. Important risk factors for radiation-induced heart disease are previous chemotherapy, radiation exposure exceeding 4000 rad, and administration next to the heart and on the left side of the chest.[185] Doxorubicin treatment for acute lymphoblastic leukemia in children was found associated with chronic progressive cardiac dysfunction at 12-year follow-up and restrictive cardiomyopathy characterized by reduced cardiac mass, decreased LV dimension, and reduced wall thickness along with reduced LV systolic function. Although seen more commonly after high-dose doxorubicin treatment, cardiomyopathy was seen even after low-dose treatment.[186]

### OTHER CAUSES OF RESTRICTIVE CARDIOMYOPATHY

Connective tissue diseases such as scleroderma and systemic lupus erythematosus[187] and pseudoxanthoma elasticum[188] may produce features of restrictive cardiomyopathy. Calcified endocardial bands may be seen in those with restrictive cardiomyopathy due to pseudoxanthoma elasticum.[189]

## Differentiating between Restrictive Cardiomyopathy and Constrictive Pericarditis

The diagnosis of restrictive cardiomyopathy or constrictive pericarditis should be considered in any patient with a disproportionate degree of right heart failure in the setting of normal or mildly depressed LV systolic function and normal valvular function. Both constrictive pericarditis and restrictive cardiomyopathy are associated with increased intracardiac filling pressures; however, stiff pericardium versus stiff ventricle differentiate the two conditions and produce specific echocardiographic signs that help differentiate them.[190-193]

Pericardial calcification on chest radiography and thickened pericardium on computed tomography (CT) scan are diagnostic findings of constriction, although CT may have difficulty differentiating pericardial fluid from thickened pericardial tissue in some cases. MRI provides comprehensive images of the pericardium and is superior to both CT and echocardiography with respect to its ability to characterize pericardial effusions and pericardial masses. Although a pericardial thickness of 3 mm or more on transesophageal echocardiography is highly suggestive of constrictive pericarditis, echocardiography is not an accurate approach for evaluation of pericardial thickness.[194] In about 18% of patients with surgically proven constriction, pericardial thickness may not be increased on noninvasive imaging because of the patchy nature of pericardial involvement.[195] If pericardial thickness is normal on CT or MRI, biochemical tests to determine the etiology of restrictive cardiomyopathy such as serum/urine protein electrophoresis or iron studies should be performed, followed by endomyocardial biopsy. This will confirm the specific etiology of restrictive cardiomyopathy in about 39% of patients.[196]

The pathophysiologic feature that best separates constrictive pericarditis from restrictive cardiomyopathy is dissociation of intrathoracic and intracardiac pressure and increased ventricular interdependence (Table 28-4).[174,197,198] With constrictive pericarditis, negative chest pressure during inspiration is not transmitted to the cardiac chambers but is transmitted to the pulmonary venous bed. Thus, during inspiration, there is a higher decrease in pulmonary venous pressure relative to LV diastolic pressure, causing a decrease in transmitral gradient during the inspiratory phase.

In addition, ventricular interdependence is increased in constrictive pericarditis due to the constrained total cardiac volume and the lack of transmission of intrathoracic forces to the ventricular chambers. In contrast, ventricular interdependence is absent in restrictive cardiomyopathy because of involvement of the ventricular septum with a normal pericardium. In constrictive pericarditis, there is abrupt diastolic shift in the ventricular

**TABLE 28-4 Echocardiographic Features of Restrictive Cardiomyopathy and Constrictive Pericarditis**

| | *Restrictive Cardiomyopathy* | *Constrictive Pericarditis* |
|---|---|---|
| Pericardium | Normal | Thickened |
| Left ventricle | Small<br>May show systolic dysfunction<br>No septal bounce | Small<br>Usually intact, may be abnormal particularly after CABG or radiation<br>Septal bounce |
| Atria | Usually dilated | Usually nondilated |
| Mitral inflow | Increased E/A ratio, short DT<br>No significant respiratory variation of E velocity<br>Diastolic MR | Increased E/A ratio, short DT<br>>25% expiratory increase in E velocity<br>Diastolic MR |
| Tissue Doppler long velocities | Markedly reduced | Normal |
| Circumferential strain | Normal | Reduced |
| Peak radial strain LV base | Normal | Reduced |
| Net twist | Normal | Reduced |
| Basal longitudinal strain | Reduced | Normal |
| Apical untwisting velocities | Normal | Reduced |
| Pulmonary vein inflow | Decreased (0.5) S/D ratio<br>Prominent atrial reversal<br>No significant respiratory change | S/D ratio = 1<br>↓ in S and D* wave with inspiration |
| Tricuspid inflow | Mild respiratory variation | >25% inspiratory increase in E wave and TR velocity |
| Inferior vena cava | Dilated | Dilated |
| Hepatic veins | Blunted S/D ratio | Inspiration: minimal increase in S and D velocity; expiration: decreased diastolic flow and increase in reversals<br>>25% increase in atrial reversal in expiration compared to inspiration |
| Peak PA pressure | >40 mm Hg | <40 mm Hg |
| Color M-mode | Decreased Vp <45 cm/s | Normal or increased >100 cm/s |
| Mitral annular Doppler | Low velocity <8 cm/s | High velocity ≥8 cm/s |

*One study found significantly greater decrease of D wave only with respiration in constriction.[210]

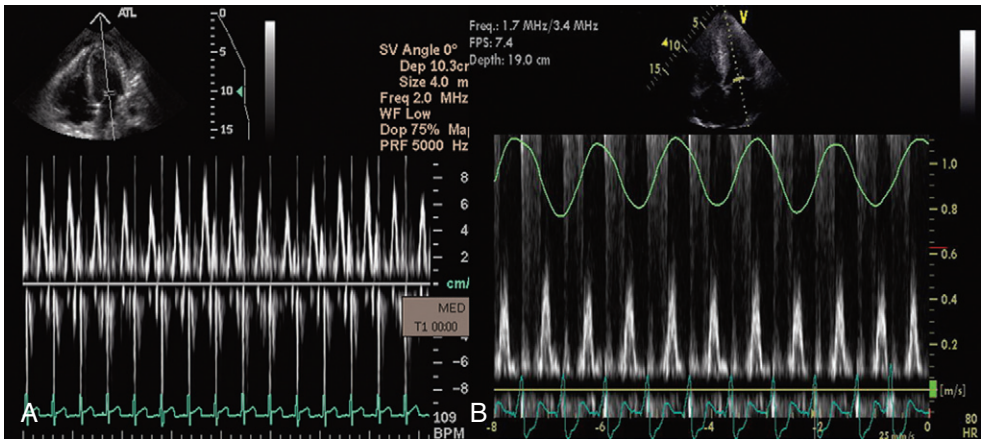

**Figure 28-15 Mitral inflow PW Doppler in a patient with constriction (A) and in a patient with cardiac amyloidosis (B).** Note marked respiratory changes with decrease in mitral inflow velocities during inspiration and increase during expiration in the patient with constriction and no significant respiratory change in the patient with cardiac amyloidosis.

septum toward the LV during inspiration and toward the RV in expiration.[199] Doppler echocardiography demonstrates exaggerated interventricular interdependence in constrictive pericarditis by showing marked respiratory variations in mitral (Fig. 28-15) and tricuspid flow Doppler. Characteristic respiratory variations in Doppler flow velocities in patients with constriction, not seen in patients with restriction, include a greater than 25% expiratory increase in mitral E velocity and an expiratory decrease in hepatic vein diastolic flow velocity, along with a greater than 25% increase in hepatic vein atrial reversal compared with inspiration; greater respiratory variation in pulmonary venous flows; and a pulmonary venous systolic flow velocity lower than diastolic velocity throughout respiration[200,201] (Fig. 28-16).

In some patients who have been aggressively diuresed, volume loading helps to bring out the specific features of constrictive pericarditis.[202] Alternatively, preload reduction helps to bring out the respiratory variation in volume-overloaded patients.[203] In some patients, there may be features of mixed restrictive cardiomyopathy and constrictive pericarditis, such as those with active myocarditis or with postradiation or other forms of cardiomyopathy. In patients with clinical as well as Doppler echocardiographic features of restrictive cardiomyopathy, constriction still must be excluded.

Recent observations using 2D speckle tracking have shown that deformation of the LV is constrained in the circumferential direction in constrictive pericarditis and in the longitudinal direction in restrictive cardiomyopathy.[204] Longitudinal tissue

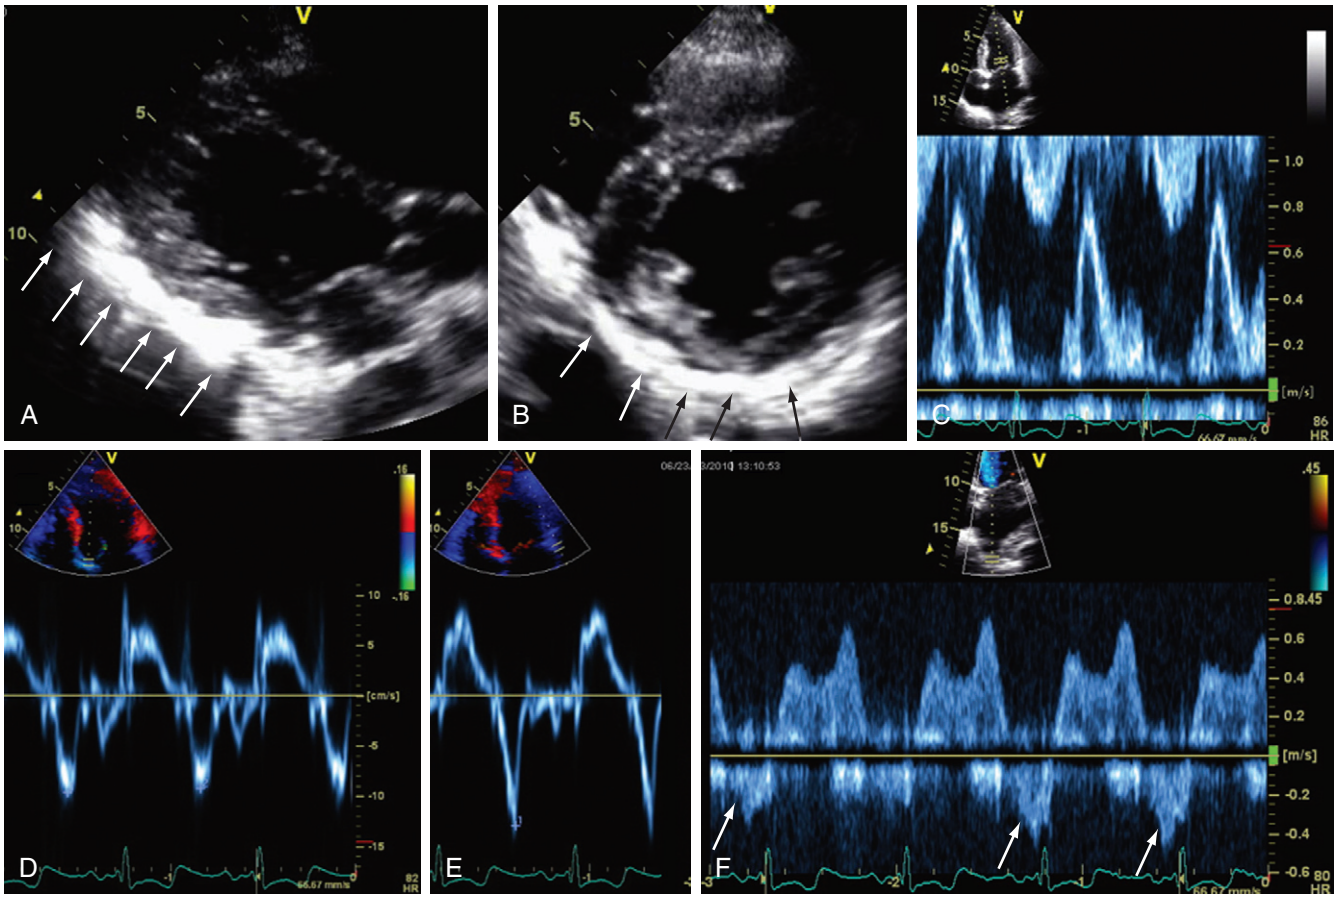

**Figure 28-16 Doppler and 2D imaging findings in constrictive pericarditis.** Parasternal long-axis (**A**) and short-axis (**B**) views showing pericardial calcification posterior to LV (*arrows*). Mitral inflow shows a higher E than A velocity with a steep deceleration slope (**C**) but tissue Doppler velocities of the septal (**D**) and lateral (**E**) mitral annulus are normal. Phasic increase in pulmonary vein flow reversal in expiration in **F** (*white arrows*). S:D reversal often seen in constriction is also shown.

Doppler velocity (E′) of 5 cm/s had 92% sensitivity and 90% specificity, peak untwisting velocity (Er) of −50°/s had 57% sensitivity and 95% specificity, and net LV twist of 10° had 83% sensitivity and 84% specificity in differentiating constrictive pericarditis from restrictive cardiomyopathy. The area under the receiver-operating characteristic curve was significantly higher for early diastolic longitudinal velocities as compared with early diastolic untwisting velocities ($P = 0.01$). Mean tissue Doppler velocities (averaged from the four basal LV walls) of greater than 5 cm/s distinguished all patients with constriction versus restriction, whereas overlap was noted for brain natriuretic peptide and basal septal PW TDI velocity.[205]

Early diastolic mitral annular velocity (E′) by tissue Doppler echocardiography can be used to differentiate constrictive pericarditis from restrictive cardiomyopathy.[35,206] Patients with constrictive pericarditis have a significantly higher E′ at septal annulus than those with primary restrictive cardiomyopathy or cardiac amyloidosis (12.3 vs. 5.1 cm/s, $P < 0.001$) (see Fig. 28-16). Specifically, an E′ cutoff value of 8 cm/s or greater is able to distinguish the two conditions with a high sensitivity and specificity (95% sensitivity and 96% specificity). Even in patients who do not manifest the diagnostic sign of greater than 25% variation of mitral inflow with inspiration in patients with constriction, mitral annular E′ velocity remains normal and helps differentiate constrictive pericarditis from restrictive cardiomyopathy.[207] Occasionally, when pericardial calcification and tethering involves the mitral annulus, E′ velocities may be reduced in constrictive pericarditis.[208] A recent study[209] found the utility of S′ velocity of septal and lateral mitral annulus in differentiating constriction versus restriction.[209] Receiver operating characteristic (ROC) analysis demonstrated an area under the curve of 0.889 (S′ septal), 0.823 (S′ lateral), 0.974 (E′ septal), and 0.915 (E′ lateral) for the differentiation of restrictive cardiomyopathy and constrictive pericarditis with a cutoff value of less than 8 cm/s.

Similar to an increased E′ mitral annular velocity, preserved diastolic function in patients with constriction is manifest by a rapid propagation slope on color M-mode of greater than 100 cm/s.[210] The myocardial velocity gradient, which is reduced in patients with restriction, also differentiates restrictive cardiomyopathy from constrictive pericarditis.[211] Even if mitral and pulmonary vein inflow are not diagnostic, TDI and color M-mode are able to correctly differentiate patients with constrictive pericarditis from those with restrictive cardiomyopathy.[207]

However, echocardiographic findings are not always diagnostic, and catheterization is often necessary for performing hemodynamic evaluation and obtaining endomyocardial biopsy specimens. The following three criteria have been proposed to differentiate the two conditions: (1) Equalization (less than 5 mm Hg difference between RV end-diastolic pressure and LV end-diastolic pressure) favors constriction.[212]

**TABLE 28-5 Echocardiographic Predictors of Outcome in Restrictive Cardiomyopathy**

| *Type of CMP* | *Study Findings* | *2D Echo Predictors* | *Other Features* | *References* |
|---|---|---|---|---|
| Amyloidosis | 132 patients with biopsy-proven systemic amyloidosis, median survival 1.1 years | Increased LV wall thickness >15 mm and reduced LV systolic function predicted decreased survival | | 78 |
| | 63 patients with biopsy-proven systemic amyloidosis, 32 deaths at a median 18 ± 12 month follow-up (78% cardiac deaths) | Shortened deceleration time of mitral inflow (<150 ms) and increased E/A ratio 2.1 were predictors of cardiac mortality | LV wall thickness and fractional shortening were not predictors of overall survival | 79 |
| | 45 patients with biopsy-proven systemic amyloidosis | Mitral inflow deceleration time, EF, and TEI on univariate analysis, MPI index on multivariate analysis. Median TEI index >0.77 vs ≤0.77 predictor of all cause mortality and cardiac death. | | 80 |
| | 208 patients with biopsy-proven primary amyloidosis, 32 cardiac deaths at 307 ± 156 days | Cycle-dependent variation of myocardial integrated backscatter (CV-IB) of the posterior LV wall is the strongest predictor of cardiovascular mortality. | Fractional shortening, mean LV wall thickness, and MPI index were not a predictor of cardiac death | 81 |
| | 37 patients with AL amyloidosis Patients with a dilated right ventricle (LV/RV area ratio <2) had a shorter median survival (4 months) compared with patients with an area ratio >2 | Right ventricular dilation | | 82 |
| Sarcoidosis | | LV dilation, reduced LVEF | | 116 |
| Idiopathic restrictive CMP | 94 patients with IRCMP. 5-year survival 64% | LA dimension >60 mm predictor of decreased survival | | 172 |

*CMP*, Cardiomyopathy; *DB*, decibel; *DT*, deceleration time; *EF*, ejection fraction; *IRCMP*, idiopathic restrictive cardiomyopathy; *LVEF*, left ventricular ejection fraction; *MPI*, myocardial performance index.

(2) Constriction is more often associated with modest elevations of RV systolic pressure (less than 50 mm Hg), whereas in restriction, RV systolic pressures frequently exceed 50 mm Hg.[213] (3) Constriction is associated with RV end-diastolic pressure exceeding one third the RV systolic pressure, whereas in restriction the ratio is characteristically less than one third. In one study that evaluated the value of these hemodynamic criteria,[214] the predictive accuracies of difference between right and LV end-diastolic pressures, RV systolic pressure, and the ratio of RV end-diastolic pressure to RV systolic pressure were 85%, 70%, and 76%, respectively.

## Echocardiography in Clinical Decision Making in Restrictive Cardiomyopathy

Echocardiography provides diagnostic and prognostic information in patients with restrictive cardiomyopathy (Table 28-5). Restrictive ventricular filling in the presence of mildly decreased or normal systolic function is strongly indicative of restrictive cardiomyopathy, particularly when associated with diffuse thickening of LV and RV walls (in the infiltrative forms and in the storage diseases) and biatrial enlargement. Echocardiography, however, is of limited value in determining the cause of restrictive cardiomyopathy.[215]

## KEY POINTS

- The primary abnormality in restrictive cardiomyopathy is diastolic dysfunction with increases in LV end-diastolic and LA filling pressures. LV systolic function is usually preserved until late stages of the disease. Patients may be asymptomatic in early stages and present with signs and symptoms of right heart failure, left heart failure, or low cardiac output.
- 2D, M-mode, and Doppler echocardiography remain the most useful clinical tools for diagnosis. Nuclear imaging is an adjunctive diagnostic modality. MRI shows specific patterns on T1- and T2-weighted images and shows specific late gadolinium enhancement patterns in infiltrative cardiomyopathies. Tissue diagnosis remains the gold standard for the diagnosis of infiltrative cardiomyopathies but carries a low sensitivity.
- Small LV cavity size with increased wall thickness, valvular, and interatrial septal thickening along with a granular, sparkling texture on echocardiography, and low voltage on electrocardiography are hallmarks of cardiac amyloidosis.
- Doppler signs of restrictive cardiomyopathy (in the absence of known coronary disease or hypertension) include: Mitral inflow E/A ratio greater than 2, short deceleration time (less than 150 ms), decreased pulmonary vein S/D ratio with blunted S, a large D wave with prominent atrial reversal, TDI E′ <8 cm/s, slow M-mode propagation, and increased pulmonary systolic pressure and RA pressure.
- A combination of diagnostic tests is often needed to differentiate restrictive cardiomyopathy from constrictive pericarditis. Tissue-Doppler imaging may help in differentiating between the two conditions.
- Prognosis of patients with restrictive cardiomyopathy is highly variable depending on underlying etiology.
- Restrictive cardiomyopathy should be considered in a patient post chest radiation who presents with heart failure of unknown etiology.
- Atrial arrhythmias and marked biatrial enlargement, in the absence of valvular and myocardial disease, are the most common presenting features in idiopathic restrictive cardiomyopathy in the elderly.
- Drug-induced cardiomyopathy and infiltrative cardiomyopathy in several storage disorders may be reversible on withdrawal of the culprit agent or by enzyme replacement therapy.

**Congenital Disorders of the Pericardium**
- Congenital Absence of the Pericardium
- Pericardial Cysts

## Basic Principles

### ANATOMY OF THE PERICARDIUM

The pericardium consists of two layers that surround the heart and proximal segments of the aorta, pulmonary artery, pulmonary veins, and venae cavae. The outermost layer is a thick fibrous structure, which blends with the adventitia of the aorta and pulmonary arteries to provide firm support for the heart. This layer has supporting ligamentous attachments to the diaphragm, sternum, and vertebrae.[1,2] The inner layer is a serous membrane consisting of a single layer of mesothelial cells, which directly overlies the epicardial fat to form the visceral pericardium. This membrane reflects back on itself to line the inside of the fibrous layer and forms the parietal pericardium. The pericardial space is enclosed between the two layers of serous pericardium. This space is limited superiorly by the attachments of the fibrous pericardium to the great arteries. It is limited posteriorly by reflections of the pericardium as the pulmonary veins and venae cavae enter the atria (Fig. 29-1). These reflections result in the formation of two blind-ending tunnels or sinuses. The oblique sinus lies behind the left atrium (LA) and left ventricle (LV) and is limited superiorly by the pericardial reflection to the upper pulmonary veins, laterally by the reflections of the pericardium around the left pulmonary veins, and medially by the reflections of the pericardium around the right pulmonary veins and venae cavae. The transverse sinus lies above the pulmonary vein reflection and is bounded anteriorly by the great arteries and posteriorly by the LA roof (see Fig. 29-1). The main arterial supply of the pericardium is from a branch of the internal thoracic artery, the pericardiophrenic artery. Venous drainage is by the pericardiophrenic veins, which drain into the brachiocephalic veins. The phrenic nerve provides sensory innervation; the sympathetic trunks provide vasomotor innervation.

### PERICARDIAL FLUID

The pericardial space normally contains 10 to 50 mL of fluid that lubricates the contact between the two serosal layers of the pericardium.[3] This fluid is an ultrafiltrate of plasma and contains proteins, electrolytes, and phospholipids. It is believed to be formed in the visceral pericardium. The pericardial space drains via the thoracic and right lymphatic ducts. Any condition obstructing lymphatic flow or raising central venous pressure will lead to accumulation of pericardial fluid. Fluid will also accumulate in conditions increasing the normal pericardial permeability. The normal pericardium has a relatively small capacitance volume; acute accumulation of fluid will result in small increases in pericardial pressure until the capacitance has been exceeded. With additional increase in pericardial volume, a rapid rise in pericardial pressure and progressive hemodynamic disturbances will ensue (Fig. 29-2).[4]

### FUNCTIONS OF THE PERICARDIUM

The pericardium serves to reduce friction between the heart and the surrounding mediastinal structures and provides a barrier against the local spread of infection or malignancy to the heart.[2] The pericardium serves to distribute the pressure within the pericardial space to the cardiac structures enclosed within the pericardium and mediates ventricular coupling or interaction.[5] Understanding the role of the pericardium in pressure modulation and ventricular interaction is important to appreciate the hemodynamic effects and therefore the echocardiographic features of compressive pericardial disease.

#### *Pericardial Pressure*

The influences of pericardial restraint and pericardial pressure are important to bear in mind when assessing ventricular filling

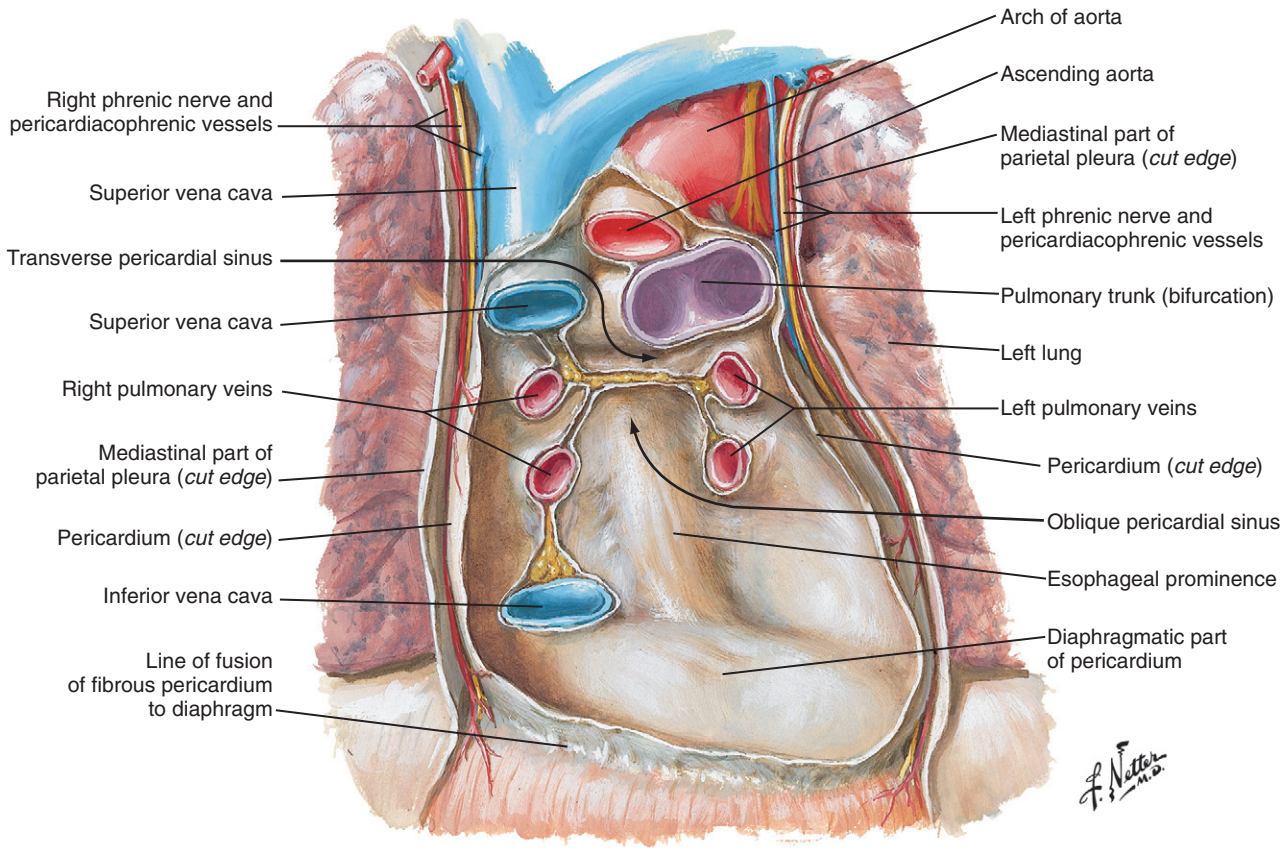

**Figure 29-1 Pericardial sac with heart removed: anterior view.** *(From Netter FH:* Atlas of human anatomy, *ed 1, Ciba-Geigy Pharmaceutical, 1989.)*

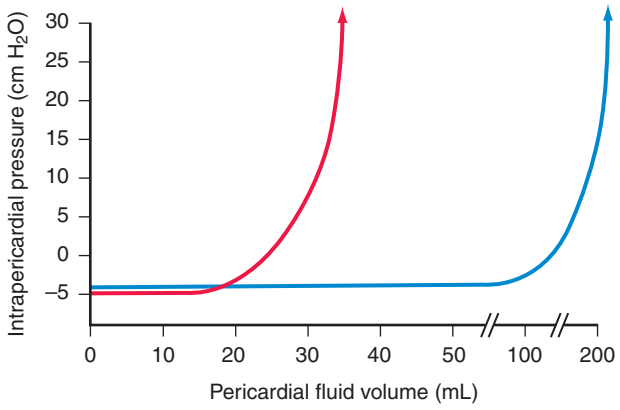

**Figure 29-2 Pericardial pressure-volume relationships in a patient with normal pericardial anatomy (*red line*) and a patient who has gradually developed a pericardial effusion (*blue line*).** *(From Edmunds HL:* Cardiac surgery in the adult, *New York, 1997, McGraw-Hill, p 1305.)*

and function. Over a century ago, Bernard concluded that the pericardium significantly constrained cardiac filling.[6] The concept of transmural pressure (the intracavity end-diastolic pressure minus the pericardial pressure) subsequently evolved to take into account this pericardial restraint. This concept is extremely important because transmural pressure is likely to be a closer representation of preload than the intracavity end-diastolic pressure. However, controversy exists as to the magnitude of this constraint because of difficulties in the accurate determination of pericardial pressure. Using a balloon to measure pericardial pressure, pericardial pressure approximates right atrial (RA) and right ventricular (RV) end-diastolic pressure. Others contend that balloon-based measurement techniques overestimate pericardial pressure and therefore underestimate true transmural pressure.[7]

### *Pericardial Restraint and Ventricular Interaction*

Because the pericardium is a relatively stiff structure, intrapericardial pressure rises rapidly as intrapericardial volume is increased acutely.[8] This increase in intrapericardial pressure may occur because of an accumulation of pericardial fluid or an increase in the volume of any intracardiac structure—particularly an increase in RV volume (Fig. 29-2). Shirato and colleagues[9] showed that acute volume loading in dogs with an intact pericardium caused a reduction in LV compliance. This is because an increase in intrapericardial volume (as a result of an increase in right-sided chamber volumes) increases intrapericardial pressure restraining LV filling. The opposite effects were seen with reductions in cardiac volume using nitroprusside. These effects were abolished by pericardectomy. Examples of ventricular interaction under different loading conditions have been seen in human studies (Fig. 29-3).[10]

The restraining effects of the pericardium are much less apparent in the chronic volume overloaded state because of adjustment in pericardial compliance[8] (see Fig. 29-2).

An increase in pericardial pressure resulting from pericardial fluid accumulation will also reduce transmural filling pressure

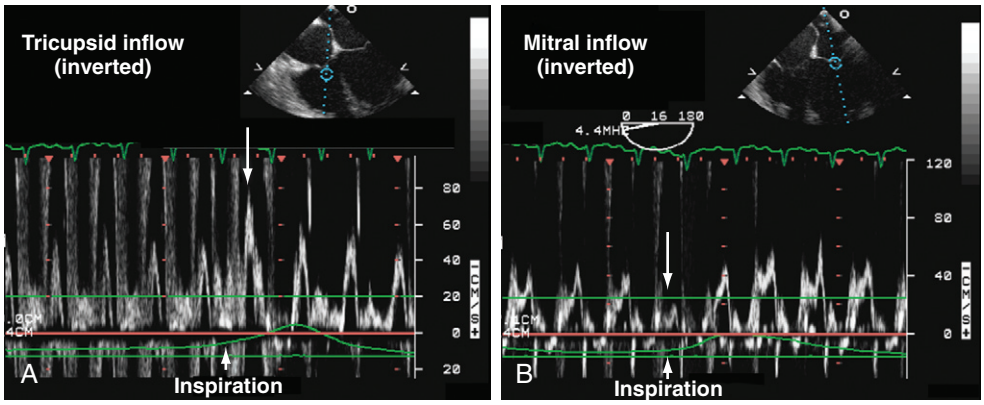

**Figure 29-3** **TEE images showing marked variation in mitral inflow velocities with respiration in a patient with dilated cardiomyopathy, RV enlargement, and volume overload. A,** Tricuspid inflow. **B,** Mitral Inflow. Note marked and opposite change in mitral and tricuspid flow velocities with first inspiratory beat (*arrow*). Marked ventricular interaction that simulates tamponade physiology can occur in settings other than pericardial effusion.

and shift ventricular pressure/volume relationships. Under conditions of raised pericardial volume and pressure or where the pericardium is stiff, there is enhanced potential for the LV and RV to interact and influence each other's diastolic function. Ventricular interaction can be either in series (i.e., the output of the right ventricle (RV) influencing left heart and LV filling), or in parallel, in which ventricular filling characteristics are changed by the side-by-side nature of the ventricles within a constrained pericardial volume. An understanding of the effects of ventricular interdependence is key to understanding the hemodynamic and therefore the echocardiographic features of compressive pericardial disease.

## ECHOCARDIOGRAPHIC EVALUATION FOR PERICARDIAL DISEASE

The pericardium covers the entire external surface of the heart and therefore is visualized from all standardized echocardiographic windows. The pericardium appears as a thin echogenic structure that is most obvious posteriorly. Normal pericardial thickness measures 1 mm or less. Normal pericardial fluid volume is minimal, and therefore the pericardial space is not appreciated in most normal subjects. Occasionally, a small amount of physiologic pericardial fluid may be seen in the posterior pericardial space. during ventricular systole. With the exception of some postsurgical pericardial effusions, the majority of pericardial processes are evident in the parasternal long-axis view.[11,12] When the clinical suspicion of a primary pericardial disease is low, therefore, a normal parasternal long-axis view has been considered adequate to rule out pericardial pathology. Unfortunately, in a recent series of patients who underwent pericardiocentesis for tamponade,[13] the diagnosis of pericardial effusion was not initially considered in 44% of patients before echocardiography. Accordingly, we advocate that the pericardial space be studied in all standard acoustic windows as part of the standard echocardiographic examination.

Because there is questionable correlation between measurements of pericardial thickness by transthoracic echocardiography (TTE) and pathologic examination,[14] we prefer computed tomography (CT) or magnetic resonance imaging (MRI) to evaluate the pericardium for thickening. These techniques also allow better visualization of adjacent thoracic structures.

**Box 29-1**

### ECHOCARDIOGRAPHIC IMAGING PROTOCOL IN SUSPECTED PERICARDIAL DISEASE

1. Full 2D examination with emphasis on the location, volume, and characteristics of the pericardial fluid and the characteristics of the pericardium. Views of RA and RV free walls are especially important. When recording digital images, extended loops (up to 10 beats) may be required to be recorded to capture changes related to the respiratory cycle.
2. M-mode examination with attention to imaging the RV free wall.
3. PW Doppler assessment of tricuspid (RV) inflow, mitral (LV) inflow, pulmonary vein flow, and hepatic vein flow. Superior vena cava flow can be imaged in selected patients. Long loops with respiratory tracking are recorded to appreciate respiratory changes in Doppler velocities.
4. Tissue-Doppler recordings of medial and lateral mitral annulus, with systolic (s′) and diastolic (E′ and A′) waves shown.
5. Careful 2D and M-mode imaging of the inferior vena cava and associated changes with respiration and a "sniff."
6. In postoperative patients, a detailed search for localized fluid collections and any resulting localized chamber compression.

Visualization of the RV and RA free walls, often with high–frame-rate M-mode or two-dimensional (2D) recordings of motion, is required to determine the hemodynamic significance of pericardial effusions. As well, pulsed-wave (PW) Doppler recordings of RV and LV inflow, with respiratory tracking and multiple complexes recorded, are needed as a minimum.

We strongly advocate that all patients with pericardial effusions undergo an initial comprehensive echocardiographic evaluation to rule out conditions that may modulate echocardiographic indicators of pericardial tamponade (such as atrial septal defects, RV hypertrophy), and detect coexisting cardiac conditions (Box 29-1). Follow-up examinations may be of a more directed, limited nature.

**Box 29-2**

**CAUSES OF PERICARDIAL INFLAMMATION**

**Idiopathic**

**Infectious Diseases**
Bacterial (including tuberculosis, *Chlamydia*, borreliosis, *Treponema pallidum*, *Haemophilus*, *Meningococcus*, *Pneumococcus*, *Gonococcus*)
Fungal (including *Candida*, histoplasmosis)
Viral (including coxsackie A9, B1-4, echo B, mumps, Epstein-Barr, cytomegalovirus, *Varicella*, rubella, human immunodeficiency virus, parvo B19)
Parasitic (including *Toxoplasma*, *Echinococcus*, *Entamoeba histolytica*)

**Trauma**
Blunt or penetrating trauma
Cardiac surgery

**Systematic Inflammatory Disorders**
Including rheumatoid arthritis, systemic lupus erythematosus, systemic sclerosis, Reiter syndrome

**Neoplasia**
Primary benign or malignant pericardial tumors
Secondary (including lung, breast, gastric, colon, leukemia, melanoma)

**Metabolic Disorders**
Including renal failure, hypothyroidism, Addison disease

**Miscellaneous**
Mediastinal irradiation
Pulmonary asbestosis

## Constrictive Pericarditis

A variety of disorders can cause pericardial inflammation and subsequent thickening, fibrosis, and calcification (Box 29-2). Pericardial inflammation and organization can lead to altered compliance characteristics of the pericardium (visceral, parietal, or with fusion of both layers). The underlying epicardium may also be abnormal. This results in impaired cardiac filling and characteristic echocardiographic signs. The echocardiographic recognition of pericardial constriction and its differentiation from other forms of diastolic heart failure (and in particular restrictive cardiomyopathy) remain among the essential challenges in echocardiography.

### PATHOPHYSIOLOGY

The thickened, fibrotic pericardium constricts the heart and reduces operative chamber compliance. Consequently, diastolic filling is impeded as the end-diastolic cardiac volume is limited by the pericardial volume. Early diastolic filling is usually not impaired (and in fact may be supranormal), whereas mid-diastolic and late-diastolic filling is impaired.

The pericardial thickening usually involves the whole pericardial surface (although the degree of thickening can vary) and leads to elevation and equalization of diastolic pressures in all four cardiac chambers, especially at end-diastole. In early diastole, ventricular filling can occur more rapidly than usual because of elevated atrial pressure. Once the pericardial volume is reached, however, filling halts abruptly, and there is little further increase in total chamber volume. This limitation to filling in mid and late diastole explains many of the M-mode, 2D, and Doppler abnormalities and leads to the typical square root sign seen with invasive hemodynamic measurement.[15]

One of the cardinal features of constriction is the dynamic changes in filling that occur throughout the respiratory cycle. At a physiologic level, these changes may be understood in terms of twin phenomena: the dissociation of intracardiac from intrathoracic pressures and ventricular interaction.[16] In the generally accepted model, thickened pericardium partially isolates the heart from the normal respiratory swings in intrathoracic pressure. Respiratory fluctuations in pulmonary venous pressure still occur (because portions of the pulmonary veins and the LA lie outside the pericardium), and a fall in pulmonary venous pressure with inspiration leads to a fall in LA filling without corresponding fall in the LV diastolic pressure.[4] The driving pressure across the mitral valve is therefore reduced. This prolongs the isovolumic relaxation time, reduces early diastolic transmitral flow velocity, and prolongs the deceleration time.[17] These changes can be useful diagnostically, as respiratory variations in flow are not characteristic of patients with other forms of diastolic heart failure such as restrictive cardiomyopathy. The pericardial limitation to filling also serves to exaggerate normal ventricular coupling/interaction. A reduction in LV filling with inspiration allows a compensatory increase in right-sided heart filling. This being said, it should be recognized that the interactions between the heart and the respiratory cycle in pericardial disease are complex and may also be modulated by abdominal venous pooling, blood volume, intraabdominal pressure, and their effects on the right side of the heart.[18,19] Irrespective of the primary driving forces, these respiratory fluctuations in left-sided and right-sided heart filling cause characteristic changes in mitral and tricuspid Doppler inflow patterns, ventricular dimensions, and hepatic vein flow dynamics.

### ECHOCARDIOGRAPHIC DIAGNOSIS

Given the challenges associated with the diagnosis of constriction, certain clinical scenarios should alert the cardiologist or sonographer and prompt the institution of a comprehensive imaging protocol appropriate to pericardial disease (see Box 29-1). Unexplained clinical evidence of right heart failure (especially in the setting of preserved LV ejection fraction) or unexplained hepatic dysfunction should arouse suspicion. Similarly, patients with a history of prior acute pericarditis or effusion, cardiac surgery, radiation, or systematic inflammatory disease are good candidates for careful pericardial evaluation.

#### *M-Mode and Two-Dimensional Abnormalities*

The abrupt cessation of flow in mid-diastole results in flattening of the motion of the posterior LV wall in mid and late diastole. This follows relatively normal motion in early diastole associated with rapid ventricular filling and is the M-mode equivalent of the square root sign. This sign is relatively sensitive, being reported in 85% of patients with constriction, but is not specific.[20] Abnormalities of interventricular septal motion are common in constriction. Septal position is influenced by pressure gradients between the LV and RV, and changes in septal position with respiration are exacerbated by the constricting effect of the rigid pericardium. Both parasternal M-mode and 2D echocardiography can demonstrate marked movement of the septum posteriorly with inspiration and the anteriorly with expiration, and consequent respiratory changes in LV and RV volumes.[21] An additional M-mode sign seen with constriction

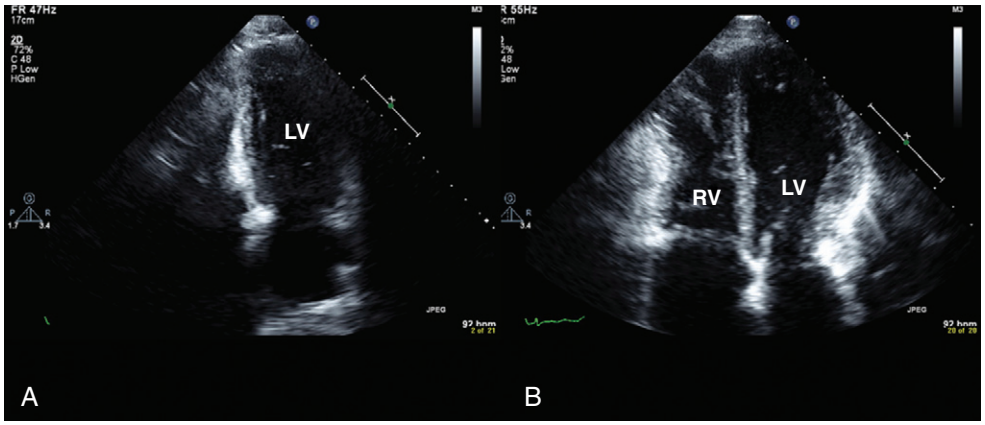

**Figure 29-4** **Pericardial thickening in surgically proven constriction. A,** Echogenic, thickened pericardium in relation to the mid and basal inferior wall of the LV. **B,** Similar pericardial thickening at mid-RV and basal lateral LV wall. Contour of RV is distorted. Cardiac MRI findings were similar. At surgery, pericardium was up to 1 cm in thickness.

is a "double component" of septal motion also known as the septal "bounce." A variety of abnormalities of septal motion after the onset of diastole have been reported,[21] with both initial anterior and posterior motion of the septum followed by restitution being described. Explanations advanced include phasic pressure differences between the LV and RV and, more recently, the effect of the tricuspid inflow jet on septal motion.[22] Tissue Doppler analysis of septal motion in the short-axis plane has revealed additional complexity: High-velocity early biphasic diastolic motion may be followed by multiple recoil waves (polyphasic diastolic septal fluttering).[23] Abrupt cessation of LV filling may sometimes be appreciated on 2D imaging as a perceptible "checking" of LV diastolic expansion.

Because of the interaction of ultrasound with thickened or calcified pericardium, suboptimal images are frequently obtained. Pericardial thickening and calcification can be appreciated using M-mode and 2D modalities (Fig. 29-4), although the sensitivity and specificity have been questioned. Early reports of M-mode sensitivity of almost 100% in diagnosing pericardial thickening[24] or diagnosing constrictive pericarditis from other findings[25] have not been confirmed in later studies.[20,26-28] A systematic overestimation of true thickness using TTE was found in dogs with experimental constrictive pericarditis.[14] These difficulties have been attributed to technical issues such as gain settings and resolution, fibrosis obscuring cardiac boundaries, and the nonuniform nature of pericardial thickening. A more recent study found that transesophageal echocardiography (TEE) was more accurate, with a sensitivity of 95% and specificity of 86% in the detection of thickened pericardium (using CT scanning as the gold standard).[29] It should be understood that while echocardiographic evaluation of the pericardium may arouse suspicion of the diagnosis, CT or MRI are the preferred imaging modalities for the diagnosis and measurement of pericardial thickening. It is also critical to recognize that surgically verified constriction has been noted in patients with normal pericardial thickness.[30] Adhesion of the epicardium to the pericardium with attendant loss of the usual sliding motion or tethering of the pericardium to surrounding anatomic structures may be appreciated on 2D imaging, especially from the subcostal view.

The inferior vena cava is also typically dilated with blunting of the normal inspiratory collapse, consistent with elevated right atrial pressure.[31]

### *Doppler Flow Abnormalities*

No single M-mode or 2D echocardiographic feature is diagnostic of constrictive pericarditis, nor is any combination. For this reason, careful analysis of Doppler imaging is an integral component in the diagnosis of constriction. In keeping with rapid early diastolic flow, the LV (mitral) inflow pattern typically shows a high E wave velocity, a short deceleration time, and a low A wave velocity. However, this restrictive filling pattern reflects elevated LA pressure and therefore is not specific to pericardial constriction. Of greater significance is the change in LV (mitral) and RV (tricuspid) inflow and hepatic vein flow patterns seen with respiration, which together form the cornerstone of the diagnosis of constriction. Several studies[17,32] have reported that in patients with pericardial constriction there is:

1. prolongation of the LV isovolumic relaxation time by greater than 25% with inspiration in all patients with constriction, whereas normal individuals changed by less than 5%;
2. reduction of greater than 25% in peak early LV inflow (E wave) velocity with inspiration in all patients compared with less than 5% in normal individuals;
3. larger expiratory decreases in RV inflow velocity than in normal individuals;
4. a 14% reduction in aortic velocity with inspiration versus a 4% reduction in normal individuals;
5. a 16% increase in pulmonary artery velocity with inspiration as compared to 5% in normal individuals;
6. changes in all parameters that were greatest in the first beat following inspiration as compared to changes two or three beats later in those patients with pulmonary disease;
7. an absence of these significant respiratory fluctuations after successful pericardectomy. In modern series, approximately 60% of patients have complete normalization of cardiac physiology postpericardectomy. There is a greater normalization of values in patients who become asymptomatic postpericardectomy.[33]

In the clinical setting, the major focus is on mitral inflow and hepatic vein Doppler; however, respiratory fluctuations in mitral inflow velocity are not invariably present. One study suggested normal respiratory fluctuations in 12% of patients with proven constriction,[32] whereas others have suggested that the proportion with less than 25% fluctuation in mitral E

velocity may be as high as 47%.[34] It is speculated that markedly elevated LA pressure forces mitral valve opening to occur on a steeper part of the LV curve, thus masking inspiratory changes in inflow velocity and isovolumic relaxation time.[32] This is supported by the finding that preload reduction in patients with constriction, and blunted respiratory change, unmasked the characteristic respiratory variation.[35]

Increased variation in flow through the right heart (with the resultant phasic changes in RV volume and pressure) also alters tricuspid regurgitation jet parameters. Increased RV preload increases the cavity pressure, increasing the regurgitation velocity and velocity-time integral (VTI). Klodas and colleagues[36] showed that in patients with constrictive pericarditis, there was a 13% increase in tricuspid regurgitation velocity with inspiration, as compared to an 8% drop in jet velocity in normal patients. Premature cessation of pulmonary regurgitant flow with inspiration has been reported in constriction.[37] Important abnormalities of hepatic vein flow have been described in association with constrictive pericarditis. Normal hepatic vein flow is biphasic and augments slightly with inspiration. There are brief flow reversals in late RV systole and atrial systole that are more prominent in expiration.[38] The predominant forward hepatic vein flow in constriction is typically during early diastole. This is the result of an elevated RA pressure inhibiting inflow during systole and driving flow across a high early diastolic transtricuspid gradient.[32] However, this pattern is not uniform, and systolic forward flow can also predominate. Expiration causes a reduction in diastolic forward flow along with significant diastolic flow reversals, although inspiratory flow reversals of lesser magnitude are sometimes also identified.[32] If the flow reversals are more prominent in inspiration, restriction is probably present. In a series of patients with surgically proven constrictive pericarditis, echocardiographic criteria based on respiratory variations in mitral and hepatic vein flow correctly diagnosed constriction in 22 of 25 patients.[32]

TEE-recorded pulmonary vein flow abnormalities and their role in distinguishing constriction from restriction have been described. Most notable are the higher systolic-to-diastolic filling ratio in constriction (as compared to restriction) and increased respiratory variation, in particular expiratory reduction in the diastolic flow component.[39]

Difficulty may occasionally arise in other clinical states where enhanced ventricular interaction is present and in which significant variation in mitral and tricuspid inflow velocities may occur. Typically constriction shows a fall in the mitral E wave velocity on the first inspiratory beat. In other settings, such as chronic obstructive pulmonary disease or marked obesity, a more gradual, phasic variation may be anticipated. Doppler interrogation of superior vena cava (SVC) flow is also useful. In chronic obstructive pulmonary disease, significant increases in superior vena cava flow velocity will be noted with inspiration. In constrictive pericarditis, minimal or no increase in superior vena caval flow velocity with inspiration is noted.[40]

### *Tissue-Doppler and Strain Imaging*

The advent of advanced Doppler and strain imaging has enhanced our understanding of myocardial mechanics in constriction. Most notably, tissue-Doppler imaging (TDI) may be useful in differentiating pericardial constriction from restriction and in solidifying the diagnosis when increased respiratory variation in mitral inflow Doppler is nondiagnostic or absent.[34] Early diastolic tissue velocities (E′) in patients with constriction are generally equivalent to those in normal controls[41] but may on occasion be supranormal. This is likely a result of the fact that whereas circumferential diastolic expansion of the heart is impeded in constriction, myocardial lengthening is relatively preserved. Most important, myocardial relaxation velocities (reflecting intrinsic myocardial disease) are usually lower in restriction than in constriction.[42] An E′ velocity 2 cm/s greater than predicted for age could differentiate patients with constriction from controls with a sensitivity of 76% and a specificity of 82%.[41] Similarly, a septal E′ cut-off value greater than 8 cm/s resulted in 95% sensitivity and 96% specificity for the diagnosis of constrictive pericarditis over a mixed group of cardiac amyloid and primary restrictive cardiomyopathy.[43] In constriction, septal E′ is more likely to exceed E′ at both lateral tricuspid and mitral annuli than in controls or restriction. This finding has been termed *annulus reversus* and may be due to tethering of the lateral wall[44,45] (Fig. 29-5). Annular mitral motion may precede mitral inflow in constriction, in contradistinction to the usual situation with restriction.[46]

Recent work has pointed to some limitations that exist in the use of TDI in differentiating constriction from restriction,[47] where myocardial dysfunction, marked segmental variation in myocardial velocities, and extensive mitral annular calcium can be problematic. It should be remembered that the two disease states can coexist in the same patients, especially after radiation therapy.[48]

Although less studied than tissue Doppler, rapid propagation of the mitral inflow wave by color M-mode has also been used to demonstrate relative preservation of early myocardial relaxation in constriction.[49]

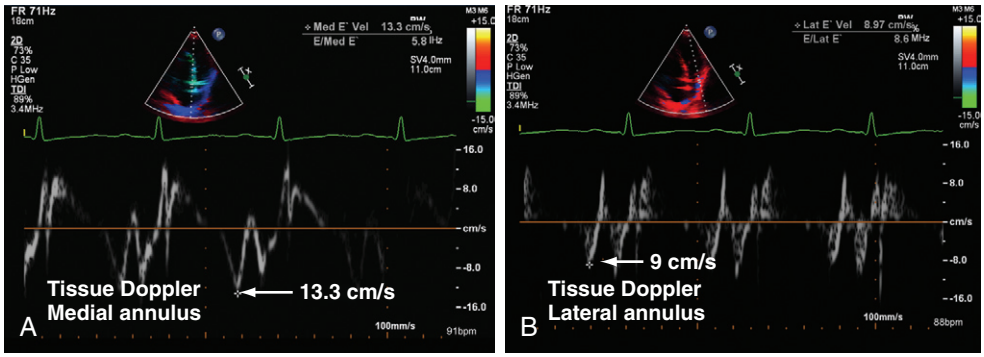

**Figure 29-5 Tissue-Doppler velocity recordings obtained from septal (medial) annulus (A) and lateral annulus (B).** Note that early diastolic septal annular velocity (E′) is supranormal, 13 cm/s. In contrast to the usual situation, lower E′ velocity is recorded at lateral annulus, termed *annulus reversus*. Patient also exhibits *annulus paradoxus*, low E/E′ ratio with elevated filling pressures. Patient subsequently had surgically confirmed pericardial constriction.

The use of speckle-tracking myocardial stain imaging is a new development that has already enhanced our understanding of myocardial mechanics but may in the future prove a useful diagnostic tool. Strain analysis confirms preserved longitudinal strain but abnormal circumferential strain in constriction compared to controls. Circumferential strain was also reduced in constriction compared to restrictive cardiomyopathy, and constrictive patients also showed significant abnormalities of torsional mechanics.[50]

### CONSTRICTION VERSUS RESTRICTION

A comparison of the echocardiographic features of constriction and restriction is presented in Chapter 28 (Table 28-4).

The echocardiographic evaluation of pericardial constriction and its distinction from restrictive cardiomyopathy remains a challenging task. Important diagnostic pitfalls may arise when localized constriction or mixed constriction and restriction or right-sided pathology can lead to heterogeneity of myocardial mechanics and atypical findings. Arrhythmias, especially atrial fibrillation, may make the interpretation of Doppler velocities difficult. The diagnosis of pericardial constriction relies on the integration of information acquired from high-quality 2D M-mode and Doppler imaging with a good understanding of the underlying clinical picture. Multimodality imaging is usually required and provides information that is complementary to echocardiography. On occasion, hemodynamic evaluation in an experienced cardiac catheterization lab will still be required.

## Pericardial Effusion

A wide variety of conditions, broadly divided into inflammatory, neoplastic, endocrine, and traumatic, can lead to an increase in the normal volume of pericardial fluid (see Box 29-2). Clinically, the consequences of this pericardial effusion are alterations in the physiology of cardiac function as intrapericardial pressure increases, reducing true (transmural) intracardiac filling pressures. Because right-sided pressures tend to be lower than left-sided pressure, direct effects of the pericardial fluid are usually first seen in right-sided chambers.[51]

### M-MODE AND TWO-DIMENSIONAL ECHOCARDIOGRAPHY

#### *Echocardiographic Appearance of Pericardial Fluid and Other Common Disorders Simulating Pericardial Effusion*

The hallmark of a pericardial effusion is visualization of an echolucent zone corresponding to a greater than physiologic volume of fluid in the pericardial space. If pericardial anatomy is relatively normal before fluid accumulation, fluid will first accumulate in the oblique sinus posterior to the left ventricle (LV)[11] (see Fig. 29-1) and is best viewed in the parasternal long-axis view. Once approximately 100 mL of fluid has accumulated in the pericardium, the fluid will tend to become circumferential, filling the entire pericardial space.

It is important to differentiate normal anatomic variants and nonpericardial processes from pericardial fluid. Left-sided pleural effusions appear posterior to the heart and should be distinguished from posterior pericardial effusion. Pericardial fluid will track anterior to the proximal descending thoracic aorta, whereas pleural effusions will not. When pericardial and pleural effusions coexist, the outline of the pericardium separating the fluid-filled spaces is often seen (Fig. 29-6). Occasionally, the use of a nonstandard imaging window through the pleural effusion may be helpful, and visualization of partially atelectatic lung in the fluid cavity confirms the diagnosis of pleural effusion.

Epicardial fat also leads to the appearance of an echolucent space within pericardium (Fig. 29-7). Unlike pericardial fluid, which tends to accumulate first in the posterior pericardial space, epicardial fat is generally more prominent anteriorly. This fat can occasionally cause diagnostic difficulty when

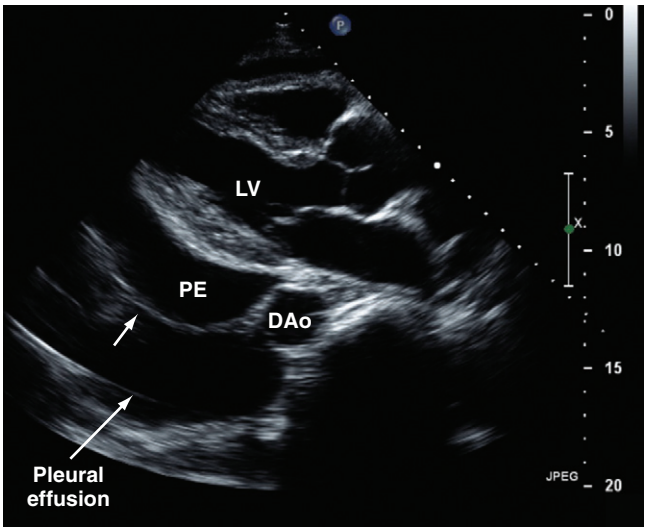

**Figure 29-6 Parasternal long-axis view of patient with both pericardial and pleural effusions.** Pericardial fluid tracks anteriorly to the descending thoracic aorta; pleural fluid is more posterior. Parietal pericardium is clearly seen separating fluid layers (*arrow*). A smaller amount of fluid is seen in the anterior pericardial space. *DAo,* Descending thoracic aorta; *PE,* pericardial effusion.

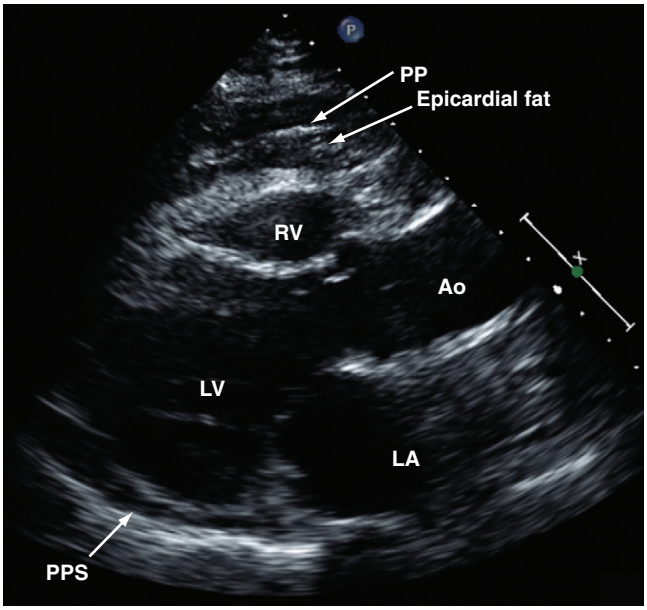

**Figure 29-7 TTE parasternal long-axis view.** Prominent echolucent zone is noted in the anterior pericardial space consistent with epicardial fat. Note the characteristic speckled appearance. There are in fact two fat layers, separated by parietal pericardium. Note also a smaller lucent zone in the posterior pericardial space, likely also due to epicardial fat. *Ao,* Aorta; *PP,* parietal pericardium; *PPS,* posterior pericardial space.

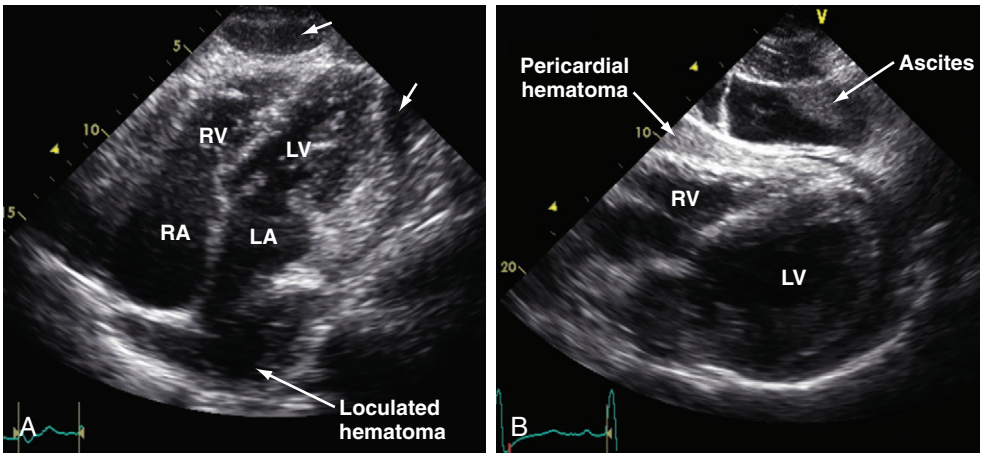

**Figure 29-8 Contrasting cases of pericardial hematoma. A,** Extensive pericardial hematoma (*arrows*) noted when the patient experienced hemodynamic collapse following an atrial septal defect repair. Contrast with **B,** where small layer of pericardial hematoma is noted on subcostal images. The fluid is relatively echogenic, consistent with blood in pericardial space. Patient experienced chest pain immediately following RV biopsy. Despite only a small volume of pericardial hematoma, severe hypotension was present. Ascites is also noted.

prominent posteriorly or when in unusual locations such as adjacent to the right atrium (RA). Epicardial fat will have echogenicity between that of the blood pool and myocardium[52,53] and tends to have a characteristic speckled appearance. Epicardial fat is more common in older, female, obese, and diabetic subjects, but correlation with severe obesity is not invariable.[54,55] MRI or CT imaging will resolve difficult cases.[56]

### FACTORS AFFECTING THE APPEARANCE OF PERICARDIAL EFFUSIONS

The echogenicity of the pericardial fluid will be influenced by features intrinsic to the fluid or related to the underlying pathologic process (e.g., tumor infiltration of the pericardium). In general, as the inflammatory nature of the fluid increases, so does its echogenicity. However, precise characterization may be elusive and tends to be more accurate with CT or MRI.[57,58]

### DETERMINATION OF PERICARDIAL FLUID VOLUME

2D (using a prolate ellipse model)[59] and especially three-dimensional (3D) echocardiography[60] has the ability to determine fluid volume. However, for clinical purposes, reporting of the effusion as minimal, small, moderate, or large is adequate. For circumferential pericardial effusions, we characterize any pericardial effusion with less than 5 mm of pericardial separation in diastole (corresponding to a fluid volume of 50 to 100 mL) as minimal, 5 to 10 mm of separation as small (corresponding to a fluid volume of 100 to 250 mL), 10 to 20 mm of separation as moderate (corresponding to a fluid volume of 250 to 500 mL), and greater than 20 mm separation as large (corresponding to a fluid volume greater than 500 mL). For any significant effusion, we report location, degree of loculation or septation, and the feasibility, risk, and suggested route for percutaneous intervention.

### CLINICAL CONSIDERATIONS

A common clinical scenario is a request for determination of the presence or absence of pericardial effusion and, if effusion is present, a determination of its size and hemodynamic effect. It should be remembered that an incompletely understood, complex interaction of factors influences the ultimate physiologic consequences of pericardial effusion and modulates the hemodynamic expression in any given patient. These include the pericardial pressure/volume relationship, the rapidity of fluid accumulation, underlying cardiac pathology (particularly hypertrophy and shunts), and systemic volume status.[61] It is well understood, for instance, that small acute pericardial effusions (occurring most commonly postintervention or traumatically) can lead to dramatic physiologic effects (Fig. 29-8), whereas moderate-sized or even large pericardial effusions that accumulate slowly can be hemodynamically well tolerated.[8] Localized cardiac compression may lead to dramatic hemodynamic consequences without producing classical echocardiographic indications of "tamponade."[62-65]

## Pericardial Tamponade

### ECHOCARDIOGRAPHIC EVALUATION

#### *Right Ventricular Compression, Inversion, or Collapse*

Perhaps the most useful echocardiographic indicator of a hemodynamically significant pericardial effusion is RV diastolic collapse. Echocardiographically, this is seen on M-mode or 2D recordings as a persistent inward motion of the RV free wall during diastole (Fig. 29-9). By the time this is noted in experimental preparations, there is already a significant reduction (approximately 20%) in forward cardiac output and elevation in heart rate without a change in mean arterial pressure.[66] There is no precise relationship between the duration or degree of RV diastolic collapse and the degree of elevation of intrapericardial pressure or the severity of the hemodynamic effect of the pericardial fluid.[67] Clinically, one can appreciate all degrees of this phenomenon, from a barely perceptible dip only seen with high–frame-rate recordings to complete collapse and obliteration of the RV throughout diastole.

Increases in intravascular volume,[68] RV pressure,[69] and increased chamber stiffness will all reduce the amount of RV diastolic collapse for any given increase in intrapericardial pressure. This means that in certain patients with pulmonary hypertension, RV hypertrophy, or RV volume overload (e.g., atrial

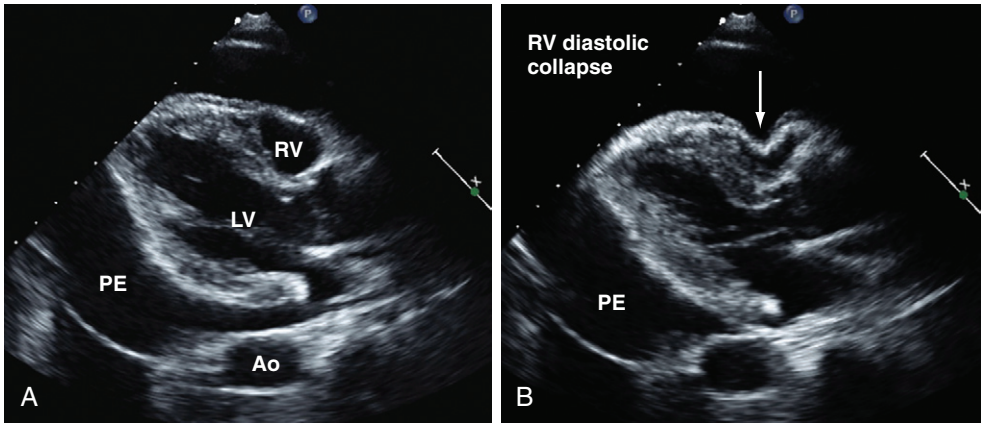

**Figure 29-9** **Parasternal long-axis image of a patient with large pericardial effusion (*PE*) and cardiac tamponade. A,** Late diastole; no RV collapse is evident. **B,** Marked RV collapse is present in early diastole (*arrow*). *Ao*, Aorta.

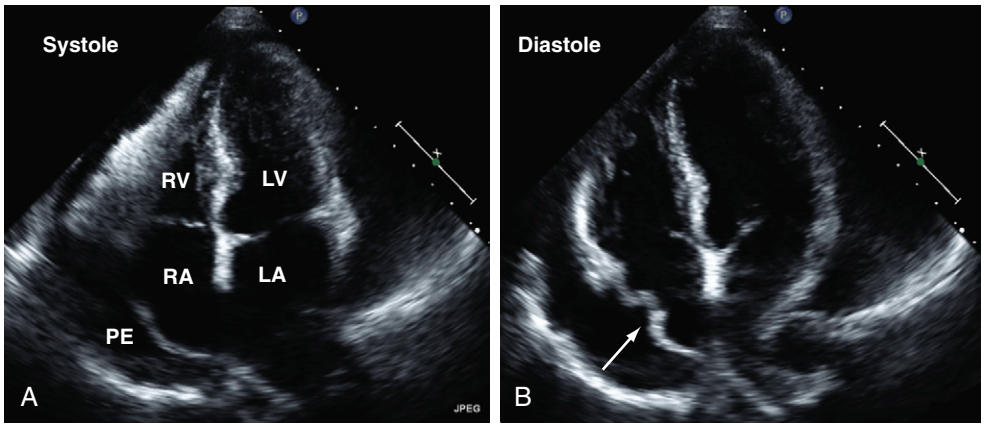

**Figure 29-10** **Apical four-chamber view of large pericardial effusion (*PE*) with transient RA collapse (*arrow*). A,** Systole. **B,** Diastole.

septal defects), RV diastolic collapse may not occur despite significant elevations in pericardial pressure.

Because the sensitivity and specificity and therefore the negative and positive predictive value of RV diastolic collapse depend on the definition of tamponade (Table 29-1),[31,51,62,70-72] we use a clinical approach to this finding. In a patient with clinical findings of tamponade, we would interpret RV diastolic collapse to indicate a significant hemodynamic contribution of the effusion to the patient's clinical state and require immediate therapy to remove pericardial fluid. In a patient without clinical tamponade, we would interpret RV diastolic collapse to indicate intrapericardial pressure at or above RV diastolic pressure and a potential for relatively acute hemodynamic deterioration. Although this is not viewed as an indication for immediate pericardial fluid removal, urgent action is indicated to reverse any factors worsening the hemodynamic effect of the effusion.

Large pleural effusions can cause RV diastolic collapse.[73] Where there is uncertainty as to the genesis of tamponade physiology, we drain the pleural effusion and then reevaluate the patient clinically and echocardiographically.

### *Right Atrial Compression, Inversion, or Collapse*

RA pressures are lower than RV pressures throughout most of the cardiac cycle. Because intrapericardial pressure is evenly distributed over the heart, one would surmise that RA compression would occur before RV compression as pericardial pressure is raised. This is borne out in imaging studies in which the RA and RV are continuously imaged during pericardiocentesis.[51] Subsequently, RA inversion, which tends to begin in late ventricular diastole but persists into early ventricular systole, is an extremely sensitive sign of cardiac tamponade[63] (Fig. 29-10). However, it is less specific than RV diastolic collapse (see Table 29-1). The depth of RA collapse bears an imprecise relationship to the hemodynamic effect of the fluid.[63,72] Conversely, the RA inversion time index (determined by counting the total number of frames showing atrial inversion divided by the total number of frames in the cycle) has been reported to have high sensitivity and specificity for the presence of clinical cardiac tamponade[72] (see Table 29-1). Marked elevation in RA pressure and ventricular pacing have the potential to influence the accuracy of this sign.[72]

### *Left Atrial Compression, Inversion, or Collapse*

Normally, mean LA pressure is higher than RA pressure. Therefore LA compression, inversion, or collapse is generally less sensitive but more specific than RA findings for tamponade.[62,63] (see Table 29-1). LA collapse may, however, be useful in settings of abnormally high right-sided pressures (e.g., pulmonary embolism) and may be the only sign of tamponade in the postoperative patient.[65]

Isolated LV diastolic collapse is occasionally seen with localized effusion, usually in the postsurgical setting.

**TABLE 29-1 Sensitivity, Specificity, Negative, and Positive Predictive Values of Echocardiographic Features of Pericardial Tamponade**

| *Study* | *Year* | *Echocardiographic Sign Evaluated* | *Patients (Total/Tamponade)* | *Definition of Tamponade* | *Sensitivity (%)* | *Specificity (%)* | *PPV (%)* | *NPV (%)* |
|---|---|---|---|---|---|---|---|---|
| Armstrong[70] | 1982 | RV diastolic collapse, M-mode, (posterior movement of the RV free wall in early and mid diastole as timed from the ECG) | 86/17 | Presence of a moderate to large pericardial effusion, plus at least two of the following: (1) elevated venous pressure, (2) systemic hypotension, (3) pulsus paradoxus and resolution of signs after pericardiocentesis | 76 | 84 | 54 | 93 |
| Armstrong[70] | 1982 | RV diastolic collapse, 2D (any indentation of the RV free wall during diastole) | 41/10 | Same as above | 100 | 87 | 71 | 100 |
| Engel[71] | 1982 | RV diastolic collapse, M-mode (persistent posterior motion of the RV free wall greater than 50 ms after mitral valve opening) | 37/21 | Pulsus paradoxus >10 mm Hg, elevated systemic venous pressure, and resolution of signs with pericardiocentesis | 81 | 94 | 89 | 80 |
| Gillam[72] | 1983 | RA collapse (inversion of the RA free wall at any point of the cardiac cycle) | 123/19 | Two or more of the following: (1) elevated jugular venous pressure, (2) relative hypotension, (3) pulsus paradoxus >10 mm Hg and resolution of the symptoms with pericardiocentesis | 100 | 82 | 50 | 100 |
| Gillam[72] | 1983 | RA diastolic collapse (RA inversion time index >0.34 [defined as the number of video fields demonstrating RA inversion divided by the total number of fields per cardiac cycle]) | 36/18 | Same as above | 94 | 100 | 100 | 95 |
| Kronzon[62] | 1983 | RA collapse, 2D (any reduction in RA size during diastole) | 29/9 | Clinical with relief after pericardiocentesis | 100 | 85 | 75 | 100 |
| Kronzon[62] | 1983 | LA collapse, 2D (posterior LA wall motion of at least 10 mm in diastole) | 29/9 | Same as above | 54 | 95 | 83 | 83 |
| Singh[51] | 1984 | RV diastolic collapse, 2D (persistent inward motion of the RV endocardial surface after opening of the mitral valve) | 16/12 | Equalization of RA, pulmonary capillary wedge, and intrapericardial pressures and elevation of these pressures to >10 mm Hg | 92 | 100 | 100 | 80 |
| Singh[51] | 1984 | RA collapse, 2D (RA free wall appears to be inverted at any point during the cardiac cycle) | 12/8 | Same as above | 63 | 100 | 100 | 57 |
| Singh[51] | 1984 | RV diastolic collapse, 2D (persistent inward motion of the RV endocardial surface after mitral valve opening) | 21/16 | Equalization of the intrapericardial, RA, and pulmonary wedge pressures with elevations of these pressures to >10 mm Hg | 93 | 100 | 100 | 83 |
| Himelman[31] | 1988 | Inferior vena cava plethora, 2D (a decrease in proximal vena cava diameter by >50% after a deep inspiration) | 115/33 | Either of the following: (1) elevation (mean >12 mm Hg) and equalization (≤5 mm Hg) of diastolic filling pressures; (2) systolic blood pressure <100 mm Hg that increased by >20 mm Hg after pericardiocentesis | 97 | 40 | 40 | 97 |
| Himelman[31] | 1988 | RA collapse, 2D (dynamic inversion of the RA wall occurring in late diastole or early systole) | 115/33 | Same as above | 55 | 66 | 39 | 78 |
| Himelman[31] | 1988 | RV diastolic collapse, 2D (early diastolic inversion of the RV free wall that varied with respiration) | 115/33 | Same as above | 48 | 68 | 38 | 77 |

Some of the values in the table differ from those reported in the original studies, as data from patients with "equivocal" tamponade have not been used. Sensitivity = true positives/(true positives + false negatives) and specificity = true negatives/(true negatives + false positives).

Data from references in the chart.

*ECG*, Electrocardiogram; *NPV*, negative predictive value (true negatives/[true negatives + false negatives]); *PPV*, positive predictive value (true positives/[true positives + false positives]).

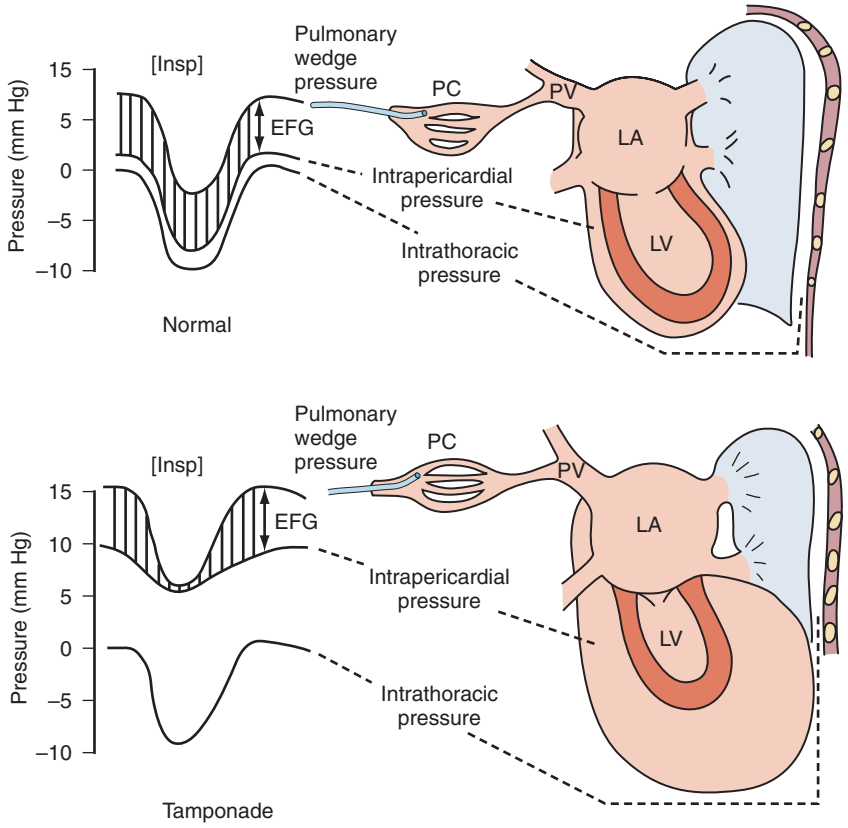

**Figure 29-11** *Top:* **Normal situation in which changes in intrathoracic pressure are transmitted to both pericardial sac and pulmonary veins.** Effective filling gradient (*EFG*) changes only slightly during respiration. *Bottom:* Cardiac tamponade. Changes in intrathoracic pressure are transmitted to pulmonary veins (*PV*) but not to pericardial sac. EFG falls during inspiration. *Insp*, Inspiration; *PC*, pulmonary capillaries. *(From Sharp JT, Bunnell IL, Holland JF, et al: Hemodynamics during induced cardiac tamponade in man.* Am J Med *29:640-646, 1960.)*

### *Phasic Respiratory Changes and Plethora of the Inferior Vena Cava*

Decreased phasic respiratory changes and plethora of the inferior vena cava have been reported in tamponade[31]; however, this is a nonspecific finding (see Table 29-1).

### *Doppler Echocardiography*

The determination of variations in intracardiac flows with respiration, specifically using PW Doppler, has been proven to aid clinical decision making in patients with pericardial effusions. Although tamponade bears certain similarities to the physiology of constriction, there are important differences. It should be recalled that, in tamponade, impedance to ventricular filling is pandiastolic and inspiratory augmentation of right-sided filling is somewhat preserved. Ventricular interaction and relative dissociation of intrathoracic from intrapericardial, and hence transmural, filling pressure are key to the understanding of both processes.[74]

During inspiration, normally intrathoracic, intrapericardial, and intracardiac pressures decrease in unison and to a similar extent. There is normally a small augmentation of right-sided transvalvular flows and a decrease in left-sided transvalvular flows accompanying inspiration.[75] Echocardiographically this is appreciated in normal subjects as minimal change in mitral E wave velocity with inspiration, and slightly more prominent respiratory changes in the right heart. The explanation for this is a combination of increased venous return secondary to decreased intrathoracic pressure, a fall in pulmonary vascular impedance, and ventricular interaction. With accumulation of pericardial fluid, there is a blunting of transmission of pressure changes from the intrathoracic compartment to the intrapericardial compartment.[75] As the pulmonary veins are intrathoracic (but extrapericardial), the pulmonary venous pressure falls with inspiration; however, the fall in pericardial pressure is blunted, resulting in a fall in driving pressure filling the LA and therefore a reduction in LV filling.[75] Respiratory augmentation remains intact on the right side, and RV filling increases during inspiration.[76] As pericardial fluid volume increases, available pericardial space becomes limited, enhancing the potential for ventricular interaction, which in turn amplifies the disparate patterns of left-sided and right-sided filling with respiration (Fig. 29-11). Although the magnitude of this flow disturbance is greater, and separation of values from normal occurs earlier with right-sided flows, in the clinical setting most attention has focused on the mitral inflow, because diagnostically adequate tricuspid inflow signals are obtained in around one third of patients.[38] In tamponade, there is characteristically an appreciable fall in mitral E wave velocity and VTI and lengthening of the isovolumic relaxation time on the first inspiratory beat. A summary of the magnitude and direction of flow disturbance in intracardiac flows are best illustrated in Figure 29-12 and summarized in Table 29-2.[38,76-78] Although most literature has concentrated on changes in transvalvular flow velocities, there is also a decrease in LV ejection time and LV inflow duration.[76]

Although some have noted a quantitative relationship between rise in pericardial pressure and the degree of respiratory variation in inflow velocities,[79] the relationship of the magnitude of this change to the severity of tamponade has been questioned.[80]

Interrogation of superior vena cava and hepatic vein flow may provide information that is complementary to analysis of mitral inflow velocities in equivocal cases. The superior vena cava is best imaged from the right supraclavicular window at a depth

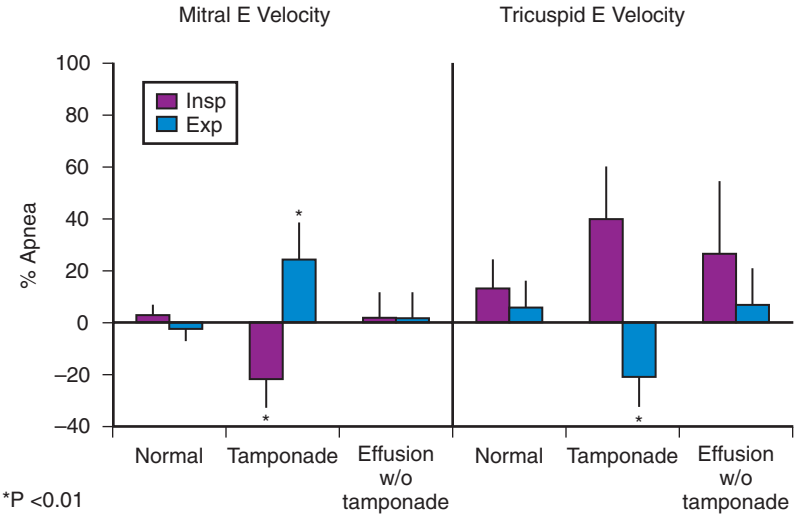

**Figure 29-12 Respiratory variation of mitral and tricuspid inflow velocities in cardiac tamponade, normal subjects, and patients with effusion without tamponade.** Mean percentage changes in mitral and tricuspid early filling velocities (*E*) with first beat of inspiration (*Insp*) and of expiration (*Exp*) are compared with mean apnea values. In comparison with normals and patients without tamponade, the mital E wave velocity in patients with tamponade decreases significantly with inspiration and increases with expiration. All patients exhibited an increase in tricuspid E wave velocity with inspiration, but only those with tamponade showed a decrease in expiratory E wave velocity. *(With permission from Burstow DJ, Oh JK, Bailey KR, et al: Cardiac tamponade: characteristic Doppler observations.* Mayo Clin Proc *64:312-324, 1989.)*

*Dogs were studies in three states: baseline, effusion without tamponade, and with tamponade.

of 5 to 7 cm. Normal superior vena cava flow patterns reflect phasic changes in RA pressure.[81] Doppler echocardiography of the superior vena cava in normal subjects reveals a biphasic, systolic flow pattern without significant flow reversals.[82] Patients with cardiac tamponade have been reported to show reduced, absent, or reversed diastolic flow with the first expiratory cardiac cycle, the Doppler counterpart of the loss of the Y descent and the prominent X descent.[76,83] In advanced tamponade, loss of diastolic filling throughout the respiratory cycle has been reported. Similar changes occur in hepatic vein flow, with marked expiratory loss of diastolic filling, along with expiratory diastolic flow reversals. Examples of abnormal Doppler flow recordings in cardiac tamponade are noted in Figure 29-13.

### *Tissue Doppler*

In eight patients with pericardial effusion and tamponade, E′ was reported to be lower than in age-matched and sex-matched control subjects, and unlike LV inflow (E wave), velocity did not show respiratory variation. E′ values returned to normal after pericardiocentesis.[41]

## THE ROLE OF ECHOCARDIOGRAPHY IN PATIENT MANAGEMENT

Echocardiographic signs of elevated pericardial pressure may precede the appearance of clinical tamponade (which we define as a fall in mean arterial pressure and a pulsus paradoxus greater

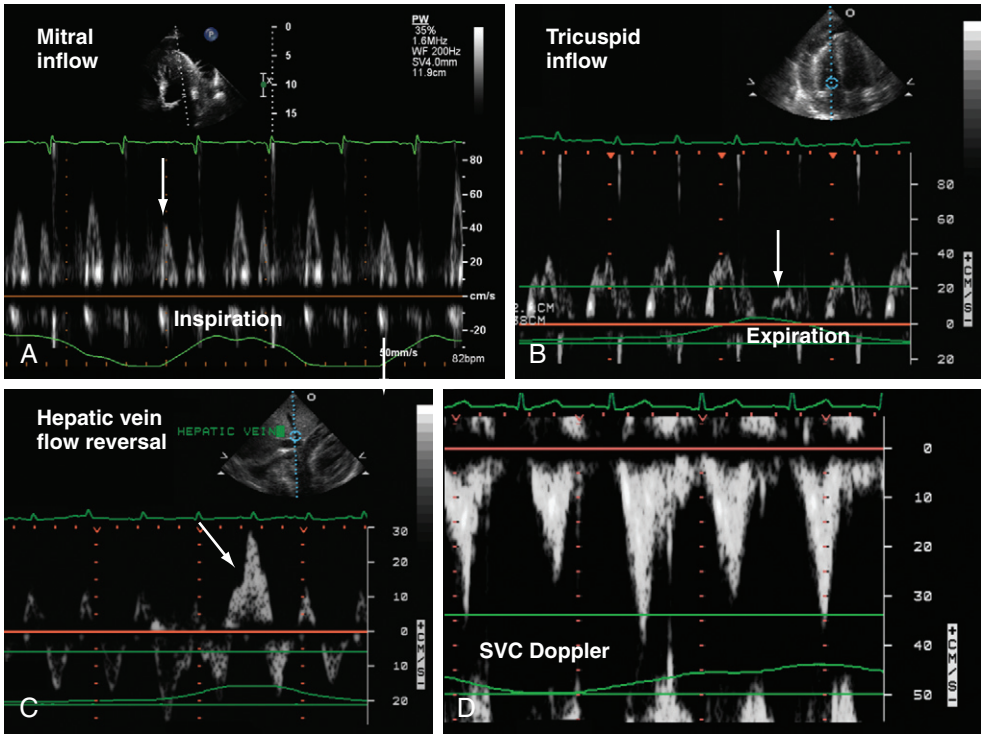

**Figure 29-13** **Doppler findings in cardiac tamponade. A,** Significant reduction in mitral inflow velocity is noted on first inspiratory beat (*arrow*). **B,** Marked fall in tricuspid inflow velocity is noted on first expiratory beat (*arrow*). **C,** Hepatic vein Doppler indicates marked flow reversal on first expiratory beat (*arrow*), after slight augmentation in forward velocities on inspiration. **D,** Superior vena cava Doppler in a patient with acute tamponade. than 10 mm Hg as a result of raised pericardial pressure).[66] Given that the clinical transformation from stable to unstable can occur abruptly, echocardiography has come to play a pivotal role in the management of patients with pericardial effusion. It must be appreciated that the physiologic effects of an increasing pericardial effusion lie on a continuum, and therefore any separation into distinct stages is arbitrary. We find it useful, however to divide patients with pericardial effusions into three hemodynamic categories. First, those without echocardiographic evidence of hemodynamic compromise, (no RV collapse, no RA or LA collapse, physiologic changes in intracardiac flows with inspiration) we describe as "no evidence of hemodynamic effect." Second, those with any degree of RV diastolic collapse, prolonged (more than 35% of the cardiac cycle) RA collapse, or marked (greater than 25% LV or greater than 50% RV) early filling [E] velocity changes with inspiration, we report as showing "echocardiographic indications of 'tamponade.'" The use of quotation marks is to underscore the fact that tamponade is a clinical syndrome. Third, we report patients who fit into neither of the aforementioned categories as having "echocardiographic indicators of elevated pericardial pressure without echocardiographic features of 'tamponade.'" It cannot be overemphasized, however, that with localized cardiac compression or abnormal physiologic states, hemodynamic compromise may be present as a result of elevated pericardial pressure without any classic M-mode, 2D, or Doppler echocardiographic indicators of raised intrapericardial pressure.[63-65]

## LOCALIZED AND LOCULATED PERICARDIAL FLUID COLLECTIONS

In some cases, localized cardiac compression can occur rendering both the diagnosis of tamponade and attribution of the pericardial process to the clinical state difficult. This is especially challenging when hypotension occurs after cardiac surgery (see Fig. 29-12).[63-65] A high index of suspicion is especially appropriate in anticoagulated patients and following transvenous pacing lead removal. In this setting, traditional echocardiographic markers of tamponade may not be present. A careful search for localized chamber compression, localized collections of blood inside or adjacent to the pericardial space, and less usual features, such as LV or LA diastolic collapse,[84] must be performed. Transesophageal echocardiography may add incremental information, especially if imaging quality is poor.[85-87] Sometimes the most important role of the echocardiogram is to rule out other cardiac causes of the patient's clinical state. If doubt remains as to the presence or hemodynamic effect of a collection, alternative imaging techniques, catheter-based hemodynamic monitoring with volume manipulation, or even surgical exploration may be required for both diagnostic and therapeutic purposes.[65]

## ECHOCARDIOGRAPHICALLY GUIDED PERICARDIOCENTESIS

Before the advent of 2D echocardiography, percutaneous pericardiocentesis was viewed with trepidation. In cardiac catheterization laboratories, for instance, clinicians in large-volume centers achieved success rates of 86% in obtaining fluid, with death rates of 4%, and a further 4% risk of other major complications.[88] In contrast, echocardiographically guided series have indicated success rates of 97% or more, rare deaths, and total complication rates of 3% to 5%. Major complications have included cardiac laceration requiring surgery, hemothorax requiring thoracotomy, major pneumothoraces, and rare bacteremia or ventricular tachycardia. Less significant or

**Box 29-3**

**PERICARDIOCENTESIS CHECKLIST**

- Review indications, urgency of pericardiocentesis
- Review echo images, determine feasibility, select approach
- Review for bleeding diathesis, anticoagulant drugs, significant electrolyte disturbance, anemia,
- Consent
- Appropriate setting, monitoring (oxygen saturation, electrocardiogram, invasive or noninvasive blood pressure minimum)
- Intravenous access
- Check pericardiocentesis kit
- Check sedation, analgesia available

self-limiting complications include transient chamber entry, small pneumothoraces, vasovagal response, and minor arrhythmias.[89-91] It should be recalled that surgical approaches may be associated with significant morbidity.[92] Needle pericardiocentesis is generally not indicated in patients with pericardial effusions as a result of aortic dissection, penetrating trauma, or ruptured ventricular aneurysm where definitive surgical therapy is indicated.

In emergencies, the physicians at our institution prefer to have echocardiographic confirmation of an effusion, if at all possible. Most often, this occurs during percutaneous interventions or ablation procedures. When effusions are found, they use the information obtained to guide the percutaneous approach. This so-called rescue pericardiocentesis is successful in relieving tamponade in 99% of cases and may be the only and definitive therapy in 82% of cases.[93]

Although minor variations in approach to echocardiographically guided pericardiocentesis exist, certain basic principles apply.[90,91,94] We have evolved an institution approach, which is outlined next in point form.

1. **Preparation and orientation:** (See Box 29-3.) Outside of emergencies, we perform this procedure in our cardiac intensive care unit. Immediately before the procedure, we image the patient at the bedside to confirm that the correct approach (i.e., the most direct route to the largest collection of fluid) has been chosen. Attention is focused on avoiding both the internal thoracic arteries (located 0.5 to 2 cm lateral to the sternal edge) and intercostal vessels (inferior border of the rib). We then mark a proposed entry point with a permanent marker or reimage from this location to determine the depth to the fluid, the depth to the nearest cardiac structure, and the correct angle of approach. Most importantly, the angulation of the transducer in 3D space is carefully noted, as this will be subsequently replicated with the pericardiocentesis needle. We find it useful to form a mental map by drawing an imaginary line along the direction of the transducer and then noting its intersection with a remote anatomic structure, such as the point of the left shoulder or tip of the scapula. In our experience it is the inability to accurately reproduce this angle that causes most unsuccessful initial attempts. After a sterile field is established, local anesthesia is administered. Adequate topicalization along the line of approach is mandatory.
2. **Imaging:** A second operator or sonographer usually images from a window remote to the puncture site (usually parasternal or subcostal) to provide real-time visualization of the procedure. Alternatively, the imaging probe can be covered with a sterile sleeve and hence be manipulated by the operator. Imaging probes that allow needle insertion in the center of the imaging plane have been described.[95] Like other operators,[96] we favor the apical route as the safest and easiest approach, but other approaches may be more appropriate in certain situations or with loculated effusions.
3. **Pericardial puncture:** We then attach the pericardiocentesis needle to a 10-mL syringe with 5 mL of 1% lidocaine. The needle is advanced until pericardial fluid is obtained or a depth of needle is inserted that could contact a cardiac structure. Constant aspiration during the advancement of the needle followed by a slight pause for injection should be performed to guard against needle plugging. There is a characteristic "feel" or "pop" associated with contact of the needle with the pericardium and its puncture. Given the tomographic nature of 2D imaging and potential for imaging artifacts, care must be taken in interpretation of the image during this phase. In particular, the tip of the pericardiocentesis needle and its course are difficult to identify with imaging from a remote acoustic window. Indentation of the pericardium by the needle just before puncture is helpful if seen. Monitoring of the needle electrogram is no longer performed.
4. **Guidewire and catheter:** Once the pericardium is entered, there should be free flow of fluid into the syringe. If we are uncertain as to the position of the needle, if we aspirate blood, or in the case of small effusions, the intrapericardial position of the needle is confirmed with the injection of 1.0 to 5 mL of agitated saline via a three-way stopcock configuration. Visualization of the contrast in the pericardial space confirms correct needle position (Fig. 29-14, *A*). In larger effusions, the needle may be advanced incrementally, once pericardial fluid is obtained. A "J" guidewire is then introduced into the pericardial space. The wire is usually well seen in the pericardial space from the remote window. The track of the guidewire is dilated, and a pigtail catheter is placed over the wire into the pericardial space. Fluid is withdrawn for analysis. We do not routinely measure pericardial pressure; however, progressive disappearance of fluid from the pericardial space and resolution of signs of tamponade provides the final confirmation of successful pericardiocentesis. Once the majority of the fluid has been removed, the catheter is secured and a suction drain attached. Analysis of pericardial fluid should be ordered according to the clinical context.
5. **Subsequent catheter management:** The pericardial drain may be removed after the pericardial fluid has been fully aspirated. However, in most cases we leave the catheter in situ for 12 to 36 hours, removing once the drainage is minimal (less than 30 mL in 24 hours). In traumatic pericardial effusions occurring in the electrophysiology or catheterization lab, our practice is early removal, as recurrence in this setting is rare. Occasionally, the catheter is withdrawn slightly to avoid kinking or facilitate drainage. Small saline flushes are occasionally necessary to maintain patency. We generally avoid readvancing the catheter because of risk of infection.
6. **Troubleshooting:** See Table 29-3.

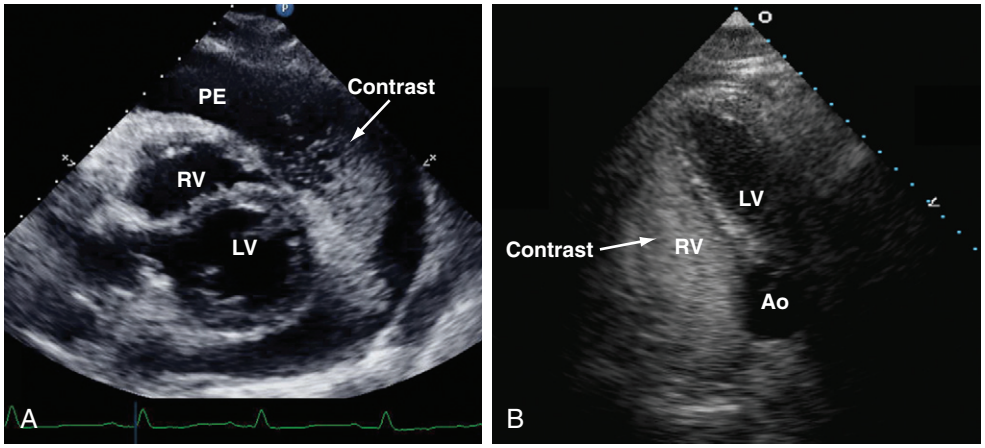

**Figure 29-14** **Use of bubble contrast in needle pericardiocentesis. A,** TTE parasternal short-axis view of saline bubble contrast in large pericardial effusion (*PE*) during pericardiocentesis. Saline contrast is seen in lateral pericardial space, confirming correct catheter position. **B,** Bedside off-axis apical five-chamber TTE. Emergency pericardiocentesis performed at bedside after patient became severely hypotensive following atrial fibrillation ablation procedure. Effusion was small and pericardiocentesis technically difficult. Bloody tap was obtained, and saline contrast was used to determine needle location. Saline contrast is seen to opacify the RV, confirming intracardiac needle position. After readjustment of needle orientation, pericardial space was entered and 150 mL of blood removed with marked hemodynamic improvement. *Ao*, Aorta.

## Acute Pericarditis

Acute pericarditis is caused by inflammation of the pericardium and can occur in isolation or secondary to an underlying systemic condition.[97,98] As an isolated entity, acute pericarditis is most commonly caused by a viral infection. In practice it is considered idiopathic when the viral agent is not identified.[99,100] Other causes include autoimmune disease; neoplastic invasion of the pericardium; uremia; acute myocardial infarction; and less commonly bacterial infections, previous cardiotomy, or aortic dissection.

Echocardiography remains the initial imaging modality of choice as it can rapidly and accurately assess the pericardium and underlying cardiac structure and function. In general, there is a paucity of echocardiographic findings. Patients with uncomplicated pericarditis will often have a normal echocardiogram.

The value of echocardiography in acute pericarditis lies in its unique ability to detect complications, at times aiding in the diagnosis of the underlying etiology or detecting other cardiac processes that may account for the patient's symptoms or clinical findings. Complications include pericardial effusion with or without hemodynamic effect, constrictive physiology, and/or myopericarditis. A large pericardial effusion or tamponade is a high-risk feature of pericarditis that warrants hospital admission and therefore is important to rule out either clinically or by echocardiography.[101] A transient constrictive phase during acute pericarditis has also been described,[102,103] and acute pericarditis may on occasion progress to overt constrictive pericarditis. In this setting echogenic inflammatory material may be noted in the pericardial space (Fig 29-15). Associated myocarditis can manifest as regional or global myocardial dysfunction. In occasional cases, tumor and/or neoplastic invasion of the pericardium may be seen. Myriad other cardiac diagnoses can mimic acute pericarditis, and the echocardiogram may be useful in this regard as well. One such scenario is in patients presenting with chest pain and electrocardiographic changes in which the differential diagnosis includes acute coronary syndrome and pericarditis. The finding of a regional wall motion abnormality in a coronary distribution without a significant effusion suggests that a diagnosis of acute coronary syndrome is more likely.

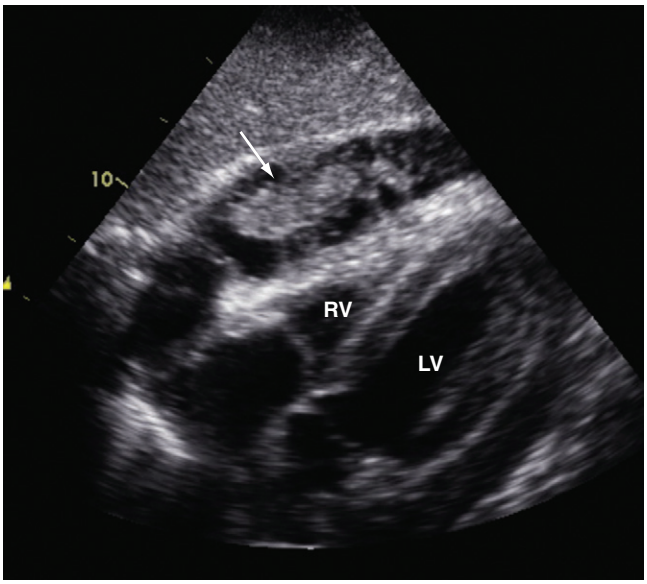

**Figure 29-15** **Subcostal view of a large pericardial effusion.** Extensive echogenic organized material is noted in pericardial space in relation to free wall of RV (*arrow*).

The finding of a pericardial effusion without a regional wall motion abnormality suggests that pericarditis is more likely.

An integrated multimodality imaging approach, in the form of cardiac CT and/or cardiac MRI in addition to TTE, may provide incremental value in more complicated cases of acute pericarditis. The complementary role of CT and MRI lies in their ability to clearly visualize pericardial thickening and inflammatory changes within the pericardium. An integrated approach can be considered in the case of therapeutic difficulty, recurrent pericarditis, development of constrictive physiology, or traumatic etiologies.

## Effusive Constrictive Pericarditis

Effusive constrictive pericarditis is an uncommon condition characterized by both a pericardial effusion and constrictive

**TABLE 29-3 Troubleshooting Pericardiocentesis**

| *Problem* | *Diagnosis* | *Action* |
|---|---|---|
| I can't hit the effusion. | Incorrect line of approach. Usually occurs with smaller, deeper pericardial effusions, especially with thick chest wall. | Recheck landmarks, reimage if uncertain. Check depth; consider long needle if deep fluid. Consider alternative window/approach. Use bubble contrast to confirm position in difficult tap. If repeated unsuccessful attempts, reconsider indication, consider surgical approach. |
| My catheter won't track over the guidewire. | Tip of catheter may not track guidewire because of tight tissue planes or thick skin. May be very thick, stiff pericardium. Guidewire may be kinked over periosteum, pleura, pericardium. | Ensure adequate skin "nick" at guidewire entry point. Consider redilatation over existing guidewire. If guidewire kinked, consider repuncture/replace guidewire. |
| I hit the effusion OK and advanced my guidewire, but now I can't aspirate pericardial fluid. | Catheter is no longer in the pericardial space, or the catheter is kinked. Occasionally dilator will displace wire from pericardial space if long tissue track or inadequate length of intrapericardial wire inserted. | Consider saline contrast to verify intrapericardial position. Usually repuncture is required (i.e., start again). |
| I keep aspirating blood from the catheter, but the effusion doesn't get any smaller. | Consider large hemorrhagic effusion. Consider intracardiac needle/catheter position. | If pulsatile flow, withdraw needle. Use saline contrast to rule out intracardiac needle/catheter placement. If dilators used and catheter intracardiac, consider surgical consult before removal of catheter. |
| I keep aspirating straw-colored fluid, but the effusion isn't getting any smaller. | Catheter in pleural effusion or ascites. | Recheck approach, depth. Give contrast bubbles if in doubt. |
| My patient is in severe pain after the pericardial catheter is placed. | Local irritation from pericardial catheter can occasionally cause intense pain; however, it may indicate more serious complication. | Check catheter position, ensure intrapericardial. Rule out other causes, including coronary artery injury, pleural catheter placement, myocardial tear. Consider nonsteroidal antiinflammatory drug, narcotic. Consider intrapericardial lidocaine. Consider early removal of catheter once effusion is drained. |
| My patient has acute shortness of breath. | Consider pneumothorax. | Chest radiograph if stable, intercostal catheter placement. |
| My patient is experiencing severe hypotension, hemodynamic collapse. | Consider vasovagal response, chamber laceration, tension pneumothorax, intrathoracic bleeding, acute myocardial infarction. | Repeat echocardiography, electrocardiogram, hematocrit. Therapy may include intrapleural drain, volume, atropine, thoracotomy. |
| The effusion recurred rapidly after the pericardial fluid was aspirated. | Needle pericardiocentesis without drainage catheter or catheter removed too soon. | Reaspirate and leave drain in situ 24-36 hours. Consider malignancy; consider surgical window. |
| The pericardial catheter has stopped draining, but there is still fluid around the heart. | Plugged or kinked catheter. Loculated pericardial fluid. | Continuous suction drainage helps prevent plugging. Consider small sterile saline flush/aspirate. Consider repuncture and guidewire placement of new catheter if significant residual pericardial fluid and/or echocardiographic signs of tamponade. |

pericarditis.[104] Based on a series of consecutive patients presenting with tamponade, the prevalence of effusive constriction is close to 8%.[104] Imaging of this entity should look for elements of pericardial effusion, a thickened pericardium or thick intrapericardial material, and evidence of constrictive physiology.[105,106] The hallmark of effusive constrictive pericarditis is persistence of constrictive physiology after removal of the pericardial fluid.[107] The hemodynamic findings may share common features of both pericardial tamponade and constriction.

The most common causes are idiopathic pericarditis and malignancy, but effusive constrictive pericarditis can also be seen after radiation, after pericardiotomy, and in tuberculosis pericarditis. The natural history of this condition is not well understood. However, in a subset of patients, constrictive pericarditis may be due to reversible inflammation, and there may be resolution of the constrictive physiology either spontaneously or following antiinflammatory treatment weeks to months after the effusion has been drained.[103]

## Pericardial Effusion as an Incidental Finding on Echocardiography

Occasionally a pericardial effusion will be noted as an incidental finding on an echocardiogram requested for another indication or as an ancillary finding during lung or abdominal imaging. Therapeutic pericardiocentesis is an absolute in the setting of cardiac tamponade. Among those with large pericardial effusions and no hemodynamic compromise, nearly one third will go on to develop tamponade.[108] Therefore, it is reasonable to perform a pericardiocentesis in the setting of a persistent large pericardial effusion (greater than 1 month) or those with nonspecific signs of tamponade such as RA collapse for less than one third of the cardiac cycle.[109] Small to moderate-sized pericardial effusions do not require drainage, provided that there is no evidence of hemodynamic compromise and the patient is asymptomatic. However, the question of diagnostic pericardiocentesis arises. This is not routinely recommended, given that the diagnostic yield is low. Instead, regardless of effusion size, a careful search for underlying disease likely to result in a pericardial effusion needs to be undertaken (see Box 29-2). In all cases, clinical and echocardiographic follow-up is imperative.

## Congenital Disorders of the Pericardium

### CONGENITAL ABSENCE OF THE PERICARDIUM

Congenital absence of the pericardium is a rare clinical entity found in approximately 1 in 10,000 autopsies. The defects,

**Figure 29-16 MRI image of patient with congenitally absent pericardium.** Abnormal position of heart in thorax explains unusual appearance of heart through usual imaging windows, including appearance of RV enlargement. Nonstandard imaging windows (axillary) are required in some patients.

classified as partial or complete, are most commonly partial, with two thirds of cases located on the left and the remainder on the right side.[110,111] Complete absence of the pericardium is rare and of minimal clinical importance. Leftward displacement of the heart is pronounced, and as a result, cardiac motion, especially of the LV posterior wall, is exaggerated. The right-sided chambers appear prominent, and there is abnormal septal motion.[112,113] Other echocardiographic signs include unusual apical imaging windows into the axilla and the appearance of compressed atria. At least one and usually two of these findings are reported in all patients with complete absence of the pericardium.[117] In contrast, partial absence of the pericardium often requires ancillary imaging techniques to fully delineate the nature and extent of the defect. In this regard, CT and MRI have proven to be especially useful (Fig. 29-16).[114,115]

Most patients are asymptomatic; however, closure of the defect can become necessary in symptomatic patients.[97] With significant leftward cardiac shift, patients may on occasion experience nonexertional chest pain or a prominent cardiac pulsation. Rarely, herniation of cardiac chambers through partial defects can occur, with reported cases of coronary artery obstruction resulting in sudden cardiac death,[116,117] LA strangulation,[118,119] herniation of the LA causing syncope,[120] or herniation of the LV or RV causing mitral or tricuspid regurgitation.[121] In addition, associated congenital defects should also be considered and include atrial septal defect, bicuspid aortic valve, patent ductus arteriosus, tetralogy of Fallot, and mitral stenosis in up to 30% of cases.[113,122] Reports of combined congenital pericardial and diaphragmatic defects also exist.[123]

## PERICARDIAL CYSTS

Pericardial cysts are rare, benign congenital lesions with an incidence of 1 in 100,000 and thought to be remnants of a defect in embryologic development of the pericardium. They are usually an incidental finding on chest radiography or TTE. The majority are located at the right costophrenic angle (70%), followed by the left costophrenic angle (20%), and the remainder are in either the anterior or posterior superior mediastinum.[124] The echocardiographic hallmark of a pericardial cyst is a round or oval echo-free structure adjacent to the cardiac border, most commonly near the RA, from which it is separated by a definite wall of echoes.[125,126] The presence of internal echoes suggesting a more solid structure should alert the clinician to the possibility of a less benign process. Color-flow and pulsed-Doppler assessment at a low velocity setting can be performed to ensure that there is no flow within the structure. Rarely, hydatid pericardial cysts[127] or a cardiac hemangioma[128] may have echocardiographic features mimicking pericardial cysts. Additional imaging with contrast CT can be performed if the diagnosis remains uncertain with echocardiography.[129,130] A pericardial cyst appears as a thin-walled, sharply defined homogenous mass with attenuation slightly higher than water, which fails to enhance with contrast on CT. Therapy is not required in the asymptomatic patient; however, there are numerous noninvasive treatments for pericardial cysts, including videoscopic resection, ethanol sclerosis, or needle aspiration and drainage if symptoms do develop. Symptoms commonly reported include chest pain and shortness of breath. Reported rare complications of pericardial cysts include cardiac tamponade,[131,132] hemorrhage,[124] or erosion of cardiac structures.[133,134]

### KEY POINTS

- An understanding of the effects of ventricular interdependence is key to understanding the hemodynamic and therefore echocardiographic features of compressive pericardial disease, such as tamponade or constriction.
- The diagnosis of pericardial constriction requires a careful integration of the results of M-mode Doppler and 2D imaging and a consideration of the clinical context. A good understanding of the uses and limitations of tissue Doppler imaging augments traditional tools for diagnosing constriction.
- Echocardiography is pivotal to management strategy and decision making in pericardial effusion.
- Traditional echocardiographic markers of cardiac tamponade may be absent in patients with localized pericardial effusions, especially in the postcardiac surgery setting.
- The presence of diastolic collapse of the free wall of the RV is a specific but not sensitive sign of pericardial tamponade.
- Percutaneous drainage of pericardial fluid may be safely performed with echocardiographic guidance.
- When an acute hemopericardium occurs, for instance in the setting of interventional cardiologic procedures, rapid and serious hemodynamic disturbance may ensue, despite the accumulation of a relatively small amount of fluid in the pericardial space.
- In acute pericarditis, the echocardiographic examination is commonly normal.
- The hallmark of effusive constrictive pericarditis is persistence of constrictive physiology following the removal of the pericardial fluid.
- In complex pericardial disease, or when echocardiographic images are suboptimal, integration of echocardiographic findings with findings from other imaging modalities may be required.

# 30 Cardiac Transplantation: Pretransplant and Posttransplant Evaluation

AUDREY H. WU, MD, MPH | THEODORE J. KOLIAS, MD

**Evaluation before Cardiac Transplantation**
Risk Assessment
Evaluation of the Donor Heart
**Structure and Function of the Cardiac Allograft**
Transplant Technique
Physiology of the Cardiac Allograft
Ventricular Systolic and Diastolic Function
Right Ventricular Structure and Function and Tricuspid Regurgitation
**Structure and Function of the Cardiac Allograft during Acute Rejection**
Changes in Systolic and Diastolic Function
Changes in Left Ventricular Mass or Wall Thickness
Echocardiographic Guidance for Endomyocardial Biopsy
**Early Postoperative Complications and Other Findings**
Early Postoperative Complications
Pericardial Effusion
**Posttransplant Monitoring**
Routine Follow-up
Diagnosis of Cardiac Allograft Vasculopathy

Improvements in medical management and advances in surgical techniques have increased the number of patients who survive with severe heart failure. Cardiac transplantation remains the treatment of choice for appropriate candidates with end-stage heart failure. More than 3000 cardiac transplants are performed worldwide annually. At the time of transplantation, roughly half of cardiac transplant recipients are treated with inotropic agents, whereas almost one quarter need some form of mechanical circulatory support, most frequently in the form of a left ventricular (LV) assist device. International registry data show that the mortality rate is greatest in the first 6 months after transplantation; the 1-year survival rate after cardiac transplantation is about 85%, with a 3% to 4% linear decrease annually thereafter and a median survival rate of 10.4 years for the cohort of patients who underwent transplantation in the 1992 to 2001 era. Survival rates have steadily improved since the early 1980s, despite the increasingly high-risk profile of the recipient population. Graft failure and infections account for a significant proportion of deaths in the first year after transplantation, whereas after 5 years, cardiac allograft vasculopathy (transplant coronary disease), late graft failure (likely a result of allograft vasculopathy), and malignancy disease are more common causes of death.[1]

## Evaluation before Cardiac Transplantation

### RISK ASSESSMENT

Box 30-1 summarizes echocardiographic markers of poor prognosis in the setting of advanced systolic heart failure. Although these generally are not included in widely used composite risk scores for heart failure (with the exception of ejection fraction), they are useful adjuncts to assessment of prognosis. In the context of evaluation before possible cardiac transplantation, right heart function and presence of pulmonary hypertension are of particular interest. Preoperative pulmonary hypertension, particularly if not medically reversible with vasodilators or if reversible at the expense of systemic hypotension, is associated with very high risk of short-term mortality, frequently as a result of right heart failure.[2] Although direct measurement of central hemodynamics with a pulmonary artery catheter is currently the gold standard, echocardiography has the advantage of being noninvasive and more widely available. Estimates of hemodynamic measurements with Doppler echocardiography have been shown to correlate closely with direct invasive measurements in patients with heart failure, with use of the following calculations for cardiac output (CO), right atrial (RA) pressure, pulmonary artery systolic pressure (PASP), pulmonary capillary wedge pressure (PCWP) and pulmonary vascular resistance (PVR)[3]:

$$CO = (HR)\,(VTI_{LVOT})\,(\pi)\,(D_{LVOT}/2)^2$$

$$\text{Mean RA pressure} = -1.263 + 0.01116 \times Ac,$$

where *Ac* is the acceleration rate ($cm/s^2$) of early tricuspid filling, D is diameter, HR is heart rate, LVOT is the left ventricular outflow tract, and VTI is the velocity time integral of flow

$$PASP = \text{RA pressure} + 4(V_{TR})^2,$$

where $V_{TR}$ is peak velocity of the tricuspid regurgitation signal.

$$PCWP = 32.16 + (-0.1045E) + (0.1345A) + (-0.17DT) + (4.95\,E/A), \text{ and}$$

$$PVR = [(PEP)/AcT/TT],$$

**Box 30-1**

## ECHOCARDIOGRAPHIC MARKERS FOR POOR PROGNOSIS AND POTENTIAL NEED FOR CARDIAC TRANSPLANTATION IN SYSTOLIC HEART FAILURE

- Left ventricular ejection fraction[1]
- Left ventricular cavity dilation[2]

## EVALUATION OF THE DONOR HEART

Echocardiography is necessary for the evaluation of potential donor hearts to help optimize the individual heart to undergo transplantation and, on a larger scale, to maximize use of this scarce resource. Once individuals with brain death are identified as potential heart donors, they typically are managed with the assistance of the regional donor procurement agency according to specific protocols to prepare the heart to undergo procurement and transplantation. In general, these protocols aim to optimize volume status and hemodynamics with volume resuscitation or diuretics, inotropes or vasopressors as needed, and hormonal manipulation with triiodothyronine, steroids and vasopressin,[4] frequently with the assistance of invasive hemodynamic monitoring with a pulmonary artery catheter.

Echocardiography is essential for assessment of structure and function of the donor heart. The evaluation for regional and global wall motion abnormalities, and for valvular or congenital abnormalities, is particularly important because these findings could potentially preclude use of the heart for transplantation. Estimates of the frequency of structural or functional abnormalities in potential donor hearts range from 10% to 45%. Although regional or global wall motion abnormalities may be present on initial assessment, in some cases, contractile function can be improved with medical therapy, particularly if the dysfunction is related to brain death or is catecholamine-induced. Serial echocardiograms can often confirm improvement in contractile function in the setting of hemodynamic and metabolic correction.[5] However, the lower the initial ejection fraction, the less likely the heart is able to be optimized for use for transplantation because this likely reflects intrinsic and irreversible causes for contractile dysfunction. Although early studies suggested suboptimal outcomes with the use of donor hearts with LV hypertrophy, more recent studies have found that transplant patients who received donor hearts with mild (interventricular septum or posterior wall 1.2 to 1.3 cm) or moderate (more than 1.3 to 1.7 cm) LV hypertrophy had similar short-term and long-term survival rates, up to 5 years after transplantation.[6]

## Structure and Function of the Cardiac Allograft

### TRANSPLANT TECHNIQUE

With the earlier biatrial technique for cardiac transplantation, bilateral atrial cuffs from the recipient were retained for direct anastomosis of the cardiac allograft. This approach produced large atrial cavities with long suture lines, which resulted in abnormal atrial geometry and function. In older series, mean measurements of left atrial (LA) diameter ranged from about 58 to 83 mm versus 41 to 42 mm for biatrial versus bicaval techniques, respectively.[7-9] Larger atrial size and atrial anatomic distortion have been implicated as contributors to mitral and tricuspid valve abnormalities and atrial thrombus formation.[10,11] The bicaval technique, with separate caval and pulmonary vein anastomoses, was developed to circumvent these problems. This approach did not become popular until the late 1980s and is currently the more commonly used technique.[12,13] Transplantation with the biatrial technique is associated with higher frequency of spontaneous contrast and atrial thrombi on echocardiography and also risk for systemic arterial embolism (roughly 15% incidence rate in one series).[7,14] Atrial thrombi are frequently located in areas not well seen on transthoracic echocardiography, such as the donor LA appendage or posterior wall, and require transesophageal echocardiography for visualization.[15] These echocardiographic findings and the elevated incidence of systemic embolism have not been observed with bicaval transplant recipients.[7,8,14] In addition to more normal atrial size and geometry, the bicaval technique results in more physiologic atrial function. Measures of atrial contractile function are significantly better in patients who underwent cardiac transplantation with the bicaval technique versus those who underwent transplantation with the biatrial technique and have been found to be comparable with those of normal controls.[16,17] Despite evidence for LA dysfunction, LA contraction appears to contribute significantly more to LV stroke volume than in nontransplant patients,[18] with the donor component of the LA contributing more to atrial emptying than the recipient atrial component.[19] Thus, the transplant patient may have poor tolerance for conditions in which the atrial contribution to cardiac output is compromised, such as with atrial tachyarrhythmias (Figs. 30-2 and 30-3).

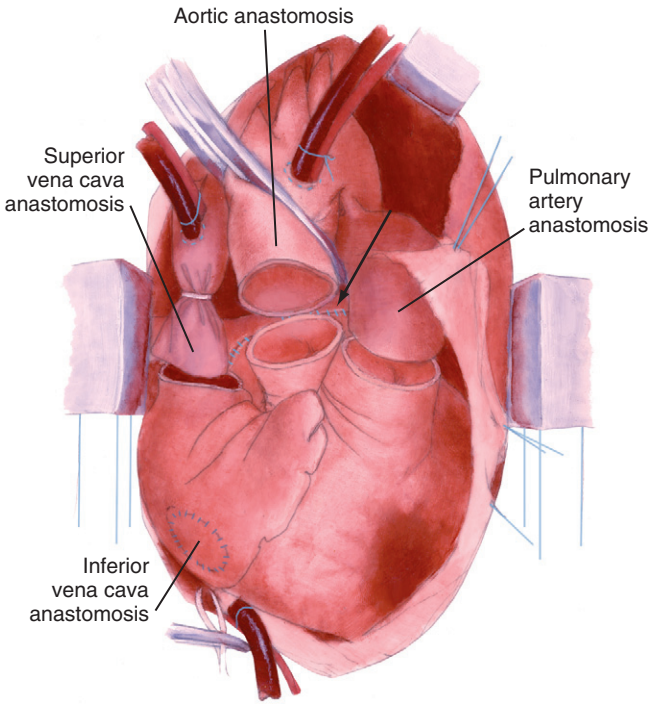

**Figure 30-2 Bicaval technique for heart transplantation.** The cardiac allograft is anastomosed to the recipient at the superior and inferior vena cavae, at the pulmonary artery and aorta, and at the LA.

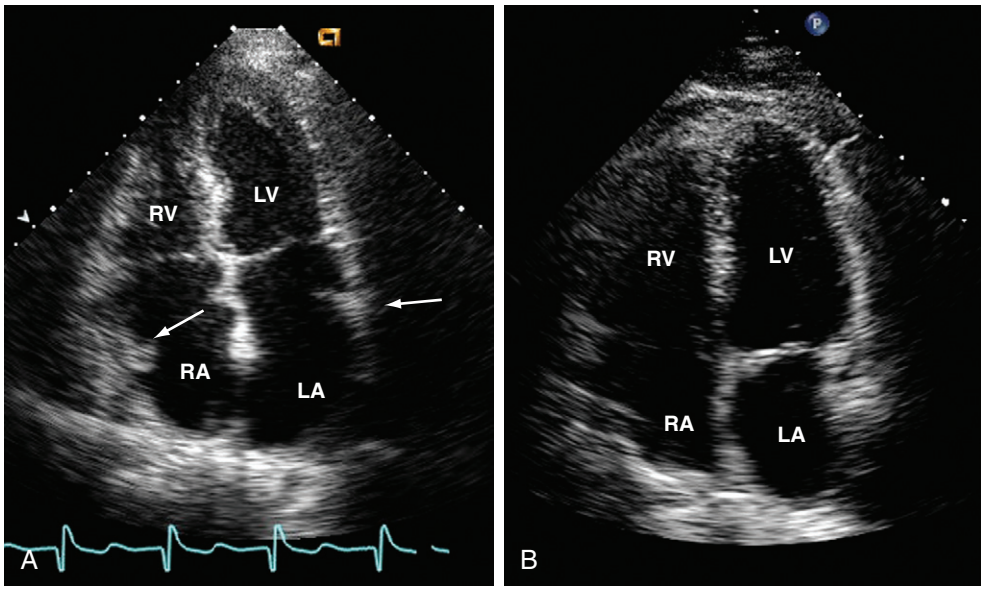

**Figure 30-3 Comparison of the echocardiographic appearance of cardiac allografts transplanted with the biatrial (A) versus bicaval (B) techniques.** In comparison with the bicaval technique, the biatrial technique results in much larger atria; prominent atrial suture lines are visible on echocardiogram (*arrows*).

## PHYSIOLOGY OF THE CARDIAC ALLOGRAFT

Although cardiac transplantation provides improved survival, functional capacity, and quality of life to patients with end-stage heart failure, the physiology of the cardiac allograft is not exactly the same as that of a normal nontransplanted heart. Hemodynamics immediately after cardiac transplantation are characterized by elevated filling pressures associated with impaired relaxation. This hemodynamic profile improves over the initial few weeks to months after transplantation and may continue to normalize over years but also may persist to a subtle degree.[20,21] Restrictive physiology early after transplantation may be the result of a combination of ischemic myocardial injury, recipient pulmonary hypertension, and volume overload, whereas persistent restrictive physiology may be attributed to donor-recipient size mismatch, ischemic fibrosis, increased afterload from systemic hypertension, or rejection. Because it is denervated, the cardiac allograft has an altered response to exercise, characterized by a slower early rise in heart rate and an overall blunted chronotropic response, with increases in cardiac output primarily the result of increases in stroke volume rather than heart rate.[21,22] Sympathetic reinnervation occurs over time and is associated with improved exercise capacity, including heart rate and ventricular contractile response to exercise.[23] Exercise capacity improves in the initial few years after transplantation but may never reach normal nontransplant levels.[24]

## VENTRICULAR SYSTOLIC AND DIASTOLIC FUNCTION

Early after transplantation, LV mass and end-diastolic volume increase; these changes may or may not persist for years, without adverse consequences to ejection fraction, although subtle decrements in systolic contractility may manifest early.[25-27] In the absence of complications that cause graft dysfunction, allograft ventricular systolic function generally remains normal as many as 10 to 15 years after transplant. LV hypertrophy is a common finding, as is postoperative septal motion.[27,28] Although systolic ventricular function remains largely normal, diastolic function is abnormal early after transplantation, the effects of which are frequently compounded by postoperative volume overload. A restrictive filling pattern may persist to some degree chronically in some patients or may reemerge during episodes of acute rejection. Early after transplantation, a restrictive filling pattern is present, characterized by shorter isovolumic relaxation time and E wave deceleration time and an increased E/A ratio (Fig. 30-4), with gradual evolution to a nonrestrictive pattern by 6 weeks after transplantation. Various clinical factors, such as preoperative pulmonary systolic pressures or pulmonary vascular resistance, duration of cardiopulmonary bypass, total ischemia time, or age of donor heart, did not significantly correlate with parameters of restrictive filling early after transplantation in one study.[29]

The incidence of diastolic dysfunction decreases over time, but diastolic abnormalities persist beyond the early postoperative period in a small proportion of patients. One estimate of the prevalence rates of diastolic dysfunction after cardiac transplantation was 22% at 6 weeks, 8% at 6 months, and 12% at 1 year. Right ventricular diastolic dysfunction (elevated right atrial pressure to stroke volume ratio) was associated with increased mortality.[30] In a series of 64 cardiac transplant recipients 1 year or more after transplant (mean, 5 years; range, 1 to 13 years) who underwent routine annual hemodynamic evaluation, 10 (15%) had a pattern of right and LV filling consistent with restrictive-constrictive physiology, with a characteristic dip-and-plateau hemodynamic tracing in early diastole. In general, transplant recipients with constrictive-restrictive hemodynamics had higher right-sided and left-sided filling pressures, shorter LV isovolumic relaxation times and E wave deceleration times, and higher mitral and tricuspid E/A ratios. Transplant recipients with constrictive-restrictive physiology had significantly more previous rejection episodes, a greater proportion had heart failure symptoms, and a significant proportion also had acute rejection diagnosed with biopsy performed concurrent with echocardiography.[31] Persistence of restrictive filling pattern up to 6 months after cardiac transplantation may be associated with reduced long-term survival.[32] The etiology of persistent diastolic dysfunction after transplantation is not fully defined but likely includes cumulative immune-mediated injury, fibrosis related to immune or nonimmune damage, and allograft vasculopathy. Newer techniques such as tissue Doppler imaging

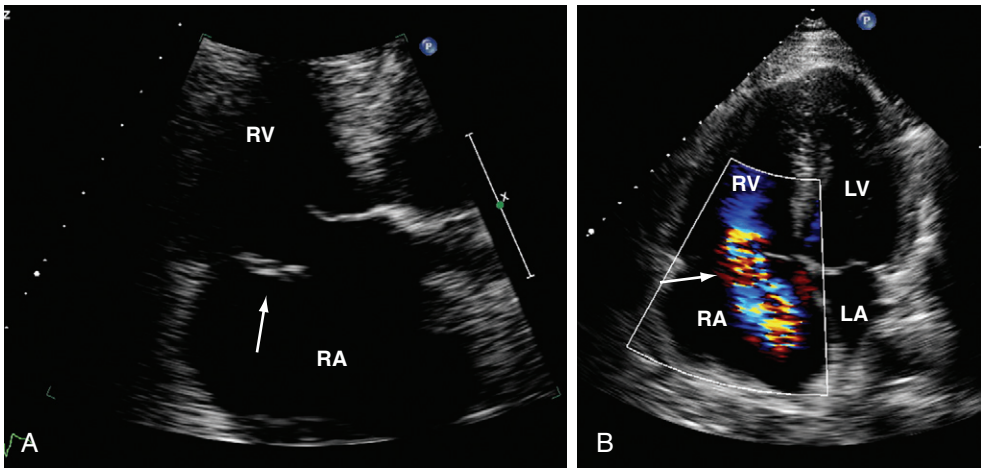

**Figure 30-5 Flail tricuspid valve leaflet with tricuspid regurgitation in a cardiac transplant recipient. A,** 2D imaging shows the flail leaflet (*arrow*). **B,** Color Doppler shows a wide jet (*arrow*) of tricuspid regurgitation.

have shown promise for assessment of early ventricular dysfunction caused by cardiac allograft vasculopathy.[33]

### RIGHT VENTRICULAR STRUCTURE AND FUNCTION AND TRICUSPID REGURGITATION

A significant proportion of patients with severe heart failure have pulmonary hypertension as a result of longstanding elevated left-sided filling pressures. Pulmonary hypertension frequently improves to normal or near-normal levels in the weeks to months after cardiac transplantation. The evolution of right-sided structure and function after transplantation parallels the resolution of pulmonary hypertension and volume overload,[34] although some right ventricular enlargement may persist long term.[35] Many patients at 10 to 15 years after transplantation have right atrial and right ventricular enlargement (right atrium, 40.7 ± 11.8 mm; right ventricle, 37.4 ± 8.3 mm, in one series). Despite the abnormalities in right-sided heart size and function, in the absence of severe tricuspid regurgitation, clinical signs and symptoms of heart failure are generally not present.[28]

Tricuspid regurgitation occurs early and late after cardiac transplantation. Early tricuspid regurgitation is more related to preoperative and postoperative pulmonary hypertension and right ventricular failure,[36] whereas valve injury from endomyocardial biopsies is often responsible for late tricuspid regurgitation (Fig. 30-5). Severity of tricuspid regurgitation on intraoperative transesophageal echocardiogram may be a marker for right ventricular dysfunction and appears to correlate with poor late survival. In one series of 181 patients, 20% of donor hearts at the time of transplantation had at least mild tricuspid regurgitation, which correlated strongly with presence of right ventricular dysfunction. The 5-year survival rate in this series was 85% for patients with no or trace intraoperative tricuspid regurgitation, versus 57% for those with mild to severe tricuspid regurgitation, even in the absence of overt right ventricular dysfunction on intraoperative transesophageal echocardiogram.[37] Donor tricuspid valve annuloplasty has not been found to have any significant effect on hemodynamics as measured with right heart catheterization and has not been shown to improve long-term survival.[38] At 10 years after transplantation, about 15% of patients may have severe tricuspid regurgitation. These patients are at increased risk for heart failure and may need tricuspid valve replacement.[39,40]

## Structure and Function of the Cardiac Allograft during Acute Rejection

Allograft rejection remains a significant limitation of cardiac transplantation. Acute cardiac allograft rejection is usually characterized by lymphocytic infiltration with or without myocyte necrosis, termed "cellular rejection."[41] A rarer, less well-understood type of rejection, termed "antibody-mediated rejection" (also called vascular or humoral rejection), involves endothelial cell activation and complement deposition that primarily involves the allograft vasculature.[42] Although the incidence rate of cellular rejection has drastically declined over the 1990s as a result of improvements in immunosuppression therapy, the incidence rate of noncellular rejection has remained stable.[43] Until recently, cardiac allograft rejection on endomyocardial biopsy was graded 0, 1A, 1B, 2, 3A, 3B, and 4 in order of increasing severity of lymphocyte infiltration and presence and amount of myocyte necrosis. In 2005, the classification was simplified into grades 0 (previous grade 0); 1R, mild rejection (previous 1A, 1B, 2); 2R, moderate rejection (previous grade 3A); and 3R, severe rejection (previous grades 3B and 4).[41] Echocardiographic abnormalities of the cardiac allograft during rejection may include changes in systolic and diastolic function and increases in LV wall thickness or mass. Currently, the gold standard for diagnosis of rejection is with endomyocardial biopsy, although this technique is limited by the risks inherent to an invasive procedure, sampling error, cost, and patient discomfort. More recently, gene expression profiling from peripheral blood samples has been tested as a noninvasive method for assessment for rejection. Although echocardiography alone has not been proven to be a definitive diagnostic method for detection of rejection, it has provided insight into the changes that occur during and around the time of rejection and may be a useful adjunct to diagnosis of rejection.

### CHANGES IN SYSTOLIC AND DIASTOLIC FUNCTION

New-onset systolic dysfunction in the setting of acute rejection is generally a late finding and indicates higher grade rejection, which is associated with hemodynamic compromise and clinical symptoms and with poorer prognosis.[44] The vast majority of rejection episodes are not associated with systolic impairment, and significant changes in echocardiographic systolic

function parameters are generally lacking. Abnormalities of diastolic filling are the earliest alterations to manifest in acute rejection.[31,45] Rejection of increasing severity has been associated with a progressive shortening of isovolumic relaxation time and pressure half-time and with an increase in peak early mitral flow velocity, although the latter has not been a consistent finding.[45-47] Measures of diastolic dysfunction generally return to baseline values after treatment of acute rejection.[47] However, in general, diastolic indices such as mitral E wave, deceleration time, isovolumic relaxation time, tissue Doppler early diastolic (E′) wave, and late diastolic (A′) wave are not sensitive enough for reliable diagnosis of acute rejection.[48]

Defined as the sum of isovolumic contraction time and isovolumic relaxation time divided by ejection time, the myocardial performance index is a single composite measurement of systolic and diastolic myocardial function. Although some studies have suggested a correlation between myocardial performance index and presence of acute rejection, sensitivity and specificity were low, and the relationship has not been a consistent finding. Concurrent decreases in isovolumic relaxation time and increases in isovolumic contraction time, which indicate development of abnormalities in diastolic and systolic function, respectively, with acute rejection resulted in an overall neutral effect on the myocardial performance index.[49,50]

Traditional Doppler-derived parameters of diastolic function, such as transmitral Doppler flow analysis, are influenced by variables other than ventricular diastolic function, such as ventricular loading conditions; and in transplant recipients specifically, the cardiac allograft may develop baseline diastolic filling abnormalities unrelated to acute rejection. Tissue-Doppler imaging is a technique for assessment of LV systolic and diastolic function with measurement of the systolic (S′) and the early (E′) and late (A′) diastolic velocities of the mitral annulus. Although late diastolic mitral annular velocity (A′) and mitral annular systolic velocity (S′) appear to be sensitive markers of acute severe rejection, they are not particularly specific.[51] Furthermore, the specificity is not significantly improved when both systolic and diastolic tissue-Doppler parameters are used. The combined peak systolic and peak diastolic velocity (peak-to-peak amplitude) of the tissue-Doppler mitral annular waveforms was significantly lower in patients experiencing any rejection (grade 1B or greater) and may be helpful in excluding presence of significant rejection.[52] Although tissue-Doppler measurements appear to be sensitive for detecting various degrees of acute rejection and for excluding rejection if measurements fall below receiver operating characteristic (ROC) determined cutoffs, they do not appear to be robust tools in differentiating impaired contraction or relaxation resulting from acute rejection rather than other causes. This poor specificity reflects confounding by the background diastolic filling abnormalities inherent to transplant physiology, which makes detection of early diastolic dysfunction as a result of acute rejection difficult. Newer modalities such as strain/strain rate imaging are being studied as methods to detect and monitor acute rejection.[53]

## CHANGES IN LEFT VENTRICULAR MASS OR WALL THICKNESS

Although older reports have suggested LV mass increases in the setting of acute cellular rejection,[54] this has not been a consistent finding,[55] and change in LV wall thickness alone has not proven to be a sensitive enough marker for diagnosis of cellular rejection.[56] Increased LV mass in the setting of rejection may be the result of increased interstitial edema or vascular leakage of fibrin. Significant increase in LV mass has been described during episodes of vascular rejection. In a series of 41 cardiac transplant patients, LV mass increased from a baseline of 109 ± 17 g to 151 ± 17 g during vascular rejection, although it did not significantly change during cellular rejection. Concurrently, LV wall thickness increased by nearly 20% during vascular rejection (1.3 ± 0.1 cm at baseline versus 1.6 ± 0.1 cm).[57]

## ECHOCARDIOGRAPHIC GUIDANCE FOR ENDOMYOCARDIAL BIOPSY

Endomyocardial biopsy remains the gold standard for diagnosing allograft rejection and following response to immunosuppressive treatment for rejection. The usual approach for introduction of the biopsy catheter is via the right internal jugular vein or, less frequently, the left internal jugular vein or femoral vein (Figs. 30-6 and 30-7). Traditionally, fluoroscopy has been used to guide the biopsy catheter tip to the interventricular septum to obtain biopsies. Echocardiography has been successfully used to guide endomyocardial biopsies with the benefits of lack of radiation exposure, portability, and provision of information on cardiac structure and function. Complication rates with echocardiography for biopsies are extremely low and comparable with those for fluoroscopic guided biopsies (about 0.4% of all biopsies attempts, or much lower with experienced operators).[58,59] One disadvantage is that initial insertion and advancement of the bioptome from the superior vena cava until entry into the right atrium is not directly visualized with echocardiography. The development of severe tricuspid regurgitation in the cardiac allograft is correlated with the total number of biopsies performed, presumably as a result of inadvertent damage to the tricuspid valve apparatus by the biopsy

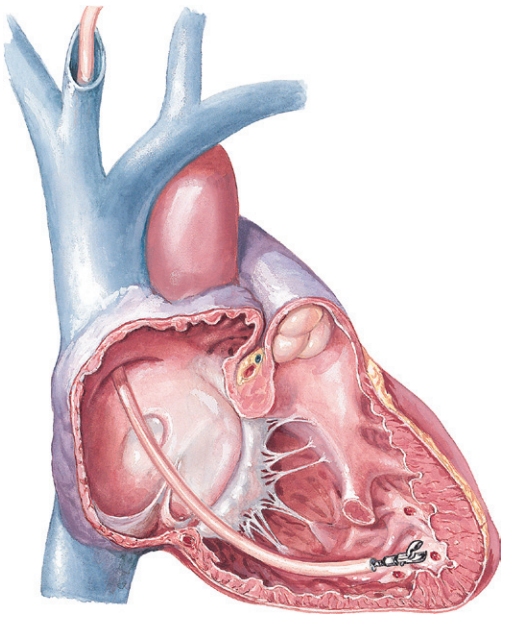

**Figure 30-6 Endomyocardial biopsy via right internal jugular vein approach.** A bioptome is advanced through the right atrium and tricuspid valve into the right ventricle. Samples are preferentially obtained from the interventricular septum to lessen the risk of cardiac perforation and tamponade, which is increased with biopsy of the right ventricular free wall.

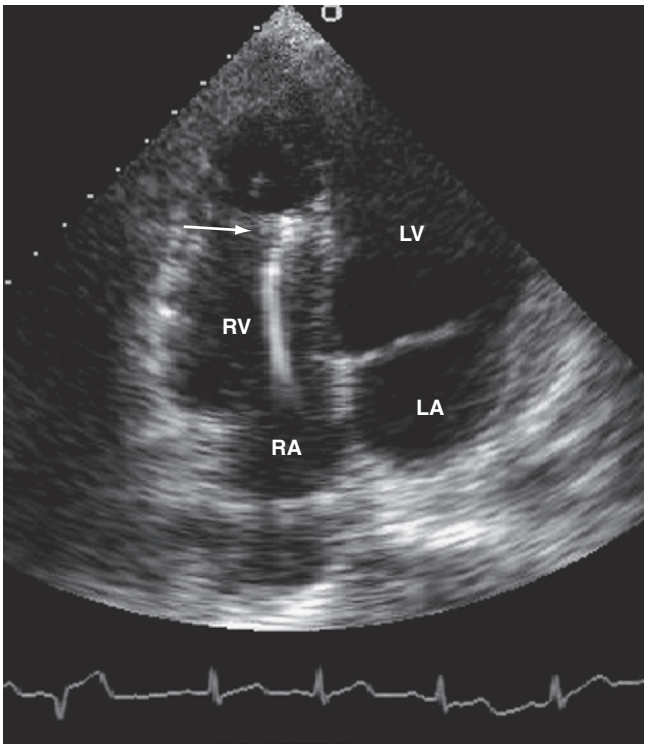

**Figure 30-7 Right ventricular biopsy of a cardiac allograft with echocardiographic guidance.** *Arrow* indicates tip of the bioptome, which is advanced through the right atrium and tricuspid valve into the right ventricle for biopsy from the interventricular septum.

catheter as it passes into the right ventricle.[60] Although measures such as use of a long sheath to introduce the bioptome directly into the right ventricle lessen the risk of development of tricuspid regurgitation, whether the routine use of echocardiography to guide biopsies lessens this risk has not been definitively established.

## Early Postoperative Complications and Other Findings

### EARLY POSTOPERATIVE COMPLICATIONS

Other than the routine use of intraoperative transesophageal echocardiography to monitor cardiac allograft function, echocardiography is generally not a significant part of routine monitoring of the recipient immediate after transplant, unless routine monitoring suggests a problem. Frequently, early indications of a problem or complication involving the cardiac allograft are detected via abnormalities in hemodynamics, either systemic blood pressure or heart rate, invasively measured central hemodynamics, or arrhythmias on telemetry monitoring. Early postoperative problems that may be diagnosed and evaluated with echocardiography include pericardial effusion or tamponade (discussed in more detail in the following section), right ventricular dysfunction, tricuspid valve regurgitation, and acute allograft failure.[61]

### PERICARDIAL EFFUSION

Estimates of occurrence of moderate to large-sized pericardial effusions that occur in the postoperative period range from 9% to 35%. The significant majority of these effusions do not appear to negatively impact short-term or intermediate-term outcomes, including hospital length of stay and survival, and there does not appear to be a correlation with occurrence of rejection.[62-64] The likelihood of development of pericardial effusion after cardiac transplantation may be higher in the absence of previous cardiac surgery or with undersized hearts.[62,63] The natural history of these effusions varies widely, with estimates of necessary intervention ranging from approximately 10% to 45% for pericardiocentesis and, in an older series, a minority for pericardiectomy.[63,64] Pericardial effusion that occurs more than 1 month after transplantation may be associated with less favorable implications. Some authors have found an association between late-onset persistent or increasing pericardial effusion with occurrence and severity of rejection.[65,66] Although pericardial fluid is usually sterile, given the altered immunity of these patients, infection and neoplasm should also be considered as possible causes.

**Box 30-2**

**STANDARD ECHOCARDIOGRAM FOR THE CARDIAC TRANSPLANT RECIPIENT**

The standard echocardiogram for the cardiac transplant recipient should include but is not necessarily limited to:

1. Standard 2D views, including parasternal long-axis and short-axis views and apical four-chamber, two-chamber, and long-axis views, for assessment of regional wall motion and overall systolic function.
2. Pulsed-wave Doppler recording of mitral inflow for assessment of diastolic function.
3. Tissue-Doppler measurement of septal and lateral mitral annular velocities for assessment of systolic and, especially, diastolic function.
4. 2D and color Doppler assessment of the valves, with particular attention to the tricuspid valve, which may have been traumatized by prior right ventricular biopsies.
5. Consideration of strain and strain rate analysis, either with Doppler-based or speckle tracking techniques, for more sensitive quantification of systolic function.

## Posttransplant Monitoring

### ROUTINE FOLLOW-UP

A general summary of consensus guidelines for routine follow-up care of the cardiac transplant recipient is shown in Figure 30-8. Echocardiography is primarily used for routine monitoring of cardiac allograft structure and function, including valvular abnormalities such as tricuspid regurgitation; as part of stress imaging for cardiac allograft vasculopathy surveillance; and as an adjunct to endomyocardial biopsy in the diagnosis of acute rejection. Elements of a standard echocardiogram of the cardiac transplant recipient are listed in Box 30-2. For patients with suspected acute rejection, an echocardiogram should be obtained with particular attention paid to identification of changes in measures of systolic and diastolic function. Comparison with prior echocardiograms obtained when no rejection was present may be helpful.

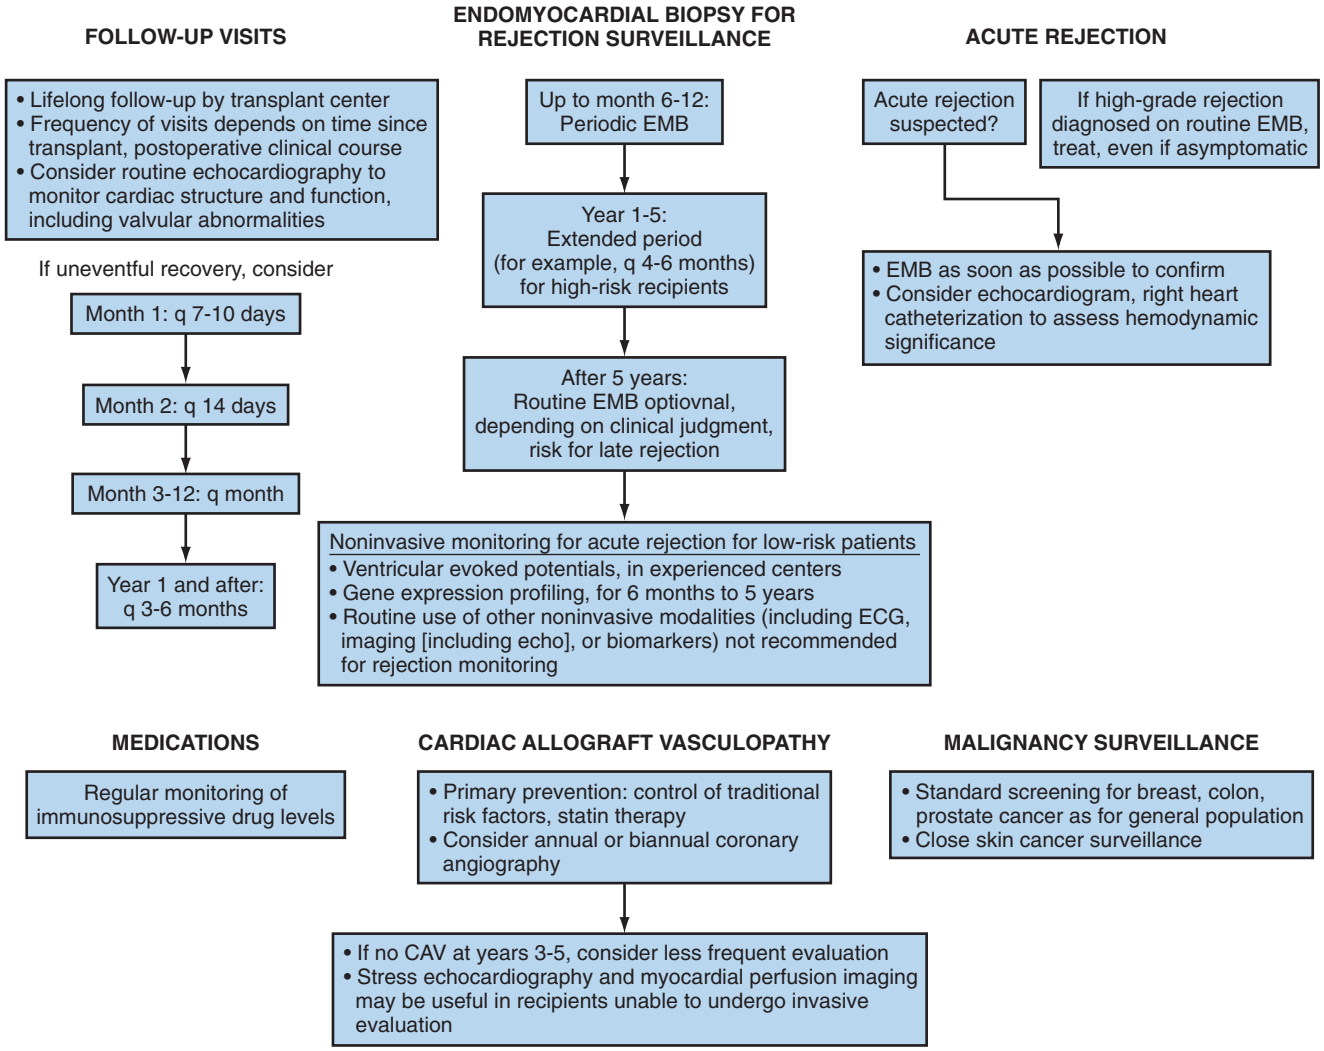

**Figure 30-8 Suggested guidelines for routine follow-up care of the cardiac transplant recipient.** In addition, chronic kidney disease, diabetes, hypertension and osteoporosis are managed as per general population with awareness of potential drug interactions with transplant medications. *CAV,* Cardiac allograft vasculopathy; *EMB,* endomyocardial biopsy. *(Adapted from Costanzo MR, et al: The International Society of Heart and Lung Transplantation guidelines for the care of heart transplant recipients.* J Heart Lung Transplant *29:914-956, 2010.)*

## DIAGNOSIS OF CARDIAC ALLOGRAFT VASCULOPATHY

Cardiac allograft vasculopathy is an entity distinct from native coronary disease of the nontransplanted heart and is one of the primary factors limiting the long-term functioning and life span of the allograft. Allograft vasculopathy is an accelerated form of intimal hyperplasia that likely results from both immune and nonimmune mechanisms. A classic finding is diffuse "pruning" of the smaller distal coronary vasculature, although discrete stenoses characteristic of native coronary disease may develop as well. In addition to transplant-specific immunologic risk factors, typical risk factors for native coronary disease, such as dyslipidemia and hypertension, also impact the development of cardiac allograft vasculopathy. Distinct from the de novo development of allograft vasculopathy, some component of atherosclerosis is also already present in the donor allograft, progression of which does not appear to be correlated with development of de novo vasculopathy.[67,68] Angiographic identification of transplant vasculopathy is associated with a fivefold greater risk of cardiac events, including myocardial infarction, heart failure, and sudden death.[69] As a result of cardiac denervation, clinical symptoms from cardiac allograft vasculopathy are frequently late and atypical, if at all.

### *Coronary Angiography with Intravascular Ultrasound*

Coronary angiography is relatively insensitive in detection of early transplant vasculopathy; up to three quarters of patients with intimal thickening with intravascular ultrasound (IVUS) have normal coronary angiograms.[70,71] Coronary angiography, which defines the luminal silhouette of the coronary artery, is not able to detect the often diffuse and concentric intimal hyperplasia that characterizes allograft vasculopathy. Because IVUS images vascular wall morphology, it has emerged as the gold standard for detection of transplant vasculopathy, particularly in its early stages. Extent of vasculopathy can be quantified according to intimal thickness and circumferential extent and also by change in measures of plaque burden over time. IVUS findings of allograft vasculopathy can be classified as Stanford class I (minimal: intimal thickness less than 0.3 mm and circumferential involvement less than 180 degrees), class II (mild: intimal thickness less than 0.3 mm and circumferential

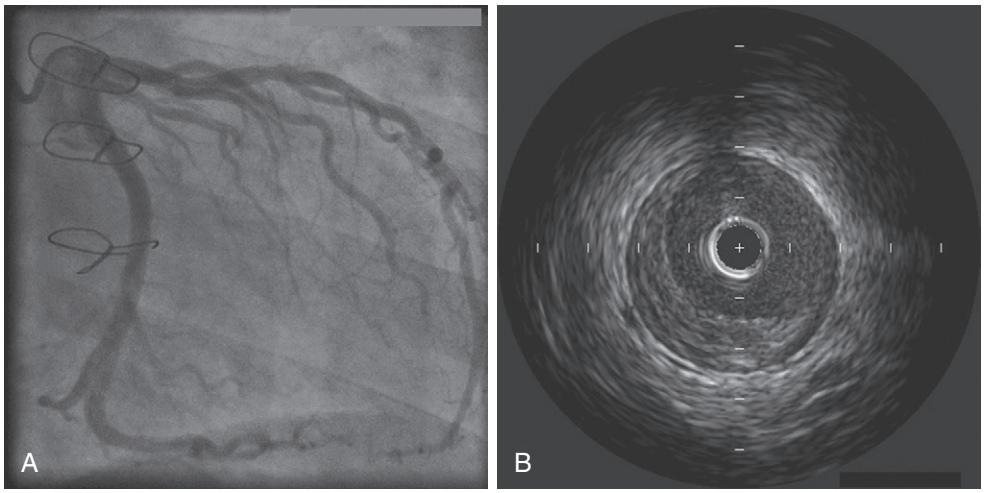

**Figure 30-9 The coronary angiogram (A) in this patient after transplant appears to show no significant narrowing of the lumen.** However, an intravascular ultrasound image in the mid left anterior descending coronary (**B**) shows a significant atherosclerotic plaque.

**TABLE 30-1 Comparative Test Characteristics for Diagnosis of Cardiac Allograft Vasculopathy**

| | *Sensitivity* | *Specificity* | *PPV* | *NPV* |
|---|---|---|---|---|
| **Dobutamine stress echocardiography, gold standard for diagnosis of CAV** | | | | |
| Angiography[a-c] | 64%-83% | 56%-95% | 40%-78% | 84%-90% |
| Intravascular ultrasound[a,d,e] | 72%-90% | 55%-88% | 75%-92% | 62%-79% |

involvement more than 180 degrees), class III (moderate: intimal thickness 0.3 to 0.5 mm, or intimal thickness more than 0.5 mm and circumferential involvement less than 180 degrees), or class IV (severe: intimal thickness more than 1 mm, or intimal thickness more than 0.5 mm and circumferential involvement more than 180 degrees).[70] Severity of transplant vasculopathy progresses most rapidly in the first 2 years after transplantation.[72] Changes in the allograft vasculature in the first year after transplantation likely reflect the cumulative result of multiple insults, such as donor explosive brain death, early rejection, and cytomegalovirus infection, which influence the recipient's immune response to the allograft and thus the likelihood of development of vasculopathy. Early changes with IVUS during the first posttransplant year correlate with long-term prognosis. Progression of maximal intimal thickening of greater than or equal to 0.5 mm in the first year after transplantation is associated with a significantly higher risk of development of angiographic disease, nonfatal major adverse cardiac events, and death or graft loss in long-term follow-up (Fig. 30-9).[73,74]

### *Dobutamine Stress Echocardiography*

Dobutamine stress echocardiography is a valuable tool for detecting cardiac allograft vasculopathy and yielding prognostic information. With intracoronary IVUS as the gold standard, dobutamine stress echocardiography is highly sensitive and specific in detection of cardiac allograft vasculopathy. Positive dobutamine stress echocardiography is associated with increased risk of cardiac events, including myocardial infarction and heart failure, and risk for death.[75-77] Estimates of accuracy of dobutamine echocardiography for diagnosis of significant coronary allograft vasculopathy vary somewhat dependant on whether the gold standard being used is angiography or angiography with IVUS. In general, dobutamine stress echocardiography appears to agree better with IVUS–diagnosed disease and overall performs better than nuclear medicine myocardial perfusion scans (Table 30-1). In contrast, the sensitivity of stress echocardiography with exercise is somewhat limited by the blunted heart rate response to exercise that occurs from cardiac denervation; estimates of sensitivity of exercise echocardiography for diagnosis of cardiac allograft vasculopathy are as low as

15% to 20%.[78,79] Although worsening on serial dobutamine stress echocardiogram studies (interval increase in number of segments with wall motion abnormalities or in wall motion score by 1.0 or more) is variably accurate in diagnosis of angiographic/IVUS cardiac allograft vasculopathy,[77,80] worsening between interval dobutamine stress echocardiographic studies was still associated with a roughly sevenfold higher risk of events.[77] The addition of quantitative M-mode analysis or strain rate imaging to standard dobutamine stress echocardiography may also improve its diagnostic accuracy.[77,81]

## KEY POINTS

- Preoperative pulmonary hypertension, particularly if not medically reversible with vasodilators or if reversible at the expense of systemic hypotension, is associated with a very high risk of short-term mortality, frequently as a result of right heart failure, after cardiac transplantation.
- Currently, the bicaval technique of cardiac transplantation is more widely used than the older biatrial technique, with resultant lesser appearance of biatrial enlargement seen on echocardiography and better structural and functional preservation of the donor atria.
- Diastolic dysfunction is common immediately after cardiac transplantation and may be related to ischemic injury, recipient pulmonary hypertension, volume overload, or recipient-donor size mismatch. Diastolic dysfunction generally normalizes over weeks to months, or in some patients over years, but may also persist to a subtle degree.
- Persistence of a restrictive filling pattern may be associated with reduced long-term survival. A restrictive filling pattern may recur in the setting of acute rejection.
- Cardiac allograft systolic function generally remains normal as many as 10 to 15 years after transplant. LV hypertrophy and postoperative septal motion are common findings.
- Tricuspid regurgitation, sometimes severe enough to need corrective surgery, may be induced by inadvertent injury during routine endomyocardial biopsies.
- New onset systolic dysfunction in the setting of acute rejection generally indicates higher grade rejection with hemodynamic compromise. Diastolic abnormalities may manifest earlier, although they are not accurate enough to be the sole criteria for diagnosis of acute rejection.
- Cardiac allograft vasculopathy is an accelerated diffuse intimal hyperplasia that ultimately limits the long-term life span of the allograft in many cardiac transplant patients. The clinical presentation is frequently atypical as a result of denervation of the cardiac allograft. IVUS is currently the gold standard for diagnosis, although dobutamine stress echocardiography is also sensitive and specific and yields prognostic information.

**Clinical Utility, Outcome Data**
**Potential Limitations, Future Directions**
**Alternate Approaches**

Cardiac assist devices are playing an increasingly important role in the treatment of heart failure. Early-generation ventricular assist devices (VADs) were used as a "bridge to recovery" to support patients expected to recover from reversible cardiac insults.[1,2] Indications soon expanded to include stabilization of patients before transplant ("bridge to transplant").[3-5] Technologic improvements reduced VAD size so that they could be implanted in the abdomen or chest, allowing patients to await transplant at home. The early devices, still used for temporary support, are the size of small refrigerators. The newest implantable pumps fit into the palm of one's hand.

The success of early VADs,[6] the limited number of donor hearts, and the large number of patients excluded from transplant candidacy because of age or comorbidities led to the use of VADs as permanent treatment. The 2001 REMATCH study demonstrated improvement in 2-year mortality and quality of life for patients randomized to permanent left ventricular assist device (LVAD) support versus medical therapy.[7] This use of LVADs as "destination therapy" has set the stage for more widespread use.[8,9]

In addition to bridge to recovery, bridge to transplant, and destination therapy, VADs are increasingly employed as "bridges to decision"—support of patients undergoing workup to determine transplant candidacy (Table 31-1). If rejected for transplant, these patients' devices become destination therapy. Conversely, some patients will unexpectedly recover ventricular function. In this case, VADs originally classified as bridge to transplant or destination therapy become bridge to recovery.

## Basic Principles of Cardiac Assist Devices and the Echocardiographic Approach

### TYPES OF CARDIAC ASSIST DEVICES

#### *Implanted Ventricular Assist Devices*

Most implanted VADs consist of a pump, an inflow cannula, an outflow cannula, a power supply, and a controller. The controller collects data from the pump and directs its action via a driveline. VADs can be classified according to the location of these components. Extracorporeal VADs have pumps and controllers outside the body. Patients with paracorporeal VADs have components strapped close to the body but not inside it. Intracorporeal VADs have implanted pumps, with drivelines connecting to a paracorporeal or extracorporeal controller (Table 31-2).

Cardiac assist devices can support the left ventricle (LVAD), the right ventricle (RVAD), or both ventricles (BiVAD) (Fig. 31-1). LVAD inflow cannulae are connected to the LV apex or the left atrium (LA). The outflow graft cannula can be attached to the ascending aorta or the descending aorta. RVADs involve right atrial (RA) or right ventricular (RV) inflow and pulmonary artery outflow cannulation.

Devices are also characterized by mechanism (see Table 31-2).[10] Early-generation cardiac VADs (still in use) use either a pneumatically compressed, distensible chamber or a pusher-plate mechanism to expel blood into the outflow cannula (see Fig. 31-1, *A*). Because of the size of the chamber, these pumps cannot be implanted in small patients. These early-generation devices mimic cardiac pulsatile action through one-way inlet and outlet valves. They can be set to pump at a fixed rate or to maintain a constant stroke volume (asynchronous with the heart rate). In this mode, they have been used in patients with refractory ventricular arrhythmias.[11] A third (rarely used) mode has pumping rate gated to the electrocardiogram.

The next VAD generation produces continuous flow. These devices have a rotating propeller and are called *axial-flow pumps*. Blood is drawn from the heart via the inflow cannula and propelled into the outflow graft cannula[12] (see Fig. 31-1, *B*). The speed of the propeller in revolutions per minute (rpm) and the pressure difference between inflow and outflow cannulae determine rate of flow. There is greater flow during systole, when the aortic-LV pressure difference drops (LV pressure rises with ventricular contraction) than during diastole (LV pressure falls with ventricular relaxation and the pressure difference increases). These devices are sometimes called "nonpulsatile" VADs, but residual ventricular function and nonuniform

**TABLE 31-1 INTERMACS* Strategy for Ventricular Assist Device at Implant**

| *Indication* | *N (%)* |
|---|---|
| Bridge to transplant | 458 (45) |
| Bridge to decision | 458 (42) |
| Destination therapy | 100 (9) |
| Bridge to recovery | 25 (2.3) |
| Other | 13 (1.2) |

*Interagency Registry for Mechanically Assisted Circulatory Support over 3 years, 1092 patients. Overall survival was 74% at 1 year and 55% at 2 years.[16]

pressure differences between the inflow and outflow cannulae produce some pulsatility. These axial continuous-flow pumps provide increased flow at lower pressures than pulsatile pumps.[12] They also tend to be more durable, because they lack valves (which wear out over time).[13,14] A 2009 trial of destination therapy LVADs demonstrated a benefit for axial flow over pulsatile devices in fewer strokes and device failures.[15] Preliminary registry results also suggest lower complication rates in continuous-flow versus pulsatile-flow devices in the first 6 months after implant.[16]

**TABLE 31-2 Examples of Ventricular Assist Devices**

| *Name (Company)* | *Pump Location* | *Mechanism* | *Cannulae* | *Specifications (Size/Flows/Rates)* | *Approved and/or Proposed Indications* |
|---|---|---|---|---|---|
| HeartMate XVE (Thoratec) | Anterior abdominal wall | Pulsatile | I = LV apex<br>O = Asc Ao | 1150 g<br>3-10 L/min at 180 bpm | FDA approved for BTT, destination therapy, CE mark for BTT and destination therapy |
| Novacor pumps (WorldHeart) (discontinued) | Anterior abdominal wall | Pulsatile | I = LV apex<br>O = Asc Ao | 1000 g<br>2-12 L/min at 120 bpm | FDA approval for BTT, CE mark |
| Excor pediatric (BerlinHeart) | Extracorporeal | Pulsatile | BiVAD<br>I = LV apex, RA<br>O = Asc Ao, PA | 6 different pump sizes from 10 to 80 mL | Investigational, CE mark pediatric |
| I-VAD (Thoratec) | Anterior chest | Pulsatile | BiVAD<br>I = LV apex, RA<br>O = Asc Ao, PA | 330 g<br>Up to 7.2 L/min at 110 bpm | FDA approved BTR (postcardiotomy), BTT, CE mark |
| p-VAD (Thoratec) | Paracorporeal | Pulsatile | BiVAD<br>I = LV apex, RA<br>O = Asc Ao, PA | 419 g<br>Up to 7.2 L/min at 110 bpm | FDA approved BTR (postcardiotomy), BTT, CE mark |
| HeartMateII (Thoratec) | Anterior abdominal wall | Axial | I = LV apex<br>O = Asc Ao | 400 g<br>3-10 L/min<br>6000-15,000 rpm | FDA approved for BTT, destination therapy, CE mark for BTT and destination therapy |
| Jarvik2000* (Jarvik Heart) | LV apex | Axial | I = LV apex<br>O = Asc Ao, DA | 90 g<br>8,000-12,000 rpm | Investigational DTT, CE mark |
| HeartAssist 5 (Micromed Cardiovascular) | Pericardium | Axial | I = LV apex<br>O = Asc Ao | 92 g<br>1-10 L/min<br>7500-12,500 rpm | CE mark pediatric and adult |
| Incor (BerlinHeart) | Pericardium | Axial | I = LV apex<br>O = Asc Ao | 200 g<br>3-10 L/min<br>5,000-10,000 rpm | HDE for BTT, CE mark |
| HeartWare* HVAD (Heartware) | Pericardium | Centrifugal | I = LV apex<br>O = Asc Ao | 145 g<br>Up to 10 L/min<br>2000-3000 rpm | FDA approved for BTT, CE mark |
| Duraheart* (Terumo Heart) | Anterior chest wall | Centrifugal | I = LV apex<br>O = Asc Ao | 540 g<br>2-8 L/min<br>1200-2400 rpm | Investigational, CE mark |
| Levacor (WorldHeart) | Anterior abdominal wall | Centrifugal | I = LV apex<br>O = Asc Ao | 440 g<br>Up to 10 L/min<br>1000-3000 rpm | Investigational BTT |
| Centrimag (Levitronix) | Extracorporeal | Centrifugal | I = LA or LV via RSPV, RA<br>O = Asc Ao, PA. Can use existing cannulae via connectors | 1700 g<br>Up to 9.9 L/min<br>1500-5500 rpm | FDA approved for support up to 6 hours and under HDE for RV support up to 30 days |

*Pumps located in or near inflow cannula create imaging artifacts.

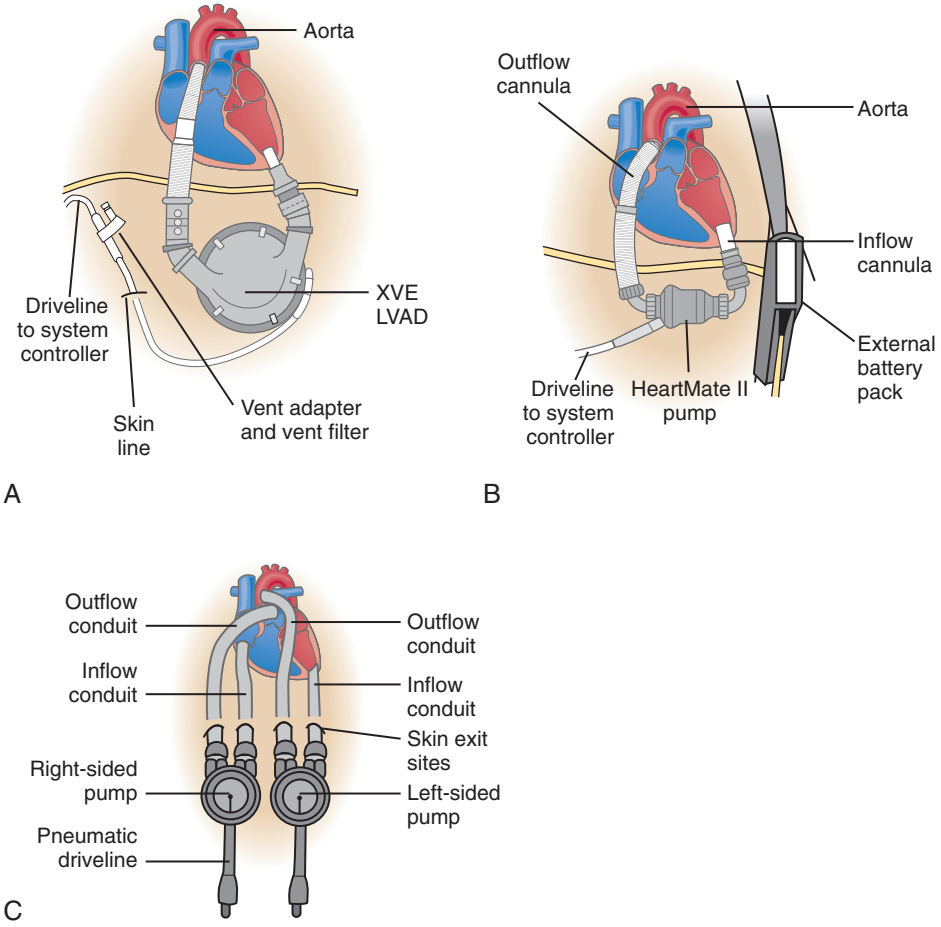

**Figure 31-1** **A,** Example of a pulsatile left ventricular assist device (LVAD) (Thoratec XVE, Thoratec, Pleasanton, Calif.). **B,** Example of a continuous-flow LVAD (HeartMate II, Thoratec). **C,** Example of a BiVAD (LVAD plus RV assist device).

The current generation of continuous-flow VADs employs centrifugal force to propel blood. Magnetic or hydrodynamic forces levitate and spin a disklike impeller, rather than a propeller. Like axial-flow pumps, centrifugal pumps have no valves, but they also lack bearings, and they may prove even more durable than axial-flow pumps. They also allow a greater degree of pulsatility than the axial-flow devices.[17-19]

### *Percutaneous Ventricular Assist Devices*

Percutaneous VADs are inserted via peripheral arteries and veins, usually in the catheterization laboratory, and can be placed quickly. Percutaneous VADs temporarily bridge patients to recovery, decision about transplant, or implanted VADs (see Table 31-2). Other indications include support during percutaneous coronary and valvular interventions.[20,21]

The Impella Recover (Abiomed, Danvers, Mass.) consists of an axial-flow pump (propeller) placed into the femoral artery, though the aorta, and across the aortic valve into the LV[22] (Fig. 31-2, *A*). The inflow port draws blood from the LV outflow tract and ejects it through the outflow port in the aorta. The Impella improves hemodynamic parameters in severe refractory cardiogenic shock, but early trials comparing it to the intraaortic balloon pump failed to demonstrate a mortality benefit.[23]

The TandemHeart (Cardiac Assist, Pittsburgh) has an extracorporeal centrifugal flow pump. The pump is connected to an inflow catheter placed into the LA across the interatrial septum and an outflow cannula in the distal aorta via the femoral artery[24] (see Fig. 31-2, *B*). The TandemHeart cannula can also be positioned in the RA (inflow) and the pulmonary artery (outflow) to support the RV. The TandemHeart improves cardiac index and pulmonary pressures in patients with decompensated heart failure after myocardial infarction and has also been used to stabilize patients with incessant ventricular tachycardia.[25]

### *Total Artificial Heart*

There are currently two available models of the total artificial heart. Both replace the ventricles with pulsatile pumps and metallic or plastic atrioventricular valves anastomosed to the native atria. The Syncardia temporary Total Artificial Heart (tTAH, Syncardia Inc, Tucson) pumping component is attached via drivelines to an extracorporeal controller and battery[26] (Fig. 31-3, *A*). The AbioCor (Abiomed, Danvers, Mass.) pump, controller, and battery are all implanted; the battery is recharged via a transcutaneous energy transfer system. (see Fig. 31-3, *B*) Only the Syncardia device is currently approved by the U.S. Food and Drug Administration (FDA) as bridge to transplant (see Table 31-2).

## PREIMPLANT ASSESSMENT

Specific criteria for placement of an LVAD as destination therapy include LV ejection fraction (EF) less than 25% to 30%, most often measured by echocardiography. Other criteria are

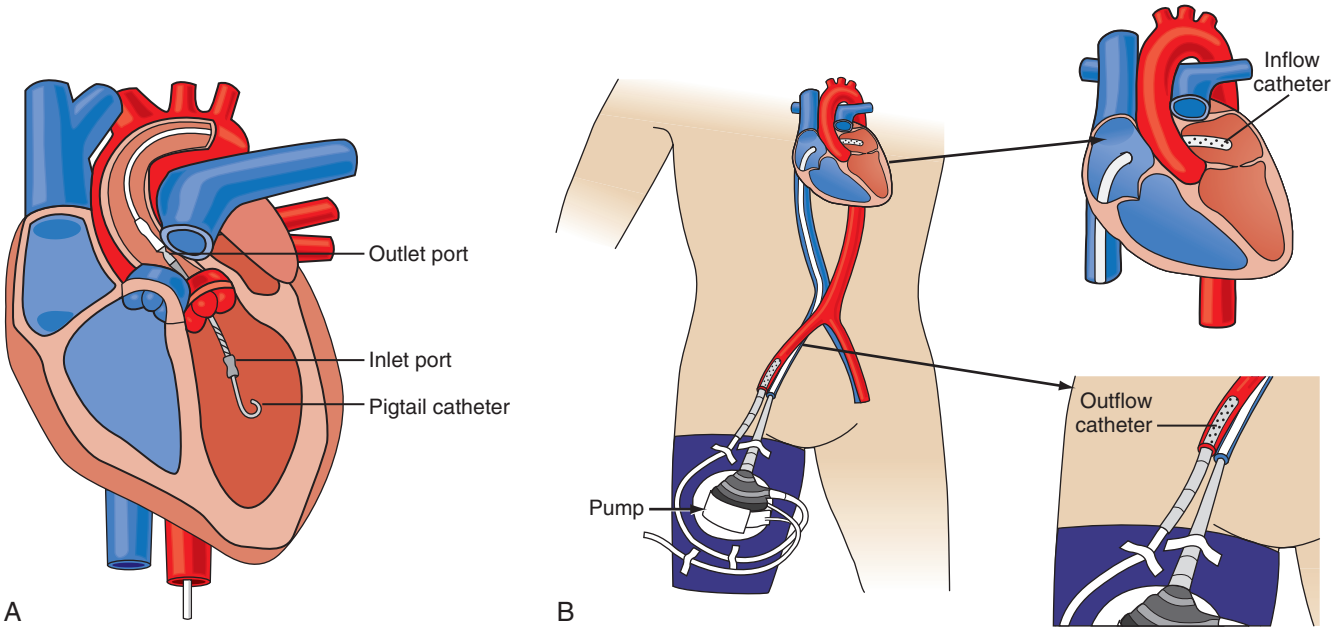

**Figure 31-2** **Percutaneous ventricular assist devices. A,** Impella Recover (Abiomed, Danvers, Mass.) consists of an axial-flow pump (propeller) inside a single 12F catheter that has a distal inflow port and a more proximal outflow port. The catheter is inserted into the femoral artery, through the aorta and across the aortic valve into the LV. A pigtail catheter is left in the central lumen for stabilization. The inflow port is positioned below the aortic valve to draw blood from the LV outflow tract. The outflow port is located in the ascending aorta. Flow is determined by the propeller speed and the aortic-LV pressure difference. The Impella can also be inserted through the chest into the ascending aorta, or into the pulmonary artery, from where it is advanced into the RV outflow tract to support the failing RV. **B,** The TandemHeart (Cardiac Assist, Pittsburgh) has an extracorporeal centrifugal flow pump connected to a 21F inflow cannula inserted in the femoral veins and advanced into the RA, across an interatrial septotomy, and into the LA. A separate 15-17F outflow cannula is inserted into one femoral artery and advanced into the distal aorta. Alternatively, a 12F outflow catheter can be inserted into each femoral artery. The TandemHeart cannula can also be positioned in the RA (inflow) and the pulmonary artery (outflow) to support the RV.

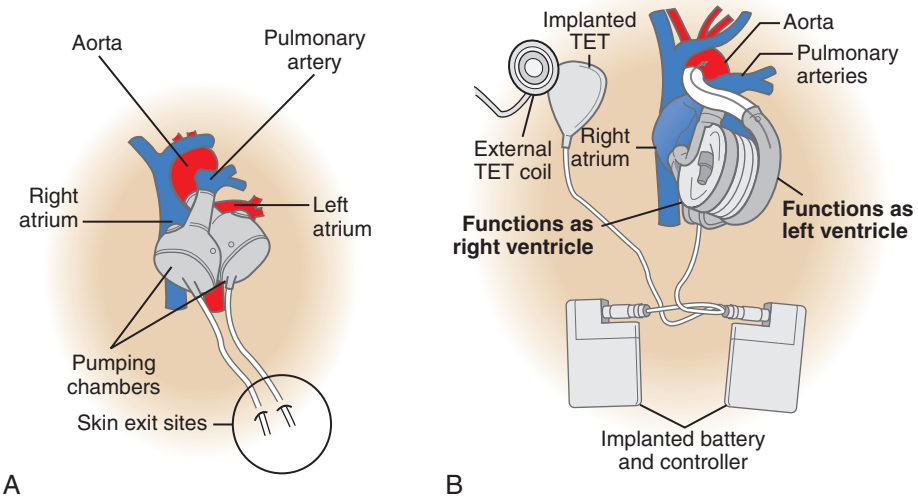

**Figure 31-3** **Total artificial hearts. A,** Syncardia. **B,** AbioCor. *TET*, Transcutaneous energy transmission.

detailed in Box 31-1.[27] Although the hemodynamic criteria refer to invasively determined measurements, echocardiography can provide noninvasive assessment of cardiac index and intracardiac pressures. In addition, echocardiography may identify pathology that warrants interventions other than or in addition to VAD implant, including valve repair or replacement.

Echocardiography identifies factors that complicate cardiac assist device placement or support use of one type of device over another[28] (Table 31-3). It is particularly important to detect thrombi that can embolize. Microbubble contrast may be necessary to exclude ventricular thrombi in patients with inadequate images, and transesophageal echocardiography (TEE)

**Box 31-1**

## CRITERIA FOR DESTINATION THERAPY VENTRICULAR ASSIST DEVICE

**Primary Criteria**

LV ejection fraction ≤25% to 30%
Refractory NYHA class IV heart failure symptoms while on maximal medical therapy, including need for continuous inotropic support
Peak maximal oxygen consumption <12 mL/kg/min
Patients usually have an estimated 1-year cardiac mortality of >50% and/or life expectancy without mechanical cardiac assistance of <2 years.[27,100]

**Additional Hemodynamic Criteria**

Cardiac index <2 L/min/$m^2$
Pulmonary capillary wedge pressure >20 mm Hg
Systolic blood pressure <80 mm Hg

**Box 31-2**

## PREOPERATIVE ECHOCARDIOGRAPHIC PREDICTORS OF POSTIMPLANT RV DYSFUNCTION

RV size
- RVEDD >85 mm
- RVEDV >200 mL
- RVESV >177 mL
- RV short-to-long axis ratio ≥0.6

RV function
- TAPSE <7.5 mm
- Qualitatively severe RV dysfunction

Moderate to severe tricuspid regurgitation
Hemodynamics (invasively determined, but measurable by echocardiography)
- Elevated RAP
- Low mean PAP
- Low cardiac output
- Low RV stroke work index
- Elevated PVR

*PAP*, Pulmonary artery pressure; *PVR*, pulmonary vascular resistance; *RAP*, right atrial pressure; *RVEDD*, right ventricular end-diastolic diameter; *RVEDV*, right ventricular end-diastolic volume; *RVESV*, right ventricular end-systolic volume; *TAPSE*, tricuspid annular planar systolic excursion.

**TABLE 31-3 Echocardiographic Findings That Complicate Ventricular Assist Device Implant**

| *Finding* | *Implications* |
|---|---|
| Thrombus in cardiac chamber | Thrombectomy<br>Placement of cannula in alternate chamber |
| Intracardiac shunting | Repair of shunt |
| Aortic aneurysms, tortuosity, atheromata | Graft repair of aneurysm<br>Placement of outflow graft cannula away from atheroma<br>Caution with Impella Recover |
| Aortic stenosis (≥ moderate) | Bioprosthetic valve replacement*<br>Impella Recover contraindicated |
| Aortic regurgitation (≥ moderate) | Bioprosthetic valve replacement*<br>Oversew valve cusps<br>Cannulation of descending aorta<br>Angle ascending aortic graft cannula away from aortic valve<br>Caution with TandemHeart (see text)<br>Impella Recover contraindicated |
| Mitral stenosis | Valvuloplasty<br>Bioprosthetic valve replacement*<br>Placement of inflow cannula in LA<br>Caution with Impella Recover |
| Mitral regurgitation | Repair or bioprosthetic valve replacement*<br>Caution with Impella Recover |
| RV failure | Caution with TandemHeart for LV support (requires the RV to provide adequate preload to the LA) |
| Ventricular septal defect | Caution with Impella Recover (right to left shunting) |
| Atrial septal defect | Caution with TandemHeart and LA cannulation (right to left shunting) |
| Interatrial septal aneurysm | Caution with TandemHeart and atrial cannulation (suckdown of aneurysm into cannula) |
| Heavy trabeculation, aneurysms/dyskinetic walls, redundant chords, prominent ridges, small inflow chamber | Orient inflow cannula away from potentially obstructing structures<br>Excise trabeculation<br>Excise aneurysm |
| Clotting diathesis | Avoid LA cannulation, caution with TandemHeart (stasis in bypassed LV)<br>Ensure aortic valve opening to "wash" aortic root<br>Higher INR target, additional antiplatelet agents |
| Pericardial effusion (chambers can collapse after decompression with VAD) | Effusion drainage |
| Peripheral vascular disease | Caution with Impella Recover<br>Caution with TandemHeart |

*INR*, International normalized ratio; *VAD*, ventricular assist device.
*Mechanical valves are generally not used in VAD patients because of concerns for thrombus formation despite anticoagulation.

should be used to examine left and right atrial appendages. Intracardiac shunting producing systemic hypoxemia and/or paradoxical emboli after LVAD placement should be repaired at the time of implant.[29] High LA pressure may prevent passage of agitated saline contrast across a patent foramen ovale (PFO), even after Valsalva. An LVAD will decompress the LV, lower LA filling pressure, and return more blood to the RA by increasing cardiac output, potentially opening the PFO.

Moderate or greater aortic regurgitation complicates the use of VADs.[30] Placement of an outflow cannula in the ascending aorta or an Impella Recover device across the aortic valve may worsen baseline aortic regurgitation, leading to circulation of blood from LV to VAD to aorta and back into the LV. High LV pressure and low diastolic pressure in the aortic root from severe aortic regurgitation can reduce coronary perfusion pressure, which is exacerbated by the fact that the TandemHeart draws blood from the LA and ejects it into the distal aorta (bypassing the coronary ostia). Preimplant grading of the degree of aortic regurgitation is complicated in end stage heart failure patients who commonly have low systemic pressure and high LV diastolic pressure (see Chapter 20). The low aortic-to-LV pressure gradient may artificially decrease the amount of regurgitation through an incompetent aortic valve.

Preimplant identification and characterization of RV dysfunction is vitally important[31-33] (Box 31-2) (see Chapter 33). RV failure is cause of morbidity and mortality in 10% to 30% of the LVAD population.[16,34,35] In patients with known RV dysfunction, planned early placement of an RVAD improves survival over delayed placement.[36] LVAD placement produces a higher cardiac output and increased venous return to the RV. An RV with preexisting dysfunction may fail in the setting of increased preload.[37,38] In addition, LVAD influence on septal motion reduces RV function and can worsen baseline tricuspid regurgitation.[39,40] On the other hand, decompression of the LV by a VAD can reduce pulmonary pressures and RV afterload, leading to an improvement in RV function.

## PERIPROCEDURAL GUIDANCE

Intracardiac echocardiography (ICE) or transesophageal echocardiography (TEE) provides real-time visualization to direct cannula placement away from potentially obstructing cardiac structures (see Chapters 5 and 6). The Impella device can be guided to position the inflow port in the LV outflow tract and the outflow port above the aortic valve. Echocardiography can guide transseptal puncture in TandemHeart insertion, preventing inadvertent puncture of the left or right atrial walls or the aortic root. As with other cardiac surgical procedures, TEE is useful in deairing the heart before coming off bypass. Air bubbles arise at cannula anastomosis sites and can embolize if not detected before the aortic crossclamp is removed. Anterior structures, including the ascending aorta, the RV, and anterior portions of the LV, should be examined for air bubbles[41] (Fig. 31-4).

## APPROACH TO CARDIAC ASSIST DEVICE DYSFUNCTION

Echocardiography is often required to elucidate the complicated processes and causes of VAD dysfunction[42-44] (Box 31-3).

### *Overfilling*

Regurgitation, obstruction and malfunction cause overfilling and pressure increase in the supported ventricle. In pulsatile VADs, failure of the one-way valves leads to regurgitation.[45] Cannula regurgitation can occur in continuous-flow devices when the systemic vascular resistance is elevated. Cannula obstruction can result from kinking, malposition, or thrombosis and can be partial, complete, or intermittent. VAD pumping mechanisms may become partially or completely obstructed, leading to increased shear stress and hemolysis. Pulsatile VADs with a special texture on the blood interface surface may be less thrombogenic, and the lower flows in third-generation VADs may be less likely to cause hemolysis. Finally, there can be primary failure of VAD components: battery, controller, or pump. These all cause the ventricle to dilate and the cardiac output to fall, and they may induce stasis and intracavitary thrombus formation.

### *Underfilling*

Underfilling of the supported ventricle shrinks the cavity size and can cause obstruction of the inflow cannula due to encroachment by normal cardiac structures, sometimes called *suckdown*. Trabeculations, papillary muscles, chordal structures, ridges, and septae are drawn into the orifice of the inflow cannula as chamber size decreases in conjunction with a rigid inflow cannula (Fig. 31-5). Obstruction of the orifice leads to a decrease in flow and reduced cardiac output, as well as arrhythmias.

Anything that reduces preload can predispose to obstruction of the inflow orifice, including dehydration, overdiuresis, sepsis, and tamponade. Bleeding is a special concern because some form of anticoagulation is advised for most VAD patients to prevent thrombosis. Up to one fourth of VAD patients may require reoperation for bleeding in the periimplant period.[46] In addition, continuous-flow VADs have been associated with increased risk of gastrointestinal bleeding, and a substantial number of patients cannot take anticoagulation for this reason.[47,48] It has been postulated that high shear stress through VADs depletes large von Willebrand factor monomers.[49-51]

### *Valvulopathy*

As described previously, relatively mild aortic regurgitation detected preimplant may worsen after LVAD placement.[16,52] Significant aortic regurgitation has been reported to arise months after implant. In addition, acquired aortic stenosis due to cusp fusion is an increasingly recognized complication of both pulsatile and continuous-flow devices.[53-55] The etiology is unknown, and echocardiographic examination of the valve leaflets reveals

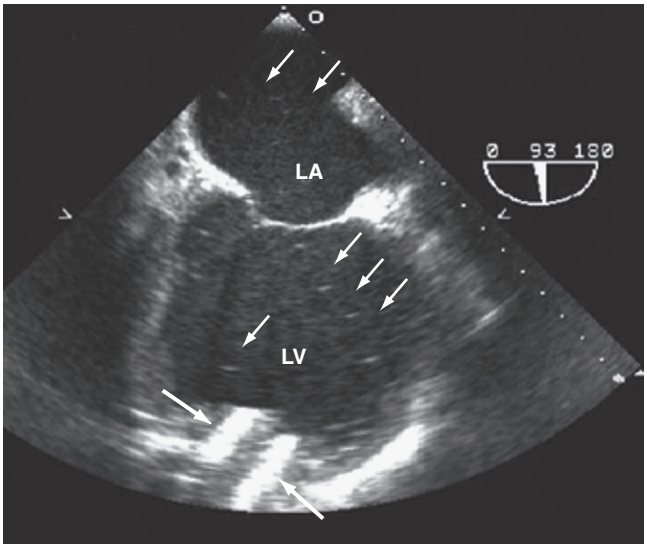

**Figure 31-4 Midesophageal TEE apex down two-chamber view.** Air bubbles (*small arrows*) in the LV and LA after placement of an LV apical inflow cannula (sides defined by *large arrows*). Echocardiography can detect bubbles arising at anastomotic sites. Ventricular chambers should be "de-aired" before coming off bypass.

**Box 31-3**

**ECHOCARDIOGRAPHIC FINDINGS IN VENTRICULAR ASSIST DEVICE DYSFUNCTION**

**Obstruction/Overfilling**
↑ LVEDD
Septum → RV
Spontaneous echo contrast
↑ Aortic valve opening
↑ cannula velocities
  Pulsatile: >2.3 m/s peak inflow, >2.1 m/s peak outflow*
  Continuous flow: >2 m/s peak
Inflow cannula regurgitation
  Pulsatile VAD peak outflow <1.8 m/s
  Flow reversal by color, spectral Doppler
Thrombus or vegetation obstructing cannula

**Underfilling**
↓ LVEDD
Septum → LV
↓ Aortic valve opening
Pericardial effusion with chamber collapse
Suckdown of cardiac structures into inflow cannula
↑ cannula velocities

*LVEDD*, Left ventricular end-diastolic diameter; *VAD*, ventricular assist device
*Few data exist on normal velocities, but for most continuous-flow devices, patients probably have peak velocities around 1 m/s.[84,101]

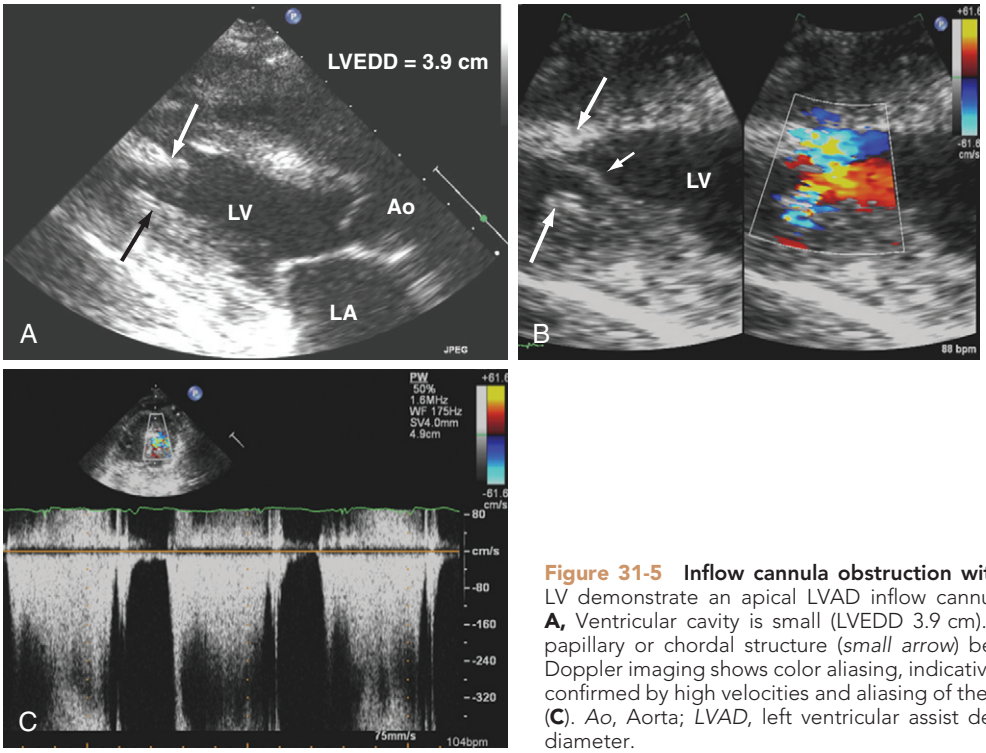

**Figure 31-5 Inflow cannula obstruction with small LV.** Parasternal long-axis views of LV demonstrate an apical LVAD inflow cannula (*large arrows* define sides of cannula). **A,** Ventricular cavity is small (LVEDD 3.9 cm). **B,** Zoomed view of the cannula shows a papillary or chordal structure (*small arrow*) being drawn into the cannula orifice. Color Doppler imaging shows color aliasing, indicative of high velocities from partial obstruction, confirmed by high velocities and aliasing of the PW spectral Doppler inflow cannula profile (**C**). *Ao*, Aorta; *LVAD*, left ventricular assist device; *LVEDD*, left ventricular end-diastolic diameter.

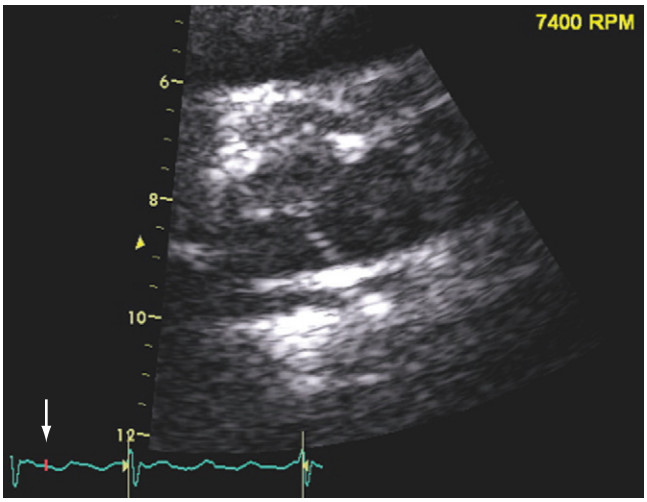

**Figure 31-6 Fused bioprosthetic aortic valve in a continuous-flow VAD patient, seen in zoomed parasternal short-axis view.** Shadowing off the struts creates a linear artifact on the right side of the image. *Arrow* demonstrates this still frame is taken in systole, when there should be some opening of the aortic leaflets at a relatively low propeller speed (for this patient with a Heartmate II device) of 7400 rpm. Despite being fused, the leaflets appear free of thickening or calcification.

relatively normal structure (Fig. 31-6). Both native and bioprosthetic cusps have been noted to fuse. Cusp fusion presents a significant problem in patients with VADs as bridge to recovery and may require balloon valvuloplasty. When the aortic valve does not open or opens minimally, there is a risk of thrombus formation in the aortic root, especially in continuous-flow VADs because of the lower, mostly nonpulsatile flows.[56]

Mitral regurgitation generally improves when an LVAD is placed, but the Impella Recover device may interfere with the chordal apparatus or the anterior mitral valve leaflet, leading to an increase in mitral regurgitation. Suckdown events that tether chordae or papillary muscles may have the same result. As noted earlier, tricuspid regurgitation can increase after LVAD placement because septal shift and annular distortion can lead to tethering on the septal leaflet.

Endocarditis on native valves or VAD components is another significant concern and one of the leading adverse events for cardiac assist devices. Infection is one of the top five causes of death in the VAD population.[16,57] Vegetations on intracorporeal VAD cannulae or pump components put patients at risk for obstruction and septic embolism. Device explant is often necessary.

### *Optimization*

In some cases, VAD pump function must be adjusted to address hemodynamic challenges. Reducing LVAD pumping rates, pumping volumes, or rotor speeds will increase preload. Higher preload may improve LV systolic function via Starling mechanisms, increasing ejection through the aortic valve. For continuous-flow devices, some degree of aortic valve opening is desirable to prevent cusp fusion and thrombus formation. Alternatively, reduced LVAD flow may overdistend the LV, leading to a reduction in residual function and symptoms of congestion.

Increasing LVAD pumping rates, pumping volumes, or rotor speeds will decrease ventricular preload, potentially alleviating distension and congestion. However, LV systolic function may fall and the aortic valve may cease to open, increasing risk of root thrombosis. Excessive reduction in pumping rates will produce underfilling and impingement of the inflow cannula.

Percutaneous VAD positioning may require guided adjustment. If the Impella migrates into the ventricle, the outflow portion may end up below the aortic valve (Fig. 31-7). If it migrates backward, the inflow portion may end up in the

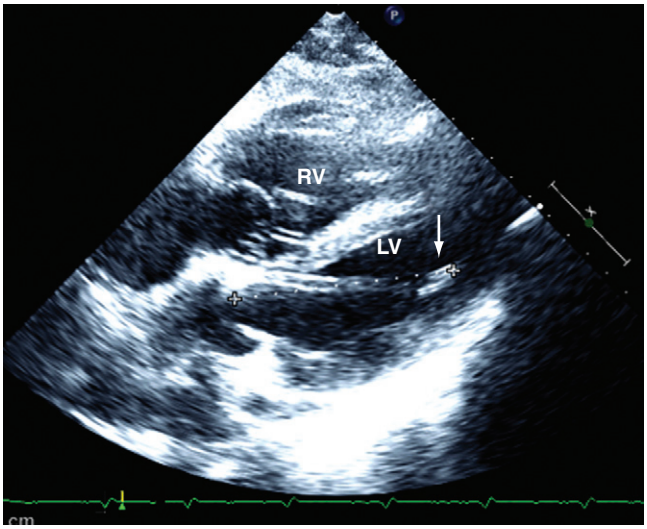

**Figure 31-7 Malposition of an Impella Recover device.** In this subcostal view, the end of the device (*arrow*) is imaged at least 8 cm below the aortic valve, twice the recommended distance of 3 to 4 cm. After appropriate initial placement, the device migrated apically. The outflow portion was located in the LV outflow tract, leading to device malfunction.

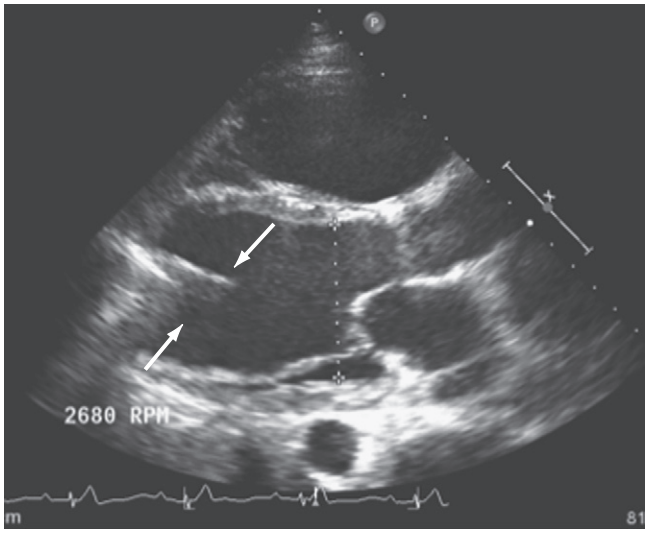

**Figure 31-8 LV size and appropriate septal position.** Parasternal long-axis view demonstrates normal LV size and a septum positioned neutrally between the LV and RV, indicative of adequate ventricular decompression. *Large arrows*: sides of continuous-flow left ventricular inflow device inflow cannula.

ascending aorta. Pressure sensors at each port can identify a problem, though loss of sensor signal has been reported.[58,59] A transseptally placed TandemHeart could move backward into the RA.

### *Ventricular Recovery*

VADs, especially percutaneous devices, are increasingly used to temporarily support patients with reversible causes of acute heart failure. In patients with chronic heart failure and VADs, ventricular unloading can produce reverse remodeling, including normalization of chamber sizes, regression of LV hypertrophy, recovery of beta receptor responsiveness, and normalization of calcium handing.[59-64] With decompression, however, reduced preload produces loss of systolic function due to reduced ventricular fiber stretch. Reductions in systolic function on VAD support are therefore not necessarily indicative of progression of myocardial dysfunction. LVAD-induced myocyte atrophy is controversial.[65] Improvements in systolic function may be a sign of overfilling or may portend resolution of an acute insult and/or reverse remodeling over time. Pulsatile LVADs may improve RV parameters, though not as rapidly,[66] and continuous-flow LVADs may lead to reductions in RV size but no improvement in RV function.[67] BiVAD/RVAD implant induces changes in RV function akin to the effect of an LVAD on the LV.[68] Early clinical results suggest that pharmacologic interventions may enhance VAD-induced recovery.[69-71]

Turning down VAD flows will lead to increases in afterload and preload. In patients with recovered heart function, increasing preload will lead to an improvement in ventricular function and maintenance of ventricular size. In patients who are dependent on VAD support, ventricles will fail and/or dilate because of inability to accommodate increased preload and afterload.

### *Ventricular Assist Device Flows*

Almost all of the currently available VADs calculate flows indirectly from changes in power consumption. Several VADs have mechanisms that directly measure flow, but they are limited in accuracy.[72] Reduced unloading in the setting of increased power consumption will set off a low-flow alarm, but the cause of the reduced flow cannot be assessed. In continuous-flow devices, changes in flow amplitude are used to calculate a *pulsatility index*.[73] Improvements in ventricular function will push blood through the inflow cannula, leading to increases in the pulsatility index from higher rotor speeds. However, the pulsatility index will also increase when there is intermittent cannula obstruction. Thus, VAD flow monitors provide a signal that dysfunction exists, but measurement of flows and definition of the cause of dysfunction require an imaging study.

## Technical Details, Quantitation, and Data Analysis

Standard echocardiographic imaging protocols provide structural, functional, and hemodynamic information about hearts supported by cardiac assist devices. Certain standard assessments deserve special emphasis, and specialized views to assess device components are necessary additions. Specific indication for the exam, device type, cannulation, mode, and pump settings should be noted on every examination, as should blood pressure (taken with a special cuff in patients with continuous-flow devices).

### LVEDD AND SEPTAL ORIENTATION

LV end-diastolic diameter (EDD) is a surrogate marker for filling status in VAD patients. It also reflects the position of the interventricular septum, which in turn reflects the interaction between the left and right ventricles. Optimal unloading of the LV has been reported with reductions in EDD of 20% to 30%.[74] In most VAD patients, the ideal position of the septum is neutral between the ventricles (parallel to the long axis of the LV) (Fig. 31-8). A neutral septum denotes adequate ventricular decompression. In the case of a dysfunctional LVAD and overfilling, the EDD size increases, in part because of a shift of the septum into the RV.

Cannula obstruction related to a small LV can manifest as a decrease in the LVEDD and septal bowing into the LV (Fig. 31-9). However, septal orientation toward the LV can also result from high right-sided pressures. Dyssynchrony from interventricular conduction delay, ischemic wall motion abnormalities, poststernotomy state, pericardial constriction, and RV pacing can also complicate assessment of septal position.

LVEDD measured in the two-dimensional (2D) parasternal long-axis view at the mitral valve leaflet tips[75] is generally reproducible, allowing detection of differences in size and septal position between serial studies, and in response to changes in VAD pump settings during optimization and weaning. Nonetheless, care must be taken to record images in the same plane each time. 2D directed M-mode can be used if the M-mode cursor can achieve perpendicular axis with respect to the ventricular walls. Although the direct measurement of LVEDD is most often used in the cardiac assist literature, it should probably be indexed to body surface area.[75] Assessment of septal position is subjective, with no validated quantitative measure currently available.

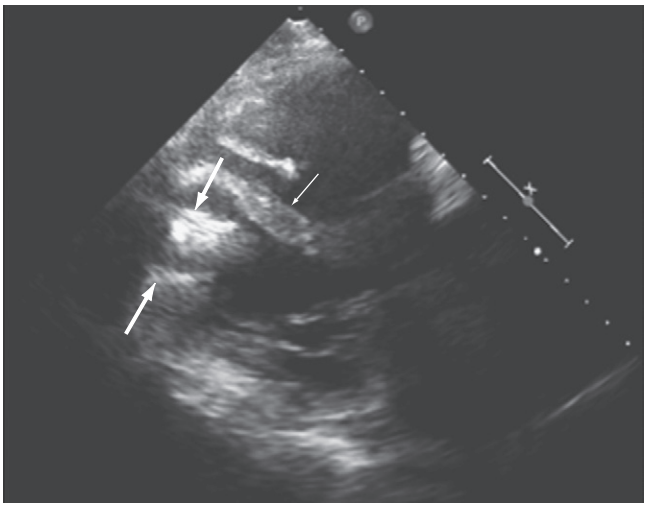

**Figure 31-9 Leftward septal bowing.** In a parasternal long-axis view, mild septal shift into LV is seen (*small arrow*), suggesting either LV underfilling or elevated right-sided pressures. *Large arrows*: sides of left ventricular assist device inflow cannula.

## VENTRICULAR FUNCTION

In the LVAD patient, it is often difficult to quantify LVEF using the biplane apical method,[75] because of artifact from the apical inflow cannula (see Chapter 9). Use of microbubble contrast to improve endocardial border definition in LVADs can be considered. Calculation of LVEF from linear measurements is confounded by LVAD effects on septal orientation and ventricular dimensions. The Quinones method, which calculates LVEF from measurements of multiple diameters in two views and does not account for motion of the apex (which may be akinetic in most VAD patients) is theoretically attractive but has not been well validated.[76,77]

Comprehensive imaging of RV function requires 2D assessment of size and systolic motion but also careful assessment of tricuspid regurgitation and measurement of right-sided hemodynamics.[78] Examination of the tricuspid valve should include assessment of leaflet flattening or prolapse, septal leaflet tethering, and annular dilatation (see Chapter 34). Noninvasive pulmonary vascular resistance, in particular, can be measured as a marker of LVAD effect on RV afterload.[79]

## AORTIC VALVE OPENING

Aortic valve opening is normally reduced because most of the LV output flows through the LVAD. Relative aortic valve opening can be a marker for both LVAD and ventricular contribution to cardiac output. The aortic valve may open minimally, briefly, and intermittently, or not at all when the ventricle is severely dysfunctional. In addition, the aortic-LV pressure difference opposes opening because the LV pressure is low as a result of decompression, and the LVAD outflow increases pressure in the aorta. Conversely, the aortic valve may open normally when there is ventricular recovery or LVAD dysfunction leading to high LV pressures. It has been proposed that the degree and frequency of aortic valve opening be assessed as complete opening, partial opening, intermittent opening, or complete closure.[77] Quantitation of the degree of opening can be obtained by planimetry of the open valve in the short-axis view, or by linear measurement of systolic cusp separation in the long-axis view. M-mode imaging at a low sweep speed gives a quantitative frequency of aortic valve opening as a percentage of recorded cardiac cycles (Fig. 31-10). Duration of opening can be measured by M-mode as time of opening or as a percentage of the R-R interval in which the valve is open.

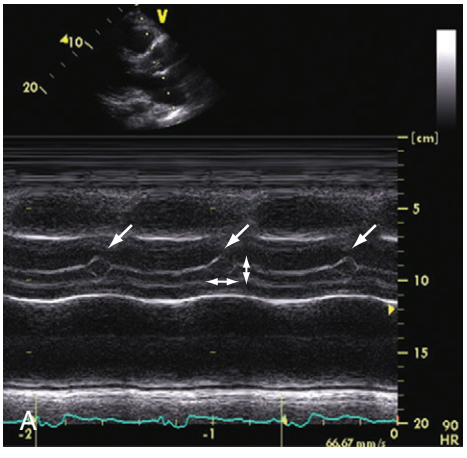

**Figure 31-10 Aortic valve opening. A,** M-mode tracing from parasternal long axis demonstrates reduced opening of aortic valve with each beat (*arrows*), consistent with normal left ventricular assist device (LVAD) function that prevents thrombus formation in aortic root. *Double-headed arrows* show duration and extent of opening, which can be measured to allow quantitative comparison between studies or at different LVAD pump settings. Increased opening can be a sign of overfilling or ventricular recovery. **B,** No aortic valve opening is seen, consistent with very low residual cardiac output, high LVAD pump flow, oversewn valve to prevent aortic regurgitation, or leaflet fusion.

## PERICARDIUM

2D imaging can visualize effusions or thrombus in the pericardial space compressing cardiac chambers, leading to underfilling and inflow cannula obstruction. Exaggerated Doppler flow variation across valves in the supported ventricle is generally unhelpful as a marker of intrapericardial pressure, because flow is affected by VAD function. The total artificial heart chambers are opaque to ultrasound, but the native atria, the superior and inferior vena cavae, and the pulmonary veins can be assessed for chamber collapse.

## CANNULAE

2D imaging, especially with TEE, can determine orientation of the cannulae and whether cardiac structures (such as trabeculations, septae and chordal structures) are sucked into the cannulae (see Fig. 31-5). 2D imaging should also assess for thrombi and vegetations on the cannulae. The LVAD inflow cannula in the LV should be imaged from all windows. Though the most parallel Doppler angle of insonation is often found in the apical views, the orientation of inflow cannulae can be variable, and the most parallel angle is sometimes found in the parasternal long-axis view or the subcostal view, especially if the cannula was placed via an inferior approach. VAD inflow cannulae placed in the left or right atrium may require TEE for visualization. The LVAD outflow cannula in the ascending aorta is often difficult to image by transthoracic echocardiography (TTE) and is best visualized from a right parasternal view or upper left parasternal view (Fig. 31-11, *A*). Using TEE, it is usually seen in the upper-midesophageal position (90-150 degrees) (see Fig. 31-11, *C*). The RVAD outflow cannula in the pulmonary artery can be seen in the short-axis view (Fig. 31-12).

The Impella Recover percutaneous VAD cannula is normally well seen from the parasternal long-axis view, but it may be necessary to angle the transducer off axis to ensure that the tip is visualized (see Fig. 31-7). Proper location of the inflow port (near the tip of the cannula) is 3 to 4 cm below the aortic valve. The outflow port should be 1.5 to 2 cm above the sinuses of Valsalva.[22]

Color Doppler examination of normal cannulae reveals laminar flow with minimal or no regurgitant flow. Aliasing of color flow may be seen at the inflow or outflow cannulae in cases of obstruction. The color Doppler jet can also help to direct angulation of the transducer to achieve a parallel alignment for spectral Doppler interrogation.

Pulsed-wave (PW) Doppler should be performed inside and immediately outside of the cannula orifice. Normal and abnormal Doppler profiles through inflow and outflow cannulae are illustrated in Figure 31-13 for pulsatile and continuous-flow devices. Partial obstruction will lead to increases in inflow and outflow velocities, depending on the site of obstruction[42,43] (see Box 31-3). Complete obstruction, as from thrombotic occlusion or kinking, leads to loss of Doppler signal or low velocities in the VAD cannulae.[80] Regurgitation can lead to low outflow velocities.[44] Continuous-wave (CW) Doppler interrogation is necessary to resolve high velocities, but, because of range ambiguity, the CW Doppler signal may become contaminated by other flows (e.g., LVAD inflow and aortic regurgitation).

Table 31-4 describes the formulas used to calculate the stroke volume through pulsatile VADs, flow through continuous-flow VADs, and VAD regurgitation using cross-sectional orifice area and PW Doppler velocity-time integral (VTI). Because continuous-flow VADs technically have no discrete stroke volume, VAD flows in liters per minute must be calculated indirectly using the residual output through the aortic valve and the output through the pulmonic valve, or directly by measuring the Doppler velocity time integral over 3 s (multiplied by 20 s to convert to minute flow rate).[81]

## OPTIMIZATION

LV EDD, septal position, and aortic valve opening are used to optimize VAD settings.[82] For a continuous-flow VAD, the rotor speed is adjusted until the septum is neutrally positioned at a near-normal LV EDD and the aortic valve opens to a small degree, for a brief period of time and/or at a reduced frequency.[83] The optimal opening characteristics to prevent aortic root thrombus and cusp fusion while signaling appropriate ventricular decompression have not been defined. Other targets of optimization can include mitral regurgitation, aortic regurgitation, pulmonary artery pressures, and Doppler-derived cannula flows (see Table 31-4). Optimization of RVAD and BiVAD function is not well described to date but could apply the same principles to RV size, septal positioning, and pulmonic valve opening.

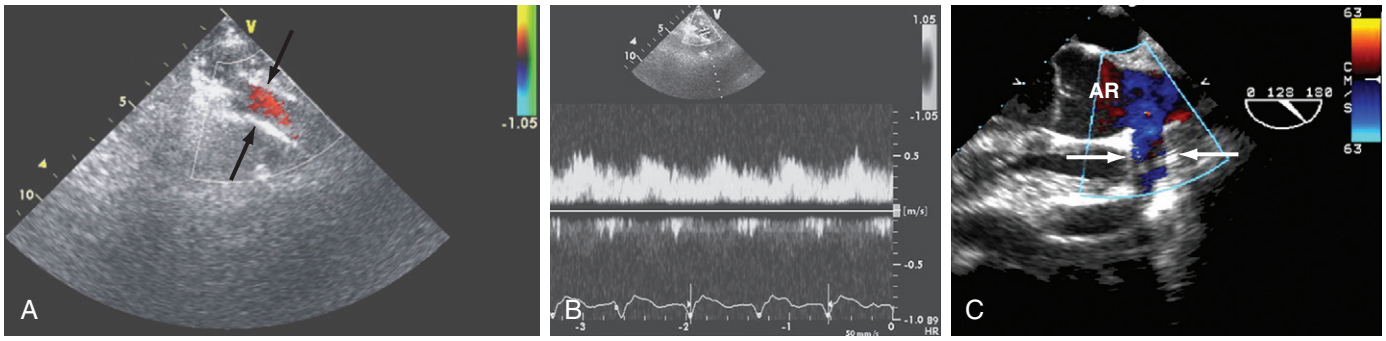

**Figure 31-11 Imaging left ventricular assist device (LVAD) outflow graft cannula. A,** LVAD outflow graft cannula can be visualized by TTE in many patients in right upper sternal border, but best imaging window depends on location of graft cannula, which can be variable. *Large arrows*: Sides of graft cannula. **B,** Although off axis with respect to axis of flow, PW Doppler profile demonstrates normal baseline flow with systolic peaks. **C,** Unlike inflow cannula (inserted through LV apical wall), outflow graft cannula is anastomosed end-to-side to ascending aorta. (See also Fig. 31-16, *B*.) Outflow graft cannula is usually very easily imaged by TEE from midesophageal position at 90° to 150°, depending on location of anastomosis. *Large arrows*: Sides of graft cannula. *AR*, Aortic root.

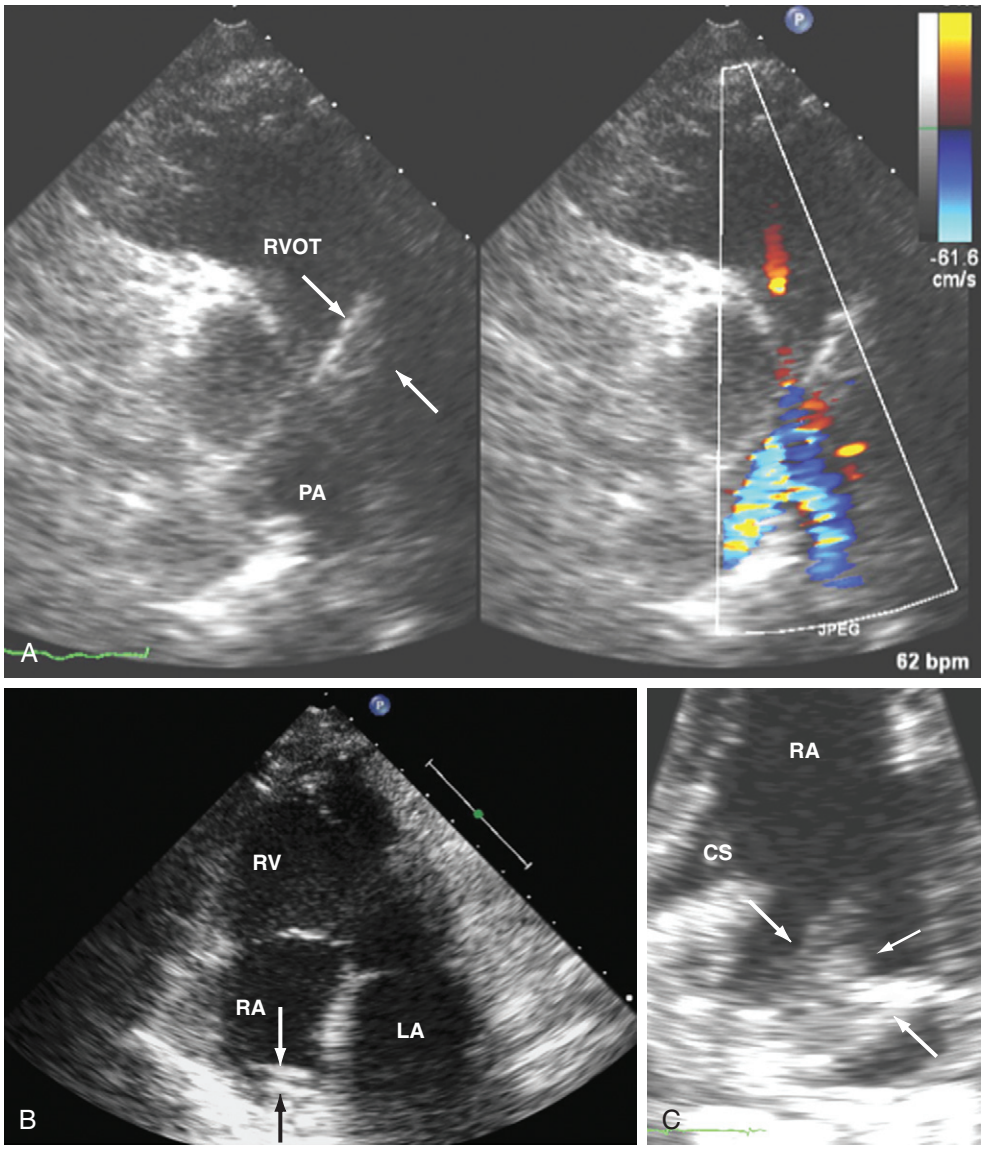

**Figure 31-12** **Imaging the right ventricular assist device (RVAD) cannulae. A,** The RVAD outflow cannula is often well seen in short-axis view in proximal main pulmonary artery (*PA*). *Large arrows, left*: Sides of cannula. *Right*: Color Doppler shows flow from cannula into main PA and left and right PA branches. Minimal pulmonic valve regurgitation is seen. **B,** RVAD inflow cannula is inserted into RA and is usually in far field by TTE (*large arrow*). **C,** Zoomed view of cannula from parasternal tricuspid inflow view demonstrates thrombus (*small arrow*) obstructing central lumen of cannula (sides denoted by *large arrows*). *CS*, Coronary sinus; *RVOT*, right ventricular outflow tract.

### WEANING/TURNDOWN

Before cardiac assist device explant, weaning is usually necessary to demonstrate the impact of reduced VAD support on cardiac structure and function. Protocols differ but generally involve echocardiography with or without invasive arterial and venous pressure monitoring. VAD support is decreased gradually, to avoid acute decompensation. Figure 31-14 provides an overview of echocardiographic parameters used during "turndown." If the results are favorable after turndown to minimal levels of support, some protocols call for exercise or dobutamine stress testing. Sometimes oxygen consumption measurement is added. Echocardiographic imaging at peak exercise is facilitated with supine bicycle stress. There may be adequate cardiac reserve to support the patient after LVAD explants if the LVEF improves, the aortic valve opens more, and stroke volume increases in response to dobutamine.[84]

Echocardiographic RVAD weaning protocols are less well described. As RVAD flows are decreased, RV failure or recovery may be predicted by central venous pressure, RV function, LV filling pressures, and tricuspid regurgitation.[23]

## Clinical Utility, Outcome Data

Echocardiography plays a major role in guiding care of VAD patients, but there are few outcome studies specifically evaluating the clinical utility of echocardiographic techniques.

Specific preimplant echocardiographic indices of RV structure and function have been reported to predict RV dysfunction post LVAD implant. (See Box 31-2.) However, only a few studies comprehensively evaluated echocardiographic techniques. Different studies tested different parameters, and most studies represent only single-center experiences.[32,35,85-87]

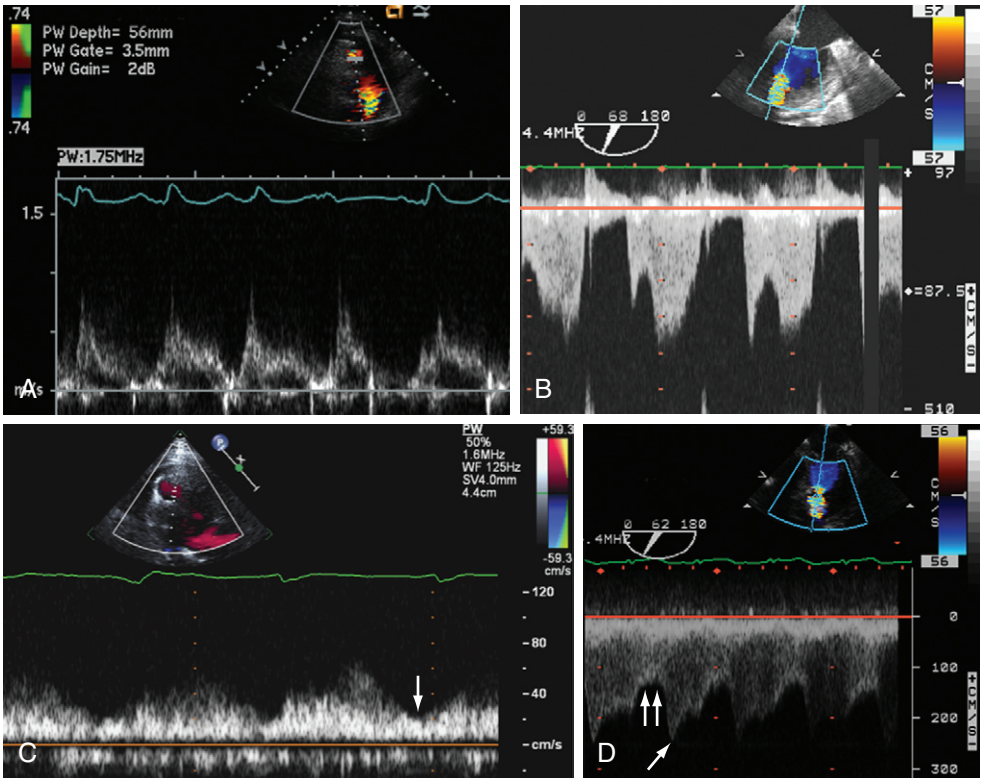

**Figure 31-13 VAD Doppler profiles.** **A,** Normal pulsatile left ventricular assist device (LVAD) inflow by PW Doppler (abnormal peak velocities >2.3 m/s). **B,** Elevated pulsatile LVAD inflow velocities by TEE (CW Doppler peak velocity measured at 3.5 m/s). **C,** Normal continuous LVAD inflow by PW Doppler. Peak velocities are 0.7 m/s, well below 2 m/s. Note continuous "background" flow during diastole (*arrow*). **D,** Increased continuous LVAD inflow velocities by TEE. *Single arrow*: CW Doppler peak velocity of 2.5 m/s. *Double arrows* show that "background" flow is also elevated at 1.3 m/s, suggesting inflow cannula obstruction.

**TABLE 31-4 Doppler Formulae for Ventricular Assist Device Flow Volumes**

| *Formulae* | *Measurements* |
|---|---|
| **Pulsatile VAD ($VAD_p$) stroke volume (SV)**<br>$SV_{VADp} = \pi(D_{can}/2)^2 \times VTI_{can}$ | $D_{can}$ = cannula diameter (usually 12-25 mm)<br>$VTI_{can}$ = VTI of the PW Doppler signal measured just within the cannula orifice |
| **Continuous flow LVAD ($VAD_c$)**<br>$SV_{VADc} = (\pi(D_{RVOT}/2)^2 \times VTI_{RVOT}) - (\pi(D_{LVOT}/2)^2 \times VTI_{LVOT})$ | $D_{RVOT}$ = RV outflow tract diameter<br>$VTI_{RVOT}$ = RV outflow tract VTI<br>$D_{LVOT}$ = LV outflow tract diameter<br>$VTI_{LVOT}$ = LV outflow tract VTI |
| $SV_{VADc} = VTI_{can3sec} \times 20 \times \pi(D_{can}/2)^2 \times C$ | C = correction factor for inflow cannula = (0.67)<br>$VTI_{can3sec}$ = 3 second tracing of VTI continuous flow in the VAD cannula |
| **Pulsatile VAD regurgitant volume (RV)**<br>$RV_{VADp} = (\pi(D_{IN}/2)^2 \times VTI_{IN}) - (\pi(D_{OUT}/2)^2 \times VTI_{OUT})$ | $VTI_{IN}$ = inflow cannula VTI<br>$VTI_{OUT}$ = outflow cannula VTI<br>$D_{OUT}$ = outflow cannula diameter<br>$D_{IN}$ = inflow cannula diameter |
| **Continuous flow VAD regurgitant volume (RV)**<br>$RV_{VADc} = (\pi(D_{asc}/2)^2 \times VTI_{asc}) - (\pi(D_{PA}/2)^2 \times VTI_{PA})$ | $D_{asc}$ = ascending aorta diameter<br>$D_{PA}$ = pulmonary artery diameter<br>$VTI_{asc}$ = ascending aorta VTI above the outflow cannula<br>$VTI_{PA}$ = pulmonary artery VTI |

*VTI*, Velocity time integral.

Even fewer studies have examined postimplant RV function and its effects on clinical parameters. Maeder and colleagues[38] showed that reduced mortality and improved renal function was associated with improved RV function after LVAD implant. Lam and co-workers[88] reported that a greater than 10% reduction in RV fractional area change postimplant portended worse quality of life and exercise capacity. Simon and associates[89] found that postimplant RV function was associated with lower maximum oxygen consumption.

Most of the studies investigating the use of echocardiographic measures to predict successful LVAD explant involve pulsatile devices.[90] An LVEDD less than 5.5 cm with LVEF greater than 45% at baseline (before turndown) predicted LV recovery in one study, with 87.5% of these patients exhibiting more than 5 years of "cardiac stability."[91] The peak systolic wall motion velocities by tissue Doppler imaging (Sm greater than or equal to 8) in both radial and longitudinal directions at the basal inferolateral wall also predicted recovery. A 2010 study from the same group reported 5-year survival free of heart-failure events was 92% for patients with an LVEF of at least 50% and 79% for those with an ejection fraction of 45% or more during "pump off" echocardiography.[92] Initial work has suggested that LVAD patients who respond favorably to exercise or dobutamine experience ventricular recovery allowing VAD explant.[84]

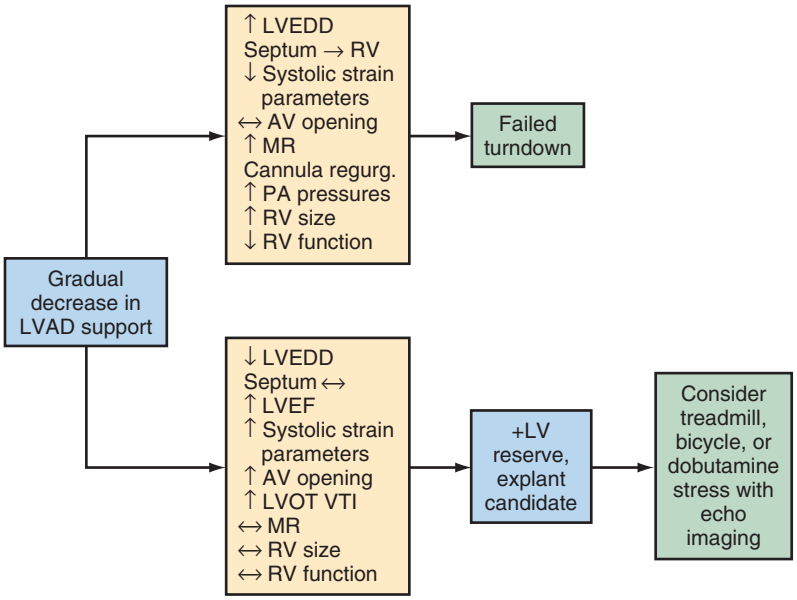

**Figure 31-14 LVAD weaning.** This flow chart outlines the echocardiographic parameters which can be used to determine whether a patient has experienced LV recovery and may be a candidate for device explant. The same parameters used during the "turndown" phase can be assessed during exercise or dobutamine stress, including LVEDD, septal orientation, LVEF, AV opening, LVOT VTI, degree of MR and RV size and function. Little data exists on the ability of any specific measures, but these parameters may form the basis for a "turndown score" to predict which patients are likely to be successfully explanted. *AV*, Aortic valve; *LVEDD*, left ventricular end-diastolic diameter; *LVEF*, left ventricular ejection fraction; *LVOT*, left ventricular outflow tract; *MR*, mitral regurgitation; *PA*, pulmonary artery; *VTI*, velocity-time integral.

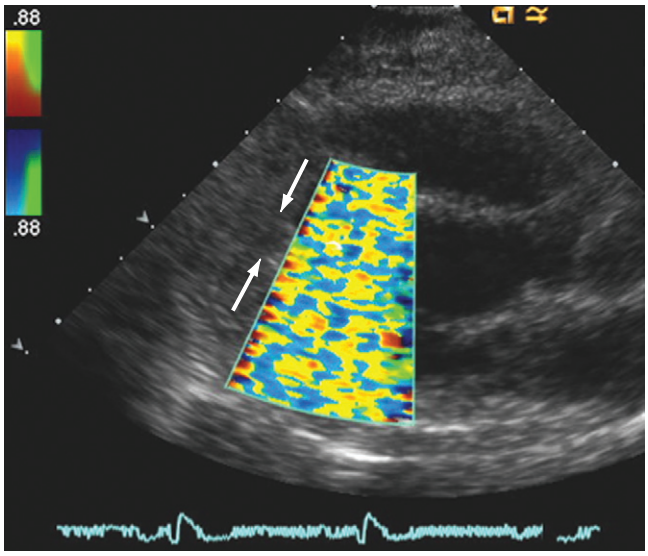

**Figure 31-15 Doppler artifact.** Ventricular assist devices with continuous-flow pumps located close to the heart (Jarvik 2000, HeartWare, Duraheart see Table 31-2) create Doppler artifacts, seen here filling entire Doppler sector in parasternal long-axis view. Artifact is located in mid-LV and precludes any assessment of flow into or out of inflow cannula (sides denoted by *large arrows*).

## Potential Limitations, Future Directions

Echocardiographic imaging is complicated in the postimplant state, when bandages, mechanical ventilation, and patient positioning compromise imaging windows. In addition to the attenuation artifacts created by LVAD inflow cannulae, significant artifacts are caused by continuous-flow rotor devices. VADs with continuous-flow pumps located very close to or in the inflow cannula (see Table 31-2) create Doppler distortion artifacts due to ultrasonic signals produced by the rotating propeller or disk (Fig. 31-15). It is possible to avoid Doppler sampling near the device and thus interrogate other cardiac structures with color and spectral Doppler. But inflow cannulae cannot be assessed for color aliasing or regurgitation, and cannula velocities cannot be measured.

Cannula orientation, orifice location, and proximity to ventricular structures are not always clear from 2D imaging planes. Real-time three-dimensional (3D) echocardiography may play a role in more precisely defining cannula position. 3D images of the LVAD inflow cannula and outflow cannulae are obtained from the midesophageal position (Fig. 31-16). 3D TEE also provides the best images of cannulae placed in the right and left atria. Real-time 3D imaging may facilitate visualization of the entire Impella Recover cannula, which tends to traverse 2D imaging planes. Real-time 3D echocardiography may also provide an assessment of RV size and function that accurately predicts which patients will experience RV failure after implant.[93]

Aortic stenosis from cusp fusion or degenerative disease is difficult to assess in the setting of an LVAD, because there is usually little flow through the valve. Detection and measurement of aortic stenosis requires a turndown procedure to elicit a greater degree of aortic valve opening. If increased preload fails to augment cardiac output, and the aortic valve opening remains reduced, dobutamine can be infused to attempt to stimulate cardiac output, as in the assessment of low-gradient aortic stenosis. Improvement in LV function without increased aortic valve opening signals cusp fusion (and should accompany increased flow through the LVAD).

Diastolic function is not well defined following cardiac assist device placement. Doppler inflow measures (E and A velocities), tissue Doppler relaxation velocities, and propagation velocity will be influenced by the LVAD inflow. A pulsatile LVAD in asynchronous mode and continuous-flow VADs draw blood to the LV apex independent of ventricular relaxation.

Although a favorable response to exercise and dobutamine stress testing may portend recovery to explant, a more precise and load-independent measure of intrinsic myocardial reserve is needed. Measures of myocardial deformation, including strain and strain rate, may provide a better way to predict recovery. Isovolumic acceleration measured by tissue Doppler or speckle tracking may also prove valuable[94] (see Chapter 10). Measures of myocardial deformation of the RV before LVAD implant may also improve the ability to predict which patients will require an RVAD.

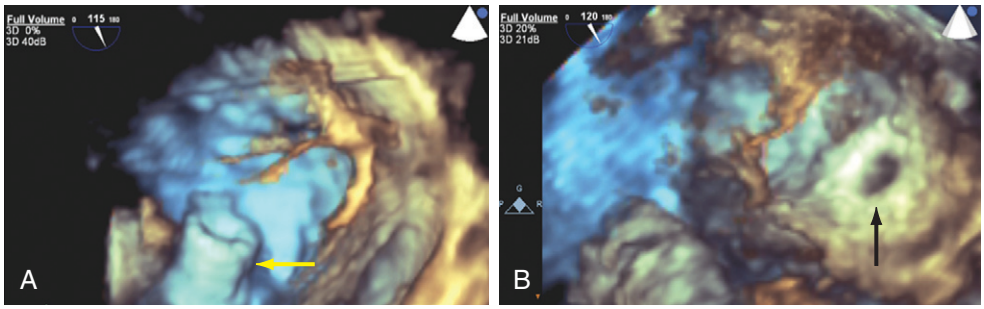

**Figure 31-16 3D imaging of LVAD cannulae. A,** Real-time 3D TEE in midesophageal position demonstrates normal positioning of inflow cannula (*arrow*) in LV apex (3D data set rotated to look inferiorly and posteriorly from anterior perspective). Orifice is unobstructed by any cardiac structures. **B,** Real-time 3D TEE in upper midesophageal position shows orifice of outflow graft cannula (*arrow*), as viewed from inside proximal ascending aorta. In contrast to inflow cannula, outflow graft cannula is anastomosed end-to-side to aorta.

## Alternate Approaches

Cardiac magnetic resonance imaging (MRI) provides highly accurate measures of ventricular volumes and function. In addition, MRI accurately measures RV size and function, potentially improving prediction of RV function post implant.[95] MRI can also accurately image the aorta and define pitfalls to Impella Recover and outflow cannula placement.[96] However, MRI cannot be used with current-generation VADs after implant.

Computed tomography (CT) can be used postimplant. Initial studies suggest a high sensitivity and specificity for the detection of cannula thrombosis and inflow cannula malposition.[97,98] Most cannulae do not cause significant CT artifact, and direct visualization of cannula orientation is easily achieved from data sets. The entire length of cannulae can be examined. CT also provides excellent preimplant imaging of the aorta.[99] The downsides to CT include radiation and nephrotoxicity of contrast—a concern in VAD patients, who often have compromised renal function.

Although preliminary studies suggest that Doppler-based estimation of pulmonary pressures and pulmonary vascular resistance is valid post-LVAD implant, validation in larger numbers of patients is needed. In the meantime, invasive measures of intracardiac hemodynamics may be necessary to establish accurate filling pressures, cardiac output, and pulmonary vascular resistance to guide therapy. Invasive hemodynamic measurements may also be necessary to assess the severity of valvular lesions, especially when echocardiographic images are limited.

### KEY POINTS

- Echocardiographic imaging and interpretation must take into account the type of cardiac assist device (e.g., LVAD, RVAD, BiVAD, percutaneous VAD, total artificial heart), location of cannulation sites (e.g., LV apex, ascending aorta), mechanism of action (pulsatile versus continuous-flow pumps), and settings (e.g., flows, rpm).
- Echocardiography plays a role before cardiac assist device implant to establish candidacy and identify specific obstacles to device placement, including thrombi, intracardiac shunts, aortic regurgitation, and RV dysfunction.
- During implant procedures, echocardiography guides device placement and deairing.
- After implant, echocardiography identifies causes and effects of cardiac assist device dysfunction including overfilling, underfilling inflow cannula obstruction, and valvulopathy.
- Optimization of cardiac assist device settings and monitoring of cardiac function during weaning/turndown studies involves 2D and Doppler assessments of LV diastolic dimensions and septal position, aortic valve opening, ventricular function, and mitral regurgitation.
- VAD stroke volumes can be calculated from cannula cross-sectional areas and pulsed Doppler VTI measurements at the cannula orifice.
- Preliminary work suggests that Doppler estimates of pulmonary pressures in cardiac assist device patients correlate with clinical outcomes.
- Real-time 3D echocardiography may overcome some of the limitations of cannula assessment by 2D echocardiography.
- CT shows promise in imaging cardiac assist device cannulae.

The right ventricle (RV) plays an important role in the maintenance of normal circulatory function, and its assessment is valuable in a wide variety of cardiopulmonary diseases. However, clinical assessment of the RV has lagged behind that of other portions of the echocardiographic examination for several reasons—intense clinical focus on the left heart, historical lack of awareness of the clinical importance of RV function, the irregular shape of the RV, and a paucity of normative data.

Although practical challenges in assessment of the right heart persist, significant progress has been made, including generation of higher-quality normative data, validation of two-dimensional (2D) and Doppler measurements, and continued improvements in three-dimensional (3D) techniques. A guideline statement from the American Society of Echocardiography (ASE) dedicated solely to the assessment of the right heart was published in early 2010, highlighting these advances and underscoring the need for increased clinical attention to the right heart.

This chapter addresses the echocardiographic evaluation of right heart function, with attention to the value and limitations of objective measurements of RV size and function. The integration of echocardiographic findings into the diagnosis and treatment of specific disorders is discussed in greater detail in Chapters 33 (Echocardiographic Evaluation of the Patient with Pulmonary Hypertension) and 34 (Right-Sided Valve Disease in Adults).

## Right Heart Anatomy and Physiology

The right atrium (RA) forms the right heart border, lying superior, posterior, and rightward of the RV. The RA drains the superior vena cava superoposteriorly, the inferior vena cava (IVC) inferiorly, and the coronary sinus posteriorly, with the coronary sinus ostium between the IVC and the tricuspid valve annulus. The interatrial septum forms the posteromedial wall of the RA and contains the fossa ovalis lying between the caval orifices.

The tricuspid valve normally inserts on the septum approximately 2 mm more apical than the mitral valve. More apical insertion of the tricuspid valve may indicate Ebstein malformation, whereas insertion of the tricuspid valve at the same level as the mitral valve may be seen in atrioventricular canal defects. Each of the three tricuspid valve leaflets receives chordae from two of the three papillary muscles. The anterior papillary muscle is the largest of the three, arising from the anterior RV and fused with the moderator band. The posterior and septal papillary muscles are often multifid.

The RV forms the majority of the anterior and inferior borders of the heart and comprises two embryologically distinct regions, the inflow (sinus) portion and a funnel-shaped outflow portion—the conus or infundibulum (Fig. 32-1). The body of the RV is formed by the free wall and interventricular septum. The normal interventricular septum is convex toward the RV cavity, imparting a crescentic shape to the RV in short-axis views.

Unlike the left ventricle (LV), the RV is heavily trabeculated. A moderator band is present in approximately 75% of patients,[1] spanning the interventricular septum and the anterior free wall. The moderator band and tricuspid valve are always contained by the RV and may help distinguish the morphologic RV in patients with complex congenital heart disease.

The inflow and outflow portions of the RV are separated by the crista supraventricularis, a U-shaped muscular ridge that originates at the tricuspid annulus, extends to the interventricular septum, and bridges across the RV cavity by way of the moderator band to attach to the anterior wall of the RV and anterior papillary muscle. The crista functions as a contractile strut, transmitting septal contraction to the RV free wall—one

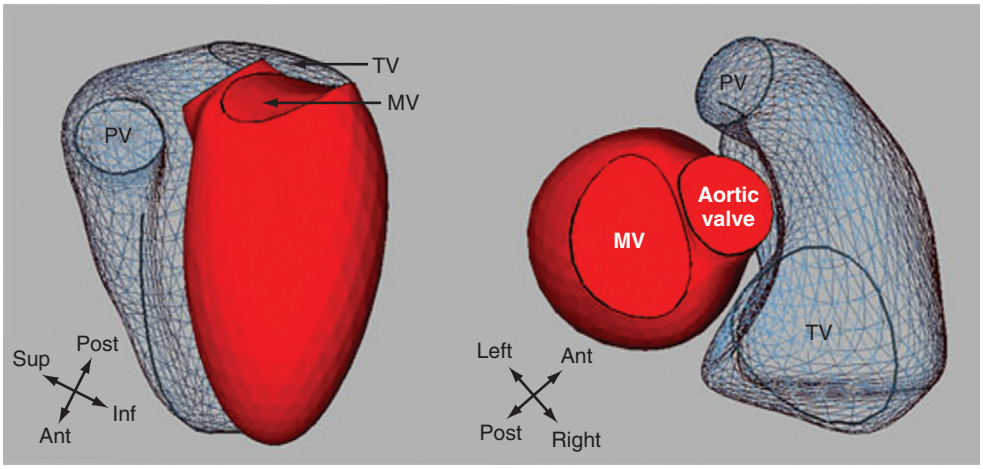

**Figure 32-1 Anatomy of normal RV.** *Left*: Left lateral view. *Right*: Basal view. Endocardial surfaces generated by reconstruction using 3D echocardiography and knowledge-based reconstruction. Hollow mesh is RV endocardial surface; solid red that of LV. RV is crescentic in short-axis section, with tricuspid and pulmonic valve orifices widely separated by crista supraventricularis. *Ant*, Anterior; *Inf*, inferior; *MV*, mitral valve; *Post*, posterior; *PV*, pulmonic valve; *Sup*, superior; *TV*, tricuspid valve. *(Images courtesy Dr. Florence H. Sheehan, University of Washington Cardiovascular Research and Training Center.)*

of many forms of ventricular interdependence. Via the crista, LV contraction narrows the tricuspid valve annulus and pulls the RV free wall toward the septum, promoting tricuspid valve competence and RV contraction. LV contraction normally accounts for an estimated 30% of pressure generation in the RV through the transmission of systolic forces from the LV to the RV.[2] Even an akinetic RV will generate some intracavitary systolic pressure as the LV "pulls" the RV free wall toward the septum. Experimental animal studies showed that damage to the RV alone did not alter central venous or systemic arterial pressure, but when a portion of the LV was also damaged via cautery, the animals rapidly succumbed to shock.[3]

The right coronary artery supplies the vast majority of the RV free wall (Fig. 32-2). A small anterior portion of the RV apex and the moderator band are supplied by the left anterior descending coronary artery, the latter via the moderator band artery, which arises from the first septal branch of the left anterior descending artery. In fewer than 10% of hearts, posterolateral branches of the left circumflex coronary artery supply a portion of the posterior RV free wall. The conus artery, arising from a separate coronary ostium in 30% of cases, supplies the infundibulum. Although coronary blood flow to the LV occurs predominantly in diastole, RV coronary blood flow occurs equally in systole and diastole because of lower intramural systolic pressure.[4] RV myocardial oxygen demand is much lower than that of the LV because of lower stroke work. Thus, the RV is far more tolerant of ischemia, and recovery of RV function following RV infarction is the rule rather than the exception. However, in the presence of pulmonary hypertension and RV hypertrophy, RV coronary flow becomes diastole-predominant[5] in like fashion to the LV and is much less tolerant of ischemia.[6]

Absent shunt, the RV generates the same stroke volume as the LV, but with one sixth the muscle mass. This is possible because of the low resistance of the pulmonary arterial vasculature. Because the normal RV is slightly larger than the LV, RV ejection fraction (EF) is normally lower than LV EF, typically between 45% and 70%.[7]

The pulmonary arterial vasculature consists of relatively thin and distensible large arteries without well-developed arterioles. Functionally, this translates to a pulse pressure that is one half, a mean arterial pressure that is one sixth, and vascular resistance one tenth that of the systemic circulation. In health, a transpulmonary gradient of only 5 mm Hg drives blood across the pulmonary circulation. Isovolumic RV contraction is brief compared to the LV,[8,9] and pulmonary artery flow continues throughout systole despite falling RV systolic pressure (the "hangout" period), due to blood inertia created by early RV ejection into a low-resistance vascular bed.

RV contraction is peristaltic, with initial activation of the RV inflow region followed in 30 to 40 ms by contraction of the conus region. Conus contraction contributes less than 15% of RV SV.[10] Whereas the LV shortens symmetrically in the transverse and longitudinal planes, normal RV contraction appears principally due to longitudinal shortening.[11] RV longitudinal shortening closely correlates with RV EF, whereas transverse RV shortening does not.[12] Similarly, longitudinal stroke work correlates with global RV stroke work, whereas circumferential regional RV stroke work does not.[13] Thus, normal RV contraction perhaps more closely resembles a piston than a bellows, which has important implications for strategies for quantifying RV systolic function noninvasively. However, chronic RV pressure or volume overload may result in relative hyperplasia of circumferential fibers[14]; in such chronically diseased RVs, circumferential contraction and free wall translation may have a greater relative contribution to systolic function.[15]

Diastolic function of the RV differs from that of the LV. The thin walls of the RV and its concave interventricular septum are relatively distensible, imparting high compliance to the RV (large changes in RV volume with only small changes in RV diastolic pressure). Thus, the RV may dilate significantly in response to acute pressure or volume overload, unlike the LV.

## Basic Principles and Echocardiographic Approach

### BASIC APPROACH TO ASSESSMENT OF THE RIGHT HEART

The complex shape of the RV makes assessment of its size and function difficult by any method, whether objective or subjective. Early studies estimated RV volume by modeling the RV as

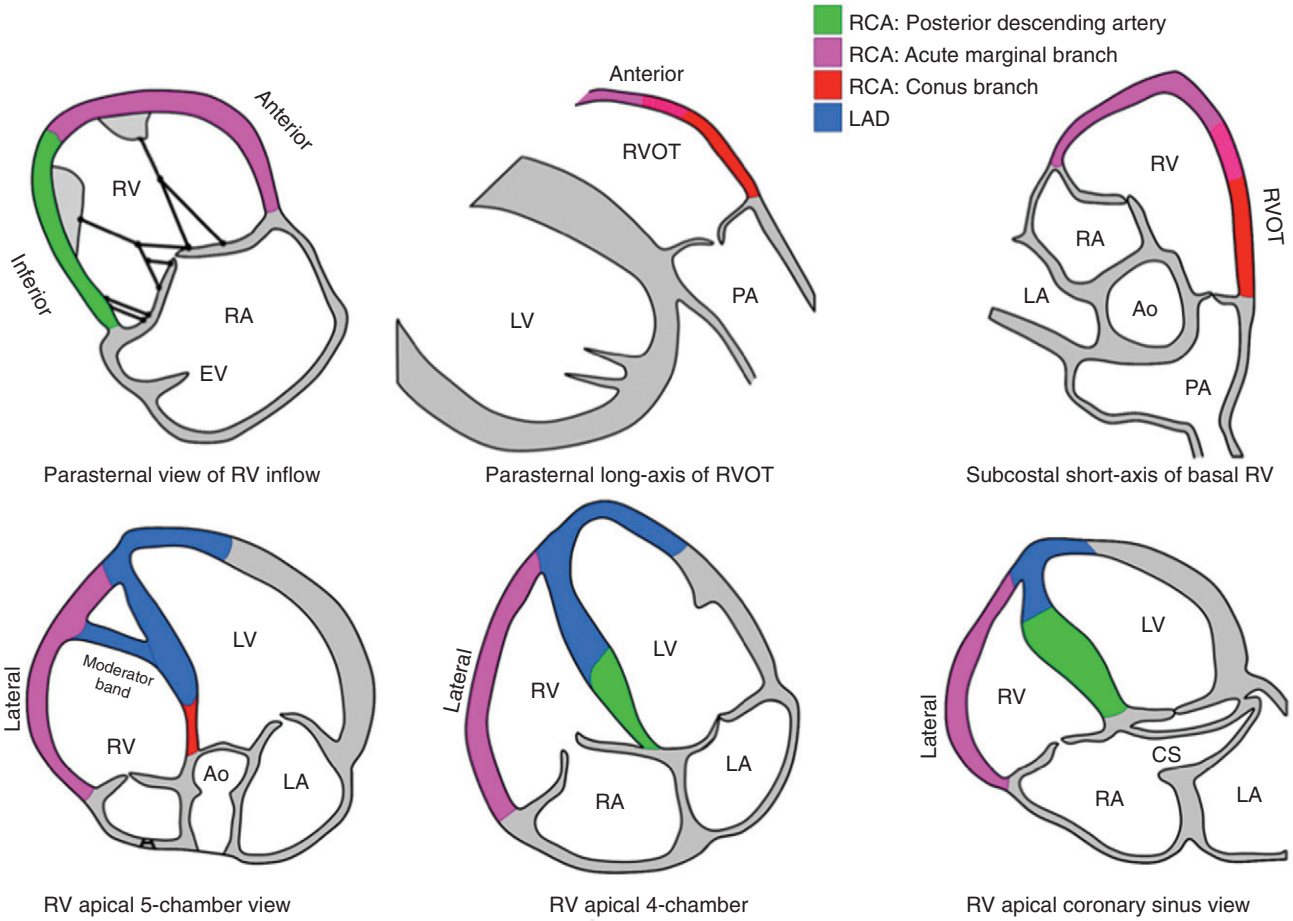

**Figure 32-2 Coronary supply of RV.** *Ao*, Aorta; *CS*, coronary sinus; *EV*, Eustachian valve; *LAD*, left anterior descending coronary artery; *PA*, pulmonary artery; *RCA*, right coronary artery; *RVOT*, right ventricular outflow tract. *(From Rudski LG, Lai WW, Afilalo J, et al: Guidelines for the echocardiographic assessment of the right heart in adults: a report from the American Society of Echocardiography endorsed by the European Association of Echocardiography, a registered branch of the European Society of Cardiology, and the Canadian Society of Echocardiography.* J Am Soc Echocardiogr *23:685-713, 2010.)*

a sum of prisms, with disk summation, or with area-length methods.[16] In brief, 2D methods of RV volume estimation are limited by geometric assumptions, resulting in only modest correlation with angiography and water displacement and significant underestimation of volumes compared to both 3D echocardiography and cardiac magnetic resonance imaging (MRI).[17] Thus, 2D-derived RV volumes and EF are not recommended for clinical use and are fading as a reference standard in research.

3D methods obviate geometric assumptions and are superior to 2D echocardiography for estimation of RV volumes and EF, but they are not yet routinely available in the community. Despite its limitations, 2D echocardiography therefore remains the principal clinical modality for assessment of the RV. Rather than attempting to calculate RV volume or EF from linear or area measurements, the clinician should compare 2D-derived measurements directly against normative values. These measurements should be considered together with visual estimation when classifying RV size and function. Because the RV lacks rotational symmetry and may remodel nonuniformly, individual 2D-derived indices of RV size may correlate poorly with RV volume, and multiple measurements should be taken when possible.

## TRANSTHORACIC IMAGING

Because RV dilation may occur regionally as well as globally, assessment of RV size requires visualization from multiple windows.

The apical four-chamber view is critical for assessment of the RV, providing the basal minor dimension (measured just apical to the tricuspid annulus, normal less than 42 mm; Fig. 32-3, *left* panel), and most 2D measures of RV systolic function: tricuspid annular plane systolic excursion (TAPSE), systolic tricuspid annular velocity (S′), fractional area change, and tissue right ventricular myocardial performance index. Most of these measurements rely heavily on good visualization of the RV free wall and lateral tricuspid annulus. If necessary, dedicated RV-focused apical four-chamber views should be obtained to ensure that the RV free wall and tricuspid annulus are well seen, away from the margin of the sector, and not shadowed. Anterior angulation or slight medial or lateral displacement of the transducer should be performed to allow this, though care must be taken to maintain a true four-chamber view (i.e., containing the crux and the true cardiac apex) to avoid misrepresenting RV size. If LV size is normal, RV size may be subjectively assessed using the ratio of RV to LV area: less than 0.66 is normal; 1.0 suggests at least moderate enlargement (Fig. 32-4). The RV apex may

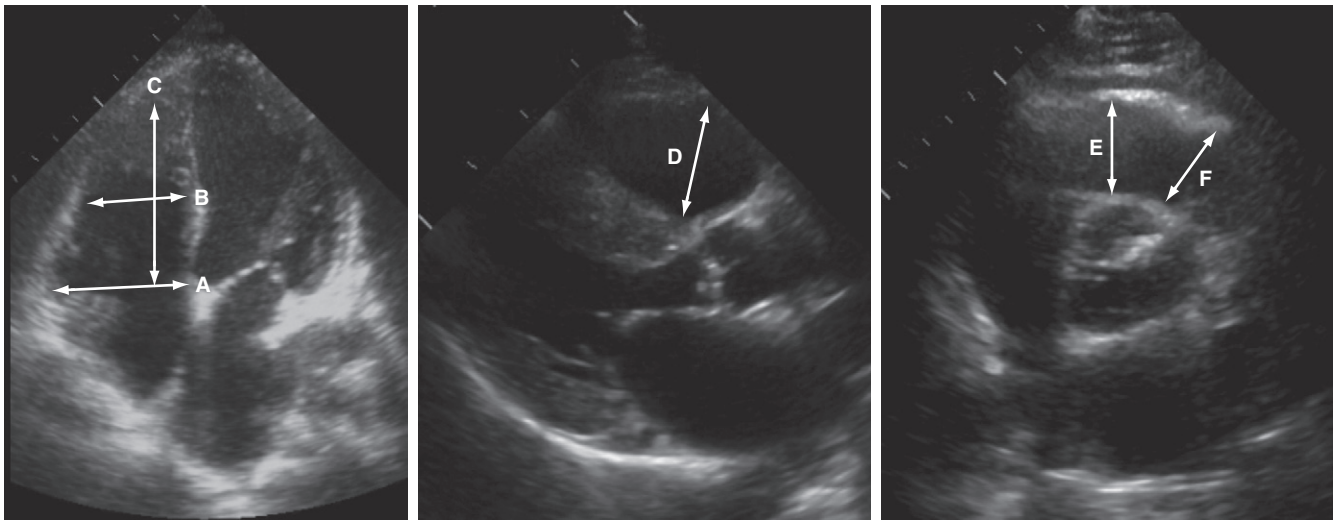

**Figure 32-3 Recommended parameters of RV size.** *Left*: Apical four-chamber view. *Center*: parasternal long-axis view. *Right*: parasternal short-axis view. *A*, Basal minor dimension; *B*, mid-cavity minor dimension; *C*, RV major (longitudinal) dimension; *D*, RVOT proximal diameter; *E*, RVOT proximal diameter; *F*, RVOT distal diameter; *RVOT*, right ventricular outflow tract.

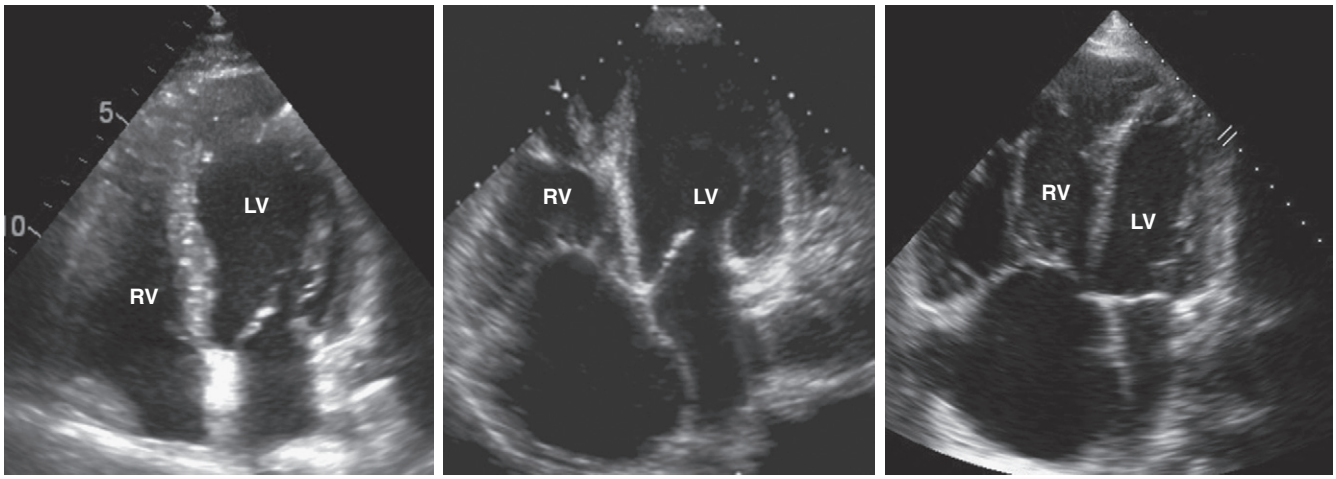

**Figure 32-4 Relative size of RV (compared to LV) in varying degrees of RV enlargement.** *Left*: Normal heart, ratio of RV area to LV area (RV:LV) approximately 0.6. *Center*: Moderate RV dilation; in this case, LV is dilated, and RV:LV is relatively low for the degree of absolute RV dilation at about 0.7-0.8. *Right*: Severe RV dilation, with RV:LV >1.5 and the RV is apex-forming.

appear "squared" if the RV is enlarged and may displace the LV to form the true apex if enlargement is severe.

If apical images are poor, the subcostal window may provide similar views of the RV (e.g., four-chamber and short-axis; Fig. 32-5). However, the difficulty in defining the anteroposterior plane needed to achieve a true four-chamber view from the subcostal window may result in foreshortening of the RV. RV wall thickness is best measured in the subcostal view, because the RV free wall is not in the near field (as in parasternal views) and is perpendicular to the ultrasound beam. The normal RV free wall is 2 mm thick, but a wall thickness of less than 5 mm is accepted as normal, because the RV free wall often cannot be resolved from the epicardium.[18,19]

The parasternal long-axis right ventricular outflow tract (RVOT) dimension is normally less than 60% of the LV dimension, but should be interpreted with care if obtained in supine position, as it can differ by up to 40% in the supine and left lateral decubitus positions. The parasternal RV inflow view shows more of the RV free wall and the anterior and posterior leaflets (the only standard view in which the posterior leaflet is

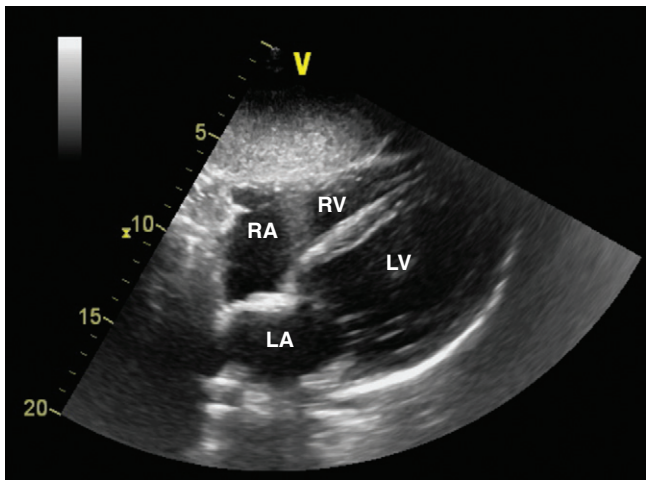

**Figure 32-5 Subcostal four-chamber view.**

seen), but the imaging plane can be highly variable and is unreliable for assessing systolic function. Although tricuspid regurgitation (TR) may be seen, the maximum jet velocity is not commonly obtained in parasternal views.

The basal parasternal short-axis view allows reliable measurement of the distal RVOT diameter (see Fig. 32-3, *right* panel). Parasternal short-axis views of the RV at midventricular levels may show septal flattening, which suggests volume overload if diastolic, pressure overload if systolic, and both if continuously present. However, beyond septal contour, the midventricular short-axis view is not reliable for assessment of RV size or systolic function, because cross-sectional area varies dramatically with the level of the short-axis plane, and the paucity of reference structures makes it difficult to reproduce planes from one study to another.

The basal short-axis view gives the best alignment for pulmonic valve velocity measurements, with trace or mild pulmonic regurgitation in most normal patients.[20] M-mode of the pulmonic valve may show notching of systolic leaflet excursion (the "flying W") in pulmonary hypertension due to a pressure wave reflected by the stiffened, abnormal pulmonary arterial bed, but specificity is limited, because this finding has also been described in pulmonary artery dilation with normal pulmonary artery pressures.[21] The spectral envelope of the pulmonary artery outflow is characteristically symmetric with a peak velocity of less than 0.8 m/s.[22] High-output states such as pregnancy, anemia, and cirrhosis may increase the velocity somewhat, but if peak velocity exceeds 1.2 m/s, pulmonic stenosis or left-to-right shunt should be suspected.

## ESTIMATION OF RIGHT HEART PRESSURES

Right atrial pressure (RAP) may be estimated echocardiographically.[23] The scheme most commonly used in clinical practice assesses the diameter of the IVC while the patient performs a "sniff" (Table 32-1). Normally, the IVC collapses as the intrathoracic pressure decreases. However, with elevated RAP, the IVC dilates and inspiratory collapse is less complete. Positive pressure ventilation makes the sniff method unreliable by altering the relationship between central venous pressure and IVC size.[24] If the IVC is poorly visualized and RA size is normal (end-systolic area 18 $cm^2$ or less), one may infer a normal RAP of 5 mm Hg. Errors made in estimation of RAP are propagated to echocardiographically calculated pulmonary artery pressures. This must be remembered especially in "torrential" TR, in which RAP may exceed 20 mm Hg by a considerable amount, leading to an underestimate of pulmonary artery pressure if 20 mm Hg is the maximum value used.

Absent pulmonic stenosis, pulmonary artery systolic pressure (PASP) may be estimated by the simplified Bernoulli equation[25]: $PASP = 4v^2_{TR} + RAP$, where $v_{TR}$ is the peak velocity of the TR jet by continuous-wave (CW) Doppler. When performed properly, this technique is highly reproducible and correlates closely with invasively derived PASP.[25-29] If pulmonic stenosis is present, peak pulmonary artery pressure may still be estimated by subtracting the gradient across the pulmonic valve from the peak RV systolic pressure. Pulmonary artery diastolic pressure (PADP) may be similarly be estimated: $PADP = 4v^2_{PR} + RAP$, where $v_{PR}$ is the end-diastolic pulmonary regurgitation velocity.[30] Mean pulmonary artery pressure (mPAP) may then be calculated: $mPAP = (2 \times PASP + PADP)/3$, where PASP and PADP are estimated as before. As with all Doppler-based measurements, interrogation from multiple windows is important to ensure parallel alignment with the TR jet and prevent underestimation of peak velocity and pressure. Only clearly visualized portions of the Doppler envelope should be measured to prevent overestimation of peak velocity (Fig. 32-6).

Invasively derived pulmonary vascular resistance (PVR) may be estimated by PVR (Wood units) $= 10 \times v_{TR}/VTI_{RVOT}$, where $v_{TR}$ is the peak TR jet velocity and $VTI_{RVOT}$ the velocity-time integral of the RVOT. This method may be helpful when it is

**TABLE 32-1 Echocardiographic Estimation of Right Atrial Pressure**

| *IVC Size* | *IVC Respiratory Change* | *RAP (mm Hg)* |
|---|---|---|
| Normal (≤21 mm) | >50% | 5 |
| Normal (≤21 mm) | <50% | 10 |
| Dilated (>21 mm) | >50% | 10 |
| Dilated (>21 mm) | <50% | 15 |
| Dilated (>21 mm) | None | 20 |

*IVC*, Inferior vena cava; *RAP*, right atrial pressure.

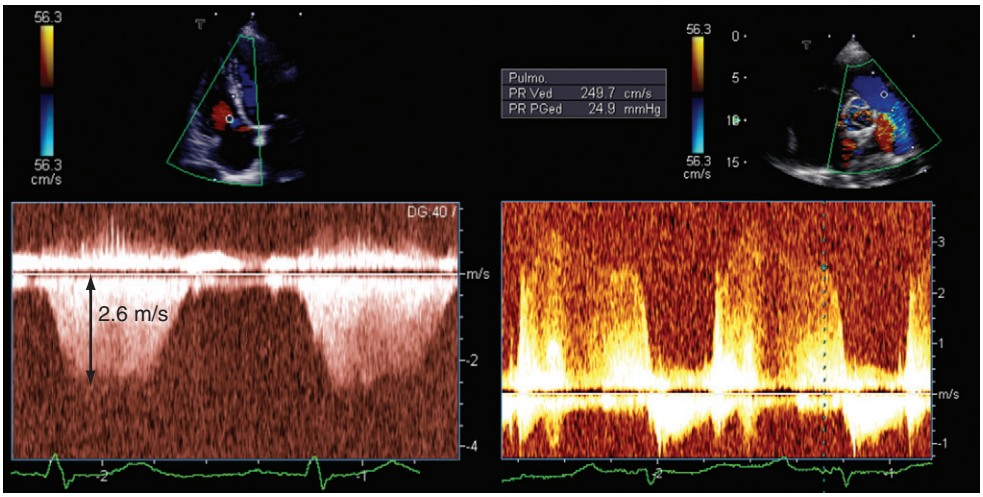

**Figure 32-6 Doppler estimation of pulmonary pressures.** *Left*: CW Doppler spectrum of tricuspid regurgitation, peak velocity 2.6 m/s, indicating systolic PA pressure = 27 mm Hg + RA pressure. Although the spectrum appears incomplete, velocity should not be "extrapolated" along a parabolic path beyond the visualized Doppler signal. *Right*: CW Doppler spectrum of pulmonic regurgitation (from a different patient), end-diastolic velocity 2.5 m/s, indicating PA diastolic pressure = 25 mm Hg + RA pressure. *PA*, Pulmonary artery; *RA*, right atrial.

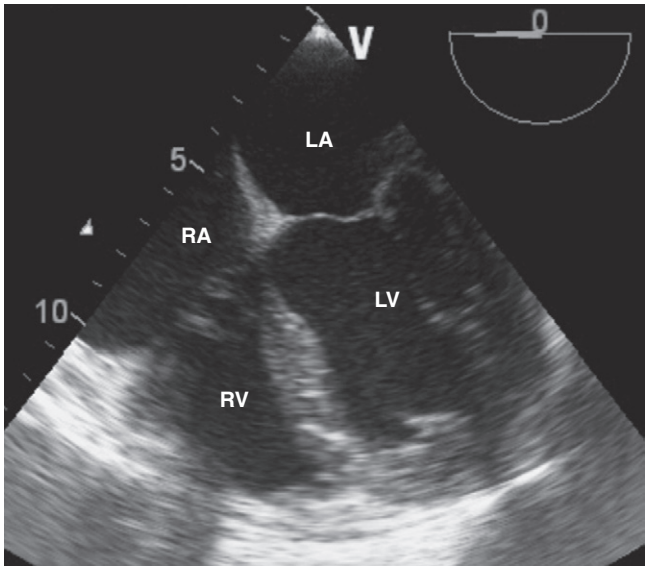

**Figure 32-7 Transesophageal modified four-chamber view.** From a standard four-chamber view, (with the LV apex centered), the transducer is turned towards the patient's right side to better visualize the right ventricle.

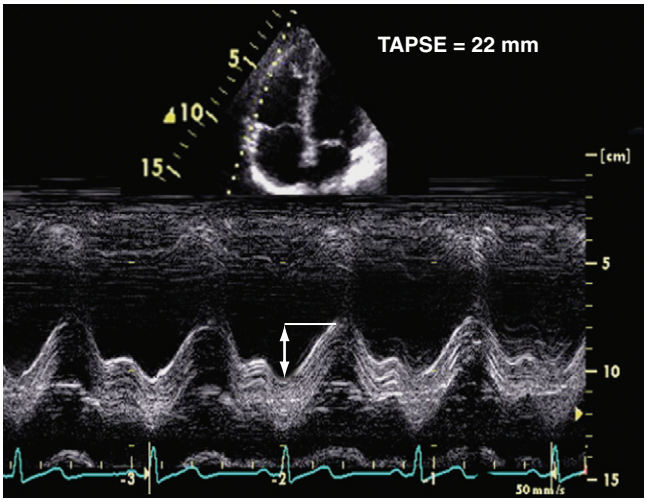

**Figure 32-8 Measurement of tricuspid annular plane systolic excursion (*TAPSE*).** The M-mode cursor is directed through lateral tricuspid annulus; apical view used to guide the cursor is shown at *top* of image.

unclear whether a modestly elevated PASP is due to increased PVR or increased cardiac output; however, it is imprecise, and catheter-derived hemodynamics remains the gold standard for diagnosis and serial clinical observation of clinically significant pulmonary hypertension.

### TRANSESOPHAGEAL IMAGING

The value of transesophageal echocardiography (TEE) in assessment of RV size and function is limited because of constraint of the transducer by the esophagus, and limited RV resolution due to its location in the far field. The modified four-chamber view (midesophageal, 0°; Fig. 32-7) foreshortens the RV considerably. Alignment with the TR jet is also difficult because of constraint of the transducer, making underestimation of the peak velocity common. Assessments of RV size and function and pulmonary artery pressures derived from transesophageal data should be interpreted with caution.

TEE is more useful for assessment of certain causes of RV dysfunction, particularly volume overload (e.g., atrial septal defects, anomalous pulmonary veins). The bicaval view (midesophageal, 90°) demonstrates the interatrial septum with high resolution, allowing interrogation by color Doppler or agitated saline contrast injection. The pulmonic valve and main pulmonary artery can be seen in the basal short-axis view (high esophageal, 60°), though visualization may be suboptimal because of their location in the far field, and the right and left pulmonary arteries are not reliably seen.

## Technical Details, Quantitation, and Data Analysis

### MEASURES OF RIGHT VENTRICULAR SIZE AND FUNCTION

#### *Linear and Area Measurements*

As with LV measurements, right heart chamber areas and dimensions should be traced from endocardium to endocardium. Trabeculations should be contained by traced chamber areas. RV basal dimension should be measured in the apical four-chamber view immediately below the tricuspid valve (see Fig. 32-3, *left* panel). The transducer should be rotated to the plane that maximizes the RV minor dimension, while still containing the LV apex and crux (neither the aortic root nor the coronary sinus should be seen). Proximal RVOT dimension should be measured at the largest anteroposterior dimension in the parasternal long-axis view, and distal RVOT dimension just below the pulmonic valve in the parasternal short-axis view.

#### *Tricuspid Annular Plane Systolic Excursion*

Tricuspid annular plane systolic excursion, sometimes referred to as tricuspid annular motion, is the distance moved by the tricuspid annulus from end-diastole to end-systole. TAPSE is obtained by M-mode in the apical four-chamber view (Fig. 32-8),[31] which is measured in most studies at the lateral annulus. TAPSE is gaining popularity because it is easy to perform, highly reproducible, requires no geometric assumptions, and correlates moderately with RV EF and RV fractional area change in a variety of patient populations.[12,31-33] It can also be obtained even when image quality is relatively poor, and it is relatively well studied and widely employed clinically. However, use of TAPSE as a surrogate for RV systolic function assumes that regional function (longitudinal translation at the tricuspid annulus) reflects global function. TAPSE may be reduced by factors other than RV global systolic dysfunction, including severe TR,[34] LV systolic dysfunction,[35] and prior cardiac surgery[36] or heart transplantation.[37] Severe TR reduces the correlation between TAPSE and RV EF (although the presence of severe TR itself suggests RV systolic dysfunction), whereas LV systolic dysfunction and cardiac surgery may reduce TAPSE independently of RV EF. TAPSE must be interpreted with caution when these conditions are present.

#### *Fractional Area Change*

Fractional area change is defined as [(RV end-diastolic area) – (RV end-systolic area)]/(RV end-diastolic area), obtained in the apical four-chamber view (Fig. 32-9). Fractional area change

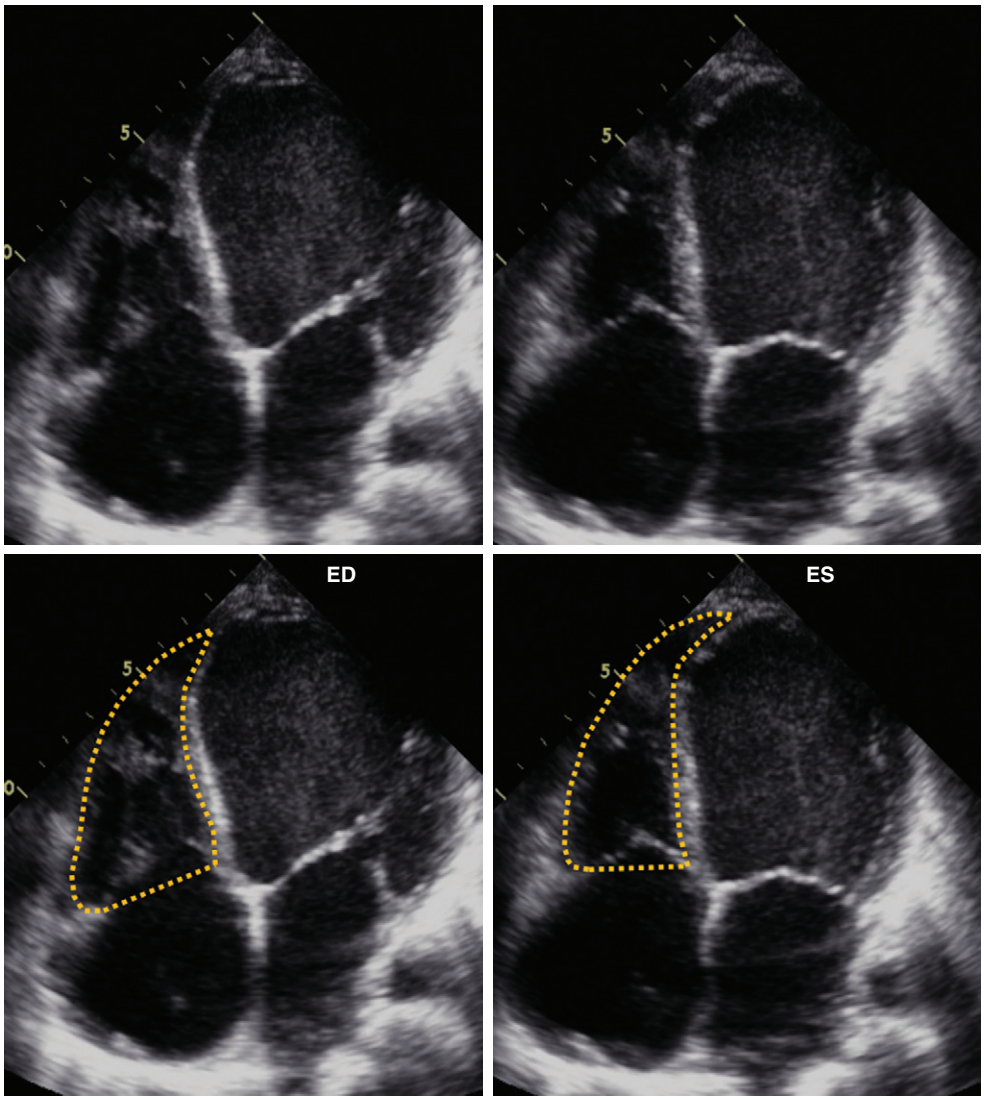

**Figure 32-9 Measurement of fractional area change from apical four-chamber view.** This patient had severe biventricular systolic dysfunction, with an RV fractional area change approximately 25%. *Left*: End-diastole (*ED*); *right*: end-systole (*ES*). *Top set of images* is identical to *bottom*, but shown without tracing to demonstrate location of borders. Trabeculations should be included in traced area.

does not require geometric assumptions and correlates well with RV EF.[38] However, measurement is often hampered by suboptimal endocardial definition, particularly of the RV free wall, and high interobserver and intraobserver variability. Care must be taken to select the true four-chamber view (containing the cardiac apex and the crux) to prevent foreshortening of the RV.

### *Peak Systolic Velocity of the Lateral Tricuspid Annulus*

Like TAPSE, the peak systolic velocity of the lateral tricuspid annulus (S′) reflects basal RV systolic motion. Echocardiographically, S′ is measured from the apical four-chamber view using tissue Doppler (Fig. 32-10), using instrument settings similar to those used for mitral tissue Doppler in assessment of LV diastolic function. S′ correlates with TAPSE[39] and shares most of its strengths and weaknesses: namely, a relatively large body of normative data, freedom from geometric assumptions, measurability in the face of suboptimal image quality, angle dependence, and blindness to systolic dysfunction in parts of the RV remote from the tricuspid annulus.

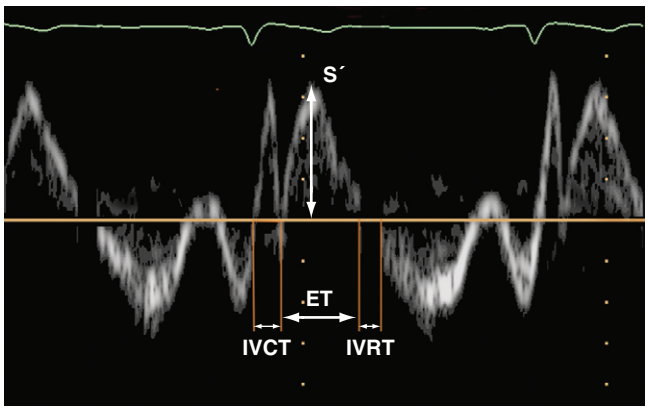

**Figure 32-10 Measurement of RV myocardial performance index.** Tissue Doppler of tricuspid annulus, with measurement of systolic peak velocity (*S′*) and elements of tissue-Doppler right index of myocardial performance. *ET*, Ejection time; *IVCT*, isovolumic contraction time; *IVRT*, isovolumic relaxation time.

### *Right Index of Myocardial Performance*

The myocardial performance index, also known as the Tei index or right ventricular myocardial performance index RV MPI, is a nongeometric combined measure of systolic and diastolic function: RV MPI = (IVRT + IVCT)/RVET, where IVRT is the RV isovolumic relaxation time, IVCT is the isovolumic contraction time, and RVET is the RV ejection time. Higher values correspond to worse ventricular function. IVRT, IVCT, and RVET can be measured by either tissue or pulsed Doppler. Because the RV inflow and outflow tracts are widely separated, two separate pulsed Doppler recordings must be made to obtain these variables in the right heart. Errors will be made if care is not taken to make measurements at comparable R-R intervals, especially if the rhythm is irregular; tissue Doppler RV MPI may often be easier to acquire (see Fig. 32-10).

RV MPI has been applied to congenital heart disease and evaluation of systemic RVs[40-42] and in adults with pulmonary hypertension. MPI has also been used to identify patients with early RV MPI dysfunction resulting from cardiac amyloidosis. In this study, nonsimultaneous recordings of pulmonary artery outflow and tricuspid valve inflow were used. The RV MPI in normal adult subjects was 0.28.[43] There is some concern that RV hypertrophy may shorten the IVRT leading to a paradoxically low MPI in the abnormal RV with hypertrophy.[44]

## REFERENCE RANGES, QUANTITATION AND DATA ANALYSIS

Parameters of RV size and their reference ranges are listed in Table 32-2 and were outlined in Figure 32-3. It should be noted that several of the ranges reported in the 2010 ASE guideline statement deviate substantially from the ranges in the 2005 ASE guideline statement on chamber quantitation,[45] which were based on very few studies.[46,47]

Selected parameters of RV systolic function and their reference ranges are outlined in Table 32-3. Although 2D methods for estimating RV EF per se have poor accuracy, individual one-dimensional, 2D, and nongeometric measures of RV systolic function do have some correlation with EF, and some have demonstrated enough individual correlation with clinical status in various diseases to be clinically useful as independent measures of systolic function. TAPSE is reproducible, easily acquired, and increasingly studied; we recommend it be measured in all comprehensive transthoracic examinations.

The 2010 ASE guideline statement does not advise any systematic method for incorporating multiple measures of RV size or function into a unified assessment (i.e., normal, or mildly, moderately, or severely abnormal). We recommend supplementing subjective assessments of both RV size and function with at least one objective measurement (we recommend RV basal minor dimension and TAPSE). Additional objective measurements should be used if initial assessments conflict or are ambiguous. Practical approaches are outlined in Figures 32-11 and 32-12, but others are possible. It should be remembered that these approaches, like the normative values themselves, are guidelines and are meant to supplement rather than replace clinical judgment.

**TABLE 32-2 Reference Values for Parameters of RV Size[7]**

| *Parameter* | *View* | *Patients (Studies)* | *Mean (LRV-URV)* |
|---|---|---|---|
| RV basal minor dimension (mm)* | A4C | 376 (10) | 33 (24-42) |

## Clinical Utility and Outcome Data

### OUTCOME DATA

The impact of RV dilation and systolic dysfunction on clinical outcomes has been studied in a variety of conditions, both right-sided (e.g., pulmonary embolism, pulmonary hypertension, RV infarction) and systemic (myocardial infarction, LV systolic dysfunction, mitral regurgitation). RV dysfunction has been associated with obstructive sleep apnea,[48-50] but correlation with clinical outcomes has not yet been shown. Of the many indices that have been studied, TAPSE and RV fractional area change are emerging as the most widely used measures of RV systolic function. Selected studies showing the association of RV systolic dysfunction and clinical outcomes are summarized in Table 32-4.[32,33,51-57] Though limited because of variable methodology and moderate size, data show convincingly that

**TABLE 32-4 Selected Studies Showing Association of Clinical Outcomes with Echocardiographic Parameters of RV Size and Systolic Function**

| Year | Study | n | Population | Follow-up | Endpoint | Results | Adjusted for |
|---|---|---|---|---|---|---|---|
| 2000 | Ghio et al[33] | 140 | LVEF <35% | 25 months | Death or OHT | TAPSE ≤14 mm → HR 2.6, adjusted | Age, LVEF, sex, NYHA class, DT |
| 2008 | Dini et al[52] | 142 | LVEF ≤45%, MR VC ≥5 mm | 20 months | Death | TAPSE <16 mm → HR 2.6, adjusted | Age, LVEF, sex, CAD, NYHA class |
| 2008 | Puwanant et al[53] | 33 | LVAD | 6 months | RV failure | TAPSE <7.5 mm → 91% specific but only 46% sensitive for post-LVAD severe RV failure | Unadjusted |
| 2006 | Forfia et al[32] | 63 | PH (47 PAH) | 19 months | Death | Adjusted HR 1.16 for every 1-mm decrease in TAPSE in PAH cohort | Effusion, WHO class |

RV systolic function correlates with prognosis across a wide spectrum of pathology.

### CLINICAL APPLICATION

Although the foregoing data form a solid basis for further investigation, they are primarily observational. It remains unclear how to incorporate RV systolic dysfunction into practical clinical decision making beyond awareness of its negative prognostic implication, and generally heightened clinical concern and attention in its presence.

Prospective randomized trials evaluating indices of RV function as the basis for allocation of therapeutic interventions (similar to those exploring LV EF as the basis for therapies such as defibrillators, medications for treatment of systolic heart failure, valve replacement, and coronary revascularization) are not yet available. Such prospective trials are needed before guidelines can be created on the use of parameters such as TAPSE and RV fractional area change in clinical decision making.

## Research Applications

### THREE-DIMENSIONAL ECHOCARDIOGRAPHY

The strengths of 3D echocardiography are particularly suited to the assessment of the RV. Interested readers should consult Chapter 4 for a detailed review of 3D echocardiography in general, and a review by Horton and colleagues[58] for a discussion of its use in the assessment of the RV.

The principal advantage of 3D echocardiography is the ability to define the entire RV endocardial surface without geometric assumptions, which results in less underestimation of RV volumes and superior correlation with MRI as compared to 2D methods.[17,59] Although MRI has become the de facto standard for measurement of RV volumes, 3D echocardiography has shown comparable performance in vitro,[60-62] and 3D echocardiographic RV volumes and EF correlate closely with MRI-derived values in healthy individuals, pulmonary hypertension, congenital heart disease, and ischemic heart disease.[52,63-68] A recent metaanalysis of 23 small (n = 12-88) studies of healthy and diseased subjects confirmed that 3D echocardiography modestly underestimates RV end-diastolic volume compared to MRI, with greater underestimation of volumes in larger RVs[69] (Fig. 32-13).

Offline analysis remains relatively time consuming, but semiautomated border detection and other algorithms such as knowledge-based reconstruction (which allows generation of an endocardial surface based on a small number of user-identified points rather than fully traced endocardial borders) may speed the process.[70]

Normative data for 3D-derived RV volumes and EF are from relatively small studies with heterogeneous methods; however, upper reference limits of 89 and 45 mL/m$^2$ for RV end-diastolic and end-systolic volumes and a lower reference limit of 44% for RV EF are suggested by the ASE, based on pooled data.[7] 3D echocardiography appears reasonable for serial assessment of RV volumes within an individual patient (i.e., to assess for disease progression or response to treatment) but is not currently recommended by the ASE for routine assessment.

### ALTERNATE MEASURES OF RIGHT VENTRICULAR SYSTOLIC FUNCTION

Several other parameters of RV systolic function have been described but are as yet less suitable for clinical use because of limited normative data and/or practical limitations in acquisition.

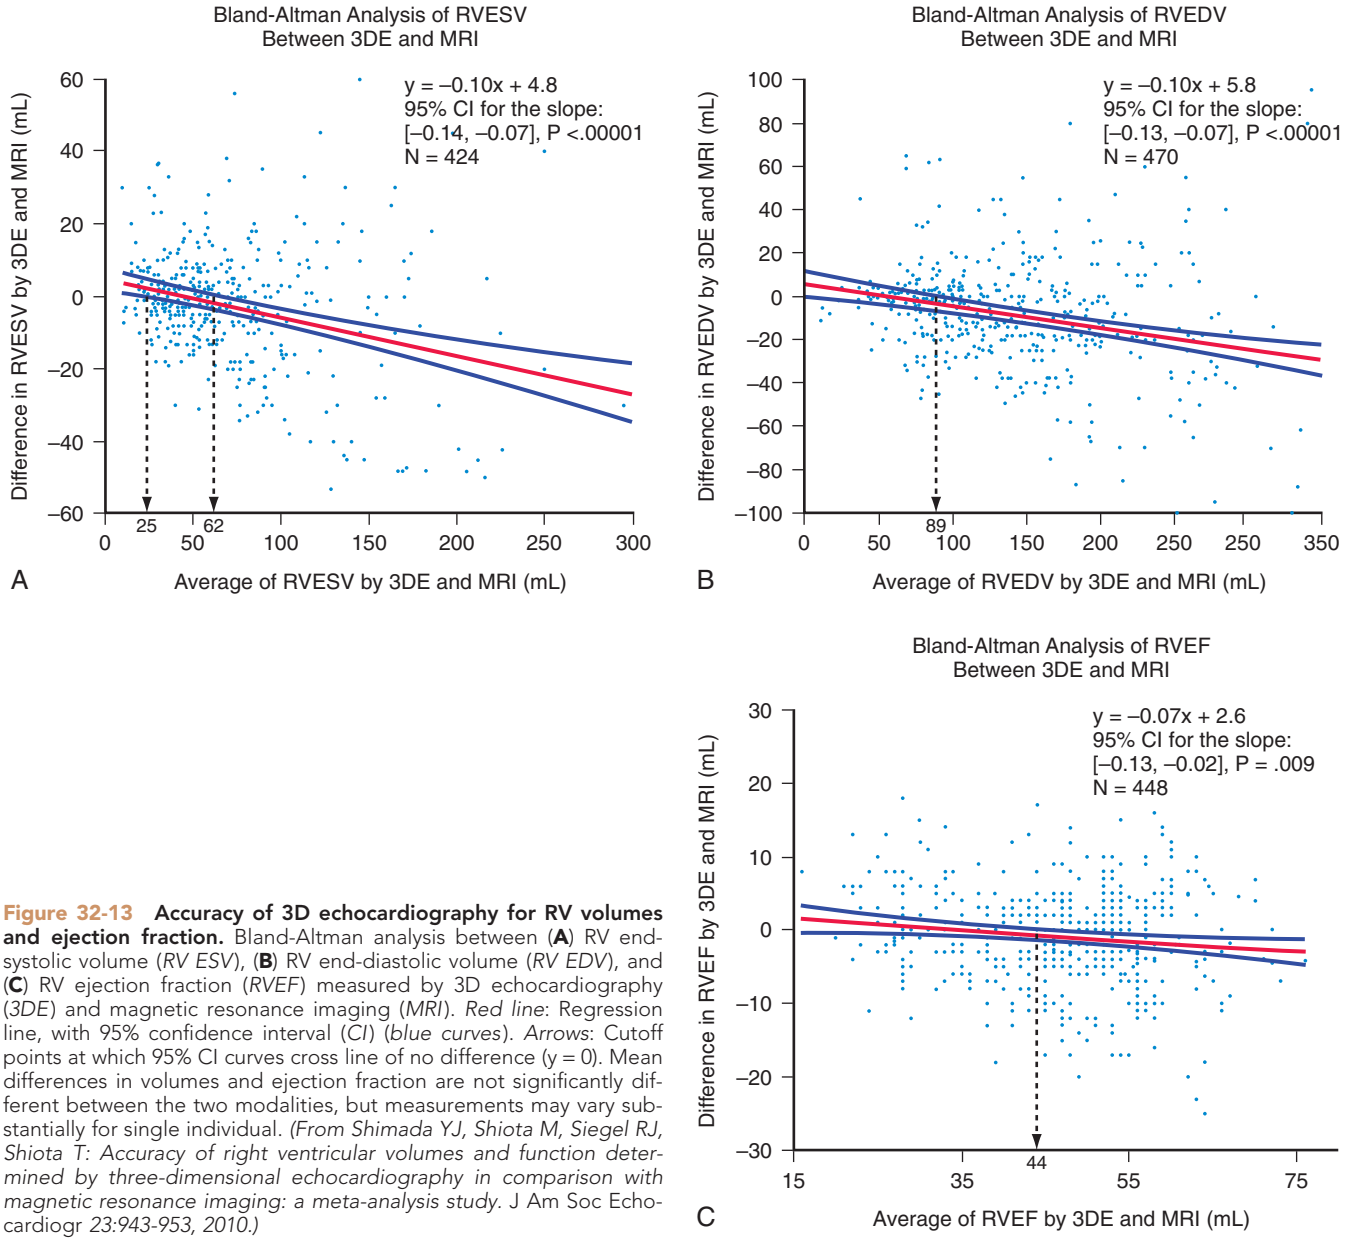

**Figure 32-13 Accuracy of 3D echocardiography for RV volumes and ejection fraction.** Bland-Altman analysis between (**A**) RV end-systolic volume (*RV ESV*), (**B**) RV end-diastolic volume (*RV EDV*), and (**C**) RV ejection fraction (*RVEF*) measured by 3D echocardiography (*3DE*) and magnetic resonance imaging (*MRI*). *Red line*: Regression line, with 95% confidence interval (*CI*) (*blue curves*). *Arrows*: Cutoff points at which 95% CI curves cross line of no difference (y = 0). Mean differences in volumes and ejection fraction are not significantly different between the two modalities, but measurements may vary substantially for single individual. *(From Shimada YJ, Shiota M, Siegel RJ, Shiota T: Accuracy of right ventricular volumes and function determined by three-dimensional echocardiography in comparison with magnetic resonance imaging: a meta-analysis study.* J Am Soc Echocardiogr *23:943-953, 2010.)*

### *dP/dt*

As RV contractility declines, the peak rate of pressure rise (*dP/dt*) decreases and can be estimated noninvasively by combining the simplified Bernoulli equation with measurements from the CW Doppler signal of TR. Because pressures are lower in the pulmonary vasculature, the time interval (*dt*) is measured between lower velocities than in the left heart, typically 1 to 2 m/s (*dP* = 12 mm Hg). Although *dP/dt* is free of geometric assumptions, it does require a complete TR spectral Doppler envelope and parallel alignment with the regurgitant jet. Normative data are very few, although the ASE suggests 400 mm Hg/s as a lower limit of normal. Indexing *dP/dt* to the peak RV systolic pressure theoretically reduces dependence on angle and preload.[71]

### *Strain and Strain Rate*

Myocardial strain (percent change in length) and strain rate (temporal derivative of strain) can be measured using tissue Doppler. Longitudinal strain and strain rate of the RV free wall have been shown to correlate with myocardial contractility[72] and with clinical events in PH.[73] However, acquisition is technically challenging, because the thin RV free wall yields a poor signal-to-noise ratio, and angle dependence may require medial displacement of the transducer from the cardiac apex to bring the ultrasound beam parallel to the RV free wall. Studies with normative values are relatively few and small, insufficient to give clinically useful reference ranges. 2D strain imaging using speckle tracking is a promising modality that allows assessment of strain and strain rate in multiple segments from a single clip

and partially overcomes the issue of angle dependence. However, normative data from this modality are even fewer than for one-dimensional strain. In general, systolic strain in the midwall of the RV is higher than either the basal or apical segments, and the RV demonstrates higher strain and strain rates compared to the LV[74].

### *Isovolumic Acceleration*

Isovolumic acceleration is defined as peak myocardial velocity during isovolumic contraction divided by the time from onset of contraction to peak velocity. This index is measured using tissue Doppler of the tricuspid annulus and may be less load dependent than other indices.[75] A lower reference limit of 2.2 m/s$^2$ based on pooled data is proposed by the ASE,[7] but limited data result in a wide 95% confidence interval (1.4 to 3.0), limiting its clinical utility.

## RIGHT VENTRICULAR DIASTOLIC FUNCTION

RV diastolic dysfunction, like RV systolic function, is associated with many clinical conditions, both "right-sided" (e.g., pulmonary hypertension, pulmonary embolism, right coronary ischemia) and systemic (left heart failure, heart transplantation, left-sided valve disease). There is not yet an established benefit to routine assessment of RV diastolic function; however, RV diastolic parameters may be useful adjuncts in assessment of right-sided filling pressures, or in identifying early disease when right-sided pathology is strongly suspected but RV size and systolic function appear normal.

Characterization of RV diastolic function is conceptually analogous to LV diastolic function. E/A and E/E′ are calculated from tricuspid inflow at the leaflet tips and tricuspid annular tissue Doppler. Ancillary measures are also similar, with hepatic vein diastolic flow predominance and RA dilation suggesting diastolic dysfunction. A reasonable clinical rubric for grading diastolic function is outlined in Table 32-5 and is largely in keeping with ASE guidelines. Tricuspid Doppler measurements should be taken from the apical four-chamber view during held end-expiration to avoid beat-to-beat variation in RV preload.

A few small studies suggest that E/E′ may be a promising measure of RAP. In two studies, E/E′ correlated well with RAP ($r \approx 0.8$).[76,77] Although E/E′ greater than 4 predicted RAP greater than 10 mm Hg with sensitivity and specificity of 88% and 85% in one study,[76] a cutoff of E/E′ greater than 8 was required to achieve similar test performance in patients after cardiac transplant.[77] Correlation of E/E′ with RAP may be better when RV systolic function is abnormal and worse early after cardiac surgery[76]. Diastolic parameters may also be confounded by TR (which may increase E velocity or blunt hepatic vein systolic flow) and tachycardia (which may decrease E/A by shortening diastole, or may cause E-A fusion).

**TABLE 32-5 Reference Values for Parameters of RV Diastolic Function[7]**

| *Parameter* | *Normal* | *Impaired Relaxation (Grade 1)* | *Pseudonormal (Grade 2)* | *Restrictive (Grade 3)* |
|---|---|---|---|---|
| *Trans-tricuspid E/A | 0.8-2.1 | <0.8 | 0.8-2.1 | >2.1 |
| *Tricuspid E/E′ | <6 | <6 | >6 | >6 |
| *RA size | Normal | Normal or dilated | Dilated | Dilated |
| Hepatic vein flow | Systolic-predominant | | Diastolic-predominant | Diastolic-predominant |
| Other parameters | | | | DT < 120 ms<br>Premature (late diastolic) PV opening |

*A*, Atrial contraction transtricuspid peak flow velocity; *DT*, deceleration time of the tricuspid valve; *E*, early diastolic transtricuspid peak flow velocity; *E′*, early diastolic tricuspid annulus velocity; *PV*, pulmonic valve.
*Recommended for clinical use by the 2010 ASE guideline statement.

## Potential Limitations and Future Directions

Although the pooled normative data published in the 2010 ASE guideline statement represent a significant step forward in our understanding of the right heart, several important limitations should be noted. None of the reported values are indexed to body size, and care must be taken when applying published values to large- or small-statured patients. Normative data on RV size and function are heterogeneous because of pooling (individual studies with average n = 20 to 50). Stratification of RV size and systolic function beyond normal and abnormal (e.g., mild, moderate, or severe) remains largely subjective. As discussed previously, prospective trials examining the benefit of using parameters of RV size and function to guide clinical decisions are lacking.

Future studies should address these limitations. Larger studies from a single center, or multiple centers with well-defined protocols for acquisition, should verify both raw and body-size-indexed normative values. Observational data suggesting worsened prognosis in the setting of RV systolic function should be extended with prospective trials examining treatment effect on populations selected using parameters of RV size and function.

3D echocardiography faces challenges similar to those faced by 2D echocardiography as described earlier. Although the superiority of 3D echocardiography in measurement of RV volumes and EF compared to 2D echocardiography is well established, 3D echocardiography is unlikely to be used routinely for assessment of the RV until a direct impact on clinical management is demonstrated.

## Alternate Approaches

MRI, computed tomography, and nuclear techniques have been applied to assessment of RV size and function. MRI has emerged as the de facto gold standard for right heart assessment. It has several advantages compared to echocardiography in assessment of the RV. MRI delineates the entire RV without geometric assumptions, is minimally affected by tissue and air interference, and has much higher myocardial-endocardial contrast, usually resulting in superior image quality (Fig. 32-14; compare to Fig. 32-9). Endocardial borders must still be generated through manual tracing, automated detection, or other methods. Like 3D echocardiography, MRI remains limited to a relatively few centers. It is not portable, may be limited by patient claustrophobia and the need to exclude metal from the imaging area, and cannot be used in patients with advanced renal failure because of the risk of nephrogenic systemic fibrosis. MRI can evaluate blood flow and calculate stroke volumes and cardiac output, but echocardiography and Doppler remain superior for evaluation of valve disease.

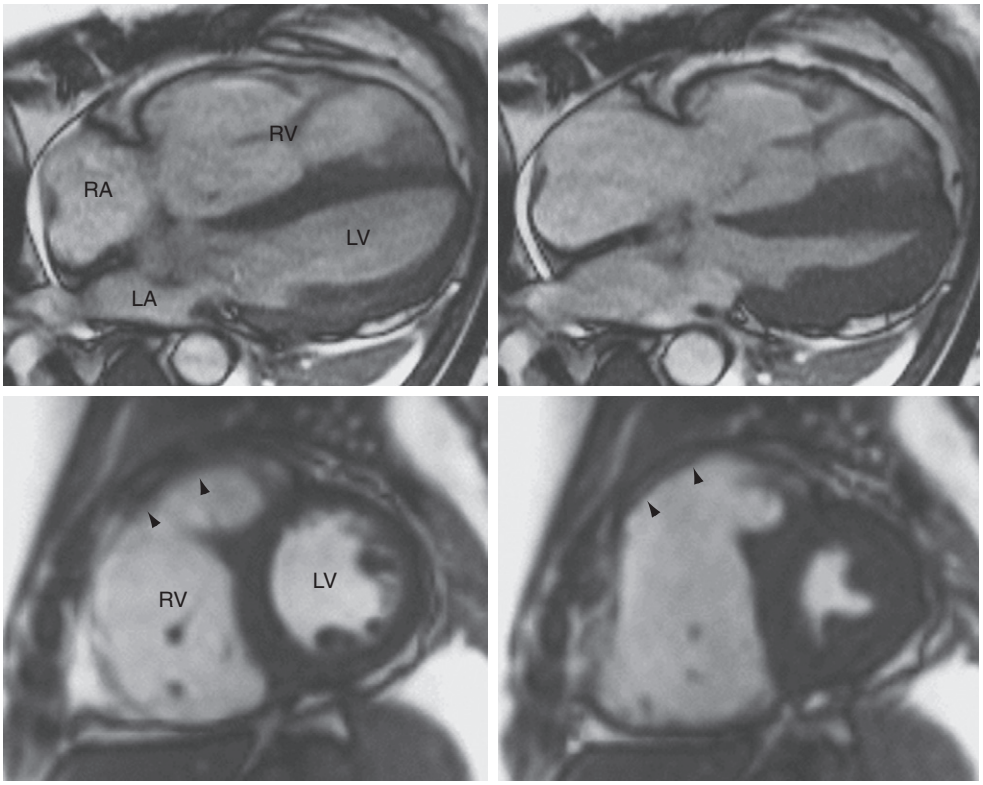

**Figure 32-14 Cardiac magnetic resonance imaging of heart affected by arrhythmogenic RV cardiomyopathy.** Global RV dysfunction is evident, as well as small dyskinetic aneurysm near RV outflow tract (*arrowheads*). *Top left*: Horizontal long-axis, end-diastole. *Top right*: Horizontal long-axis, end-systole. *Bottom left*: Short-axis, end-diastole. *Bottom right*: Short-axis, end-systole.

Cardiac computed tomography shares several of the strengths of MRI, including true 3D analysis independent of geometric assumptions and excellent myocardial-endocardial contrast, but radiation and potentially nephrotoxic contrast exposure have rendered it unpopular relative to MRI.

Nuclear imaging techniques with blood-pool imaging (e.g., first-pass or equilibrium radionuclide angiography) also measure RV EF without geometric assumptions. Correlation with correlation with MRI-derived RV EF is favorable,[78] but because nuclear imaging provides little other information about the right heart and requires radiation exposure, it is rarely used as a first-line modality for right heart assessment.

## ACKNOWLEDGMENTS

## KEY POINTS

- Complex RV geometry mandates assessment of size and function from multiple echocardiographic views.
- 2D echocardiography remains the dominant clinical modality for assessment of RV size and function because of its widespread availability, but it does not yield accurate RV volumes or RV EF.
- "Standard" 2D transthoracic echocardiography views may not optimally demonstrate the right heart. Dedicated views of the RV (e.g., apical four-chamber view angled to bring the RV free wall and lateral tricuspid annulus toward the center of the field) should be used as needed.
- Normal reference values for recommended parameters of RV size (95th percentile upper limit) include basal minor dimension less than 42 mm, proximal RVOT diameter less than 33 mm (from the parasternal long-axis view), and distal RVOT diameter less than 27 mm (parasternal short-axis). If the LV is normal-sized, RV area greater than two-thirds LV area in the apical four-chamber view suggests RV enlargement.
- Normal reference values for recommended parameters of RV systolic function (95th percentile limit) include TAPSE greater than 16 mm, fractional area change greater than 35%, peak tricuspid annular velocity (S′) greater than 10 cm/s, and pulsed-Doppler right ventricular myocardial performance index (RV MPI) less than 0.40.

## KEY POINTS—cont'd

- TAPSE and fractional area change appear to correlate with clinical status in broad range of cardiovascular diseases. TAPSE is gaining clinical popularity because of its reproducibility and ease of acquisition and measurement. We recommend combining TAPSE with visual assessment when reporting RV systolic function. Prior cardiac surgery and LV dysfunction may reduce TAPSE independently of RV dysfunction. If TAPSE and visual assessment are discordant, other parameters (fractional area change, S′, RV PMI) help resolve the ambiguity.
- PASP is calculated by the peak velocity of the TR jet with the formula PASP = $4v_{TR}^2$ + RAP. The RAP is calculated by the degree of collapse of the IVC with inspiration or sniff. The diastolic pressure can be calculated from the pulmonary regurgitant jet velocity.
- 3D methods for assessment of RV size and function have shown promising results, but clinical use remains restricted by availability and limited normative and outcome data. MRI and 3D echocardiography show comparable performance for measurement of RV volumes and EF.

Differentiating Pulmonary Vascular (Arterial) from Pulmonary Venous Hypertension
Exercise Echocardiography

Pulmonary hypertension (PH) is defined as a mean pulmonary artery pressure (mPAP) of more than 25 mm Hg, which typically coincides with a pulmonary artery (PA) systolic pressure (PASP) of more than 40 mm Hg.[1,2] An increased mPAP is the hemodynamic consequence of perturbations in pulmonary blood flow (cardiac output [CO]), pulmonary vascular resistance (PVR), and left atrium (LA) pressure, as expressed in the following equation:

$$\text{mPAP} = \text{CO} \times \text{PVR} + \text{LA pressure}$$

where mPAP and LA pressure are measured in mm Hg, cardiac output in L/min, and PVR in mm Hg/L/min. Clinically PVR usually is expressed in Wood units, with a normal PVR less than 1.6 Wood units.

Many clinical diagnoses can cause or contribute to PH, including left heart disease with pulmonary venous hypertension (PVH; World Health Organization [WHO] group II), chronic respiratory conditions typically associated with hypoxia (WHO group III), chronic thromboembolic PH (CTEPH; WHO group IV), and miscellaneous/multifactorial causes (WHO group V). In addition, PH may arise from severe pulmonary vasculopathy in the absence of chronic left heart disease, respiratory disease, or prior pulmonary emboli, which is referred to as pulmonary arterial hypertension (PAH; WHO group I).[3] Given the highly diverse nature of PH, careful clinical and hemodynamic distinctions need to be made for the appropriate PH diagnosis. This is particularly true with discerning PAH from PVH because PH-specific therapy (i.e., prostacyclin analogues, endothelin receptor antagonists) intended for patients with PAH has either no effect or worsens the condition of a patient with left heart disease (Box 33-1).

The echocardiographic examination is central to the initial diagnosis of PH, and the serial assessment of PH. Fundamental to the diagnostic assessment is a variety of Doppler imaging–based pulmonary pressure estimations, as outlined in Chapter 32. However, many other ways exist to diagnose, infer, and assess PH and its hemodynamic causes aside from Doppler pressure estimation. Overreliance or exclusive focus on the Doppler pressure estimates and a failure to integrate other salient two-dimensional (2D) and Doppler findings into the overall echocardiographic interpretation greatly increase the risk of false-positive and false-negative diagnoses of PH. Conversely, a more integrated and pathophysiologic approach to the assessment not only enhances the diagnostic accuracy of PH but also allows for a much greater degree of pathophysiologic insight into an individual patient's PH.

## Pulmonary Artery Pressure and Right Ventricular Afterload

The level of pressure elevation does not correlate well with functional limitations or prognosis in PAH.[4] Similarly, right ventricular (RV) size, septal position, and RV systolic function vary widely at the same level of mean PAP, depending on the specific hemodynamic cause.[5] These observations relate to the fact that PAP is a relatively poor and incomplete measure of RV afterload. Afterload is the force that opposes RV ejection, and thus pulmonary blood flow, and is most completely described by PA input impedance. Input impedance is a composite measure of afterload that includes vascular resistance (PVR = mPAP – LA pressure/pulmonary blood flow), large PA stiffness, and the effects of these two factors on the magnitude and timing of reflected arterial waves arriving at the RV during systole.[6]

Thus PH can be present with normal pulmonary vessels when there is a high flow state or an elevated LA pressure, even when the pulmonary vessels themselves are normal. Conversely, abnormal changes in the pulmonary vessels themselves, or pulmonary vascular disease (PVD), may be present with only modest elevations in pulmonary pressure. Increased RV afterload is present in PH associated with PVD and is comparatively

**Box 33-1**

**PULMONARY HYPERTENSION DEFINITIONS AND WHO GROUPS**

**Pulmonary hypertension (PH):** an elevated pulmonary artery pressure of any cause
- **Group I. Pulmonary arterial hypertension (PAH):** PH due to severe pulmonary vasculopathy in the absence of an identifiable underlying cause
- **Group II. Pulmonary venous hypertension (PVH):** PH due to left sided heart disease
- **Group III.** PH due to chronic lung disease with hypoxia
- **Group IV.** Chronic thromboembolic pulmonary hypertension (CTEPH)
- **Group V.** Miscellaneous and other causes

Other definitions:
- **PASP**, pulmonary artery systolic pressure
- **mPAP**, mean pulmonary artery pressure
- **PVD**, pulmonary vascular disease (abnormal pulmonary vessels)

low in PH without PVD. PVR accounts for approximately 80% of total afterload in most clinical circumstances.[6] Increased PAP does increase afterload indirectly via increased PA stiffening, but to a relatively small degree. For example, in a patient with a large atrial septal defect but normal PVR, the RV can eject 15 L of flow through the lung (Qp), despite severe PH, and maintain normal RV systolic function. In this same patient, however, if the PVR increases from 2 mm Hg/L/min to 8 mm Hg/L/min, the Qp falls dramatically and frank RV dysfunction manifests.

The distinction between PAP and RV afterload has considerable practical value in the context of an echocardiographic evaluation of a patient with known or suspected PH. RV afterload, not PAP, is what impairs RV function and leads to the stereotypical triad of RV enlargement, interventricular septal flattening, and RV systolic dysfunction in PH. With this in mind, the clinician should remain highly suspicious for PH related to PVD if RV dilation, dysfunction, and septal bowing are present, even if the Doppler image–estimated PASP is reported as normal. This point cannot be overemphasized. Fisher et al[7] reported that more than 80% of subjects with severe PH that was related to an increased PVR and with PASP that was significantly underestimated with Doppler imaging possessed at least one of three features of the RV dysfunction triad on 2D examination. Conversely, if a patient has PH without significant rise in afterload (i.e., normal PVR), as in cases of high output PH or PH related to LA hypertension, RV structure and function remain comparatively normal, with the conspicuous absence of the RV dysfunction triad. Therefore, one can think of the RV as bearing witness to what is occurring within the pulmonary circulation. For these reasons, we consider PH associated with PVD ($PH_{+PVD}$) separately from PH in the relative absence of PVD ($PH_{\varnothing PVD}$).

## Right Ventricular-Pulmonary Vascular Interaction

The RV and the pulmonary circulation function as a coupled unit. In health, a normal pulmonary vasculature couples to an appropriately thin-walled, distensible RV that generates large amounts of blood flow without a resulting high pressure. As PVD develops, the PVR increases and the large arteries stiffen. As a result, the (formerly appropriate) nonmuscular RV is typically incapable of completely matching or of coupling its contractile performance to its new afterload.[8,9] This relative RV-PA uncoupling leads to a stereotypical triad of changes that occur at the level of the RV, including RV systolic dysfunction, increased size and altered shape of the RV, and varying degrees of systolic and diastolic bowing of the interventricular septum (Fig. 33-1). This triad of changes forms the basis of the echocardiographic diagnosis of $PH_{+PVD}$. The degree to which these changes occur is contingent on the degree of RV-PA uncoupling. Thus, at a PVR of 5 Wood units, a patient with depressed RV contractility has far more uncoupling to the vascular load than a patient with an intrinsically normal RV coupled to the same afterload. As such, the RV dysfunction triad helps to adjudicate and assess the physiologic and clinical significance of any given degree of PVD. The greater the RV impairment, the greater the clinical and physiologic significance of the $PH_{+PVD}$, no matter what the noninvasive (or invasive) pressure may be.

The RV outflow tract (RVOT) is a key anatomic and physiologic interface between the RV and pulmonary vasculature (Fig. 33-2, *A*). The pulsed-wave Doppler RV outflow velocity curve provides a wealth of physiologic information about RV and pulmonary vascular function. As such, analysis of the Doppler velocity signal represents perhaps the single most important aspect of the echocardiographic examination in a patient with known or suspected PH.

Early work from Kitabatake and associates[10] showed that the time to peak velocity, or acceleration time (AcT), of the RV outflow velocity curve provides an estimate of mPAP (Fig. 33-2, *C*). An average AcT of 137 ± 24 ms was seen in subjects with a mean PA pressure of 19 mm Hg or less, whereas AcTs of 97 ± 20 ms and 65 ± 14 ms were seen in patients with a mPAP of 20 to 39 mm Hg and 40 mm Hg or more, respectively. This method is relatively easy to perform and highly reproducible; and unlike pressure estimates based on tricuspid regurgitation (TR) velocity, Doppler recordings from the RVOT are available in virtually all patients. The AcT can provide useful corroborative information that aids in the accuracy of PH diagnosis; for example, in the presence of borderline PH by TR jet velocity, an AcT of more than 100 ms suggests there is no PH, whereas an AcT of less than 70 ms greatly increases the likelihood of significant PH.

In addition to AcT measurement, visual inspection of the shape of the RV outflow velocity signal has also been be used to qualitatively differentiate varying levels of PH. Prior work has shown that a rounded velocity curve with no evidence of Doppler "notching" has been associated with normal PA pressures, and that patients with mild-moderate PH more often have a triangular, or dagger-shaped, curve (often with late-systolic notching) and those with severe PH typically manifest prominent midsystolic notching of the Doppler velocity signal.[10] However, these same authors pointed out that only 53% of patients with PH evidenced a notched flow curve, which suggests that pressure is an associate cause but not the actual physiologic cause of this notching pattern.

The actual cause of Doppler notching is early arrival of reflected arterial waves from the pulmonary vasculature that leads to "real-time" impedance to RV ejection.[11] This was initially described in the setting of acute and chronic pulmonary emboli, related to proximal vascular obstruction.[12,13] However, Torbicki and colleagues[12] showed that the time to midsystolic

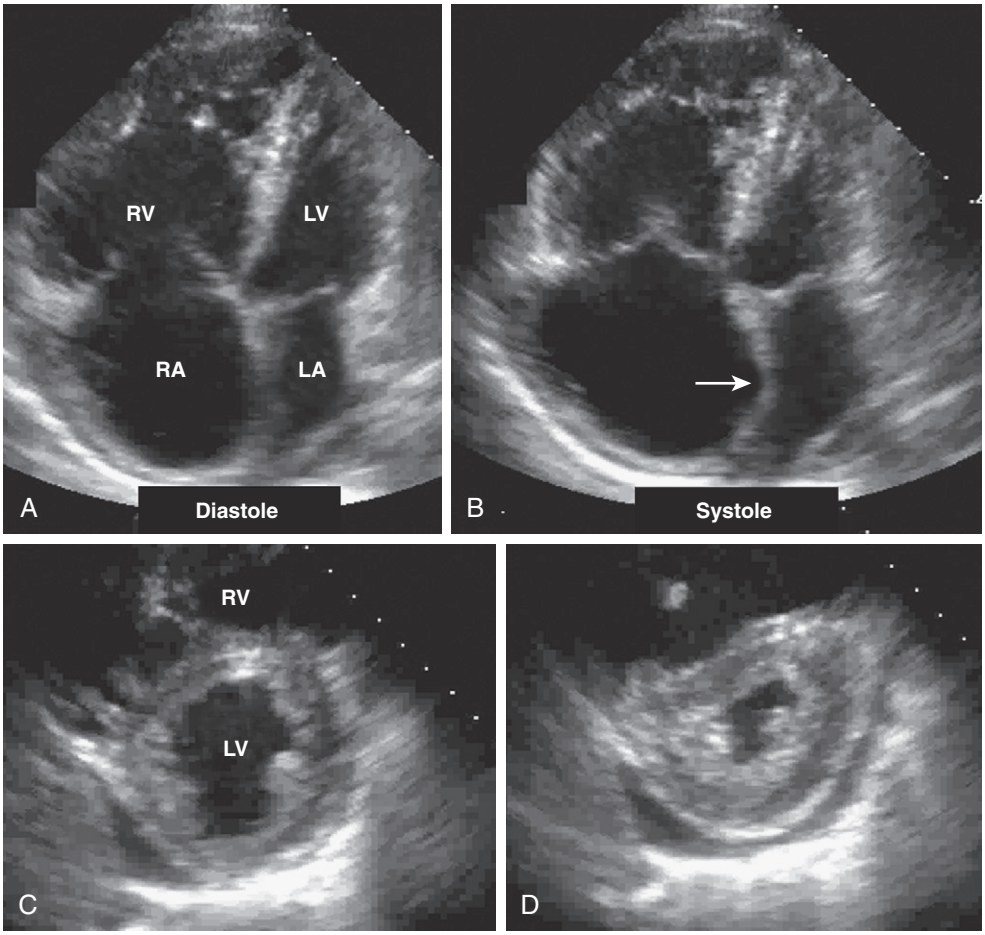

**Figure 33-1** **Apical four-chamber view in diastole (A) and systole (B) in a patient with idiopathic pulmonary arterial hypertension. A** and **B,** The RV is enlarged, and the interventricular septum bows to the left. Note the lack of significant fractional area change between diastole and systole, which indicates severe RV systolic dysfunction. The interatrial septum bows to the left as a result of severe RA hypertension (*arrow*). **C** and **D,** Parasternal short-axis view is shown in a similar patient in diastole (**C**) and systole (**D**). In diastole, the RV is noted to be enlarged, but the septal configuration is normal. In systole, severe septal bowing indicates markedly increased RV afterload (i.e., pulmonary vascular resistance). A moderate circumferential effusion is also present, a frequent finding in pulmonary arterial hypertension, especially with an increased right atrial pressure.

flow deceleration did not differ between patients with CTEPH and idiopathic PAH. Thus, analyses of the RV outflow velocity curve may be applied more broadly for detection of PVD.

Recent work was reported on a cohort of 79 patients (acute and chronic pulmonary embolic excluded) with undifferentiated PH and the hemodynamic differences seen on the basis of differences in the shape of the Doppler velocity curve.[5] In contrast to prior work, this study showed that the absence of Doppler notching did not necessarily indicate a lack of PH. Instead, the lack of Doppler notching (see Fig. 33-2, *C*) was strongly associated with a relative lack of PVD; when PH was present in these patients, it was the result of an increased LA pressure and a relatively normal PVR ($PH_{øPVD}$). In contrast, in the presence of increased PA stiffness and high PVR, reflected waves return to the RV during systole, impede RV ejection, and cause "notching" of the Doppler profile. A late systolic notch pattern typically coincides with moderate increases in the PVR (i.e., 3 to 6 Wood units; Fig. 33-3, *A*), most commonly seen in patients with milder degrees of PAH and in patients with chronic left heart disease or respiratory disease with concomitant PVD. A midsystolic notch pattern is especially abnormal and is the typical finding in patients with PAH and CTEPH. A midsystolic notch pattern is associated with an average PVR of more than 8 Wood units (Fig. 33-3, *B*); and a midsystolic notch pattern is 96% specific for a PVR of more than 5 Wood units. These findings indicate RV outflow velocity mid systolic notching is far more indicative of PVD (high PVR, low compliance) than high pulmonary pressure and help explain why notching is present in some, but not all, patients with PH.

In parallel with its associated RV afterload, the midsystolic notch pattern was associated with more advanced RV systolic dysfunction, lower tricuspid annular plane systolic excursion (TAPSE; Fig. 33-4, *B*), RV fractional area change, and the ratio of stroke volume index to RV end-diastolic area compared with normal patterns (no notching) and late-systolic notch groups. In contrast, patients with an elevated mPAP but normal pattern typically had either normal RV function or RV dysfunction associated with normal PVR and PA compliance. Taken together, these findings indicate that normal RV function without outflow notching suggests a relatively normal RV-PA interaction. In contrast, RV dysfunction in the presence of a notched outflow velocity curve strongly suggests an afterload-dependent mechanism, and RV dysfunction in the absence of RV outflow notching relates to primary afterload-independent RV dysfunction.

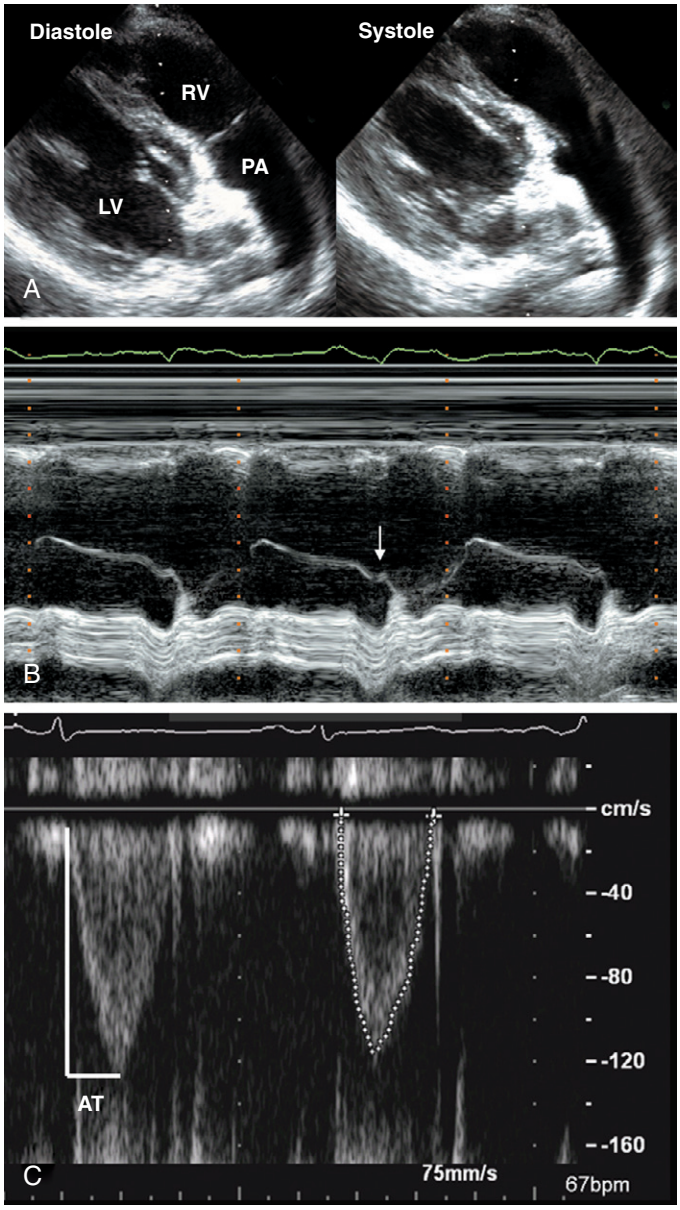

**Figure 33-2 A, Parasternal long-axis view of the pulmonary valve in diastole.** The RV outflow tract is clearly imaged in this view and is the best for pulsed wave Doppler sampling of the RV outflow tract flow velocity envelope (**C**). The PA bifurcation is out of plane. **B,** M-mode imaging of the pulmonary valve from the same view with normal movement of the valve leaflets away from the transducer in atrial systole. **C,** Normal (no notching pattern) pulsed wave flow velocity envelope taken in the RV outflow tract. The acceleration time (*AT*) is 110 ms, which is normal. Both findings strongly suggest normal pulmonary vascular resistance. If pulmonary hypertension is present in the absence of RV outflow tract Doppler notching, the increased PA systolic pressure is highly likely to arise from an increased LA pressure.

Thus, visual inspection of the RV outflow Doppler flow profile represents a simple rapid method of gleaning insight into the relative presence ("notched" pattern) or absence ("no notch" pattern) of PVD. This approach is extremely useful and applicable in clinical practice.

## Pulmonary Vascular Disease

Pulmonary vascular disease states are associated with varying degrees of increased PVR, loss of PA compliance, and pathologic arterial wave reflection. These changes within the pulmonary circulation impose a true afterload on the RV, such that specific 2D and Doppler "signatures" are highly prevalent in $PH_{+PVD}$, whereas such changes are relatively absent in $PH_{øPVD}$. The most prominent causes of $PH_{+PVD}$ are PAH and PH related to acute or chronic pulmonary emboli.

### PULMONARY ARTERIAL HYPERTENSION

Pulmonary arterial hypertension is the prototype of $PH_{+PVD}$ and can be familial or idiopathic (formerly referred to as primary PH) or associated with various predisposing conditions, including connective tissue disease (i.e., scleroderma), congenital systemic to pulmonary shunts, HIV infection, toxin-mediated pulmonary vascular injury, and other conditions.[3] Patients with PAH, by definition, have a mPAP of more than 25 mm Hg and an LA pressure of 15 mm Hg or less and universally have a PVR of more than 3 mm Hg/L/min (average PVR at index diagnosis, 8 to 10 mm Hg/L/min).[3,14,15] In addition to these hemodynamic criteria, a diagnosis of PAH requires the exclusion of chronic left heart disease, respiratory disease, and chronic pulmonary emboli. All approved forms of PH-specific therapy are particularly intended for patients with PAH. Importantly, the response to PH therapies and patient prognosis are linked to the relative stage of the disease at the time therapy is implemented.[4] This places a premium on early detection of PAH and, thus, on the importance of the echocardiographic examination, as this is one of the first noninvasive tests performed in the workup of a patient with suspected PAH. Echocardiography is a highly sensitive test for the detection of the physiology that underlies PAH, so long as the study is interpreted in an integrated manner, with due attention to RV size, shape, and function and other Doppler features that are nearly universally present in these patients. A normal or mildly elevated PASP Doppler estimate should not dissuade a suspected diagnosis of PAH when the other 2D and Doppler features of PAH are present.

In 1973, Goodman, Harrison, and Popp[16] reported the salient 2D echocardiographic findings of idiopathic PAH. All patients had RV dilation, and 50% had an RV:left ventricle (LV) dimension ratio of 1 or more. Patients commonly showed paradoxical septal motion, where the interventricular septum moved away from the center of the LV cavity in systole (Fig. 33-5). Aside from being a common echocardiographic feature in PAH, the relative loss of inward septal motion can account for a mild loss of LV systolic function in PAH, and thus, a low-normal or mildly reduced LV function can occur in PAH on this basis. Bossone and co-workers[17] published a larger observation series with idiopathic PAH and showed that 96% of patients had a Doppler-estimated pressure of more than 60 mm Hg at diagnosis; however, the overall correlation between Doppler and invasive pressure estimates was relatively low ($r$ = 0.31). Ninety-eight percent of subjects had RV enlargement, and 75% of subjects had qualitative evidence of RV systolic dysfunction. Systolic flattening of the interventricular septum occurred in 90% of subjects. Moderate or severe TR occurred in 80% of subjects, whereas mild to moderate mitral regurgitation was present in only one patient. A small or moderate-sized pericardial effusion was also noted in about 16% of subjects.[17]

In PAH, at least 70% of subjects manifest a transmitral Doppler E wave velocity to A wave velocity ratio (E:A ratio) of less than 1.0, consistent with grade I LV diastolic dysfunction. All subjects in this study had normal LA pressure with

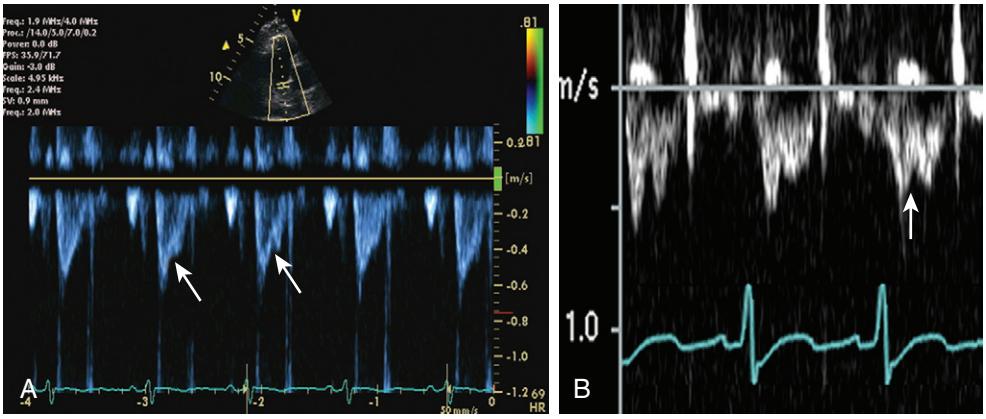

**Figure 33-3 A, Pulsed-wave Doppler signal from the RV outflow tract.** The Doppler signal displays late systolic notching (*arrow*), which typically coincides with a moderately shortened acceleration time (i.e., 70 t o 90 ms). Both findings suggest moderately increased pulmonary vascular resistance (i.e., 3 to 6 mm Hg/L/min). **B,** Pulsed-wave Doppler signal from the RV outflow tract. The Doppler signal displays midsystolic notching (*arrow*), which typically coincides with a severely shortened acceleration time (i.e., less than 70 ms). Both findings suggest a markedly elevated pulmonary vascular resistance (i.e., more than 6 mm Hg/L/min).

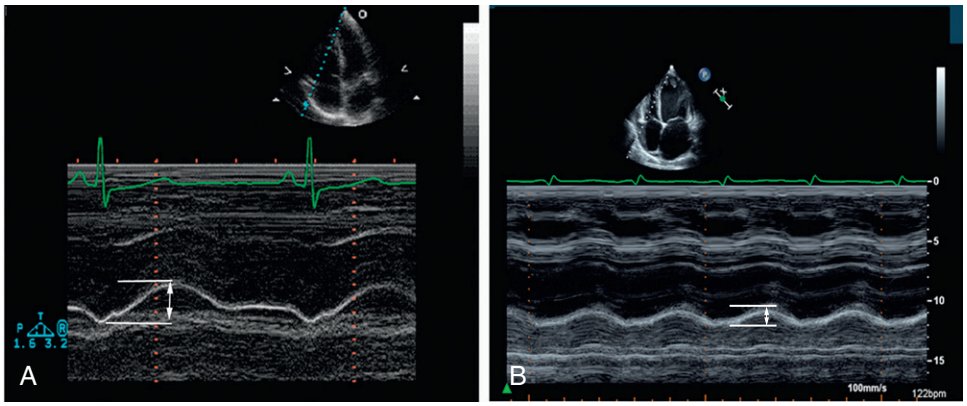

**Figure 33-4 A, M-mode imaging through tricuspid annulus recording of tricuspid annular plane systolic excursion in a patient with normal RV function.** The maximal excursion from diastole to systole is measured. The tricuspid annular plane systolic excursion is 2.4 cm. **B,** Tricuspid annular plane systolic excursion in a patient with severely reduced RV systolic function. The tricuspid annular plane systolic excursion is 1.3 cm.

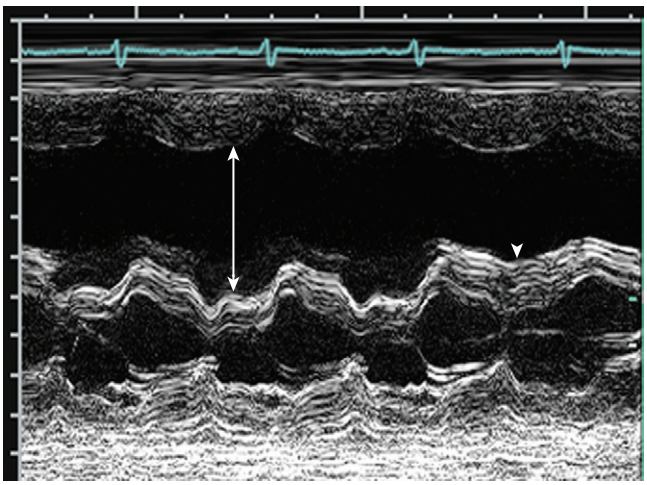

**Figure 33-5 M-mode imaging from the parasternal position in a patient with severe pulmonary arterial hypertension.** The RV:LV dimension ratio is greater than 1. The RV size increases with inspiration (*arrow*), with a resultant decrease in LV diameter. Paradoxical septal motion (*arrowhead*) is present.

right heart catheterization. In fact, grade I diastolic dysfunction in the vast majority of cases indicates normal LA pressure, reflecting the necessary redistribution of LV filling into late diastole that must occur when LV relaxation is impaired in the context of a normal LV filling pressure.[17,18] In clinical practice, the presence of any or all of the triad of findings of RV dysfunction, accompanied by grade I diastolic dysfunction, is a strong indicator of severe PH in the context of a normal LA pressure and high PVR. Arkles and associates[5] recently showed that a notched RV outflow velocity curve was seen in 100% of patients with an incident diagnosis of PAH, which coincides with prior data that show that 94% of subjects with PAH have an AcT of the RV outflow velocity curve less than 100 ms.[17] In our experience, the combination of a midsystolic notch RV outflow pattern with an E:A ratio of less than 1.0 is a highly sensitive and specific predictor of a markedly elevated PVR and a normal LA pressure.

Indices of right heart size, ventricular interdependence, and depressed RV function have been correlated with disease severity and patient outcome in patients with PAH.[4,19] In addition, studies have consistently shown that the presence and size of a

pericardial effusion predict poor outcome in patients with PAH.[20] Larger effusion size correlates with greater degrees of exercise intolerance, right atrium (RA) dilation, greater interventricular septal displacement, and more severe TR than in patients without an effusion.[19,21,22] The mechanism of the pericardial effusion in PAH most likely relates to slow progressive accumulation of intrapericardial fluid as a result of longstanding RA hypertension from decompensated right heart function. When the effusion is of moderate size or greater, the temptation is to intervene with percutaneous or surgical drainage. However, great caution should be exercised in this regard because drainage of pericardial effusions in patients with PAH has been associated with very poor outcomes, with death occurring within 12 to 24 hours of the procedure.[23] Importantly, the pericardial effusion is a marker of, but not the cause of, the right heart decompensation in this context. Thus, before pericardial drainage is considered, a right heart catheterization should be performed; if markedly elevated PVR, high RA pressure, and depressed cardiac index are found, the effusion is highly likely to be the direct result of afterload-induced RV failure. In the authors' experience, pericardial effusions in PAH almost invariably decrease in size or resolve over days or weeks as the RV failure is treated with pulmonary vasodilation therapy and diuresis.

Eysmann and colleagues[24] showed that a peak pulmonic flow velocity of more than 60 cm/s was predictive of a drop in PVR of more than 30% on acute vasodilator testing; no patient with a peak velocity of less than 60 cm/sec had a condition that was vasoreactive. Likewise, decreased LV and LA area, increasing RV:LV area ratio, and the degree of leftward septal bowing are also associated with an increased risk of systemic hypotension in response to calcium channel blocker therapy, likely reflecting the inability to sufficiently recruit RV stroke volume to overcome the drop in systemic vascular resistance.[25]

Other studies have focused on more direct assessment of RV systolic function. Tei et al[26] showed that the mean RV myocardial performance index (MPI) of patients with idiopathic PAH (0.83) was higher than in healthy controls (0.28) and that patients with an RV MPI of more than 0.83 had a less than 10% event-free survival rate at 5 years, versus more than 70% in those with an RV MPI of more than 0.83 (see Fig. 32-10).[27] A prospective study in patients with idiopathic PAH and PAH associated with connective tissue disease showed that a TAPSE of less than 1.8 cm was associated with lower invasively derived stroke volume index, higher RA pressure, greater RV dilation, right to left heart disproportion, and septal bowing and a higher incidence rate of pericardial effusion. Two-year survival rate estimates were 88% and 50% for patients with a TAPSE of 1.8 cm or more and less than 1.8 cm, respectively.[28] The prognostic value of TAPSE persisted after adjustment for several echocardiographic and invasive hemodynamic variables of known prognostic significance. The peak systolic tissue Doppler velocity is another practical measure of RV longitudinal function and is strongly correlated with TAPSE (see Fig. 32-10).

The typical changes in RV size, function, and septal position have been shown to improve in response to varying therapies. After 4 months of therapy with bosentan in patients with PAH, repeat echocardiographic examination showed improved RV MPI, reduced RV end-systolic area and RV:LV diastolic area ratio, improved early diastolic LV filling, and decreased pericardial effusion scores.[29] Similarly, after 3 months of intravenous epoprostenol infusion, RV size decreased, as did peak TR velocity and the noninvasive PVR estimate.[30]

Preliminary data from the authors' group have shown that after 6 months of PH-specific therapy, 78% of patients had increased TAPSE of more than 0.2 cm (mean, +0.5 cm), in association with significant improvements in 6-minute walk distance (median, +115 m), B-type natriuretic peptide levels (−210 pg/mL), and New York Heart Association functional class (−1.0 functional class). In those patients who reached a TAPSE of 2.0 cm or greater at 6 months, no deaths or right heart failure admissions were seen, as compared with two deaths and four right heart failure hospitalizations in those with a TAPSE of less than 2.0 cm on follow-up examination.[31] The increase in TAPSE in response to therapy is consistent with recent data that show that in PAH, PH-specific therapy leads to relatively selective improvement in longitudinal RV shortening, which suggests that long-axis shortening of the RV may represent the most afterload-responsive element of RV systolic function.[32]

Given the limited clinical and prognostic value of serial pressure assessment in PAH, along with concerns with the accuracy of Doppler-estimated PASP, most centers do not routinely follow or titrate therapy on the basis of changes in echocardiographic estimated PAP. Further study is needed to determine whether changes in various echocardiographic parameters have similar clinical and prognostic value as the invasive hemodynamic assessment of PVR and how such information can be used to determine favorable response and necessity of escalation of medical therapy or referral for lung transplant evaluation. It will also be important to determine whether certain threshold values exist (i.e., TAPSE, 2.0 cm or more) in PAH, such that TAPSE or other RV function measures may be added to the goal-directed therapeutic approach in PAH.

## ACUTE PULMONARY EMBOLISM

Acute pulmonary embolism and especially large proximal emboli lead to a sudden increase in the pulmonary vascular impedance without a marked rise in the PAP. This relates to the fact that the normal RV is typically incapable of generating a sufficient stroke volume to maintain a PASP of more than 60 mm Hg (mean pressure, 40 mm Hg) when suddenly uncoupled from a normal pulmonary vascular bed.[33,34] As a result, RV failure and cardiogenic shock may ensue despite a mean PA pressure between 20 and 40 mm Hg.[35] It follows that the degree of RV dysfunction predicts the extent of perfusion defects with ventilation/perfusion scan.[36] In contrast, small subsegmental pulmonary emboli that are not associated with a marked rise in PA impedance do not lead to abnormal echocardiographic findings, highlighting the fact that echocardiography cannot rule out an acute pulmonary embolism.[37] The relative degree of PH helps establish the chronicity of the embolic event, as the average transtricuspid flow velocity in acute proximal pulmonary emboli (3.0 m/s) is significantly lower than in patients with subacute pulmonary embolism (4.2 m/s).[34] In contrast, patients with acute pulmonary embolism with a PASP of more than 50 mm Hg at the time of diagnosis are at increased risk of persistent PH at 1-year follow-up.[38]

From a physiologic viewpoint, acute pulmonary embolism is an important and often dramatic clinical example that underscores the concept that PAP is a poor measure of RV afterload. RV dilation is almost universally present in the setting of a large pulmonary embolism, as the normally compliant RV rapidly distends in response to the increased vascular load. However, unlike in PAH or other forms of chronic PVD, RV hypertrophy is conspicuously absent. Another common finding in acute

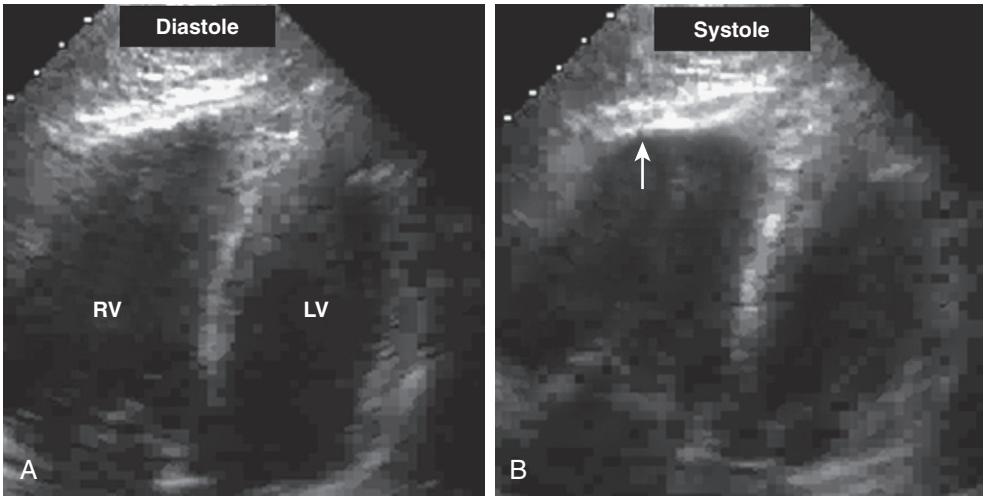

**Figure 33-6** **A, A close-up view of RV apex in diastole from the apical four-chamber view in a patient with acute pulmonary embolism.** The RV apex appears normal. **B,** Same view in systole. The RV free wall does not contract, but there is a hinge point (*arrow*) at the apex with some contraction; McConnell's sign is consistent with acute pulmonary embolism.

pulmonary embolism is McConnell's sign (Fig. 33-6), which is visually appreciated as RV dysfunction along the RV base and mid segments, with a hinge point or "buckling" of the RV free wall near the RV apex.[39] This relative sparing of RV apical wall motion likely is caused by tethering of the RV apex by a normal or hyperdynamic LV across the interventricular septum. Other studies have shown that the RV ejection fraction, RV stroke volume measured with pulsed Doppler imaging, and TAPSE are reduced in the setting of an acute pulmonary embolism.[40] A characteristic Doppler finding in acute pulmonary embolism is the "60/60 sign," which refers to a markedly shortened AcT (less than 60 ms) in the RV outflow velocity curve, because of the increased PA impedence, combined with a PASP of less than 60 mm Hg.[41] Similarly, midsystolic notching of RV outflow is a common finding in acute pulmonary embolism, relating to early arrival of reflected pressure waves from proximal vascular obstruction.

Another important finding to look for on the initial examination is right-sided heart thrombi and thrombi-in-transit, which complicate approximately 4% of cases with acute pulmonary emboli (Fig. 33-7).[42] Thrombi may be visualized within the RA and ventricle and occasionally are seen straddling the interatrial septum. Right heart thrombi are a high-risk feature, typically associated with prior massive pulmonary embolism, severe RV dysfunction, and high in-hospital mortality.[42] In such cases, thrombolysis or catheter-based versus surgical embolectomy is often warranted.[42,43]

The main PA and its bifurcation are well visualized with transesophageal echocardiography (TEE; Fig. 33-8). TEE has been shown to have comparable sensitivity (80% to 97%) and specificity (86% to 100%) with spiral computed tomographic (CT) scan for the detection of central pulmonary emboli. Thus, TEE may play a role in the diagnosis of central pulmonary emboli, perhaps best applied in the setting of clinical instability, where bedside assessment and monitoring with TEE may be preferred over transporting the patient out of the intensive care unit for spiral CT examination.[44]

The primary value of echocardiography in acute pulmonary embolism is in the risk assessment of the individual patient. Echocardiographic evidence of RV hypokinesis predicts a two-fold increase in mortality at 2 weeks and 3 months.[45-48] Even in patients with hemodynamically stable conditions, identification of RV dysfunction with echocardiography may be an indication for thrombolytic therapy.[49] Echocardiography should be rapidly performed in every patient in whom the diagnosis of acute pulmonary embolism is made.[50] Likewise, patients with severe RV dysfunction in whom thrombolysis is contraindicated, or those with severe RV dysfunction and shock, may need more aggressive surgical or catheter-based therapies.[51,52] In addition, significant PH at the time of diagnosis (RV systolic pressure, more than 50 mm Hg) predicts the presence of CTEPH at 1 year; thus, these patients should be referred to a PH center for monitoring and management after recovery from the acute event.[53]

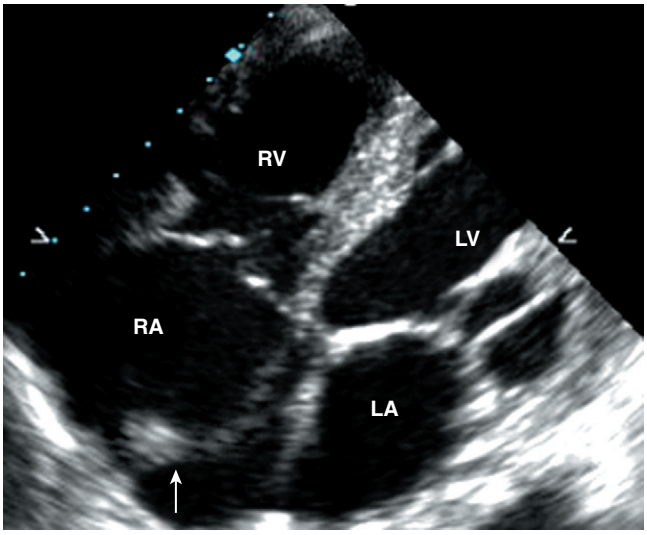

**Figure 33-7** **Venous thromboembolism.** In this off-axis four-chamber view, the RA and RV are dilated. A mass in the RA (*arrow*) represents a venous cast in transit. This cylindrical mass was highly mobile within the RA. RA hypertension is shown by the shift of the interatrial septum to the left. The patient had already sustained a pulmonary embolism but was a risk for another and probably lethal event. The patient was taken to the operating room immediately after these images were obtained.

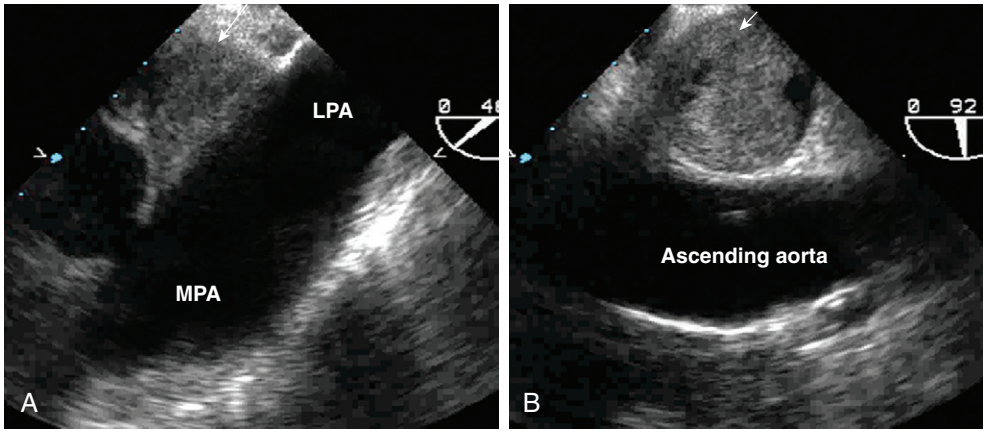

**Figure 33-8** **Pulmonary embolus. A,** TEE from the mid esophagus shows the pulmonary artery bifurcation. The right pulmonary artery is filled with thrombus and appears to be completely occluded. **B,** TEE from the same level in the transverse plane. The right pulmonary artery is filled with thrombus and is seen in the short-axis view. The ascending aorta is below the right pulmonary artery on the screen (anterior). *Asc Ao,* Ascending aorta; *LPA,* left PA; *MPA,* main PA.

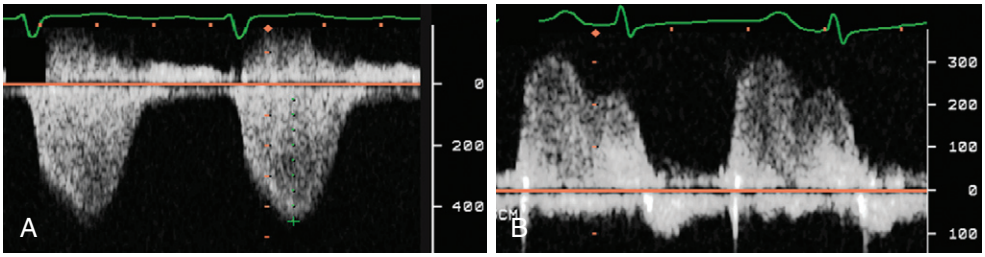

**Figure 33-9** **Pulmonary hypertension. A,** Continuous-wave Doppler image across the tricuspid valve in systole from the apical position. The peak velocity is 4 m/s. The RA pressure was estimated at 15 mm Hg. The pulmonary artery systolic pressure is 79 mm Hg. **B,** Continuous-wave Doppler across the pulmonic valve in diastole from the parasternal position. The peak velocity at end diastole is 2.4 m/s. The RA pressure estimate is 15 mm Hg. The pulmonary artery diastolic pressure is 38 mm Hg. The pulse pressure is thus calculated as 41 mm Hg (79 systolic minus 38 diastolic).

## CHRONIC PULMONARY EMBOLISM

Chronic thromboembolic PH is a relatively rare complication of prior acute pulmonary emboli that occurs in less than 5% of cases.[54,55] The major site of vascular impedance is often the proximal pulmonary vasculature because of the persistence of clot and vessel remodeling in the affected area. However, small vessel pulmonary arteriopathy is also known to occur in CTEPH, such that the degree of PVR elevation may be equal to or greater than that seen in idiopathic PAH.[56] The end result is often that the overall burden of PVD is comparable with that in PAH and, in some cases, worse because of the added hemodynamic load from the proximal obstruction. Thus, the typical triad of RV dysfunction, RV dilation, and septal bowing is present in CTEPH and is largely indistinguishable from the various forms of PAH. Nevertheless, hemodynamic differences between CTEPH and PAH can aid in differentiating the two conditions. Namely, in CTEPH, the presence of a discrete proximal obstruction leads to more exaggerated, earlier arrival of arterial reflected waves and thus a more pulsatile pulmonary vascular bed.[13] This increased pulsatility can be expressed as the fractional pulse pressure (FPP = PA pulse pressure/mean PA pressure); the typical FPP is 0.8 in PAH and 1.4 or more in CTEPH.[57,58] The FPP can also be estimated with Doppler imaging (Fig. 33-9), with a noninvasive FPP of 1.35 predicting CTEPH with a sensitivity of 95% and specificity of 100% over idiopathic PAH.[59]

Serial examinations after pulmonary endarterectomy have shown increases in RV fractional area change and reductions in RV size, decreased septal bowing, and improved early diastolic LV filling.[60,61] A study by Hardziyenka and co-workers[62] showed that patients with early arrival of arterial reflected waves, as measured by a shorter time to notching of the pulmonary flow velocity curve, were the only patients with CTEPH to benefit from endarterectomy. These findings prove that simple RV outflow velocity curve analysis is able to predict clinical response to surgery and that a requisite degree of pulmonary vascular impedance and arterial wave reflection is needed for sufficient RV-PA recoupling to occur after surgical intervention.

## PULMONARY VENOUS DISEASE

The prototype, and most severe form of pulmonary venous disease, is pulmonary venoocclusive disease (PVOD). This relatively rare entity may be idiopathic but has also been associated with toxin exposure, infectious agents including HIV, and autoimmune disease (see Chapter 37). In addition, PVOD or a PVOD-like state has also been reported repeatedly in sarcoid-associated pulmonary disease.[63,64] Given that the hemodynamics of PVOD are similar to PAH, with marked increases in the PVR and normal LA pressure, it follows that the echocardiographic findings in PVOD are essentially the same as in PAH. A diagnosis of PVOD should be suspected in a patient who shows echocardiographic features suggestive of PAH but with symptoms (orthopnea) and radiographic findings (pulmonary vascular congestion, pleural effusions) suggestive of left heart congestion.

Acquired pulmonary vein stenosis may be detected with echocardiography. Pulmonary vein stenosis should be suspected when the inflow velocity to the LA is greater than 1.1 m/s and the flow is turbulent with little variation in velocity.[65] Clinically, this should be suspected in a patient after pulmonary vein isolation for ablation of atrial fibrillation.[66] Although the presentation may be acute and fulminant, most commonly, patients present months after the procedure, with a symptom complex suggestive of left heart congestion yet *without* classic echocardiographic features of PAH, such as marked RV dilation, dysfunction, and septal bowing.[67,68] Intracardiac echocardiography guidance during the procedure may reduce the risk of injury.[69] Magnetic resonance imaging (MRI) may be necessary to confirm the presence of pulmonary vein stenosis and to guide in stenting. Patients should be monitored with follow-up echocardiography after stenting because restenosis may occur.[70] The right inferior pulmonary vein cannot be imaged with transthoracic echocardiography and TEE or repeated MRI may be necessary for surveillance. Pulmonary vein thrombosis and occlusion have also been reported after heart and lung transplantation.[71,72] Intraoperative TEE may reduce the incidence of pulmonary venous complications and help with hemodynamic monitoring during these complicated surgeries.[73-75]

## Pulmonary Hypertension as a Result of Chronic Respiratory Disease

The chronic respiratory disorders most commonly associated with PH include chronic obstructive pulmonary disease (COPD), interstitial lung disease (i.e., idiopathic pulmonary fibrosis), and disorders of alveolar hypoventilation, which include chronic neuromuscular disorders and sleep-disordered breathing. The pathogenesis of PH in COPD and interstitial lung disease is multifactorial and relates in part to parenchymal lung destruction and secondary loss of pulmonary vascular surface area. In addition, both acute hypoxic pulmonary vasoconstriction and the effects of chronic hypoxemia (and hypercapnia) on pulmonary vascular remodeling contribute to increased RV afterload in these conditions. Lastly, it is relatively common for patients with advanced lung disease to have an increased CO (as a result of adrenergic stimulation). Thus, the most common hemodynamic profile of PH in lung disease is that of mildly increased PVR (i.e., 2 to 4 Wood units), combined with mild or moderately increased CO. LA pressure is most often normal; however, this should be verified and not assumed. Given the modest increase in PVR, significant RV dysfunction and dilation is relatively uncommon in these patients. However, because of the chronicity of the conditions, RV hypertrophy is often present. Thus, the common constellation of findings in patients with chronic parenchymal lung disease includes mild to moderate PH; some degree of RV hypertrophy, typically with mild or lesser degrees of RV dilation; dysfunction; and septal flattening. The presence of PAH-like echocardiographic findings represents a departure from the norm in these patients and signifies a greater degree of PVD. The clinical circumstance under which the echocardiographic examination is performed is highly relevant in these patents because the hemodynamics in the setting of an acute respiratory exacerbation can differ greatly from those obtained under steady state conditions.[76] As a result, if the examination was initially performed in the context of an acute respiratory decompensation, the study should be repeated once the patient's condition is compensated and at the clinical baseline for more accurate assessment of the impact of the respiratory condition on the heart and pulmonary circulation.

Alveolar hypoventilation also predisposes to PH; however, intermittent hypoxemia (either nocturnal or daytime) is typically insufficient to result in chronic PH. Even in the setting of severe nocturnal desaturation, most patients with severe obstructive sleep apnea do not have significant PH. In contrast, PH is far more common in the setting of chronic daytime hypoxia and hypercarbia, as seen in patients with obesity-hypoventilation syndrome. As a result, the most significant predictors of PH in patients with sleep-disordered breathing are daytime $PO_2$ and $PCO_2$, and a lower forced expiratory capacity ($FEV_1$) and a higher body mass index.[77] Even in the setting of severe obesity and sleep apnea, RV systolic dysfunction and an increased PVR are not common, as shown in a cohort of patients at the time of referral for gastric bypass surgery.[78] As a result, PAH-like findings are uncommon in obstructive sleep apnea or obesity hypoventilation syndrome. When present, findings such as significant RV dilation, dysfunction, septal flattening, and a notched RV outflow pattern should greatly increase the suspicion for conditions such as PAH and CTEPH, as the pathophysiology of PH in obstructive sleep apnea is typically not sufficient to cause such findings.

Although most PH in the setting of respiratory disorders is precapillary, arising from an increased PVR and normal LA pressure, the presence of an increased LA pressure should not be overlooked as a contributor to PH in the setting of lung disease. This is especially true with comorbid conditions (i.e., COPD with hypertension and coronary artery disease) that may lead to the coexistence of both pulmonary and left-heart related causes of PH and is especially important given that pulmonary venous congestion is very poorly tolerated in the setting of significant lung disease and is a relatively easily reversible cause of dyspnea in these patients. An increased LA pressure is common in patients with morbid obesity and significant sleep-disordered breathing, given the high incidence rate of hypertensive heart disease and LV diastolic dysfunction in these patients.[79,80] In our experience, LA hypertension is the single most common cause of moderate or greater PH in patients with severe sleep-disordered breathing and also the most underappreciated.

Although most PH in the setting of parenchymal lung disease is rather modest and typically fits the previous hemodynamic profile, the degree of PH and the degree of PVR vary widely. Thus, the hemodynamic composition of PH within the context of chronic respiratory disorders is quite heterogeneous. As a result, the echocardiographic findings in this context can also vary widely.

A minority of patients with PH related to COPD or interstitial disease have severe PH as a result of a much greater degree of PVD. Approximately 1% to 5% of patients with COPD have hemodynamics comparable with patients with PAH, with an mPAP of more than 50 mm Hg in the context of a markedly elevated PVR and decreased cardiac index.[81,82] Interestingly, subjects with COPD and PAH-like hemodynamics are significantly more hypoxic than those with mild to moderate PH and have a $pCO_2$ less than 40 mm Hg; these arterial blood gas findings are more consistent with the findings of PAH than COPD. Moreover, these patients showed lesser degrees of airway obstruction than subjects without PVD. In the authors' experience, the echocardiographic examination of these patients mirrors their underlying physiology, and thus, they have similar

degrees of RV dilation, dysfunction, and septal flattening as patients with PAH.

Pulmonary sarcoid has a particular predilection for pulmonary vascular involvement, and thus, $PH_{+PVD}$ is seen in a significant minority of these patients. Other parenchymal lung disorders that present a higher risk of significant pulmonary vascular involvement include Langerhans cell histiocytosis and interstitial lung disease associated with scleroderma.[83-85] In each of these three diagnoses, the degree of PVD may occur in varying proportion to the severity of the parenchymal disease. Nevertheless, when the PVR is significantly elevated (i.e., 5 Wood units or more), the imaging and Doppler findings seen are typical for a patient with PAH or CTEPH, with comparable degrees of RV dilation, septal bowing, and RV systolic dysfunction. In addition, either late or midsystolic RV outflow notching is present and carries essentially the same pathophysiologic significance in these patients as described for patients with PAH. In patients with chronic lung disease and PH, subjects without a notched RV outflow velocity curve had an average mean and PASP of 30 mm Hg and 52 mm Hg, respectively, with a PVR of 3.2 Wood units. In contrast, subjects with a RV outflow notching had a mean and PASP of 48 mm Hg and 77 mm Hg, respectively, and a PVR of 8.0 Wood units. Moreover, RV function differed significantly, with relatively normal RV function (TAPSE, 2.0 cm) seen in the non notched group and moderate RV dysfunction observed in the RV outflow notching group (TAPSE, 1.6 cm).[86] Thus, the RV outflow notching pattern helped discern PH that was "proportionate" versus "disproportionate" to the degree of parenchymal lung disease.

As a word of caution, echocardiographic image quality can be suboptimal as increased lung volumes, obesity, and pulmonary fibrosis attenuate ultrasound penetration. Cardiac orientation is often abnormal, which may confound optimal Doppler alignment with the TR jet. These issues are well illustrated in a report of 374 patients with advanced lung disease who underwent right-sided heart catheterization and Doppler echocardiography less than 72 hours apart. Estimation of PASP was only possible in 44% of the population. There was only a modest overall correlation ($r = 0.69$) between invasively derived PASP and Doppler-estimated pressure, with 52% of the patients having a pressure estimate that was greater than 10 mm Hg from the catheter-derived value.[87] As a result, an integrated echocardiographic assessment is of particular importance in these patients. Appreciation of right heart size, septal position, and systolic function and careful inspection of the RV outflow pattern always provide a better assessment of PH in general and greatly offset the risks of overreliance on a single Doppler pressure estimate in these patients.

## Lung Transplantation

A decrease has been seen in the need for single or double lung transplantation as medical therapies for PAH have improved. Nevertheless, a minority of patients with PAH has progression despite maximal medical therapy and eventually needs lung transplantation. For the individual patient, lung transplantation may be lifesaving and markedly improve quality of life. In addition, the physiologic changes that occur after lung transplantation have provided important insight into the physiology of the RV-PA interaction that have helped improve medical therapy for those not in need or ineligible for transplantation.

Although RV dysfunction is nearly universally present in PAH, this is not primarily the result of intrinsic impairment of RV contractility. Instead, the ventricular dysfunction relates to chronic and severe mismatch between RV function and RV afterload. Pressure-volume loop studies have shown that intrinsic RV contractility (RV end-systolic elastance) is two-fold higher than in healthy subjects. However, this relative improvement in RV function is not sufficient to match the four-fold increase in RV afterload as compared with healthy subjects.[9] Restoration of afterload toward normal restores normal RV-PA coupling, and thus, RV function.[8] This is well demonstrated after lung transplantation. In a series of 17 patients with severe refractory idiopathic PAH, the average RV ejection fraction and cardiac index were 32% and 2.2 L/min/m$^2$ before transplantation. The average mean PA pressure was 61 mm Hg, and the PVR was 10 to 12 Wood units. All patients showed marked RV dysfunction, RV dilation, and right to left septal bowing. Three months after bilateral lung transplantation, there were significant reductions in RV diastolic dimensions and RV end-diastolic area and near complete resolution of TR. All patients had normal septal position on follow-up examination, and the average RV ejection fraction increased to 67%.[88] These findings underscore the concept that in the vast majority of patients with PAH, it is not impaired RV contractility per se, but rather excessive RV afterload that leads to RV failure. For these reasons, as long as RV afterload is massively elevated, there is no degree of pre–lung transplant RV dysfunction "cutoff" that precludes double lung transplantation.

## Pulmonary Hypertension without Pulmonary Vascular Disease

By definition, $PH_{øPVD}$ (i.e., normal PVR) must arise from either a rise in pulmonary blood flow or a rise in LA pressure. As such, $PH_{øPVD}$ occurs in the context of a relatively normal RV afterload, and therefore, the RV dysfunction triad of RV dilation, dysfunction, and septal flattening and RV outflow notching are conspicuously absent. Thus, the *lack* of typical Doppler findings of $PH_{+PVD}$ should serve as a critical clue to the presence of $PH_{øPVD}$, be it related to a high CO disease state, a congenital heart disease-related systemic to pulmonary shunt, or left heart disease.

### PULMONARY HYPERTENSION RELATED TO INCREASED CARDIAC OUTPUT

Because of the relative distensibility and low resistance nature of the pulmonary circulation, an increased CO alone is often insufficient to cause PH. The pulmonary flow required to cause significant PH is quite high. For example, with a PVR of 1.5 Wood units and a LA pressure of 10 mm Hg, the CO would need to be approximately 11 L/min to produce an mPAP of 25 to 30 mm Hg (mild PH). More typically, a high CO is paired with at least one other abnormality (i.e., an increased LA pressure) in the pulmonary circulation to cause PH.

An increased CO may be caused by increased inotropic stimulation, increased preload, or excessive reduction in LV afterload. An often underappreciated and relatively common cause of increased CO is the presence of a arteriovenous fistula or graft in the context of end-stage renal disease. Each can be associated with at least an additional liter of CO through their direct rerouting of blood flow and their indirect effect on lowering LV afterload. In isolation, they typically do not lead to PH; however, when combined with the common associates of LV

diastolic or systolic dysfunction, systemic hypertension, and generalized arteriosclerosis, PH is a common byproduct. In the authors' experience, the 2D examination typically shows some degree of RV dilation; however, systolic septal flattening and RV systolic dysfunction are notably absent. In fact, hyperdynamic RV function is more often present, given the excess preload returning to the right heart via the upper extremity veins. Moreover, stigmata of left heart disease are very frequently present, including LA enlargement, LV hypertrophy, and grade II or III LV diastolic dysfunction.[89]

Liver disease is another important cause of increased CO because of the presence of a markedly reduced systemic vascular resistance, at times combined with hypervolemia. Appreciation for the type of PH present in the setting of advanced liver disease is of great importance because the diagnostic and treatment strategies associated with portopulmonary hypertension (portoPH) are dramatically different from those associated with the vast majority of PH associated with liver disease. PortoPH is a form of PAH and is thus associated with a markedly increased PVR and shows echocardiographic findings similar to other forms of PAH. However, even amongst a cohort of 101 patients with advanced liver disease and a Doppler-estimated PASP of more than 50 mm Hg, 35% of subjects did not have portoPH and instead had PH related to increased CO or increased LA pressure.[90] The percentage of patients with flow-induced or left heart disease–related PH is likely to be even higher in a more general liver disease referral cohort. The echocardiographic findings between portoPH and high-flow, low-PVR causes of PH differ greatly. In the authors' experience, proper interpretation of the screening echocardiographic examination minimizes the risk of misclassification of the type of liver disease–associated PH and identifies those at risk of poor outcome with liver transplantation (portoPH) versus those with a poor outcome without liver transplantation (non-portoPH).

### SYSTEMIC TO PULMONARY VENOUS SHUNTS

Echocardiographic findings associated with congenital heart disease–related systemic to pulmonary shunts are discussed in Chapters 44 and 45. A variety of 2D and Doppler findings are associated with shunting at the venous, atrial, and ventricular levels. For the purpose of this discussion, we focus on the general principles of RV structure and function and basic shunt assessment.

In the setting of smaller shunts or larger shunts in the absence of PVD, the RV is primarily subject to an increased volume load. In the context of increased RV volume and normal RV afterload, RV function is typically increased on the basis of increased preload recruitable cardiac work (Starling effect). Thus, a dilated and hyperdynamic RV is an important initial clue to the presence of a left to right shunt. On short-axis imaging, bowing of the interventricular septum is often found, however, only appreciated in ventricular diastole. The degree of PH varies in proportion to the relative shunt fraction and increase in pulmonary blood flow. Herein lies another example of the disconnect between PA pressure and RV afterload, as the increased pressure is owed to, but not opposing, pulmonary blood flow.

Over time, excess pulmonary blood flow can lead to pulmonary endothelial dysfunction and PVD, with the degree of PVR reaching levels equal to or greater than that seen in other forms of PAH. In these conditions, the RV must accommodate the persistent volume load and the rise in PVR. However, the rise in RV afterload in the setting of a chronic systemic to pulmonary shunt occurs relatively slowly, often over decades. As a result, the structure and function of the RV in PAH associated with a chronic shunt often differ from other forms of PAH. Namely, the degree of RV hypertrophy is often greater than the degree of RV dilation.[91] Marked RV hypertrophy can often be appreciated by both wall thickening and excess RV trabeculations, and by a conspicuous moderator band; these findings alone can often help distinguish PAH related to an intracardiac shunt from other forms of PAH. RV dilation and dysfunction in the setting of a chronic shunting is especially worrisome and often coincides with very late stage disease.

Qualitative initial shunt assessment is often performed with rapid injection of agitated saline solution ("bubble study"), which opacifies the right heart chambers and allows for detection of both right to left shunts (early passage of bubbles from right to left) and left to right shunts (via a negative contrast jet created from the passage of blood into the opacified right heart chamber; Fig. 33-10). Shunt quantification with Doppler imaging is expressed by the ratio of pulmonary to systemic blood flow. Doppler flows in the RVOT (Qp) and LVOT (Qs) are assessed to derive the Doppler Qp:Qs ratio. The RVOT diameter is typically about 0.5 to 1.0 cm greater than the LVOT diameter; given that flow is equal to the product of cross-sectional area and velocity, it follows that the Doppler velocity time integral (VTI) in the RVOT is typically less than the VTI in the LVOT. Thus, a simple clue to a sizeable left to right shunt is when the RV outflow VTI is equal to or greater than the LV outflow VTI. A saline solution contrast study may reveal early passage of bubbles across a patent foramen ovale or atrial septal defect with shunt reversal (i.e., Eisenmenger syndrome) or a negative contrast jet in patients with left to right shunting (see Fig. 33-10). Shunt localization is performed by first assessing for 2D and color Doppler evidence of interatrial or interventricular septal defects. Of note, at least 20% of sinus venosus–related atrial septal defects may be missed with transthoracic Doppler examination and may require imaging with TEE, intracardiac echocardiography, or MRI for full characterization. Further shunt characteristics, such as blood flow direction, blood flow velocity, and estimated pressure gradients across shunts, can be performed with color, pulsed-wave, and continuous-wave Doppler examinations.

## Pulmonary Hypertension Related to Left Heart Disease (Pulmonary Venous Hypertension)

By far the most common cause of PH relates to passive elevation of the PAP from an increase in LA pressure. A variable degree of reactive pulmonary vascular remodeling may also occur, typically related to the severity and chronicity of the LA hypertension.[92,93] As a result, patients with PVH comprise a large percentage of patient referrals for PH evaluation. Thus, knowledge of the basic noninvasive manifestations of PVH is critically important in the initial approach to patients with undifferentiated PH.

It follows that the noninvasive predictors of PVH include 2D and Doppler findings that either reflect or predispose to LA hypertension and more direct Doppler estimates of increased LA pressure.[92-94] Importantly, the LV ejection fraction is a poor predictor of LA hypertension, and thus, a normal ejection fraction in no way provides reassurance that the LA pressure is normal.

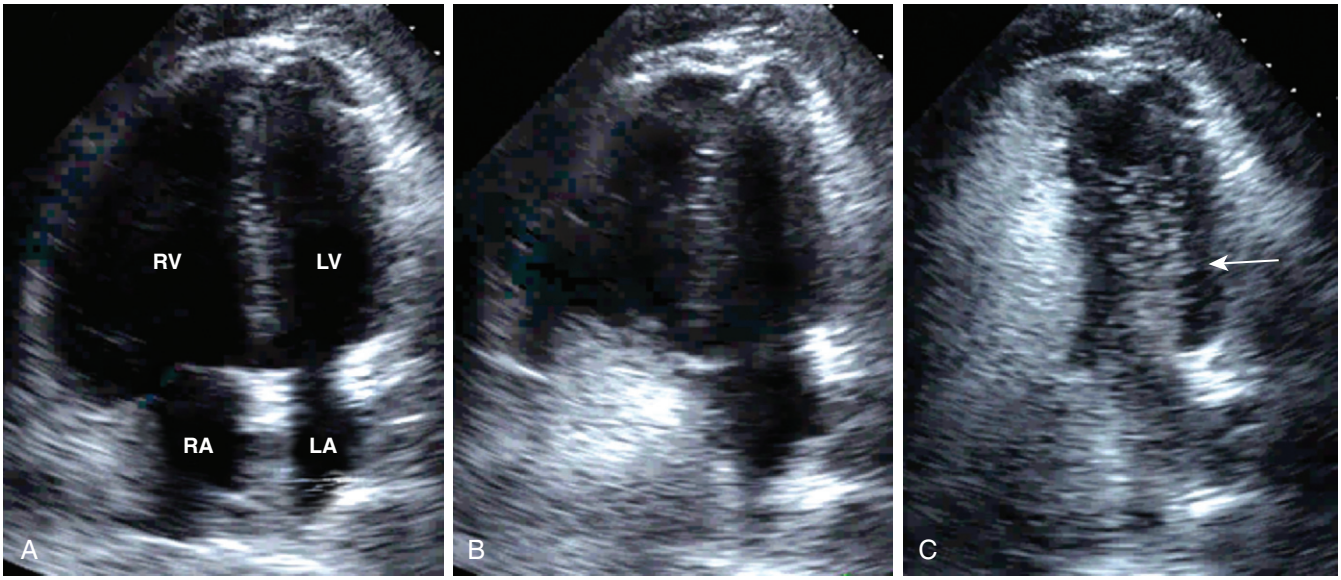

**Figure 33-10 A, Apical four-chamber image in a patient with dilated RV and moderate pulmonary hypertension as a result of idiopathic pulmonary fibrosis.** The patient's hypoxia was out of proportion to the lung disease. **B,** Agitated saline solution contrast entering the RA. **C,** Agitated saline solution contrast filling the RV and passing into the LA and subsequently the LV through a patent foramen ovale.

The 2D echocardiographic examination can provide compelling initial evidence that either supports or refutes the presence of LA hypertension. One of the first clues to past or present LA hypertension is LA enlargement, which should certainly not be considered a physiologic measurement of LA pressure. However, increasing LA size typically denotes chronically increased LA impedance and either the presence of, or predisposition for, increased LA pressure. LA enlargement is best appreciated in the parasternal long-axis view, with a LA dimension at end-systole of 4.0 cm or more generally being the accepted cutoff. However, the more reliable method is use of the biplane method of disks to measure LA volume. The apical four-chamber and apical two-chamber views are used, with care taken to avoid the pulmonary veins. The volumes are indexed to body surface area. Abnormal volume is considered more than 28 mL/m$^2$. Another important finding is the presence of LV hypertrophy; LV hypertrophy, even when mild, denotes chronic remodeling of the LV, typically the result of longstanding systemic hypertension. This is a significant form of structural left heart disease and is typically associated with increased LV chamber stiffness. Melenovsky and associates[94] showed that LA size (expressed as LA volume) and LV mass index, and the product of these two variables, were the strongest discriminates of nonsystolic heart failure from hypertensive heart disease without a history of heart failure. In the context of PVH as a result of elevated LA pressure, the interventricular septum typically maintains a normal configuration on short-axis imaging, convex toward the RV. In the apical four-chamber view, the ratio of RV:LV dimension (or area) typically remains less than 1.0, with the RV apex maintaining its sharp apical angle and with the LV forming the apex of the heart alone.

The Doppler examination also provides important physiologic information with respect to valvular function, diastolic function, and LA pressure assessment. As a general statement, moderate or greater dysfunction of either the aortic or the mitral valve is relatively uncommon when PVD is the primary source of the increased PA pressure. Of course, moderate or greater mitral stenosis is well known to cause severe PH, largely on the basis of passive pulmonary venous congestion. However, moderate or greater mitral regurgitation is also distinctly uncommon in the setting of PAH and provides fairly compelling evidence for a pulmonary venous source of PH.[17] Lastly, Doppler interrogation of the mitral valve inflow provides a key component to the patient with known or suspected PH. Grade II and III diastolic dysfunction are strongly suggestive of an increased LA pressure at the time of the examination and are uncommon findings in PAH.[5,17] In contrast, a PASP between 40 and 70 mm Hg (mean PA pressure, ~25 to 45 mm Hg) in the presence of pseudonormal or restrictive transmitral flow is strongly suggestive of PVH as the dominant source of PH. If this is coupled with normal septal position and normal RV size and shape, the diagnosis of PVH becomes almost certain. When PVH occurs in the context of some degree of PVD (e.g., in many patients with COPD), then the echocardiographic examination possesses 2D and Doppler features indicative of increased RV afterload and LA hypertension (i.e., LV hypertrophy and LA enlargement, grade II diastolic dysfunction), yet evidence of RV enlargement, RV dysfunction, and a late-systolic notching pattern in the RVOT Doppler profile.

## DIFFERENTIATING PULMONARY VASCULAR (ARTERIAL) FROM PULMONARY VENOUS HYPERTENSION

From the clinician's perspective, a useful initial diagnostic framework considers whether a patient's PH is from a pulmonary venous (postcapillary) or pulmonary arterial (precapillary) source. This approach is both rational and practical, given the prevalence of PVH and the fact that the diagnostic and therapeutic considerations for these patients differ considerably.

As outlined in the previous sections, a variety of echocardiographic parameters have significant diagnostic and prognostic value in PH. A transthoracic echocardiographic report customarily provides a list of normal and abnormal findings related to cardiac structure and function. Table 33-1 summarizes some of the salient 2D and Doppler features that aid in differentiating

**TABLE 33-1 Two-Dimensional, Doppler, and M-Mode Echocardiographic Features of Pulmonary Venous Hypertension and Pulmonary Arterial (and Related) Hypertension**

| *Pulmonary Venous Hypertension* | *Pulmonary Arterial* Hypertension* |
|---|---|
| **2D Imaging** | |
| Normal or dilated LV size | Normal or small LV size |
| LV hypertrophy | No LV hypertrophy |
| Variable LV ejection fraction | Normal or increased LV ejection fraction |
| Mitral annular calcification | No mitral annular calcification |
| Dilated LA size | Normal or small LA size |
| RV:LV ratio <1 | RV:LV ratio >1 |
| Sharp RV angle | Open/round RV angle |
| RV not apex forming | Apex-forming RV |
| Preserved septal shape (no flattening) | Septal flattening/D-shaped LV cavity |
| No pericardial effusion | Pericardial effusion |
| Normal RV function, TAPSE ≥2.0 cm | Reduced RV function, TAPSE <2.0 cm |
| **Doppler Imaging** | |
| E > A, type II or III (pseudonormal or restrictive diastolic filling pattern) | Normal or E < A, type I diastolic filling pattern |
| MR grade ≥2+, MR > TR | MR grade ≤1+, TR > MR |
| Variable PA systolic pressure (typically <70 mm Hg) | Variable PA systolic pressure (typically ≥ 70 mm Hg) |
| No systolic notching of flow velocity envelope in RV outflow tract | Mid-systolic notching of flow velocity envelope in RV outflow tract |
| Acceleration time of flow velocity envelope in RV outflow tract >95 ms | Acceleration time of flow velocity envelope in RV outflow tract <70 ms |
| TDI with RV S′ >10 cm/s | TDI with RV S′ <10 cm/s |
| **M-Mode Imaging** | |
| TAPSE ≥2.0 cm | TAPSE <2.0 cm |

*Pulmonary arterial causes to include pulmonary arterial hypertension (World Health Organization group I pulmonary hypertension), chronic thromboembolic pulmonary hypertension, and World Health Organization group III pulmonary hypertension with a normal LA pressure and pulmonary vascular resistance of more than 3 Wood units.

*A*, Atrial, or late diastolic inflow velocity; *E*, early diastolic inflow velocity; *MR*, mitral regurgitation; *TAPSE*, tricuspid annular systolic excursion; *TR*, tricuspid regurgitation.

the type of PH. This integrated assessment can help identify patients who need to be referred for invasive right heart catheterization.

Two examples of this integrated assessment are shown in Figures 33-11 and 33-12. All images in Figure 33-11 correspond to patient 1 (PVH), and the images in Figure 33-12 to patient 2 (PAH). In patient 1, the parasternal long-axis view (see Fig. 33-11, *A*) reveals LA enlargement and LV hypertrophy. The apical four-chamber view (see Fig. 33-11, *B*) also reveals LA enlargement and bowing of the interatrial septum to the right, which suggests higher LA than RA pressure. The LV ejection fraction is normal. The transmitral Doppler pattern reveals grade III diastolic dysfunction (see Fig. 33-11, *C*). The RV:LV ratio is less than 1.0 with a non–apex-forming RV and a relatively normal TAPSE (see Fig. 33-4, *A*). The RVOT Doppler pattern is not notched (see Fig. 33-11, *D*). This is highly suggestive of PVH without PVD. This patient would not likely be referred for invasive right heart catheterization at this stage because suspicion for PAH or an elevated PVR is low. Instead, the left heart condition would be managed and the patient's symptoms and PH monitored closely.

The parasternal long-axis view in patient 2 (see Fig. 33-12, *A*) shows normal LV wall thickness and LA size. Note the dilated coronary sinus, often indicative of high RA pressure (see Fig. 33-12, *A*, *arrow*). On the apical four-chamber view (see Figure 33-12, *B*), the RV:LV ratio is more than 1.0, with a rounded RV apical angle and an apex-forming RV. The LV ejection fraction is normal. The transmitral flow pattern reveals grade I diastolic dysfunction (see Fig. 33-12, *C*). The TAPSE (not shown) is reduced (1.7 cm), consistent with moderate RV dysfunction. The RVOT Doppler pattern has a midsystolic notching pattern (see Fig. 33-12, *D*), which has been shown to be 96% specific for a PVR of more than 5 Wood units.[5] The findings are highly consistent with PH of pulmonary vascular origin. This patient would be referred for urgent right heart catheterization, and the

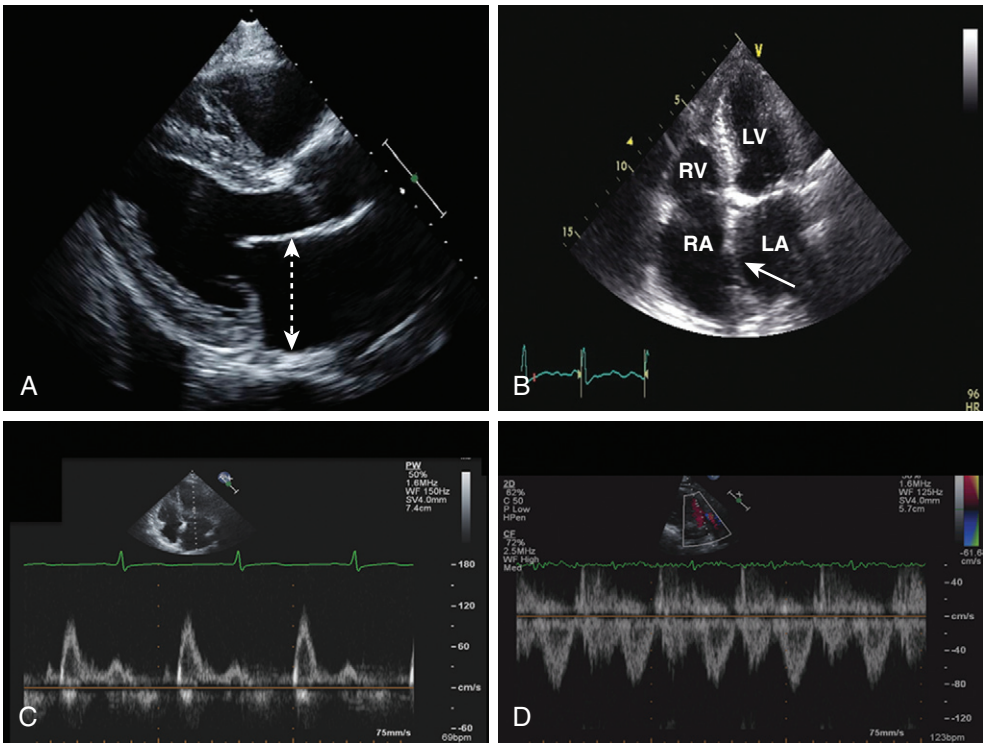

**Figure 33-11 Integrated 2D and Doppler echocardiographic assessment of a patient with pulmonary venous hypertension.** Note the LA enlargement (**A** and **B**) and the left to RA septal bowing (**B;** *arrow*). **C,** A restrictive transmitral flow pattern is shown. The pulsed wave Doppler of the RV outflow tract reveals no notching in the RV outflow velocity curve (**D**), consistent with a normal pulmonary vascular resistance

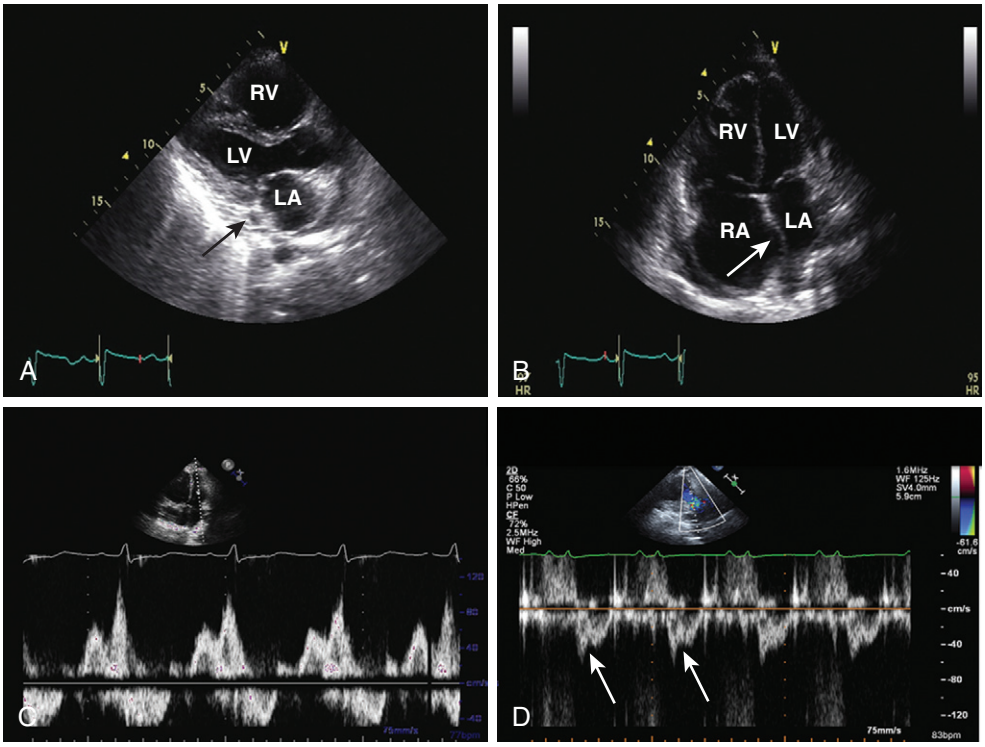

**Figure 33-12 Integrated 2D and Doppler echocardiographic assessment of a patient with pulmonary arterial hypertension.** Note normal LA size with a dilated coronary sinus (**A;** *arrow*) and right to LA septal bowing (**B**). **C,** A grade I diastolic dysfunction pattern is shown, and the pulsed wave Doppler of the RV outflow tract reveals a midsystolic notching in the RV outflow velocity signal (**D;** *arrows*), consistent with a high pulmonary vascular resistance.

needed imaging and functional studies would be completed to rule out underlying lung disease or CTEPH.

## EXERCISE ECHOCARDIOGRAPHY

Exercise stress echocardiography is used with increasing frequency in the assessment of patients with known or suspected PH and in the context of dyspnea of unclear etiology. In the former case, the presence or absence of exercise-induced PH is thought to increase the diagnostic sensitivity for the early stages of PVD; in the latter case, a rise in PASP is often thought to provide "proof" of PH as an important source of a patient's dyspnea. Although conceptually attractive, exercise stress echocardiographic assessment and interpretation has multiple important limitations that need be addressed to best apply this modality in clinical practice.

The first issue to address is whether a rise in PA pressure should occur with exercise. The time-honored teaching on this subject is that the PA pressure should not increase with exercise. However, studies do not support this and indicate that exercise-induced PH is more common than once appreciated. In 1966, Damato, Galante, and Smith[95] reported on the hemodynamic responses of 24 healthy male volunteers who underwent upright treadmill exercise with a PA catheter in place. The average peak oxygen consumption was 30 mL $O_2$/kg/min (~8 to 9 METS), which indicated normal but not elite exercise performance. At peak exercise, 10 of the 24 healthy subjects had a mPAP of more than 30 mm Hg, which met the definition of exercise-induced PH; the increases in PA pressure correlated with increasing CO, and the pressure-flow relationship and total pulmonary resistance remained normal in all subjects.[95] Bossone and colleagues[96] showed that highly conditioned college athletes routinely increased Doppler-estimated PASP to more than 50 mm Hg at peak exercise, whereas the healthy nonathletes typically did not exceed a PASP of 30 mm Hg. The degree of PASP elevation correlated best with changes in stroke volume, again indicating a normal pressure-flow relationship.

The second important limitation of exercise echocardiographic assessment of PA pressure is that changes in LA pressure are not accounted for during exercise. This is critical, given that exercise-induced PH (in health and in disease) most commonly arises from the interaction between an increased CO and a rise in the LA pressure.[97,98] To the contrary, Laskey and co-workers[99] showed that the PVR of patients with idiopathic PAH remained elevated during exercise but unchanged from resting values. Thus, exercise-induced pulmonary vasoconstriction is not typical, even in patients with established severe PVD. In the authors' experience with exercising patients with all forms of PH in the catheterization laboratory, a 1 to 2 Wood units increase in the PVR with exercise is quite unusual; and when it does occur, it is an abnormal finding that typically occurs in subjects with a significantly elevated baseline PVR.

The third limitation of exercise Doppler echocardiography is the accuracy of Doppler PASP assessment. Also, age likely exerts an important influence on the relative change in PA pressure with exercise because of age-related increases in pulmonary vascular stiffness; thus, exercise-induced PH, even at relatively low workloads, may be a part of the normal aging process, similar to the exaggerated increase in systemic arterial pressure with aging.[100] Lastly, the systemic blood pressure response to exercise should be factored into the interpretation of an exercise-induced rise in PA pressure. For example, a rise in PASP from 35 to 70 mm Hg in the context of a rise in systemic systolic pressure from 120 to 210 mm Hg indicates that the relative

proportion of pulmonary to systemic blood pressure has remained quite similar from rest to exercise, thus questioning the clinical significance of the rise in PA pressure in this context.

Taken together, one must exercise caution in the interpretation of a rise in Doppler-estimated PA pressure with exercise. A rise in PA pressure with exercise in many cases amounts to an association, but not a diagnosis, of the source of dyspnea in an individual patient. For many of these reasons, the recently published expert consensus document from the American College of Cardiology/American Heart Association recommends that at this time no treatment decisions for PH be made on the basis of exercise echocardiography.[1]

An alternative approach to exercise echocardiography may be a focus on the RV functional response to exercise, especially considering that impaired RV functional reserve is the mechanism of exercise limitation in PAH and other forms of PVD.[101] This approach may provide a more direct and clinically relevant answer as to whether a patient has clinically significant latent PVD or PH as the cause of dyspnea. If the RV function augments normally with exercise, the rise in PA pressure is likely flow mediated and of far less clinical significance. In contrast, a dilating and nonaugmenting RV seems to indicate an impedance-mediated process of greater clinical significance. In healthy subjects, TAPSE increases from approximately 2.5 cm at rest to 2.8 to 3.0 cm at peak exercise. Preliminary evidence suggests that the RV functional response to exercise (change in TAPSE) is linked to clinical outcome. In a relatively small cohort of patients with stable PAH, subjects either maintained a TAPSE similar to the resting TAPSE after graded supine ergometry or had a fall in TAPSE with exercise. A fall in TAPSE with exercise was strongly associated with adverse clinical events within 1 year of follow-up.[102] Importantly, a rise in the peak TR jet velocity after exercise was associated with better exercise-induced RV function and better clinical outcome. We suspect that more evidence will arise in the near future to support the notion that the focus of exercise echocardiography should be primarily on the RV functional response to exercise and away from the PASP change with exercise.

## KEY POINTS

- The pulmonary artery systolic pressure (PASP) is calculated by the peak velocity of the TR jet with the formula $PASP = 4v_{TR}^2 + RA$ pressure. The RA pressure is calculated from the collapse of the inferior vena cava during inspiration. The diastolic pressure can be obtained from the pulmonic regurgitation jet velocity at end diastole. The pulse pressure is the systolic minus the diastolic pressure.
- The RV shortens more in the longitudinal plane than in the transverse plane. TAPSE correlates well with RV function because it is a measure of longitudinal shortening. Assessment of free wall motion is not reliable, in itself, as a measure of RV function.
- The PASP depends on flow and LA pressure and on the afterload facing the RV (PVR). An elevated PASP is not synonymous with elevated afterload.
- The inspection of the RV outflow tract flow velocity envelope is an important part of the evaluation of a patient with elevated PASP. A short acceleration time (i.e., less than 80 ms) and a late or midsystolic notch are consistent with pulmonary hypertension (PH) from PVD; a normal acceleration time and flow velocity envelope without notching are not suggestive of elevated PVR no matter what the level of PASP.
- The classic triad of RV enlargement, decreased RV systolic function, and interventricular septal bowing into the LV suggests pulmonary vascular disease. The presence of these findings, even in the setting of a normal noninvasive PASP, should lead to further investigation.
- Chronic thromboembolic PH has similar echocardiographic features to idiopathic pulmonary arterial hypertension, but the pulmonary pulse pressure is usually greater than in other forms of PH.
- The most common cause of PH and RV dysfunction is LA hypertension. Increased LA volume, Doppler evidence of elevated LA pressure (grade II or III diastolic dysfunction), LV hypertrophy, and LV systolic dysfunction are present to varying degrees.
- Porto-pulmonary hypertension is a form of PAH. It is an important diagnosis in patients with end-stage liver disease because untreated it portends a poor prognosis with or without liver transplant. It must be distinguished from the far more common elevation in PAP in these patients from high CO.
- An integrated approach to the Doppler echocardiographic examination, which factors in both 2D and Doppler evidence that supports or refutes the presence of PVD, provides powerful insight into the hemodynamic basis of PH. This approach provides far greater physiologic information that the PASP assessment alone.

## Introduction

Right-sided valvular disease has historically received less attention than left-sided valve disease, in part because of how well these valve lesions are initially tolerated and the associated protracted latent asymptomatic period. Moreover, because tricuspid regurgitation (TR) is often the result of left-sided valve disease and pulmonic regurgitation (PR) is often the result of an underlying congenital cardiac lesion, the underlying disorder tends to dominate the clinical picture. However, right-sided valve disease, even if the result of an underlying disorder, is not benign, and the impact of tricuspid valve (TV) and pulmonic valve disease on morbidity and mortality is increasingly recognized. In this era of increasing awareness and improved treatment options for patients with valve disease, clinicians must consider the diagnosis of right-sided valve disease, understand the pathophysiology, choose appropriate confirmatory testing, and refer patients for timely intervention to prevent clinical deterioration with associated adverse consequences. Echocardiography plays a critical role in facilitating this process.

## Tricuspid Valve Disease

The normal TV is characterized by three sail-like leaflets: the anterior, posterior, and septal (Figure 34-1). The anterior leaflet is the most anatomically constant of the three; the other leaflets vary more often in size and position. The leaflets are attached to the TV annulus, a nonplanar structure with an elliptical saddle shape.[1] Similar to the mitral valve leaflets, the TV leaflets are restrained by chordae tendinea attached to the papillary muscles usually arranged in three groups, which are in turn inserted into the right ventricle (RV) wall beneath each of the three commissures. TV chordae may also insert directly into the RV free wall, a feature that distinguishes the right and left ventricles.

## Tricuspid Regurgitation

### BACKGROUND

Differentiation of a primary valve abnormality from valve dysfunction as a result of pulmonary hypertension or primary right heart disease is an important first step in the evaluation of patients with TR. Primary anatomic abnormalities of the TV, such as TV prolapse or endocarditis, are infrequent causes of TR. Rather, TR is more commonly the result of pulmonary hypertension, which in turn is often the result of left-sided heart disease.

### BASIC PRINCIPLES AND ECHOCARDIOGRAPHIC APPROACH TO DIAGNOSIS

Echocardiography is currently the reference standard for diagnosis and evaluation of TR. Because of nonspecific symptoms and subtle physical examination findings, severe TR is most often an incidental diagnosis at the time of echocardiographic evaluation of left-sided heart disease.

The echocardiographic evaluation follows the same principles as evaluation of left-sided lesions (see Chapter 18) and not only confirms the presence and severity of TR but also provides important information regarding etiology. Noninvasive estimation of pulmonary artery (PA) pressure and assessment of the

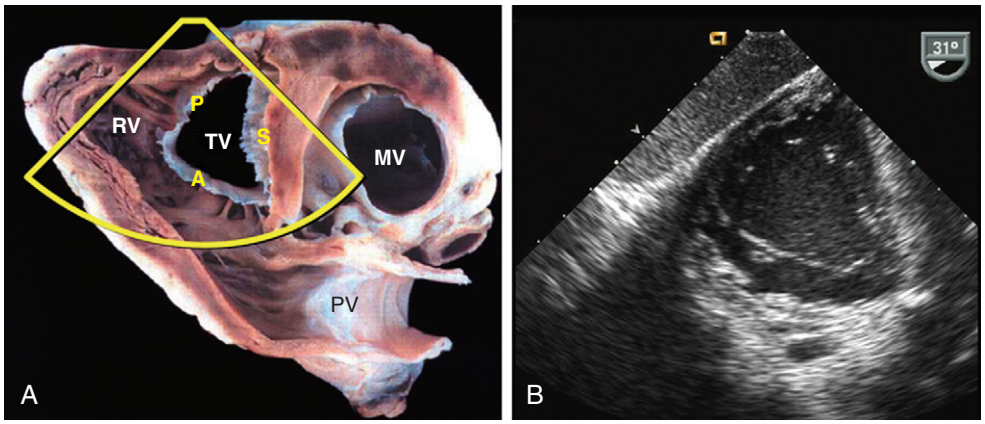

**Figure 34-1 Normal tricuspid valve anatomy. A,** Pathology image shows the RV with the tricuspid valve in a short-axis view. The pathologic section is oriented to replicate the transesophageal transgastric view obtained at a transducer angle of 31 degrees (**B**). Note the septal, anterior, and posterior leaflets. **B,** Transesophageal transgastric echocardiographic image with the same imaging plane (defined by the border in **A** shows the RV with tricuspid valve septal, anterior, and posterior leaflets. *A,* Anterior leaflet; *MV,* mitral valve; *P,* posterior leaflet; *PV,* pulmonic valve; *S,* septal leaflet. *(Pathologic image courtesy Dr William D. Edwards, Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine.)*

consequences of TR on RV size and function are essential components of the echocardiographic examination. The approach to echocardiographic assessment of RV size and function and estimation of PA pressure are discussed in detail in Chapter 32.

## TECHNICAL DETAILS, QUANTITATION, AND DATA ANALYSIS

### *Determining the Etiology of Tricuspid Regurgitation*

Determination of the etiology requires careful assessment of TV leaflet morphology, annular dimension, subvalvular apparatus, and RV size and function (Box 34-1). Coexisting left-sided valvular heart disease or intracardiac shunt should be identified, and the presence of an intracardiac device (e.g., pacer or defibrillation lead) should prompt careful assessment of TV leaflet mobility. Also, assessment of the consequences of the valve abnormality on RV size and function is important.[2-4]

Transthoracic two-dimensional (2D) imaging of the TV involves ventricular inflow and short-axis views from the parasternal window and four-chamber views from both the apical and the subcostal windows. With 2D echocardiography, visualization of all three leaflets in one view is challenging.[5] The septal and anterior leaflets are consistently seen in the parasternal short-axis and apical four-chamber views.[6] Imaging with an anterior to posterior sweep in an apical four-chamber or subcostal view can overcome the limitation of reliable identification of the posterior leaflet. When the coronary sinus is seen, because this is a posterior structure, the posterior leaflet is identified. In addition, the posterior TV leaflet may occasionally be visualized from the parasternal short-axis view and from the RV inflow view with rotation of the transducer 90 degrees clockwise, resulting in a two-chamber view of the right heart. With transesophageal echocardiography (TEE), the TV is often best seen in the transgastric long-axis and short-axis views with the probe rotated towards the patient's right side (see Fig. 34-1). This view provides the only opportunity to visualize an en face view of the TV with 2D echocardiography. The TV can also be visualized from the mid esophageal four-chamber and basal short-axis views.[7]

Tricuspid regurgitation that is at least moderate or greater in severity is most frequently "functional" in nature. Functional

**Box 34-1**

**CAUSES OF TRICUSPID VALVE REGURGITATION**

**Congenital**
- Ebstein anomaly
- Tricuspid valve dysplasia
- Tricuspid valve hypoplasia
- Tricuspid valve cleft
- Double orifice tricuspid valve
- Unguarded tricuspid valve orifice

**Right Ventricular Disease**
- Right ventricular dysplasia
- Endomyocardial fibrosis
- Increased right heart pressure

**Acquired**
- Annular dilation
- Left-sided valvular heart disease
- Endocarditis
- Trauma
- Carcinoid heart disease
- Rheumatic heart disease
- Tricuspid valve prolapse
- Iatrogenic (radiation, drugs, biopsy, pacemaker, implanted cardiac defibrillator)

**Right Ventricular Dilation**
- Pulmonary hypertension
  - Primary pulmonary hypertension
  - Secondary to left-sided heart disease (valvular heart disease, cardiomyopathy, etc)
- Right ventricular volume overload
  - Atrial septal defect
  - Anomalous pulmonary venous drainage

TR by definition is not related to primary TV leaflet pathology but rather is the result of another disease process that causes RV dilation, distortion of the subvalvular apparatus, tricuspid annular ditation, or a combination of these.

On the basis of 2D imaging, the average normal annular diameter is 31 ± 1 mm, measured in a single plane from an apical four-chamber view. However, this measurement may be misleading because the tricuspid annulus is a dynamic structure and its dimensions change during the course of the cardiac cycle and in phases of respiration.[8,9] Furthermore, the tricuspid annulus

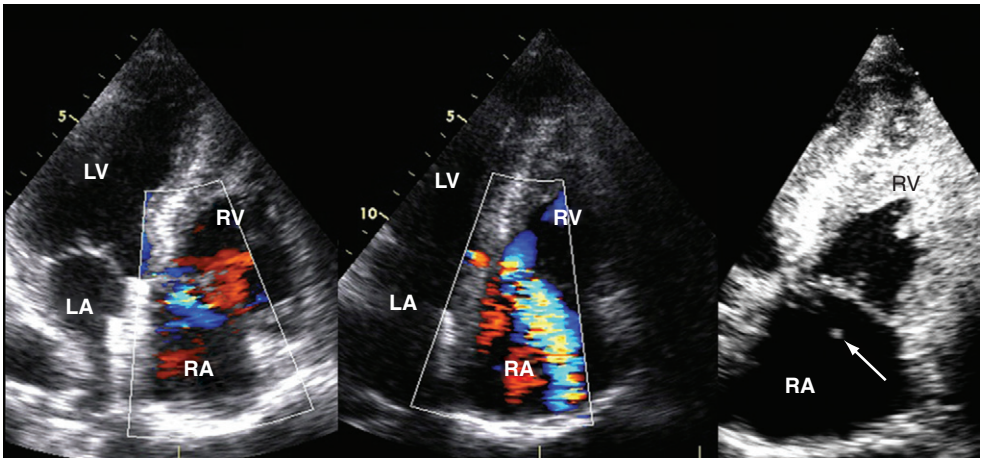

**Figure 34-2 Composite image showing a complication of endomyocardial biopsy.** In the *left image* (apical four-chamber view), mild tricuspid regurgitation is seen with color flow Doppler imaging. In the *center image*, obtained from the same view, an eccentric laterally directed jet of severe tricuspid regurgitation is seen. In the *right image*, a zoomed view of the tricuspid valve is seen. In addition, the severed tricuspid chordae is appreciated (*arrow*).

has a complex, three-dimensional (3D) saddle-like shape that make 2D assessment challenging. Three-dimensional echocardiography has shown that as functional TR worsens, the tricuspid annulus progressively becomes flatter and more circular, tending to dilate in the septal-lateral and posteroseptal to anterolateral dimensions.[1,8] Thus, 3D echocardiography holds promise in better definition of tricuspid annular dimensions and geometry, overcoming the inherent limitations of 2D imaging.

Causes of clinically significant TR are outlined in Box 34-1. Furthermore, a moderate or greater degree of TR, regardless of the primary etiology, usually engenders additional TR because of the adverse hemodynamic consequence of RV volume overload that results in a slow and inexorable clinical and hemodynamic deterioration.

Functional TR as a result of pulmonary hypertension is seen in patients with significant left-sided heart disease, commonly rheumatic in origin; in those with primary pulmonary hypertension; and in those with pulmonary disease that leads to cor pulmonale.[10] As a general rule, when systolic PA pressures increase beyond 55 mm Hg, TR can occur despite anatomically normal TV leaflets; whereas more than mild TR that occurs in the setting of lower systolic pulmonary pressures (less than 40 mm Hg) likely reflects a structural abnormality of the valve leaflets or the subvalvular apparatus.[2,11] Functional TR also results from tricuspid annular dilation in patients with RV enlargement from RV infarction, dilated cardiomyopathy, or left-to-right shunt, such as an atrial septal defect or anomalous pulmonary venous drainage.[12-14]

Primary TV pathology that leads to TR may result from blunt trauma or iatrogenic injury or from direct leaflet involvement by specific diseases. When the cause is by permanent pacemaker or internal cardiac defibrillator leads, the mechanism of valve injury is variable, related to lead entrapment in the tricuspid apparatus, direct leaflet perforation at the time of lead insertion, fibrotic adhesion of the lead to the leaflet, or avulsion or laceration of the TV leaflets on lead removal.[15] Because leaflet injury may be underappreciated in patients who have undergone lead implants, a high clinical index of suspicion is warranted, particularly when these patients present with worsening right heart failure.

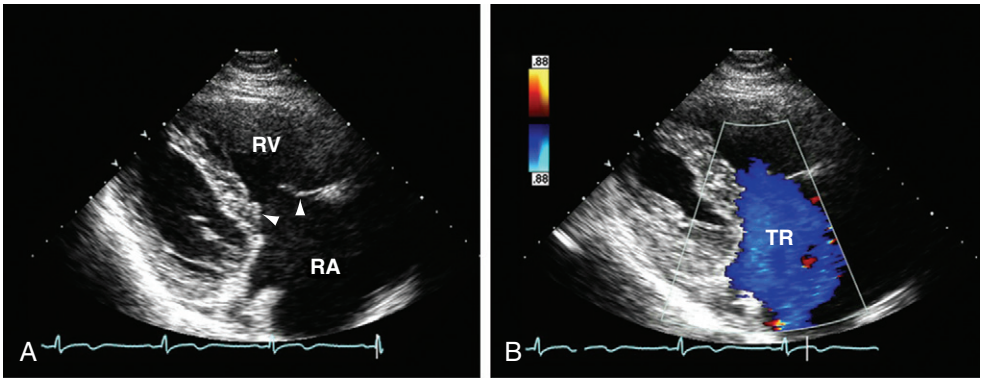
Direct trauma from transvenous endomyocardial biopsy may occur, particularly in patients for cardiac transplantation who undergo repeated biopsies for rejection surveillance (Fig. 34-2).[16] Echocardiographic guidance during the biopsy may avert damage to the TV or subvalvular apparatus.

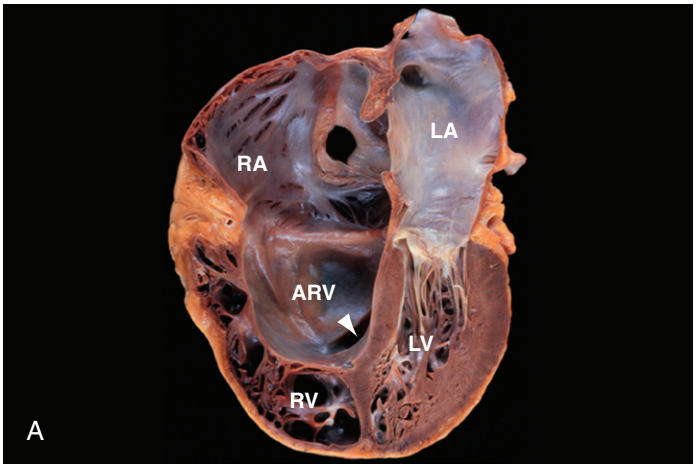
The TV leaflets and supporting structures may also be damaged indirectly with blunt chest trauma, most often after a motor vehicle accident that results in papillary muscle, valve, or chordal rupture. Routine use of echocardiography in the evaluation of victims of blunt chest trauma enhances detection of traumatic TR, overcoming the limitations of the history and physical examination.

Direct damage to the TV may occur as a result of infective and marantic endocarditis.[16,17] Right-sided infective endocarditis may be a manifestation of intravenous drug abuse.[2,18] It is also increasingly seen in patients with indwelling venous catheters used for dialysis or chemotherapy or with infected pacemaker or defibrillator devices. *Staphylococcus aureus* is responsible for 80% of these TV infections.[2] Infrequently, marantic or noninfective endocarditis may occur in the setting of connective tissue diseases, such as systemic lupus erythematosus, rheumatoid arthritis, or antiphospholipid antibody syndrome.[19] The TV may also be affected directly in as many as 30% to 50% of patients with rheumatic mitral valve disease.[20]

Serotonin active drugs may also induce TR by directly damaging the valve leaflets. This association was first described with the ergot alkaloids, ergotamine and methysergide, used for migraine therapy.[21] The anorectic drugs fenfluramine and dexfenfluramine, and pergolide and cabergoline, both dopamine agonists used in treatment of Parkinson disease and restless leg syndrome, may also induce TR with a similar mechanism.[22-24] The histopathologic changes seen in these drug-related valves include a fibroproliferative response that appears to be mediated by the 5-$HT_{2B}$ receptor.[25] These pathologic features are similar to those seen in carcinoid heart disease.

Carcinoid heart disease is a rare but distinctive form of valve disease that primarily affects the right-sided cardiac valves. Carcinoid is a tumor that arises from argentaffin cells. The primary tumor is usually located in the small bowel and metastasizes to the liver. The primary tumor and metastases produce active substances, including serotonin. Serotonin is recognized to be an agent involved in the development and progression of valve disease in patients with carcinoid syndrome.[26] Carcinoid heart disease involves a combination of TR (Fig. 34-3) with rare





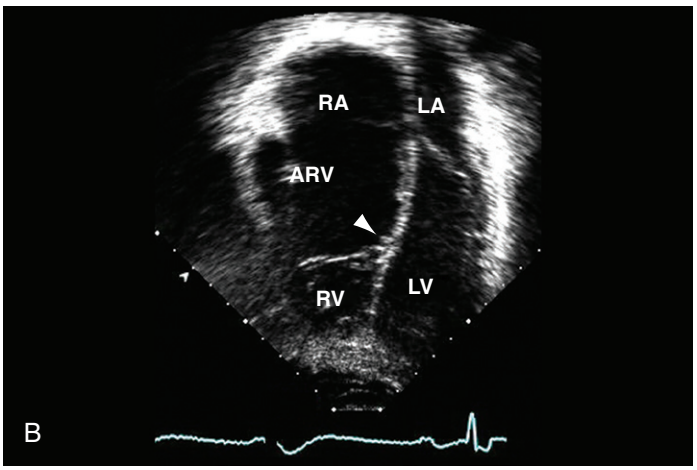


**Figure 34-3 Carcinoid heart disease.** **A,** Two-dimensional echocardiographic systolic image (RV inflow view) shows thickened septal and anterior tricuspid valve leaflets (*arrowheads*) and enlargement of the RV and RA. **B,** Color flow Doppler image shows severe tricuspid regurgitation (*TR*) in the same patient. Note laminar color flow (*blue*) filling an enlarged RA.

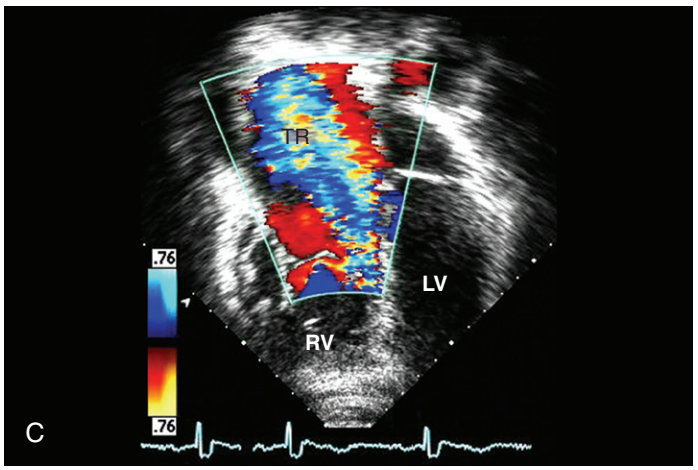

**Figure 34-4 Ebstein anomaly is characterized by apical displacement of the septal leaflet of the tricuspid valve (*arrowhead*) and variable tethering of the anterior leaflet.** The segment of RV myocardium between the leaflet insertion and the anatomic annulus is "atrialized" (*ARV*), as seen in the pathology specimen shown in the apical four-chamber "apex down" imaging format (**A**) and the 2D echocardiographic image shown in the same format (**B**). Because of associated valve disease, severe tricuspid regurgitation (*TR*) was noted with color flow imaging (**C**), resulting in a severely enlarged right heart chamber. *(Pathology image courtesy Dr. William D. Edwards, Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine).*

stenosis and pulmonic stenosis (PS) and PR. Left-sided valvular abnormalities occur in approximately 10% of patients with carcinoid valve disease, characteristically as a result of shunting of blood from the right-to-left atrium through a patent foramen ovale or atrial septal defect and less commonly as a result of a bronchial carcinoid or active carcinoid disease with high levels of circulating serotonin.[27] Rarely, carcinoid valve disease occurs in patients without hepatic metastases; an ovarian carcinoid should be sought in this setting.[28]

Mediastinal radiation can directly damage the TV leaflets. The associated postinflammatory fibrosis and calcification that usually manifest 5 or more years after the radiation insult result in distortion of the leaflets that cause TR.[2,29,30] Assessment and treatment of TR in this setting may be complicated by concomitant dysfunction of other cardiac valves and pericardial, myocardial, and coronary artery involvement.

Endomyocardial fibrosis, which is prevalent in tropical Africa, causes fibrosis of the papillary muscle tip and thickening and shortening of the leaflets and chordae, which lead to regurgitation. This process may affect both mitral valves and TVs.

Congenital causes of TR are rare and include congenital TV prolapse, which may occur as an isolated abnormality or be associated with mitral valve prolapse and other connective tissue disorders.[31,32] The most common congenital cause of TR is Ebstein anomaly (Fig. 34-4).[33] In Ebstein anomaly, apical displacement of the septal and posterior TV leaflets into the RV and variable tethering of the anterior leaflet occur. The severity of TR depends on significant adherence of the leaflets to the RV

wall, the degree of annular tethering, and valve leaflet fenestrations. A patent foramen ovale or atrial septal defect occurs in more than 50% of patients with Ebstein anomaly. Other associations that should be considered include PS or ventricular septal defect.[34]

### *Determining the Severity of Tricuspid Regurgitation*

As many as 80% to 90% of patients referred for echocardiography have some degree of TR.[35] Thus, screening for significant TR often relies primarily on visual assessment of the jet area with color flow Doppler imaging. When this technique is used in research settings, the ratio of the jet area to the right atrial (RA) area is calculated. These areas are measured from the same view after ensuring the sector width allows visualization of the entire right atrium. A jet area of more than 10 $cm^2$ or a jet area-RA area ratio of 30% or more suggests severe TR.[4,7] However, although jet area has been reported to correlate with angiographic grading[36,37] and quantitative Doppler echocardiographic methods,[38] significant limitations are found with this approach. The regurgitant jet area, even corrected for the receiving chamber size, is strongly limited by its dependence on hemodynamic conditions,[39] instrument settings,[40] and jet interaction with the receiving chamber.[41] Accordingly, only a mediocre correlation exists between jet size and TR severity.[9,38,42-44] In addition, TR severity may be underestimated with color flow Doppler imaging when the jet is eccentric because the extent of the jet may not be appreciated in standard views.

Quantitative assessment of TR severity is possible with color flow Doppler to estimate the effective regurgitant orifice area with measuring the vena contracta. The vena contracta is the smallest regurgitant flow area immediately beyond the flow convergence region and before expansion of the turbulent regurgitant jet and corresponds hydrodynamically with the effective regurgitant orifice area. Imaging is usually performed from an apical view with use of the narrowest sector angle to optimize the imaging frame rate. The color gain should be adjusted step by step to obtain the maximal color gain level that does not introduce signal outside of flow areas. If necessary, the position of the transducer should be modified to optimize visualization of the flow convergence region and the regurgitant flow proximal and distal to the TV. With use of a zoom of the region of interest, the vena contracta is visualized (Fig. 34-5).[44] Measurements of the vena contracta width, made in mid systole, over four consecutive cardiac cycles should be averaged.[44] A vena contracta width of 6.5 mm or more identifies severe TR, with 89% sensitivity and 93% specificity. This measurement has a better correlation with the effective regurgitant orifice than that of TR jet area or jet-RA area ratio. On the basis of published guidelines for assessment of TR, when the vena contracta measures greater than 0.7 cm (with prioritization of specificity and positive predictive value), severe TR is present.[2,4,45,46]

Quantitative Doppler assessment is also feasible with the proximal isovelocity surface area (PISA) method, although this requires angle correction.[4] Color Doppler images of the proximal flow convergence of TR are obtained from an apical or paraapical view with a zoom of the region of interest. The position of the transducer should be modified to minimize the angle between the centerline of the flow convergence and the ultrasound beam. The color flow velocity scale is maximized and the baseline shifted downward until the flow convergence region is clearly visualized. After downshifting of the color baseline, the radius of the flow convergence is measured in mid systole and the corresponding aliasing velocity is noted. The ratio alpha/180 is then calculated, where alpha is the angle of the systolic inverted TV funnel (measured with a protractor from the same apical view), to account for the shape of the TV. With this angle correction, the midsystolic instantaneous regurgitant flow is then calculated as

$$\text{Rflow} = (2\pi \times r^2 \times \text{Vr}) \times (\text{alpha}/180)$$

where Rflow is the regurgitant flow, r is the radius, and Vr is the corresponding aliasing velocity. The effective regurgitant orifice area is then calculated as

$$\text{ERO} = \text{Rflow}/\text{V}$$

where ERO is the effective regurgitant orifice (Fig. 34-6). An effective regurgitant orifice of 0.4 $cm^2$ or more and a regurgitant

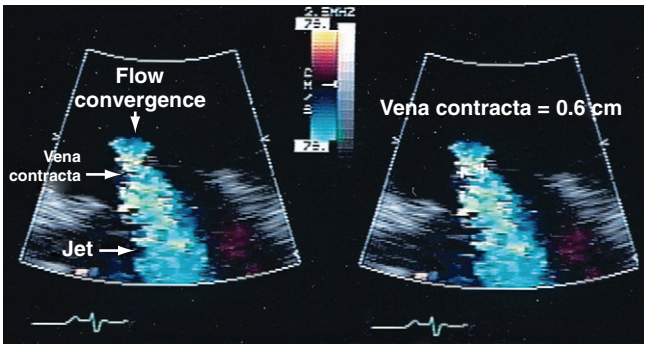

**Figure 34-5 Measurement of vena contracta.** Example of tricuspid regurgitant flow from the apical view with definition of the three components of the regurgitant flow (*left*) and measurement of the vena contracta width (*right; crosses*). *(With permission, from Tribouilloy CM, et al: Quantification of tricuspid regurgitation by measuring the width of the vena contracta with Doppler color flow imaging: a clinical study.* J Am Coll Cardiol *36:472-478, 2000.)*

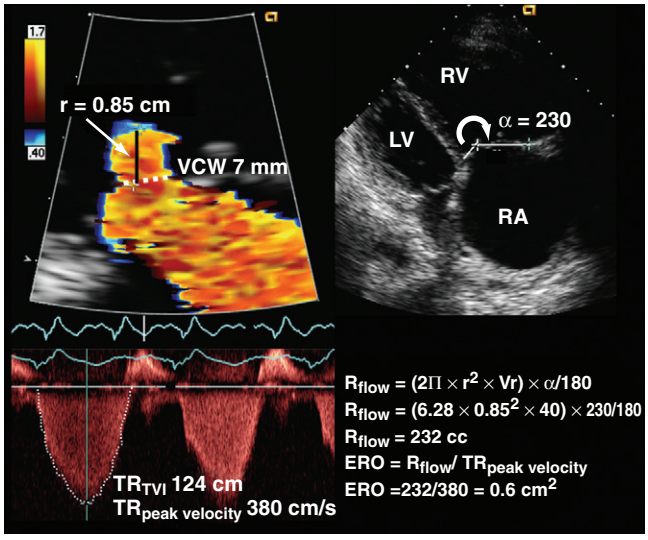

**Figure 34-6 Quantitative measurement of tricuspid regurgitation *(TR)* severity with the proximal isovelocity surface area method.** These images were obtained from a patient with severe pulmonary hypertension from pulmonary thromboembolic disease. The tricuspid regurgitation jet area is broad, and the vena contracta (*VC; top left panel, dashed line*) measures 0.7 cm, consistent with severe tricuspid regurgitation. The calculation of the effective regurgitant orifice *(ERO)* from the Doppler data as described in the text is illustrated. Note the angle correction illustrated in the *top right image*. In this patient, the effective regurgitant orifice is 0.6 $cm^2$, consistent with severe tricuspid regurgitation. *r,* Hemisphere radius.

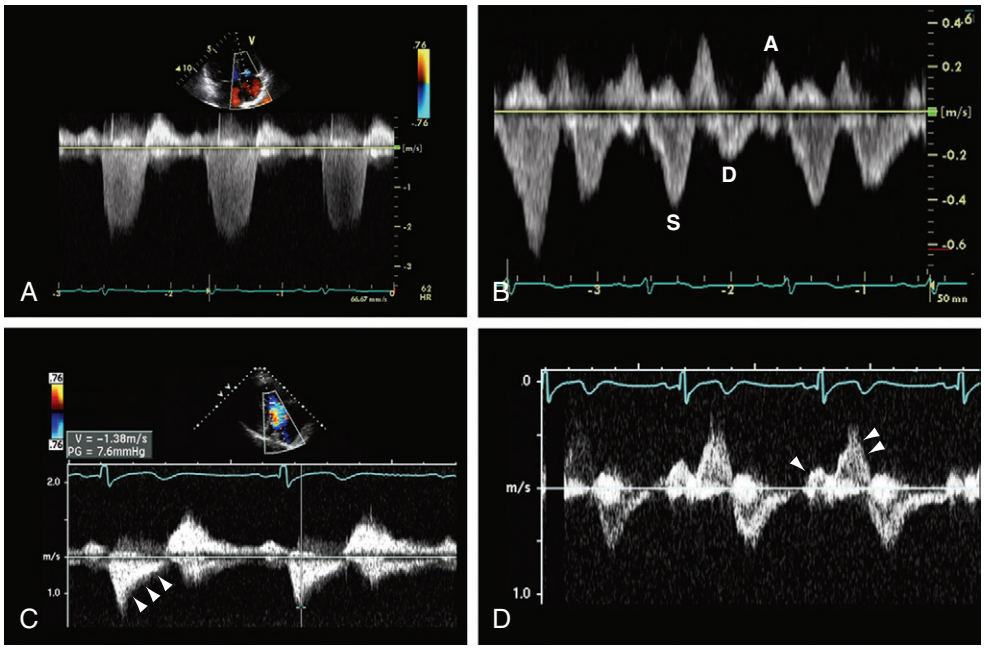

**Figure 34-7 Doppler findings in mild and severe tricuspid regurgitation. A,** Continuous wave Doppler signal across the tricuspid valve shows a low-velocity systolic jet (2 m/s) with a symmetrical rounded appearance consistent with mild tricuspid valve regurgitation. Measurement of the peak systolic velocity provides an indirect assessment of RV systolic pressure with the modified Bernoulli equation. **B,** Hepatic vein pulsed wave Doppler signal with accompanying electrocardiographic tracing shows normal hepatic vein flow in this patient with mild tricuspid regurgitation. Systolic flow *(S)* and diastolic flow *(D)* is seen emanating from the hepatic veins into the inferior vena cava (flow seen displayed below the baseline) and atrial reversal flow *(A)* representing normal flow refluxing into the hepatic veins resulting from atrial contraction. **C,** A dense systolic continuous wave Doppler signal is shown in a patient with severe tricuspid valve regurgitation. Severe tricuspid regurgitation results in a triangular or "dagger-shaped" *(arrowheads)* early peaking tricuspid regurgitant jet profile as a result of early equilibration of pressures between the RA and RV. **D,** Hepatic vein pulsed wave Doppler signal shows both atrial *(single arrowhead)* and systolic reversed flow *(double arrowhead)*, indicating elevation in RA pressure and severe tricuspid valve regurgitation in a patient in sinus rhythm. These systolic reversals reflect retrograde flow in the hepatic veins that can be appreciated clinically as a pulsatile liver. Hepatic vein systolic reversals may not be specific for severe tricuspid regurgitation when atrial fibrillation is present.

volume of 45 mL or more are considered diagnostic thresholds for severe TR.[7,43] Although the proximal isovelocity surface area method is quantitative,[18] it is not widely used in clinical practice because it is time consuming, requires technical experience in addition to angle correction, and is less well validated.

In general, the shape of the continuous wave TR Doppler signal is parabolic in patients with less than severe TR. In patients with severe TR, the continuous wave regurgitation jet may have a dense signal and a dagger-shaped appearance as a result of rapid equalization of pressures between the RA and the RV (Fig. 34-7).

Ancillary echocardiographic findings in patients with severe TR include increased tricuspid inflow velocity (1 m/s or more), inferior vena cava dilation of more than 2 cm, and systolic flow reversals in the hepatic veins.[4,46-48] The utility, advantages, and limitations of these measurements and the assessment and grading of TR severity are summarized in Tables 34-1 and 34-2.[4]

Recent research has highlighted the dynamic changes in TR severity with respiration. Large respiratory variations in TR occur with a striking inspiratory increase in vena contracta, effective regurgitant orifice, and regurgitant volume. This results principally from marked RV plasticity, inspiratory widening that results in annular enlargement and leads to less systolic annular coverage by the TV leaflets, and increased valvular tenting that contributes to mal coaptation. Thus, quantitative measurements of TR severity should take into account these large respiratory variations, avoiding the measurement of largest values and ensuring that measurements are included over the entire respiratory cycle (Fig. 34-8).[9]

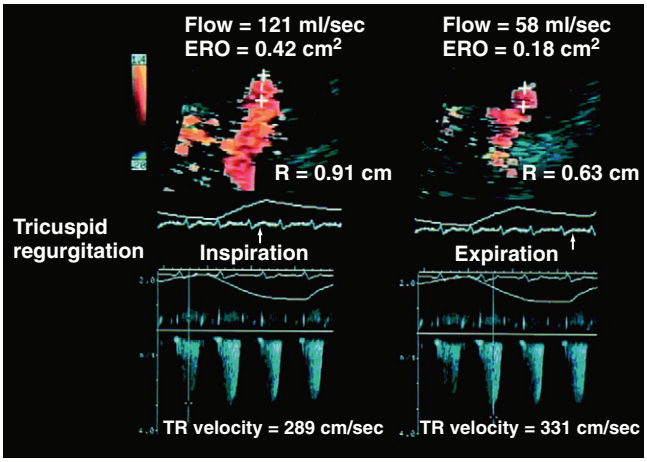

**Figure 34-8 Proximal flow convergence method: influence of respiration on tricuspid regurgitation severity.** Example of quantitative measurement of tricuspid regurgitation with inspiration and expiration. Shown are the measurements of regurgitant flow with the flow convergence method (*top*) and peak velocity with continuous wave Doppler imaging (*bottom*) with calculation of effective regurgitant orifice (*ERO*) in inspiration (*left*) and expiration (*right*). Respirometer curves ascend with inspiration and descend with expiration. During inspiration, maximal velocity decreases, regurgitant flow increases, and effective regurgitant orifice increases considerably. *(With permission, from Topilsky Y, et al: Pathophysiology of tricuspid regurgitation: quantitative Doppler echocardiographic assessment of respiratory dependence.* Circulation *122:1505-1513, 2010.)*

**TABLE 34-1 Echocardiographic and Doppler Parameters for Evaluation of Tricuspid Regurgitation: Utility, Advantages, and Limitations**

| *Parameter* | *Utility/Advantages* | *Limitations* |
|---|---|---|
| RV/RA/IVC size | Enlargement sensitive for chronic significant TR. Normal size virtually excludes significant chronic TR. | Enlargement seen in other conditions. May be normal in acute significant TR. |
| TV leaflet alterations | Flail valve specific for significant TR. | Other abnormalities do not imply significant TR. |
| Paradoxical septal motion (volume overload pattern) | Simple sign of severe TR. | Not specific for TR. |
| Jet area–color flow Doppler | Simple, quick screen for TR. | Subject to technical and hemodynamic factors. Underestimates severity in eccentric jets. |
| Vena contracta width | Simple, quantitative; separates mild from severe TR. | Intermediate values require further confirmation. |
| PISA method | Quantitative. | Validated in only a few studies. |
| Flow quantitation–pulse wave Doppler | Quantitative. | Not validated for determination of TR regurgitant fraction. |
| Jet profile–continuous wave Doppler | Simple, readily available. | Qualitative, complementary data. |
| Peak tricuspid E velocity | Simple, usually increased in severe TR. | Depends on RA pressure and RV relaxation, TV area, and atrial fibrillation; complementary data only. |
| Hepatic vein flow | Simple; systolic flow reversal is sensitive for severe TR. | Influenced by RA pressure, atrial fibrillation. |

*IVC,* Inferior vena cava; *PISA,* proximal isovelocity surface area; *VC,* vena cava.
*Unless there are other reasons for RA or RV dilation. Normal 2D measurements from the apical 4-chamber view: RV medio-lateral end-diastolic dimension ≤4.3 cm, RV end-diastolic area ≤35.5 $cm^2$, maximal RA mediolateral and superoinferior dimensions ≤4.6 cm and 4.9 cm respectively, maximal RA volume ≤33 $ml/m^2$.
†Exception: acute TR.
‡At a Nyquist limit of 50-60 cm/s. Not valid in eccentric jets. Jet area is not recommended as the sole parameter of TR severity due to its dependence on hemodynamic and technical factors.
§At a Nyquist limit of 50-60 cm/s.
‖Baseline shift with Nyquist limit of 28 cm/s.
¶Other conditions may cause systolic blunting (e.g., atrial fibrillation, elevated RA pressure).

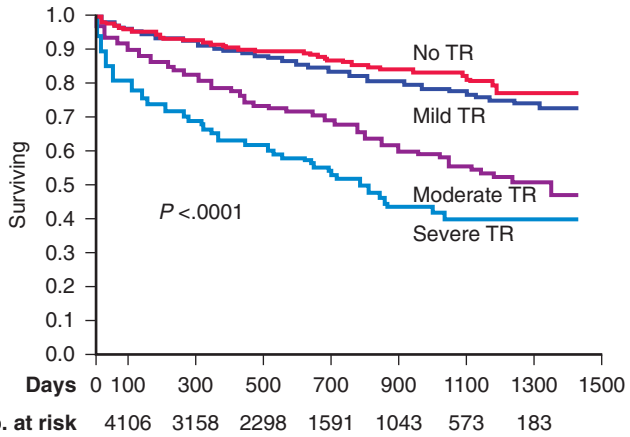

**Figure 34-9 Kaplan-Meier survival curves for all patients with tricuspid regurgitation (*TR*).** Survival is significantly worse in patients with moderate and severe tricuspid regurgitation.[51]

Also, note that the severity of TR can be difficult to appreciate or underestimated with TEE with Doppler techniques because of the limited views afforded and suboptimal beam alignment.

## CLINICAL UTILITY, OUTCOME DATA

Severe TR has an important impact on clinical outcome and survival. Patients with severe TR have a significant reduction in exercise capacity caused by impaired cardiac output response.[49] TR also has a negative impact on long-term survival, which was seen in patients with mitral stenosis after percutaneous balloon mitral valvuloplasty[50] and in a retrospective study of more than 5000 patients in whom increasing TR severity was associated with worse survival regardless of left ventricular ejection fraction or PA pressure. Moreover, severe TR was associated with a poor prognosis that was independent of age, biventricular systolic function, and RV size (Fig. 34-9).[51]

The independent effect of TR on prognosis was evaluated by Messika-Zeitoun and colleagues.[16] They reported the outcome of flail TV leaflets in patients who were seen at Mayo Clinic over a 20-year period.[16] The 60 patients with TV flail were divided into three groups depending on symptoms and associated cardiovascular disease. Half of the patients underwent operative intervention (27 repairs and 6 TV replacements). The natural history of TR from flail leaflets without associated cardiovascular disease showed an increased risk of atrial fibrillation, symptoms, heart failure, surgery, and death (Figure 34-10). Symptomatic improvement was noted in 88% of patients who underwent operation. The long-term survival rate of patients with unoperated TR caused by flail leaflets compared with the expected survival rate in a U.S. matched population showed excess mortality (4.5%; *P* less than .01). The effect of right-sided chamber enlargement in patients with severe TR, even in asymptomatic patients, was noteworthy in this series. The clinical outcome stratified according to degree of right-sided cardiac chamber enlargement showed a marked difference in events

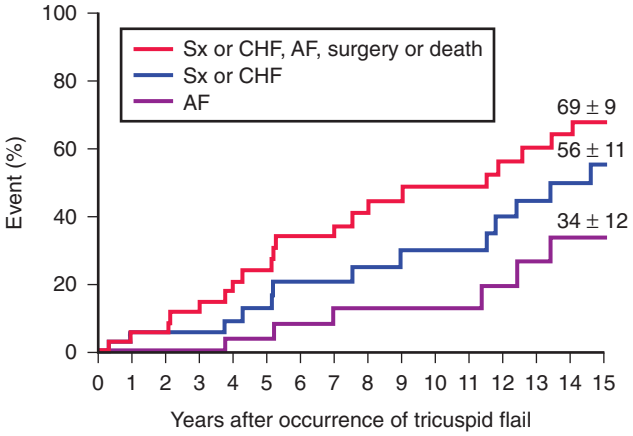

**Figure 34-10 Outcomes with severe tricuspid regurgitation due to a flail leaflet.** The Kaplan-Meier curves depict the incidence rate of new atrial fibrillation (2.8% yearly): class III or IV symptoms, or congestive heart failure (symptoms or *CHF*, 4.4% percent yearly); and the composite endpoint and first occurrence of symptoms or for heart failure, new atrial fibrillation (*AF*), tricuspid surgery, or death (6.5% per year).[16]

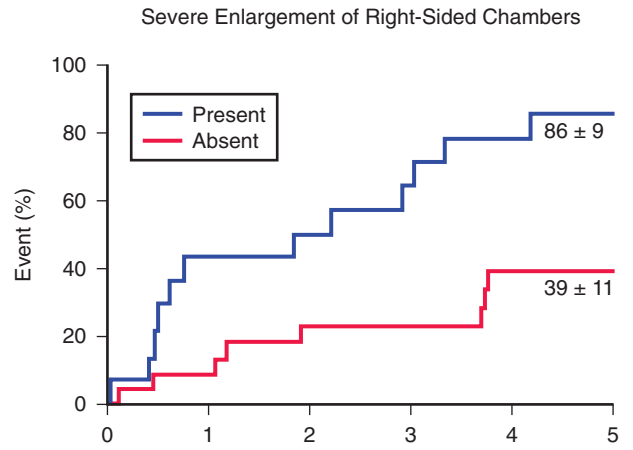

**Figure 34-11 Kaplan-Meier curves depict the incidence rate of combined endpoints of symptoms or heart failure, new atrial fibrillation, cardiac surgery, or death in patients with initial conservative management.** Note that patients with severe tricuspid regurgitation due too flail leaflet and severe right-sided cardiac chamber enlargement had a higher incidence rate of events.[16]

when severe enlargement of the right heart chambers was present (Fig. 34-11). An increase in morbidity was also noted even in asymptomatic patients with right heart enlargement. The operative risk for TV repair or replacement is low for these patients, and symptomatic improvement can be expected. Unfortunately, arrhythmia risks persist even after successful repair because surgery is mostly performed at an advanced stage.

The patient's clinical status and etiology of the TV abnormality usually determine the appropriate therapeutic strategy (Table 34-3).[2] If a correctable cause is identified, this is treated initially if possible.

Tricuspid valve surgery is the only demonstrated effective treatment for symptomatic TV regurgitation. At the authors' institution, where operative outcomes for TV disease are excellent, TV repair or replacement is recommended for patients with severe TR and:

1. Symptoms of reduced cardiac output, declining exercise capacity, or medically refractory right heart failure.

**TABLE 34-3 Management of Patients with Severe Tricuspid Regurgitation**

| *Level of Evidence* | *Class* |
|---|---|
| Tricuspid valve repair is beneficial for severe tricuspid regurgitation in patients with mitral valve disease that requires mitral valve surgery. | IB |
| 1. Tricuspid valve replacement or annuloplasty is reasonable for severe primary tricuspid regurgitation when it is symptomatic. | IIaC |
| 2. Tricuspid valve replacement is reasonable for severe tricuspid regurgitation as a result of diseased/abnormal tricuspid valve leaflets not amenable to annuloplasty or repair. | IIaC |
| Tricuspid annuloplasty may be considered for less than severe tricuspid regurgitation in patients undergoing mitral valve surgery when pulmonary hypertension or tricuspid annular dilation exists. | IIbC |
| 1. Tricuspid valve replacement or annuloplasty is not indicated in patients with tricuspid regurgitation who are asymptomatic and whose PA systolic pressure is less than 60 mm Hg in the presence of a normal mitral valve. | IIIC |
| 2. Tricuspid valve replacement or annuloplasty is not indicated in patients with mild primary tricuspid regurgitation. | IIIC |

Classification of recommendations and levels of evidence are expressed in the American College of Cardiology/American Heart Association 2006 Guidelines as follows:
**Class I:** Conditions for which there is evidence for and/or general agreement that the procedure or treatment is beneficial, useful, and effective.
**Class II:** Conditions for which there is conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a procedure or treatment.
**Class IIa:** Weight of evidence/opinion is in favor of usefulness/efficacy.
**Class IIb:** Usefulness/efficacy is less well established by evidence/opinion.
**Class III:** Conditions for which there is evidence and/or general agreement that the procedure/treatment is not useful/effective and in some cases may be harmful.
**Level of Evidence B:** Data derived from a single randomized trial or nonrandomized studies.
**Level of Evidence C:** Only consensus opinion of experts, case studies, or standard of care.

2. Mitral valve disease, or other cardiac disease that necessitates surgery.
3. Progressive RV enlargement or dysfunction.
4. Select asymptomatic patients, such as patients with traumatic TV flail with severe TR.

Surgery is also recommended in patients with moderate or more TR who are undergoing other cardiac surgery. The American College of Cardiology/American Heart Association guidelines for the timing of TV repair and replacement and those from the European Society of Cardiology are summarized in Tables 34-3 and 34-4 .[2,46] Predictors of long-term outcome after tricuspid valve replacement for severe tricuspid regurgitation include the Charlson comorbidity score, symptom severity, and the RV myocardial performance index.[46a]

Early surgery should be considered for patients with severe TR that results from blunt chest trauma because the long-term prognosis of flail TV leaflets is poor[16] and the likelihood of repair is high. When severe symptomatic TR is the result of leaflet perforation or lead impingement from a pacemaker lead, removal or repositioning of the lead may decrease the degree of TR.[52] If removal or repositioning is not feasible, TV repair or replacement should be performed.[15]

Carcinoid heart disease is best treated surgically with valve replacement to beneficially impact patient survival.[26] Indications for surgery include progressive symptoms and right heart failure. Asymptomatic patients with severe carcinoid heart disease may need valve replacement that enables partial hepatic resection or liver transplantation.

In patients with severe TR from pulmonary thromboembolic disease–related pulmonary hypertension, pulmonary thromboendarterectomy alone has been shown to reduce pulmonary hypertension and usually reduces TR without the need for

**TABLE 34-4 Indications for Intervention in Tricuspid Valve Disease (European Society of Cardiology 2007 Guidelines)**

| | *Class* |
|---|---|
| Severe TR in a patient undergoing left-sided valve surgery | IC |
| Severe primary TR and symptoms despite medical therapy without severe RV dysfunction | IC |
| Severe TS (±TR), with symptoms despite medical therapy* | IC |
| Severe TS (±TR), in a patient undergoing left-sided valve intervention* | IC |
| Moderate organic TR in a patient undergoing left-sided valve surgery | IIaC |
| Moderate secondary TR with dilated annulus (>40 mm) in a patient undergoing left-sided valve surgery | IIaC |
| Severe TR and symptoms, after left-sided valve surgery, in the absence of left-sided myocardial, valve, or RV dysfunction and without severe pulmonary hypertension (systolic PA pressure, >60 mm Hg) | IIaC |
| Severe isolated TR with mild or no symptoms and progressive dilation or deterioration of RV function | IIbC |

*TR,* Tricuspid regurgitation; *TS,* tricuspid stenosis.

*Percutaneous technique can be attempted as a first approach if TS is isolated.

Recommendation classes and levels of evidence:

**Class I:** Evidence and/or general agreement that a given treatment or procedure is beneficial, useful, and effective.

**Class II:** Conflicting evidence and/or a divergence of opinion about the usefulness/efficacy of a given treatment or procedure.

**Class IIa:** Weight of evidence/opinion is in favor of usefulness/efficacy.

**Class IIb:** Usefulness/efficacy is less well established by evidence/opinion.

**Level of Evidence A:** Data derived from multiple randomized clinical trials or meta-analyses.

**Level of Evidence B:** Data derived from a single randomized clinical trial or large non-randomized studies.

**Level of Evidence C:** Consensus of opinion of the experts and/or small studies, retrospective studies, registries.

concomitant TV annuloplasty, even when tricuspid annular dilatation is present.[53] In contrast, TR from severe primary pulmonary hypertension is usually treated with pulmonary vasodilator and diuretic therapy alone because of the high risk of morbidity and mortality related to valve replacement and poor overall prognosis.

The 2006 American College of Cardiology/American Heart Association Valvular Heart Disease Guidelines advocate TV annuloplasty at the time of left-sided valve surgery if the tricuspid annulus is dilated, even when only mild TR is present.[2] Interestingly, a number of observational studies have documented improvement in TR severity when percutaneous balloon mitral valvuloplasty is performed in patients with mitral stenosis, severe pulmonary hypertension, and significant functional TR.[54,55] Nevertheless, TV repair combined with mitral valve replacement is better than percutaneous balloon mitral valvuloplasty alone in patients with severe functional TR, especially if atrial fibrillation or RV enlargement in present.[56]

Unfortunately, the outlook is poor for patients who have previously undergone left-sided valvular heart disease surgery and subsequently present with symptomatic severe TR. Repeat surgery to specifically address the TR in these patients can be performed with an acceptable early mortality rate (8.8%). In the survivors, significant symptomatic improvement can be expected. However, the late mortality rate remains high (event-free survival rate, 41.6% ± 9.2%), predicted by age and the number of previous cardiac operations.[57] Video-assisted endoscopic minimal access procedures to correct atrioventricular valve disease after previous cardiac surgery were recently shown to be not only feasible but also accomplished with lower than predicted mortality, holding promise for treatment of these patients as an alternative to conventional redo open heart surgery.[58]

### RESEARCH APPLICATIONS

Although early experience with 3D echocardiography as a routine clinical tool has been disappointing, evaluation of TV morphology and annular geometry may be improved with newer transducers. Research to determine whether improved TV anatomy and functional assessment results in better patient selection or improved surgical outcomes is currently under way. The use of real-time 3D echocardiography may also be able to better define device lead complications and guide endocardial biopsy, improving safety of the procedure.

### POTENTIAL LIMITATIONS, FUTURE DIRECTIONS

Limitations exist regarding TR assessment with TEE. The TV is poorly visualized with TEE, principally because of its anterior location far from the transducer and in part because of the thinness of the leaflets. Also, the severity of TR can be difficult to appreciate or can be underestimated with TEE with Doppler techniques because of the limited views afforded and suboptimal beam alignment. These inherent limitations are unlikely to be overcome in the future.

The biggest promise for the future rests with the implementation of 3D echocardiography. With assessment of TR, a number of limitations are encountered with 2D echocardiography. Only two of the three TV leaflets are routinely imaged in a single 2D view. Also, the maximal dimensions and spatial geometry of the saddle-shaped tricuspid annulus cannot be easily measured with a single linear measurement. Lastly, the TV commissures and coaptation orifice cannot easily be assessed because an en face view of the TV is not readily available. Clinical research to determine whether 3D echocardiography will overcome these limitations is ongoing. As yet, no evidence shows that 3D assessment of TV anatomy and function results in better patient selection for operative intervention or improved surgical outcomes. Other challenges with regard to implementing 3D echocardiographic assessment include lack of standardized measures and specific software to facilitate tricuspid annulus and leaflet analysis. Lastly, real-time 3D echocardiography may be useful to guide transcatheter-based interventions for the treatment of TR in the future.

## Tricuspid Stenosis

### BACKGROUND

In developed countries, tricuspid stenosis (TS) is an exceptionally rare clinical condition, particularly because rheumatic heart disease accounts for about 90% of cases. Moreover, in patients with rheumatic mitral valve disease, only 3% to 5% have concurrent TS.[59,60] Unusual causes of TS include carcinoid heart disease,[61] congenital anomalies, infective endocarditis from large (often fungal) vegetations, and Whipple disease.[62] An RA myxoma might present with signs and symptoms that mimic obstruction at the TV level (Box 34-2).

### BASIC PRINCIPLES AND ECHOCARDIOGRAPHIC APPROACH

Echocardiography enables a definitive diagnosis of the severity of TS and provides clues to the etiology. Lesion severity is quantified with continuous wave Doppler to derive the mean gradient and valve area in valve stenosis.

**Box 34-2**

**ETIOLOGY OF TRICUSPID STENOSIS**

Rheumatic heart disease
Congenital tricuspid stenosis
Right atrial tumors
Carcinoid heart disease
Endomyocardial fibrosis
Valvular vegetations
Extracardiac tumors

Rheumatic involvement parallels the changes seen with rheumatic mitral valve disease, including commissural fusion and diastolic doming with thickened and shortened chordae. Even on echocardiography, findings can be subtle so that TV involvement may be overlooked unless specific attention is directed towards to TV anatomy and motion in patients with rheumatic mitral valve disease.

### TECHNICAL DETAILS, QUANTITATION, AND DATA ANALYSIS

Evaluation of the degree of TS includes calculation of:

1. The mean pressure gradient throughout both phases of respiration.
2. the pressure half-time valve area (the proposed constant to determine TV area is 190).[7,63]

Unlike the evaluation of mitral stenosis, short-axis 2D imaging of the valve orifice is rarely feasible.

Tricuspid stenosis is considered severe when the mean gradient is 7 mm Hg or more and the pressure half-time is 190 ms or longer.[7]

### CLINICAL UTILITY, OUTCOME DATA

Medical therapy for significant TS usually is ineffective because diuresis to improve systemic venous congestion further reduces cardiac output; thus, surgery should strongly be considered. If atrial fibrillation is present, ventricular rate control is important to promote diastolic filling. TS that requires surgery is most commonly the result of rheumatic heart disease and is best treated with valve replacement (see Table 34-4).[2,46]

Tricuspid valve balloon valvotomy has been advocated for TS of various causes. However, severe TR is a common consequence of this procedure, and results are poor when severe TR develops.[2,64,65]

### ALTERNATE APPROACHES

Tricuspid stenosis can be evaluated at catheterization with measurement of the transvalvular pressure gradient and calculation of valve area. According to the American College of Cardiology/American Heart Association guidelines,[2] severe TS is defined as a valve area of less than 1.0 $cm^2$. Nevertheless, because of the ease and accuracy of an echocardiographic assessment, cardiac catheterization is seldom necessary.[66-68]

## Pulmonic Valve Disease

Pulmonic valve disease is underappreciated and often overlooked because this valve is least commonly diseased. In the setting of RV pressure or volume overload, PS or PR should always be considered and specifically excluded with echocardiography.

## Pulmonic Valve Stenosis

### BACKGROUND

Valvular PS is usually an isolated congenital or genetic disorder and accounts for 80% to 90% of all RV outflow tract obstruction. The abnormal pulmonic valve may be classified as acommissural, unicommissural, bicuspid, or dysplastic (Fig. 34-12). Carcinoid syndrome and rheumatic valve disease may be associated with PS; in both conditions, PS generally occurs in conjunction with PR and TV or other valve disease. Congenital dysplastic pulmonic valve with PS, dysmorphic facial features, and variable intelligence characterize Noonan syndrome, an autosomal dominant disorder with variable penetrance.

Patients with mild and moderate PS are asymptomatic; they have minimal progression of disease and carry an excellent prognosis. Auscultatory findings include a pulmonic ejection sound that decreases in intensity with inspiration and a pulmonic ejection murmur that increases with inspiration. The electrocardiogram is normal in mild and moderate PS.[69]

Severe PS may be asymptomatic or cause fatigue and dyspnea. Systemic or suprasystemic RV pressures from PS may cause reduced exercise capacity, exertional lightheadedness, syncope, and eventually right-sided heart failure.[69] In severe PS, a jugular venous "a" wave and RV lift are common. A pulmonic ejection systolic murmur is audible and may be palpable at the upper left sternal border with radiation to the neck. With increasing PS severity, the ejection click moves closer to the first heart sound and eventually disappears; the second heart sound becomes widely split. A right-sided fourth heart sound may be heard. The electrocardiogram in severe PS is characterized by RA enlargement, right-axis deviation, RV hypertrophy, and RV strain pattern. Dilation of the main and left pulmonic arteries, diminished vascular lung markings, and occasionally, calcification of the pulmonic valve may be noted on the chest radiograph.

### BASIC PRINCIPLES AND ECHOCARDIOGRAPHIC APPROACH

Transthoracic echocardiography is the diagnostic test of choice for the initial diagnosis and follow-up of PS.[2] The echocardiographic examination follows the same basic principles as evaluation of aortic stenosis (see Chapter 23) and not only confirms the presence and severity of PS but also provides important information regarding etiology. Noninvasive estimation of RV pressure and assessment of RV size and function are essential components of the echocardiographic examination and are important in determination of management.

### TECHNICAL DETAILS, QUANTITATION, AND DATA ANALYSIS

Two-dimensional echocardiography shows thickened pulmonic valve cusps with systolic doming and reduced cusp mobility, which is usually best appreciated from the parasternal, the subcostal (Fig. 34-13), and occasionally, the anteriorly angulated apical views. The presence of subvalvular, annular, or supravalvular obstruction may also be noted with 2D echocardiography.

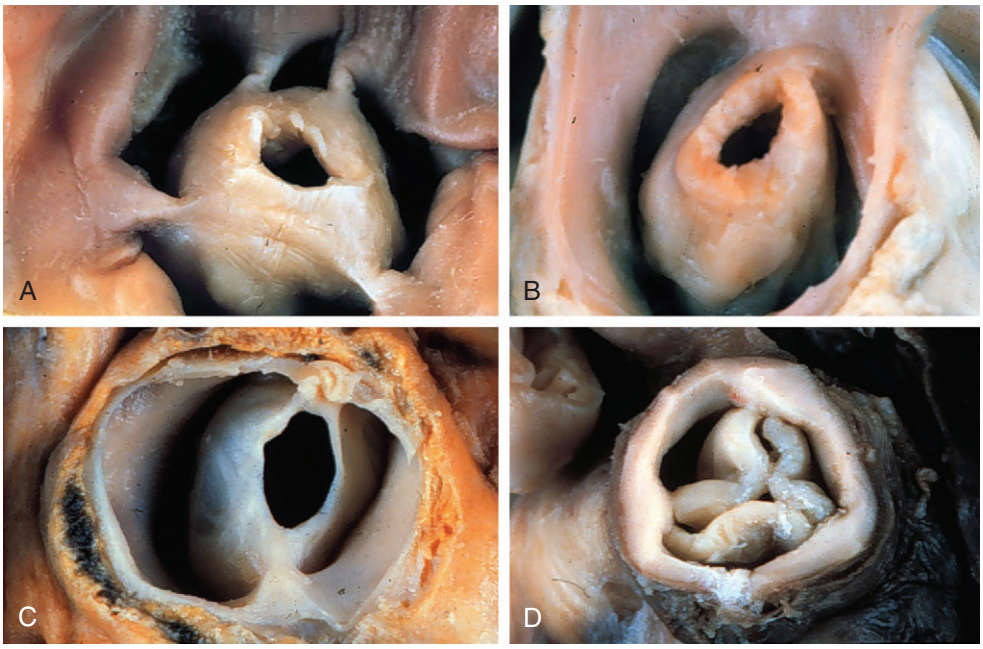

**Figure 34-12 Congenital pulmonic valve disease.** The abnormal pulmonic valve may be classified as acommisural (**A**) with prominent systolic doming of the valve cusps and an eccentric orifice; unicommissural (**B**); bicuspid with fused commissures (**C**); or dysplastic (**D**) with severely thickened and deformed valve cusps. *(Courtesy Dr. William D. Edwards, Department of Laboratory Medicine and Pathology, Mayo Clinic College of Medicine. With permission, from Otto CM, Bonow RO:* Valvular heart disease, *ed 3. Philadelphia, 2009, WB Saunders.)*

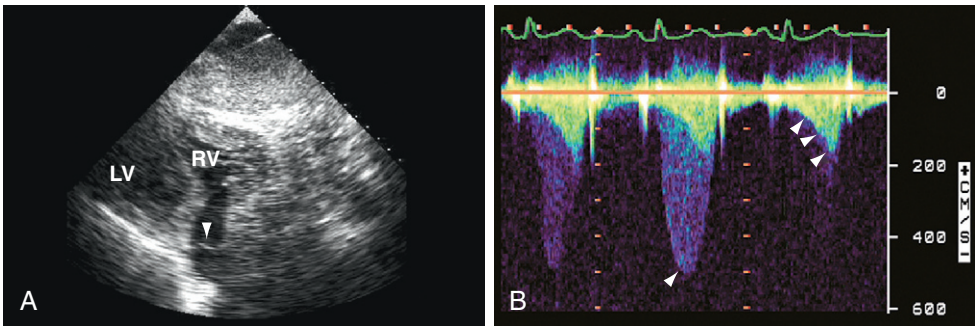

**Figure 34-13 Severe pulmonic valve stenosis. A,** Two-dimensional echocardiogram from a patient with severe pulmonic valve stenosis. The best alignment between the Doppler beam and the pulmonic flow signal was from a subcostal long-axis window with the transducer angled anteriorly. Marked RV hypertrophy was noted, and there was systolic doming of the pulmonic valve (*arrowhead*). **B,** From the same patient, the peak velocity recorded with continuous wave Doppler ultrasound scan for calculation of the transvalvular pressure gradient (*single arrowhead*) suggests a peak gradient of more than 100 mm Hg. Note the late peaking infundibular gradient (*three arrowheads*) from dynamic RV outflow tract obstruction. *(With permission, from Otto CM, Bonow RO:* Valvular heart disease, *ed 3. Philadelphia, 2009, WB Saunders.)*

RV wall thickness and function provides an indirect indicator of the degree of PS and adaptation of the RV to pressure overload. Poststenotic dilation of the pulmonic artery may become marked, with the degree of dilation unrelated to the degree of PS.

The severity of PS is determined with continuous wave Doppler peak transpulmonic velocity and gradient. The continuous wave Doppler spectrum of PS appears similar to the Doppler signal of aortic stenosis but is best obtained from the left upper parasternal or subcostal window. The maximal instantaneous gradient is generally reported for PS[70] and historically has been used to determine timing of PS intervention. Pulsed wave Doppler interrogation of the pulmonic annulus velocity should be obtained; if the proximal velocity is more than 1 m/s, then the modified Bernoulli equation ($\Delta P = 4[V_2^2 - V_1^2]$) is used to calculate the maximal instantaneous gradient. It is now recognized that the severity of PS is systematically overestimated with this technique. The mean PS gradient appears to correlate better with catheter-derived peak-to-peak gradients than the peak instantaneous PS gradient.[71] Ultimately, with determination of whether intervention is needed, correlation of the echocardiographic-Doppler gradient with other clinical findings is important.[72]

In the assessment of PS severity, integration of all available echocardiographic-Doppler data is important because the peak and mean gradients may be lower in patients with severe PS and reduced RV function, decreased cardiac output, and severe TR, which could potentially lead to an underestimate of PS severity. Pulmonic valve area is not generally reported with echocardiography because of inaccuracy in measurement of the RV outflow tract diameter. Pulsed-wave Doppler interrogation of the hepatic veins may show prominent atrial reversal, analogous to the jugular venous "a" wave noted in severe PS.

Severe PS is defined as a peak Doppler gradient of more than 50 mm Hg, moderate PS as a peak gradient of 30 to 50 mm Hg, and mild PS as a peak gradient of less than 30 mm Hg.[72]

Transesophageal echocardiography rarely provides improved visualization of the pulmonic valve compared with transthoracic echocardiography because of interposition of the bronchus between the transducer and the pulmonic valve, which causes shadowing, and because the pulmonic valve is in the far field of the imaging plane. The pulmonic valve is best visualized with the multiplane transesophageal probe rotated to about 90 degrees, resulting in a long-axis view of the RV outflow tract and pulmonic valve with the aortic valve in an oblique short-axis orientation. Alternatively, the pulmonic valve can be visualized in a transverse plane (0-degree rotation) with the probe at the level of the PA bifurcation to obtain an image that looks directly at the pulmonic valve from the bifurcation.

Three-dimensional echocardiography may allow improved visualization of the pulmonic valve morphology in select cases.[73]

## CLINICAL UTILITY, OUTCOME DATA

Patients with PS need lifelong informed clinical and echocardiographic follow-up. The frequency of follow-up depends on the severity of the lesion and results of the intervention performed. Patients with mild PS need to be seen once in 5 years with clinical and echocardiographic-Doppler examination. Patients with moderate PS should be seen with clinical and echocardiographic-Doppler examination every 2 to 5 years, and patients with severe PS who have not had intervention should be seen with testing annually.[69,72] Periodic clinical and echocardiographic follow-up is recommended for all patients after pulmonic balloon valvuloplasty or surgical management of PS, with specific attention given to the degree of PR and the impact of PR on the right heart. The frequency should be individualized based on the severity of hemodynamic abnormalities but should be at least every 5 years.

The event-free survival rate of PS is good and depends on the severity of obstruction. The long-term follow-up study of 592 patients with PS in the Second Natural History Study reported an overall survival rate at 25 years of 96%.[74] In this surgical series, event-free survival was related to preoperative pressure gradient.

Intervention in the Second Natural History Study involved surgical valvotomy. Reoperation was reported in only 4% of patients during a 10-year follow-up period.[74] In a subsequent longitudinal study of 90 consecutive patients with PS treated with operation, reoperation was required in 15%, primarily for PR (9%). At the last follow-up examination, moderate to severe PR was present in 37%, which emphasizes the importance of follow-up after PS intervention.[75]

Relief of PS is recommended for all patients with a peak instantaneous gradient of more than 60 mm Hg.[2,72] Additional recommendations for intervention are outlined in Table 34-5.[72] Percutaneous pulmonic balloon valvuloplasty is the procedure of choice for children and adults with severe or symptomatic PS and carries a low risk of morbidity, mortality, and restenosis.[2,69,72,76,77]

Pulmonic balloon valvuloplasty produces PS gradient relief with commissural splitting, and thus, patients with a dysplastic pulmonic valve generally have suboptimal results. In the Valvuloplasty and Angioplasty of Congenital Anomalies registry that involved 784 cases, the mean transvalvular gradient declined from 71 to 28 mm Hg in patients with typical PS and from 79 to 49 mm Hg in patients with a dysplastic PS.[78] Pulmonic balloon valvuloplasty is not recommended in patients with acquired PS related to carcinoid or rheumatic disease because of the nature of valve involvement, commonly associated PR, and concomitant valve involvement.

**TABLE 34-5 Recommendations for Intervention in Patients with Pulmonic Stenosis**

| *Level of Evidence* | *Class* |
|---|---|
| Balloon valvotomy is recommended for patients who are asymptomatic with a domed pulmonic valve and a peak instantaneous Doppler gradient greater than 60 mm Hg or a mean Doppler gradient greater than 40 mm Hg (in association with less than moderate PR). | IB |
| Balloon valvotomy is recommended for patients who are symptomatic with a domed pulmonic valve and a peak instantaneous Doppler gradient greater than 50 mm Hg or a mean Doppler gradient greater than 30 mm Hg (in association with less than moderate PR). | IC |
| Surgical therapy is recommended for patients with severe PS and an associated hypoplastic pulmonic annulus, severe PR, subvalvular PS, or supravalvular PS. Surgery is also preferred for most dysplastic pulmonic valves and for associated severe TR or the need for a surgical Maze procedure. | IC |
| Surgeons with training and expertise in congenital heart disease should perform operations for the RV outflow tract and pulmonic valve. | IB |
| Balloon valvotomy may be reasonable in patients who are asymptomatic with a dysplastic pulmonic valve and a peak instantaneous Doppler gradient greater than 60 mm Hg or a mean Doppler gradient greater than 40 mm Hg. | IIbC |
| Balloon valvotomy may be reasonable in selected patients who are symptomatic with a dysplastic pulmonic valve and peak instantaneous Doppler gradient greater than 50 mm Hg or a mean Doppler gradient greater than 30 mm Hg. | IIbC |
| Balloon valvotomy is not recommended for patients who are asymptomatic with a peak instantaneous Doppler gradient less than 50 mm Hg in the presence of normal cardiac output. | IIIC |
| Balloon valvotomy is not recommended for patients who are symptomatic with PS and severe PR. | IIIC |
| Balloon valvotomy is not recommended for patients who are symptomatic with a peak instantaneous Doppler gradient less than 30 mm Hg. | IIIC |

*PR,* Pulmonic valve regurgitation; *PS,* pulmonic valve stenosis; *TR,* tricuspid regurgitation.

Severe PS often is associated with some degree of subvalvular muscular obstruction resulting from hypertrophy of the RV myocardium (see Figure 34-13). After relief of PS, infundibular obstruction may worsen transiently but then tends to regress over months with eventual resolution.[79,80] Acute severe muscular obstruction can cause "suicide" RV, which results in suprasystemic RV pressure with resultant cyanosis and hemodynamic instability. Beta-blocker therapy is recommended before pulmonic balloon valvuloplasty to prevent or reduce the severity of this complication; therapy generally is discontinued after 3 to 6 months.

A high frequency rate of PR has been reported after pulmonic balloon valvuloplasty; 57% of children had moderate or severe PR at the last follow-up.[81,82]

In patients who have unfavorable pulmonic valve morphology, hypoplastic pulmonic annulus, fixed subvalvar or supravalvar PS, severe PR, additional cardiac lesions that require operative intervention, or a poor result with pulmonic balloon valvuloplasty, surgical valvotomy or valve replacement may be preferred. The choice of pulmonic valve prosthesis type must be individualized.[83]

### ALTERNATE APPROACHES

Echocardiographic-Doppler assessment of PS severity remains challenging in patients with suboptimal echocardiographic image quality. Alternate imaging options, including 3D echocardiography with color flow mapping, may provide additional future data but require validation. Cardiac magnetic resonance imaging and cardiac computerized tomography can be performed to better define the level of obstruction; these techniques are particularly helpful when multiple levels of RV outflow obstruction are present in series.

Cardiac catheterization should be considered when discordant data are present, to confirm the extent, severity, and level of obstruction or to facilitate intervention.

## Pulmonic Valve Regurgitation

### BACKGROUND

In adults, pathologic PR most often is the consequence of prior interventions for congenital heart disease, such as tetralogy of Fallot repair with placement of an outflow tract patch[84] or valvotomy (surgical or balloon) for isolated congenital PS.[75] Additional causes of PR include pulmonary hypertension, rheumatic or carcinoid heart disease, trauma, endocarditis, and PA and annular dilation.

Patients with long-standing severe PR eventually have development of progressive RV dilation and reduced RV function. This development can lead to the inability to augment cardiac output with exercise, progressive TR from annular dilation, increased propensity to atrial and ventricular arrhythmias, and ultimately, right heart failure.

Patients with PR may have a parasternal lift as a result of RV enlargement. The murmur of PR is typically a soft, diastolic, decrescendo murmur best heard at the left upper sternal region. It begins after the pulmonic closure sound and may be accompanied by a pulmonic systolic ejection murmur. An increase in intensity of the murmur may be noted during inspiration or with pulmonary hypertension.

The dilated and dysfunctional RV associated with long-standing severe PR can cause QRS prolongation, ventricular arrhythmias, and sudden death. This mechanical-electric association has been documented in patients with transannular patch repair of tetralogy of Fallot.[85] Chest radiography may show cardiomegaly, involving the right-sided chambers and PA enlargement.

### BASIC PRINCIPLES AND ECHOCARDIOGRAPHIC APPROACH

Transthoracic echocardiography is the diagnostic test of choice for the initial diagnosis and follow-up of PR.[2] The echocardiographic examination follows the same principles as evaluation of aortic valve regurgitation (see Chapter 20), confirming the presence and severity of PR and also providing information regarding etiology. Noninvasive estimation of RV size and function are essential components of the echocardiographic examination, and are important in determination of management.

### TECHNICAL DETAILS, QUANTITATION, AND DATA ANALYSIS

The diagnosis of PR is usually made with echocardiography and graded with color Doppler imaging. A trivial or mild degree of PR is detectable in most healthy individuals.[35] Echocardiographic and Doppler parameters that are useful in the evaluation of PR are listed in Table 34-6.[4]

The mechanism of PR is usually determined with 2D echocardiographic evaluation of the RV outflow tract and pulmonic valve from the parasternal, the subcostal, and occasionally, the apical views. Identification of anatomic pulmonic valve abnormalities, such as absence of the pulmonic valve, flail cusp, or annular dilation, may help define the cause and delineate severity of PR. RV size and function provides an indirect indicator of the significance of PR and adaptation of the RV to volume overload.

Color Doppler imaging is the most common initial echocardiographic method used in identification of PR severity. When PR is unrestricted and the pulmonary pressures are low, the Doppler color-flow map may be laminar.[4,86] PR severity is generally determined by jet size and duration that in turn is affected by driving pressure, regurgitant volume, and the RV pressures. Pathologic PR is typically a wide holodiastolic jet (Fig. 34-14). In severe PR, equalization of PA and RV pressures early in diastole cause early and abrupt cessation of the color and continuous wave Doppler jet. Thus, reliance on the color flow jet alone may lead to underappreciation of the PR severity. It is therefore important to note the vena contracta width and continuous wave Doppler signal contour to recognize that severe PR is present.

The density and contour of the continuous wave Doppler signal and deceleration pressure half-time correspond to the degree of PR and RV pressures (Fig. 34-14, *C*).[87] Rapid continuous wave Doppler deceleration with a pressure half-time of less than 100 ms is suggestive but not specific for severe PR. Equal intensities of antegrade and retrograde flow across the pulmonic valve suggest severe PR but are influenced by RV diastolic properties and filling pressures. In severe PR, equalization of RV and PA pressures can occur before the end

**TABLE 34-6 Echocardiographic and Doppler Parameters Used in the Evaluation of Pulmonic Regurgitation Severity: Utility, Advantages, and Limitations**

| *Parameter* | *Utility/Advantages* | *Disadvantages* |
|---|---|---|
| RV size | RV enlargement sensitive for chronic significant pulmonic regurgitation. Normal size virtually excludes significant pulmonic regurgitation. | Enlargement seen in other conditions. |
| Paradoxical septal motion (volume overload pattern) | Simple sign of severe pulmonic regurgitation. | Not specific for pulmonic regurgitation. |
| Jet length–color flow | Simple. | Poor correlation with severity of pulmonic regurgitation. |
| Vena contracta width | Simple quantitative method that works well for other valves. | More difficult to perform; requires good images of pulmonary valve; lacks published validation. |
| Jet deceleration rate–continuous wave | Simple. | Steep deceleration not specific for severe pulmonic regurgitation. |
| Flow quantitation–pulsed wave | Quantitates regurgitant flow and fraction. | Subject to significant errors because of difficulties of measurement of pulmonic annulus and a dynamic RV outflow tract; not well validated. |

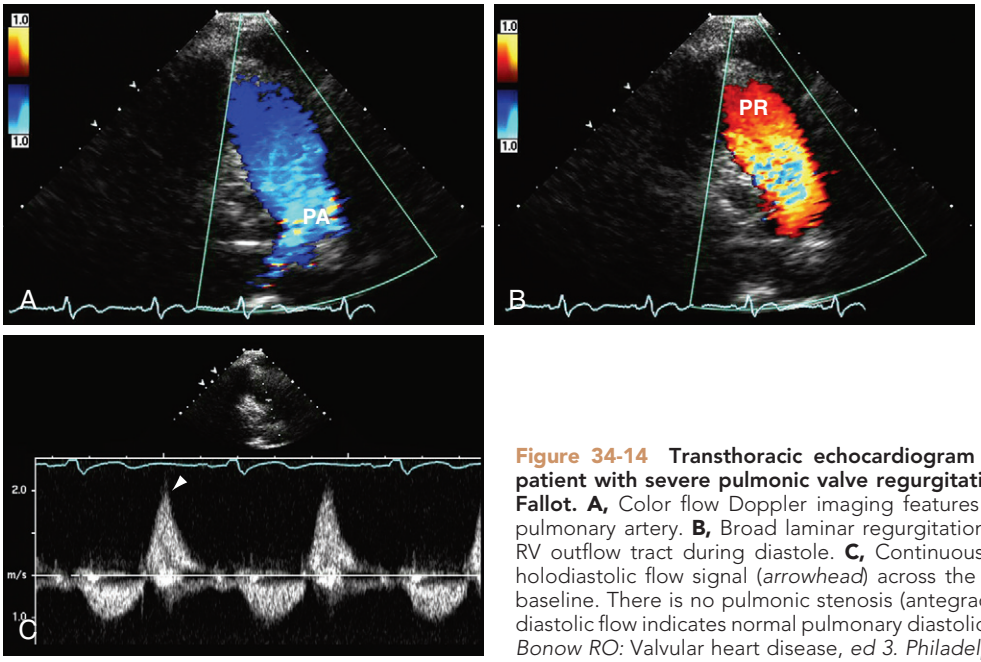

**Figure 34-14 Transthoracic echocardiogram images of the RV outflow tract from a patient with severe pulmonic valve regurgitation related to prior repair of tetralogy of Fallot. A,** Color flow Doppler imaging features show laminar flow during systole into the pulmonary artery. **B,** Broad laminar regurgitation jet of pulmonic regurgitation that fills the RV outflow tract during diastole. **C,** Continuous wave Doppler imaging shows an intense holodiastolic flow signal (*arrowhead*) across the pulmonic valve that decelerates rapidly to baseline. There is no pulmonic stenosis (antegrade velocity of 1.0 m/s), and the low-velocity diastolic flow indicates normal pulmonary diastolic pressures. *(With permission, from Otto CM, Bonow RO:* Valvular heart disease, *ed 3. Philadelphia, 2009, WB Saunders.)*

of diastole. The RV end-diastolic pressure may exceed the PA pressure during atrial contraction, resulting in antegrade flow across the pulmonic valve during atrial contraction. Pulsed wave Doppler scan determination of the ratio of the reverse-to-forward time velocity integral has been used to estimate the percent of PR flow.

Transesophageal echocardiography rarely provides improved visualization of the pulmonic valve compared with transthoracic echocardiography because of interposition of the bronchus between the transducer and the pulmonic valve that causes acoustic shadowing and because the pulmonic valve is an anterior structure located in the far field of the imaging plane. The pulmonic valve is best visualized with the multiplane transesophageal probe rotated to about 90 degrees, resulting in a long-axis view of the RV outflow tract and pulmonic valve with the aortic valve in an oblique short-axis orientation. This allows visualization of the PR jet size and vena contracta. Alternatively, the pulmonic valve can be visualized in a transverse plane (0-degree rotation) with the probe at the level of the PA bifurcation to obtain an image that looks directly at the pulmonic valve from the bifurcation. This view provides a parallel intercept angle that optimizes beam alignment for Doppler recordings. TEE is generally not performed for the diagnostic assessment of pulmonic valve disease.

Three-dimensional echocardiography may allow improved visualization of pulmonic valve morphology in select cases.[73]

A comprehensive multimodality echocardiographic evaluation of PR involves primarily a qualitative assessment that provides clinically useful estimates of PR severity and is feasible in most patients.[4] Information about right heart size and function is taken into account in the comprehensive approach to patients with PR (Table 34-7).

Insufficient data exist on the echocardiographic quantitation of PR to recommend routine use. Validation studies are lacking because of difficulties in imaging of the pulmonic valve and the low prevalence of severe PR. The vena contracta width is the smallest regurgitant flow area immediately beyond the flow convergence region and before expansion of the turbulent regurgitant jet, which corresponds with the effective regurgitant orifice area. The vena contracta appears to be a more accurate method of evaluation of the severity of PR with color Doppler imaging than regurgitant jet area; however, standards for PR vena contracta width have not been established.

Magnetic resonance imaging has become a common diagnostic tool used to assess PR severity and RV size and function in patients with PR. Two-dimensional and Doppler echocardiographic measurements that have been shown to be independent predictors of severe PR compared with cardiac magnetic resonance imaging include diastolic flow reversal in the main or branch PAs, PR jet width of 50% or more of the pulmonic annulus, and PR pressure half-time of less than 100 ms.[88] For assessment of PR severity after RV outflow tract reconstruction or pulmonic valve replacement, PR jet width-annulus ratio combined with diastolic flow reversal was found to be the most valuable echocardiographic measure with magnetic resonance imaging as a reference tool.[89]

## CLINICAL UTILITY, OUTCOME DATA

Most patients with mild degrees of PR have a benign clinical course. Chronic severe PR often is well tolerated for many years. However, the RV may dilate and develop systolic dysfunction, analogous to the effect of chronic aortic regurgitation on the left ventricle. Severe RV dilation is associated with an increased risk of sudden death, related primarily to arrhythmias.[85] No medical therapy has been shown to be effective in reducing the degree of PR or affecting the impact of PR on the RV. The impact of isolated late PR is increasingly recognized; PR not only affects RV size and function but also affects exercise capacity.[90] As the intervention options improve and the morbidity related to long-standing PR is increasingly recognized, indications for intervention are being refined.

Consensus Guidelines on the Management of Adults with Congenital Heart Disease recommend pulmonic valve replacement for severe PR and symptoms or decreased exercise tolerance (Table 34-8). Pulmonic valve replacement is also thought to be reasonable in adults with previous surgery for tetralogy of Fallot, severe PR, and: (1) moderate to severe RV

**TABLE 34-7 Echocardiographic and Doppler Parameters Used in Grading Pulmonic Regurgitation Severity**

| *Parameter* | *Mild* | *Moderate* | *Severe* |
|---|---|---|---|
| Pulmonic valve | Normal | Normal or abnormal | Abnormal |
| RV size | Normal* | Normal or dilated | Dilated |
| Jet size with color Doppler† | Thin (usually <10 mm in length) with a narrow origin | Intermediate | Usually large, with a wide origin; may be brief in duration |
| Jet density and deceleration rate–continuous wave Doppler‡ | Soft; slow deceleration | Dense; variable deceleration | Dense; steep deceleration, early termination of diastolic flow |
| Pulmonic systolic flow compared with systemic flow–pulsed wave Doppler§ | Slightly increased | Intermediate | Greatly increased |

*PR,* Pulmonic regurgitation.

dysfunction; (2) moderate to severe RV enlargement; (3) development of symptomatic or sustained atrial or ventricular arrhythmias; and (4) moderate to severe TR.

In the authors' practice, pulmonic valve replacement for severe PR is also recommended for: (1) decline in functional aerobic capacity; (2) severe PR in a patient needing another cardiac operation; and (3) concern about risk of arrhythmia in patients with prolonged or increasing QRS duration (total QRS duration of 180 ms or more or QRS duration increase of 3.5 ms/y or more).[85]

Right ventricle size tends to decrease or normalize and functional status improves after pulmonic valve replacement for PR late after tetralogy of Fallot surgery.[91] Preoperative N-terminal-pro brain natriuretic peptide elevation and QRS prolongation may indicate patients with poorer outcome regarding RV function and volumes after surgery.[92] However, RV function may not fully recover after pulmonic valve replacement once marked enlargement and systolic dysfunction are evident.[93,94] When pulmonic valve replacement is recommended, the type of pulmonic valve prosthesis should be individualized.[83]

## ALTERNATE APPROACHES

Echocardiographic quantitation of PR remains challenging and not well validated. Future alternate imaging options, including 3D color flow mapping, may provide additional future data. Cardiac magnetic resonance imaging is considered the clinical gold-standard method for the noninvasive quantitation of PR and is commonly used to assess right-sided heart size and function in asymptomatic patients with severe PR to determine the optimal time of valve replacement. Cardiac catheterization is rarely performed to assess PR.

Pulmonic valve disease is underappreciated clinically and with echocardiography. In patients with RV pressure or volume overload, PS or PR should always be sought with multimodality echocardiographic imaging.

## KEY POINTS

- Moderate or more TR is most frequently "functional" in nature, that is, not related to primary tricuspid leaflet pathology but rather the result of another disease process that causes RV dilation, distortion of the subvalvular apparatus, tricuspid annular dilation, or a combination of these.
- Echocardiography is currently the reference standard for diagnosis and evaluation of tricuspid and pulmonic valve disease.
- An integrated assessment that incorporates 2D and Doppler qualitative and quantitative parameters is necessary to grade TR.
- Data suggest severe TR as a result of a flail leaflet is associated with adverse outcomes that favor early surgical repair.
- Severe TV regurgitation has an important impact on clinical outcome and survival in patients with concomitant cardiovascular disease.
- Tricuspid stenosis occurs infrequently and is essentially never seen in isolation.
- Pulmonic stenosis is most commonly an isolated congenital cardiac lesion.
- Pulmonic stenosis should always be considered in the setting of RV hypertension.
- Determination of PS severity requires comprehensive clinical and echocardiographic assessment.
- Pulmonic regurgitation is most commonly found in patients with prior intervention for congenital PS (balloon or surgical) or tetralogy of Fallot.
- Severe PR is often missed because of laminar color flow appearance and short duration.

**Limitations of Echocardiography and Alternative Approaches**

Echocardiography is often requested in pregnant women to evaluate preexisting heart disease or to assess women with cardiac symptoms or abnormal findings on physical examination. Many healthy women experience symptoms of fatigue, decreased exercise tolerance, or dyspnea during pregnancy. Clinical examination may be nondiagnostic, prompting a request for echocardiographic evaluation. Although a "flow murmur" is present in most pregnant women, this normal finding cannot always be clinically distinguished from a pathologic murmur. Diagnostic testing can differentiate between the normal alterations in cardiovascular physiology and anatomy resulting from pregnancy and from pathologic findings.

In pregnant patients with known cardiac disease, expected findings (and appropriate normal reference values) may be different from those in nongravid patients. Echocardiography may be used to monitor cardiovascular function during pregnancy and the peripartum period. In pregnant patients with concurrent systemic disease or with preeclampsia, echocardiography can provide important insights into the effect of the disease process on cardiovascular physiology and can assist in management of individual patients.

In this chapter, the normal hemodynamic and echocardiographic changes during pregnancy are reviewed and the role of echocardiography in management of pregnant women with known or suspected cardiac disease is summarized.

## Normal Hemodynamic and Echocardiographic Changes with Pregnancy

### NORMAL HEMODYNAMIC CHANGES

During normal pregnancy, plasma volume, erythrocyte volume, and cardiac output (CO) increase substantially over baseline values (Table 35-1 and Fig. 35-1). Many original studies of hemodynamic changes during pregnancy were based on right-sided heart catheterization with Fick or thermodilution CO data. These studies included small numbers of patients with evaluation of limited points during pregnancy.[1,2] More recent use of Doppler CO measurement techniques has greatly increased our understanding of the magnitude and timing of CO changes during pregnancy.[2-4]

CO increases during pregnancy by as much as 45% over baseline values.[4-7] Noninvasive Doppler measurements consistently show a definite rise in CO that occurs as early as 10 weeks gestation. Some studies suggest that maximum CO is reached at 24 weeks gestation with no further increase in later pregnancy (Fig. 35-2). Other studies (Figs. 35-3 and 35-4) show a continued increase in CO throughout pregnancy, with higher stroke volume accounting for much of the first-trimester increase, followed by a continued elevation in heart rate (and thus CO) in the last two trimesters. On average, heart rate

**TABLE 35-1 Normal Anatomic and Hemodynamic Changes of Pregnancy**

| | |
|---|---|
| **Anatomic** | |
| Aortic root | Slight increase in diameter (2-3 mm) |
| LV | Slight increase in end-diastolic dimension and slight decrease in end-systolic dimension |
| LA | Slight increase in size |
| **Hemodynamic** | |
| Cardiac output | Increased beginning in first trimester; maximum increase (at term) of 45% over baseline value |
| Stroke volume | Increased |
| Heart rate | Increased by 25% to 30% |
| Blood pressure | Unchanged |
| Systemic vascular resistance | Decreased |
| Pulmonary artery pressure | Unchanged |
| LV end-diastolic pressure | Unchanged |

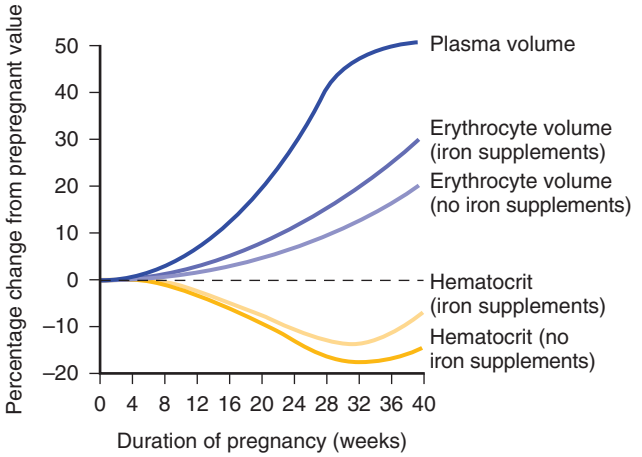

**Figure 35-1 Plasma and erythrocyte increase during pregnancy.** *(From Pitkin PM: Nutritional support in obstetrics and gynecology.* Clin Obstet Gynecol *19:489-513, 1976.)*

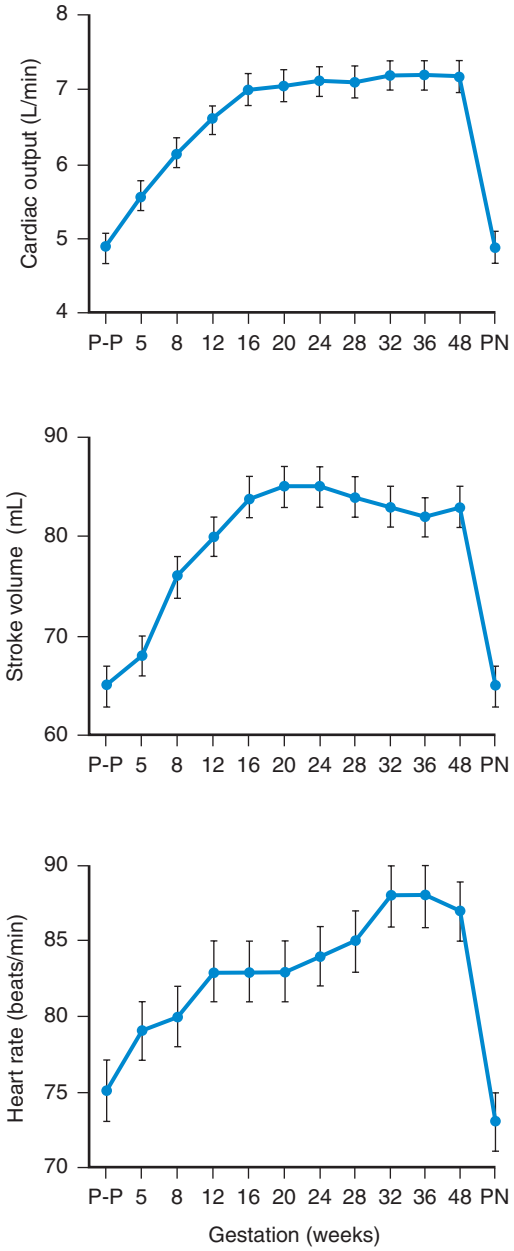

**Figure 35-2 Increase in cardiac output from the nonpregnant state throughout pregnancy.** *P-P*, Prepregnancy; *PN*, postnatal. (From Hunter S, Robson SC: Adaptation of the maternal heart in pregnancy. *Br Heart J* 68:540-543, 1992.)

increases 25% to 30% over baseline values during pregnancy[8] (Fig. 35-5).

The underlying etiology of increased CO with pregnancy is presumably hormonal, but the exact mechanism remains unclear.[9] Vasodilation may be mediated by nitric oxide[10] and hormones, such as relaxin.[11] An increase in venous tone during pregnancy contributes to preload augmentation.[4] In addition, decreased aortic stiffness reduces afterload.[6] Arterial capacitance increases during pregnancy, accounting for the decrease in total peripheral resistance.[12] This fall in systemic vascular resistance allows blood pressure to rise only slightly despite increased stroke volume (see Fig. 35-5). Some studies suggest that pregnancy is associated with an increased ventricular wall stress.[13] However, this view is challenged by other studies demonstrating a 30% decrease in wall stress.[4,14] Left ventricular (LV) contractility may to be depressed in pregnancy, based on measurement of the afterload adjusted velocity of circumferential fiber shortening.[13,14] LV systolic performance is maintained, despite this possible decrease in contractility, as a result of the altered loading conditions of pregnancy. However other studies suggest that there is no change in ventricular contractility.[1,12] Pulmonary pressures remain normal during pregnancy,[15] suggesting a similar decrease in pulmonary vascular resistance to balance the increased blood volume. Diastolic filling pressures in both the right-sided and left-sided heart also remain normal in pregnancy.[16]

## TECHNICAL ASPECTS OF DOPPLER CARDIAC OUTPUT MEASUREMENTS

Doppler measurement of CO in pregnancy is based on the same principles as in nonpregnant patients. Stroke volume (SV) is calculated from the cross-sectional area (CSA) of flow multiplied by the velocity-time integral (VTI) of flow at that site:

$$SV = CSA \times VTI$$

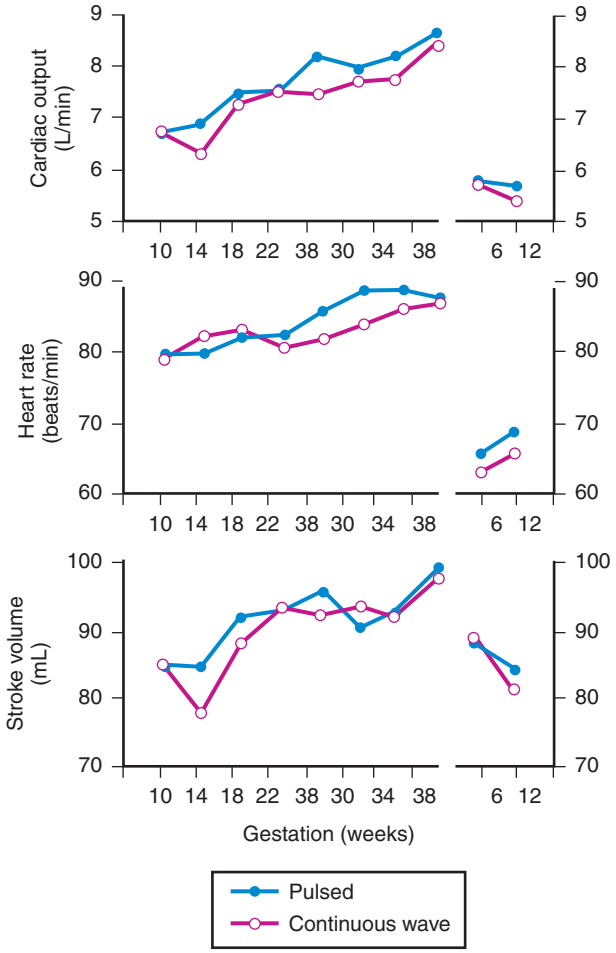

**Figure 35-3 Hemodynamic changes during pregnancy and postpartum.** *(From Mabie WC, DiSessa TG, Crocker LG, et al: A longitudinal study of cardiac output in normal human pregnancy.* Am J Obstet Gynecol *170:849-856, 1994.)*

Typically, the cross-sectional area is assumed to be circular and is calculated from a two-dimensional (2D) echocardiographic diameter measurement recorded with the ultrasound beam perpendicular to the flow diameter. The velocity-time integral is measured by either pulsed-wave (PW) or continuous-wave (CW) Doppler ultrasound, with the Doppler beam aligned parallel to the flow stream. As in nonpregnant patients, it is critical that (1) diameter is measured accurately, (2) the Doppler beam is aligned parallel to the direction of blood flow, and (3) diameter and velocity data are obtained almost simultaneously from the same intracardiac site. In addition, this method assumes that flow is laminar with a relatively flat (or blunt) flow-velocity profile and that flow fills the anatomic cross-sectional area. Although these assumptions appear to be warranted in nonpregnant patients according to numerous studies validating this approach,[17] the potential effect of the altered flow conditions during pregnancy warrants reevaluation. Specific concerns in pregnant patients include the possibility that the flow profile may not be blunt or may be asymmetric given the higher flow volumes. Possible changes in cross-sectional flow areas during pregnancy may also affect these measurements.

Validation of CO measurements in pregnancy has been performed by several groups of investigators using either of two

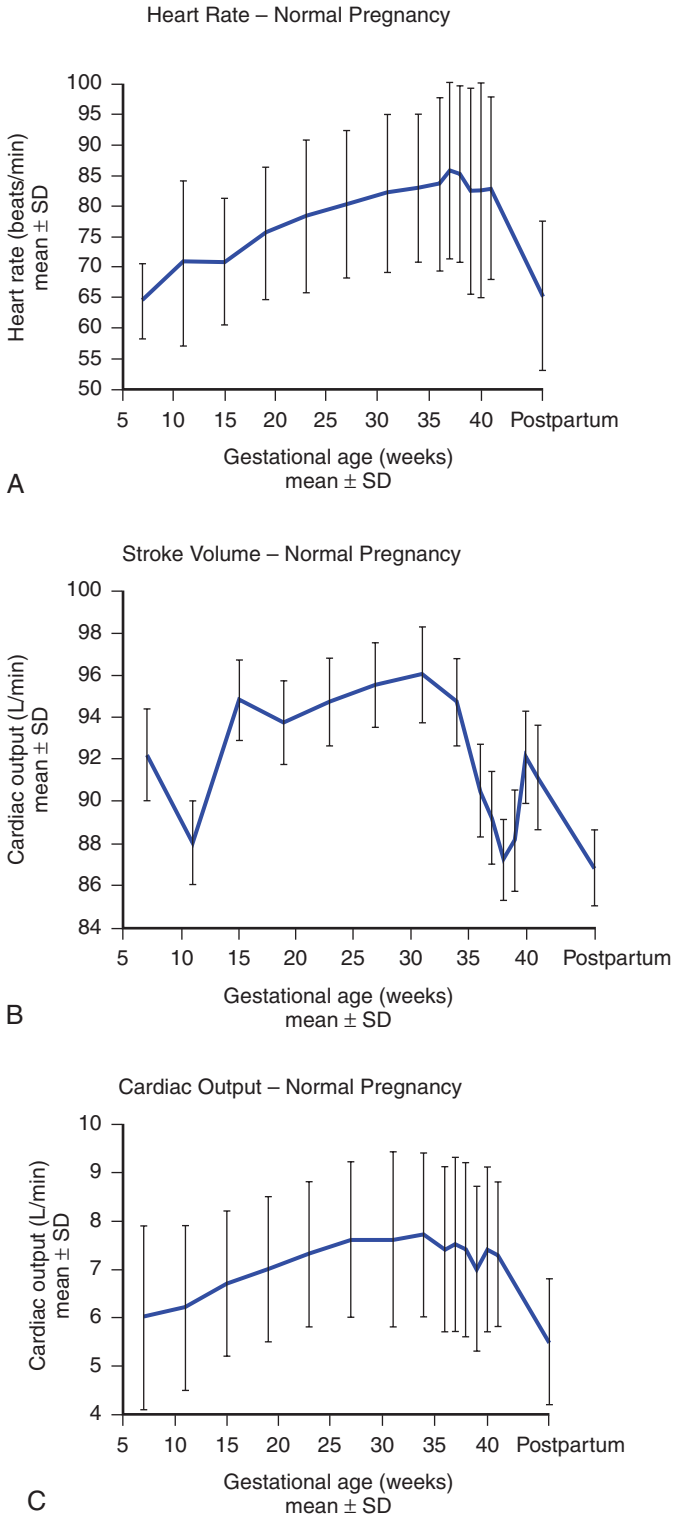

**Figure 35-4** Serial changes in heart rate (**A**), stroke volume (**B**), and cardiac output (**C**) recorded using Doppler echocardiography in a series of 89 women with no cardiac disease and a normal pregnancy. *SD,* Standard deviation. *(Data from Easterling TR, Benedetti TJ, Schmucker BC, Millard SP: Maternal hemodynamics in normal and preeclamptic pregnancies: a longitudinal study.* Obstet Gynecol *76:1061-1069, 1990.)*

basic Doppler approaches (Table 35-2). Some investigators have applied the technique of measuring ascending aortic flow with a CW Doppler probe from a suprasternal approach.[18,20] The cross-sectional area of flow is calculated from a carefully recorded A-mode aortic diameter measured at the sinotubular junction, the narrowest segment of the aorta, because the highest flow velocity (as obtained with CW Doppler) will correspond to the smallest flow area. Doppler COs calculated with this method correlated well with simultaneous thermodilution COs in pregnant women undergoing right-sided heart catheterization for clinical indications.[18] Of note, serial studies in pregnant women suggest that aortic root diameter increases during pregnancy,[21,22] so that repeat aortic diameter measurements are needed at each time point. This contrasts with the situation in nonpregnant adults in whom both left ventricular outflow tract (LVOT) and aortic diameters tend to remain relatively constant over time.

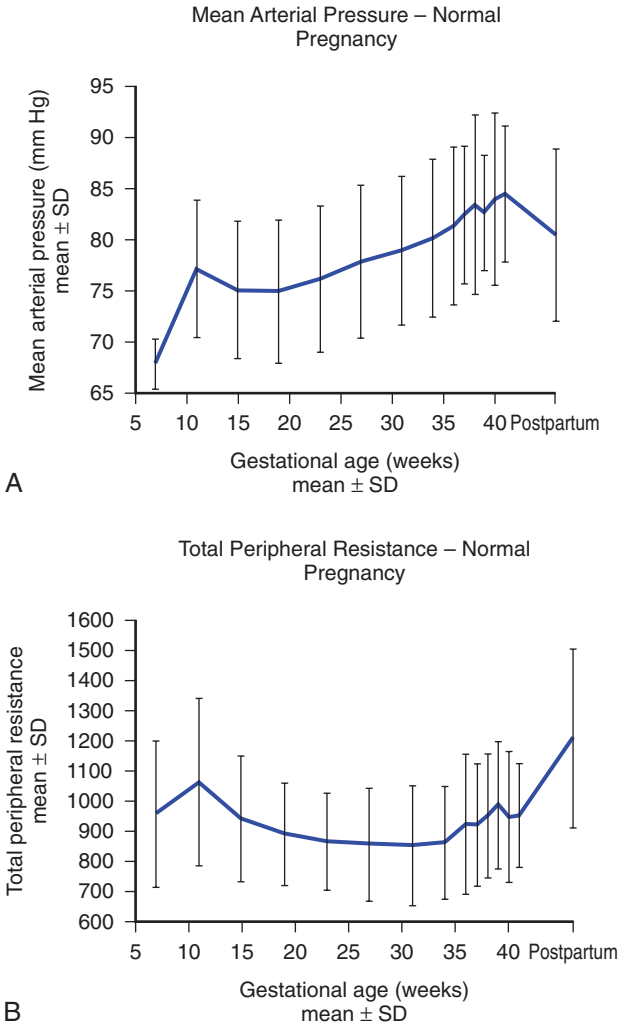

**Figure 35-5** Sequential changes in mean arterial pressure (**A**) and total peripheral resistance (**B**) in 89 women with no cardiac disease and a normal pregnancy. *SD*, Standard deviation. *(Data from Easterling TR, Benedetti TJ, Schmucker BC, Millard SP: Maternal hemodynamics in normal and preeclamptic pregnancies: a longitudinal study.* Obstet Gynecol *76:1061-1069, 1990.)*

Other investigators have measured CO in pregnant women using standard clinical cardiac ultrasound systems.[5,23-25] LVOT diameter is measured from a 2D parasternal long-axis view; LVOT flow is recorded via an apical approach using pulsed Doppler echocardiography, with the sample volume positioned just proximal to the aortic valve plane.[26] This method correlates well with simultaneous Fick COs in nonpregnant patients.[17] In a group of pregnant women, internal consistency between Doppler COs measured from diameter and flow data across the aortic, mitral, and pulmonic valves was demonstrated.[27]

Reproducibility, in addition to accuracy, is critical for the application of these methods in following individual patients during the course of pregnancy. Several studies suggest that both these methods can be performed reproducibly with an acceptable degree of recording and measurement variability in pregnant patients, with a coefficient of variation of 5% to 8%.[18,27] Although there is still concern that these methods have been validated against invasive standards in only small numbers of pregnant women, the data should still accurately reflect hemodynamic changes over time (if not absolute values) both in individuals and in groups of patients.

Compared with the 2D/pulsed Doppler approach, the advantage of the A-mode/CW method is that a smaller, less expensive, dedicated instrument can be used for CO measurements. Although optimal results require careful data acquisition, focused education and training of appropriate individuals allows more widespread application of this technique. Potential disadvantages include (1) the possibility of a nonperpendicular measurement of aortic root diameter (resulting in overestimation of CO), (2) a nonparallel intercept angle between the Doppler beam and the direction of aortic flow (resulting in underestimation of CO), and (3) failure to recognize abnormal aortic flow conditions (e.g., aortic stenosis or aortic regurgitation) that invalidate the Doppler method. When any of these problems are suspected, a standard clinical echocardiographic examination should be performed to resolve the difficulty.

## M-MODE AND TWO-DIMENSIONAL ECHOCARDIOGRAPHIC CHANGES

The increased CO of pregnancy is reflected in changes in LV dimensions, volumes, and geometry (Table 35-3). M-mode studies show that LV end-diastolic dimension increases slightly (by 2 to 3 mm on average) and end-systolic dimension is unchanged, so that there is a slight increase in fractional shortening during pregnancy.[20,27,29,31] The change in LV diastolic dimension correlates with increased preload caused by changes in systemic venous tone.[30] LV wall thickness also increases slightly, with a corresponding increase in calculated LV mass. Similar changes in right ventricular (RV) dimensions have been noted.

With 2D echocardiography, a slight increase in end-diastolic volume and in ejection fraction is seen, with little change in end-systolic volume.[6,22,29,31,33,34] These findings are consistent with the altered loading conditions of an increased end-diastolic volume and decreased systemic vascular resistance and do not imply an increase in LV contractility. There are conflicting data on the changes in contractility with pregnancy.[4,14,16,31] There have been few studies evaluating LV geometry in normal pregnancy; however, no dramatic changes in ventricular shape have been observed.

Several investigators have found consistent increases in aortic and LVOT diameters during pregnancy, with the magnitude of this change averaging 1 to 2 mm.[20,35] Even this small average change is significant for accurate CO calculations, and given the wide range of values, some individuals have more pronounced changes in outflow tract geometry.

Left atrial (LA) anteroposterior dimension increases by about 4 mm. When compared with echocardiograms obtained several weeks postpartum, the maximal atrial size is seen at term.[22] Changes in atrial dimension in the peripartum period are associated with changes in serum atrial natriuretic peptide levels.[36] A small increase in mitral annulus diameter has been documented in conjunction with a much larger change in tricuspid annulus diameter.[22]

A small pericardial effusion is seen on echocardiography is as many as 25% of normal pregnant women, with a higher prevalence in women with preeclampsia.[36]

## DOPPLER FLOWS

Although enlargement in annular diameters partially compensate for the increased transvalvular volume flow of pregnancy, higher transvalvular flow velocities are also seen[24] (Table 35-4). Both the maximum aortic and LVOT flow velocity rises by approximately 0.3 m/s compared with the nongravid state. Less dramatic changes in transmitral velocities are seen with an increase in early (E) velocity of only 0 to 0.1 m/s and an increase in atrial (A) velocity of only 0.1 to 0.2 m/s. However, the relative increase in E and A velocities being unequal, the E/A ratio

changes from the normal pattern in young women (higher E than A with an E/A ratio greater than 1.5) to a pattern of equalized or reversed E/A velocities (E/A ratio less than 1) later in pregnancy. Peak pulmonary venous A-wave velocity but not duration also increases during pregnancy.[6]

### POSTPARTUM CHANGES

Interestingly, the estimated magnitude of changes in hemodynamics and cardiac anatomy during pregnancy depends on whether the values obtained during pregnancy are compared to postpartum values or to values obtained in the same patient before pregnancy. It is often difficult to obtain data in the prepregnant time period (because women typically present to the physician after the onset of pregnancy), but a few studies have followed women prospectively starting from preconception. These studies found hemodynamic and anatomic changes of greater magnitude than studies that compared values obtained during pregnancy with postpartum data. This suggests that at least some of the changes of pregnancy may persist into the postpartum period or may be permanent. Although in the postpartum period hemodynamic and anatomic changes return rapidly toward baseline over 6 to 12 weeks (see Fig. 35-4),[5,26] the postpartum baseline may be different from the prepartum baseline. Specifically, aortic and LV dimensions, although remaining within normal adult limits, may remain larger than the prepregnant values in that individual. Analysis of these data is complicated by the small number of subjects studied, by the possibly confounding effects of breastfeeding or other factors, and by the measurement variability of the techniques. Further studies are needed because if there are significant, persistent changes after pregnancy, perhaps adult normal values not only should be indexed for body size and gender but also should consider parity.

### NORMAL VALVULAR REGURGITATION

As in nonpregnant patients, a small degree of valvular regurgitation is often found on Doppler echocardiography.[5,32,37] It is unlikely that these small regurgitant leaks are audible on auscultation or account for the presence of a murmur in pregnant patients. Early studies suggested an unusually high prevalence of tricuspid regurgitation in pregnant women.[32] With the recognition of the extremely high prevalence of small amounts of tricuspid, mitral, and pulmonic regurgitation in normal individuals, it is now apparent that the prevalence of physiologic degrees of valvular regurgitation in pregnant women is similar to that in nonpregnant normal adults.

### SIMILARITY OF HEMODYNAMIC CHANGES WITH EXERCISE AND DURING PREGNANCY

Many of the hemodynamic changes of pregnancy are similar to the normal changes seen with exercise. The increase in heart rate and CO and decrease in systemic vascular resistance are analogous to changes seen at a moderate level of physical exertion. In addition, the changes in cardiac anatomy seen with pregnancy are similar to those seen with repetitive activity in physically conditioned individuals. Specifically, the increases in LV end-diastolic dimensions, volume, and LV mass, with normal diastolic filling patterns, are analogous to the changes seen with regular physical activity in nonpregnant women and in men. Presumably, these changes represent a similar hemodynamic response to chronic elevation in volume flow rate. In contrast, the increase in aortic root dimension observed in pregnant women by several groups of investigators has not been seen with physical conditioning, suggesting that the mechanism of this effect is related to physical changes in the vessel wall, possibly mediated by hormonal effects.

## Doppler Echocardiographic Evaluation of Hemodynamics in Pregnancy

### POSITIONAL HEMODYNAMIC CHANGES

Doppler echocardiography can readily evaluate the effect of positional changes on hemodynamics. Orthostatic changes from sitting to standing positions are similar to the changes seen in nonpregnant individuals, with no significant differences between early and late pregnancy.[34] When a pregnant patient changes from a supine to a standing position, heart rate increases, stroke volume and CO decrease, and systemic vascular resistance rises, maintaining mean arterial pressure. During pregnancy, the supine position is associated with compression of the inferior vena cava by the gravid uterus, resulting in a decrease in venous return to the right atrium (RA) and a decline

in stroke volume and CO.[24] This supine decrease in CO can be reversed (or prevented) by placing the patient in a left lateral decubitus position. Accordingly, diagnostic echocardiographic studies should be performed with the pregnant patient in a left lateral decubitus position whenever possible. If optimal imaging requires a supine position, the length of time the patient is positioned on her back should be limited.

## PERIPARTUM PERIOD

Dramatic changes in loading conditions occur in the peripartum period related to the effects of (1) uterine contractions, (2) the pain associated with labor and delivery, (3) anesthetic medications, (4) the immediate blood loss associated with delivery (Fig. 35-6), and (5) the delivery of the placenta. Although these physiologic changes are well tolerated by healthy women, they can result in acute decompensation in women with underlying heart disease.

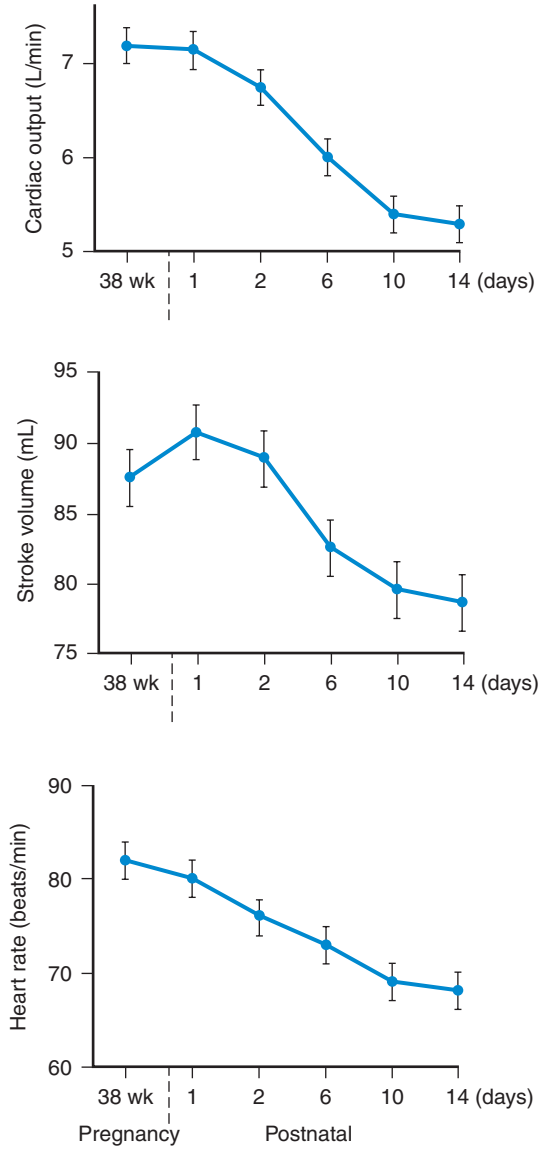

**Figure 35-6 Changes in heart rate and cardiac output after normal delivery.** *(From Hunter S, Robson SC: Adaptation of the maternal heart in pregnancy.* Br Heart J *68:540-543, 1992.)*

During labor, uterine contractions result in an acute increase in both heart rate and intravascular volume as uterine blood is forced into the circulation. The magnitude of CO rise during contractions increases as labor progresses, with an augmentation of as much as 20% in CO with each contraction.[38,39] There are also mild increases in pulmonary and LV pressures, which may be accentuated in patients with decreased LV compliance (e.g., those with aortic stenosis or LV hypertrophy). Despite the acute blood loss associated with delivery, stroke volume and CO actually rise after delivery of the placenta (by about 10%)[26] and remain elevated for about 24 hours.[26,38] Over the next several days to 2 weeks, CO declines by about 25% to 30% compared with the immediately prepartum value, related to a decrease in both heart rate and intravascular volume.

Volume changes associated with cesarean section and delivery are greater than those associated with vaginal delivery, so there is rarely hemodynamic advantage to this mode of delivery in patients with heart disease.[40]

The hemodynamic effects of pain include increased heart rate and systemic vascular resistance. In patients with cardiac disease, the hemodynamic effects of pain may lead to a decline in CO. The negative effects of pain can be eliminated by appropriate anesthesia. However, anesthesia-related changes in preload and afterload also affect cardiac function, especially in patients with heart disease. Thus, the choice of anesthetic agent and route of administration depends on the specific cardiovascular concerns in an individual patient.[40]

## EXERCISE PHYSIOLOGY

Exercise physiology in pregnant women is similar to that in nonpregnant women, except that the basal values are altered by pregnancy. Resting heart rate and stroke volume are elevated during pregnancy. With exercise, heart rate and CO rise appropriately.[41,42] Exercise in pregnant women at 32 weeks gestation was associated with a higher exercise heart rate, higher maximal oxygen consumption, and high atriovenous oxygen difference compared to 3 months postpartum.[43]

Conditioned pregnant women have a greater CO than sedentary women for any given heart rate, as is seen in nonpregnant, physically conditioned individuals.[44-48] However, the cardiovascular effects of aerobic conditioning are most evident during strenuous (not during mild or moderate) exercise in pregnant women.[49]

## SYSTEMIC DISEASES

Doppler echocardiography is a useful tool for examining the hemodynamic changes associated with systemic diseases in pregnant patients. For example, in hyperthyroid pregnant women, elevated CO and decreased systemic vascular resistance can be documented, and the resolution of these changes with therapy can be monitored.[50] Echocardiographic evaluation of the effects of beta-agonist tocolysis,[51] pheochromocytoma,[52] sickle cell disease,[53] and renal artery stenosis[54] has also been reported.

# Pregnancy-Induced Hypertension and Preeclampsia

## HEMODYNAMICS

There are four hypertensive conditions in pregnancy: preeclampsia, chronic hypertension, chronic hypertension with superimposed preeclampsia, and gestational hypertension.[55]

Preeclampsia is defined as systolic blood pressure greater than or equal to 140 mm Hg or diastolic blood pressure greater than or equal to 90 mm Hg and proteinuria greater than 0.3 g per 24 hours, developing after the 20th week of pregnancy in a previously normotensive woman. Eclampsia is the onset of seizures in a woman with preeclampsia. Gestational hypertension is hypertension after the 20th week of pregnancy in a previously normotensive woman, without proteinuria or signs of preeclampsia. Gestational hypertension may progress to preeclampsia but frequently resolves after delivery and has a more benign course than preeclampsia.[56] In a prospective study of 400 primigravid women, gestational hypertension developed in 24 and preeclampsia in 20 women.[57] Chronic hypertension is defined as systolic blood pressure greater than or equal to 140 mm Hg or diastolic blood pressure greater than or equal to 90 mm Hg that antedates pregnancy, develops before 20 weeks gestation, or persists longer than 12 weeks postpartum. If proteinuria develops after 20 weeks gestation in a woman with chronic hypertension, she is diagnosed with preeclampsia. Preeclampsia in a woman with preexisting hypertension and proteinuria is diagnosed if she develops severe hypertension (systolic greater than 160 mm Hg or diastolic greater than 110 mm Hg) in the last half of pregnancy.

The hemodynamics of preeclampsia and gestational hypertension are complex. There is a growing body of literature regarding the pathophysiology of preeclampsia.[23,47,58-60] Preeclampsia may be a heterogeneous disease with different hemodynamic subsets.[61] Investigators have identified that early in the disease course, CO is elevated, and later in the course, elevated systemic vascular resistance is seen associated with decreased CO and clinical decompensation.[57] For any given CO, mean arterial pressure is elevated in preeclamptic in comparison with normotensive pregnant women.[57,60,62] Central venous pressures, pulmonary capillary wedge pressures, and pulmonary artery pressures tend to be normal. The exception is decompensated patients with pulmonary edema, in whom central venous and pulmonary wedge pressures can be discrepant to the point that invasive hemodynamic monitoring is needed. However, because serum oncotic pressure is reduced even more than normal in preeclamptic pregnant patients, interstitial fluid in the lungs and pulmonary edema can occur at relatively low LA and pulmonary wedge pressures.

### ECHOCARDIOGRAPHIC FINDINGS

In the few studies that have compared cardiac structure in preeclamptic versus normotensive pregnant patients, there have been few or no differences in LV dimensions, volumes, fractional shortening, or LV mass (Table 35-5). Aortic root dimension appears to be slightly greater in preeclamptic than in normotensive pregnant patients and tends to be inversely related to total peripheral resistance.[21]

### IMPACT ON PROGNOSIS AND TREATMENT PLANS

The use of Doppler CO measurements and calculation of systemic vascular resistance in patients with pregnancy-induced hypertension and preeclampsia to tailor medical therapy is controversial. Some authors have described medication choice based on whether the patient has an elevated CO or elevated systemic vascular resistance.[63] For example, hypertension related to a high CO might respond to beta-blocker therapy, whereas elevated systemic vascular resistance might respond to vasodilator therapy. Importantly, maternal hemodynamics affect fetal growth: High-resistance hypertension is associated with lower birth weights.

Investigators identified women at risk of preeclampsia based on an elevated CO (greater than 7.4 L/min by Doppler echocardiogram) before 24 weeks gestation. In a subsequent double-blind, randomized trial of women with an elevated CO early in pregnancy, atenolol decreased the incidence of preeclampsia (1 of 28 versus 5 of 28, $p = 0.04$) but increased the risk of a low–birth-weight infant ($p = 0.02$).[64]

## Heart Disease in Pregnancy

Given the low prevalence of heart disease in women of childbearing age in the general population, few pregnant women have significant heart disease. Despite this low prevalence, heart disease is a leading cause of maternal morbidity and mortality. The prevalence of specific types of heart disease in pregnancy reflects both the geographic distribution of these diseases and the patterns of health care in the overall population.[65] For example, in the United States and Europe, the prevalence of rheumatic valvular disease in young women is decreasing, whereas that of surgically treated congenital heart disease with survival to adulthood is increasing. Several studies have demonstrated that severe complications related to chronic heart disease have increased, including one study demonstrating that although overall prevalence of heart disease in delivery hospitalizations in the United States had not changed from

1995-1997 to 2004-2006, the number of hospitalizations for severe cardiac complications tripled in that time and there was a linear increase in congenital heart disease, arrhythmias, and heart failure. These authors concluded that the severity of heart disease had increased and that specific diagnoses, such as congenital heart disease, were increasingly common.[66]

Although the incidence of significant heart disease is low, suspected cardiac disease is a common reason for echocardiographic evaluation of pregnant women. The most common symptoms and signs prompting a suspicion of cardiac disease are (1) evaluation of a murmur; (2) evaluation of cardiac symptoms, such as heart failure; and (3) a history of preexisting heart disease. It is important that the normal hemodynamic changes of pregnancy be distinguished from pathologic abnormalities when these patients are evaluated.

The echocardiographic diagnosis of significant heart disease in a pregnant woman can affect patient management in several ways.[67] First, the cardiac diagnosis may have important prognostic implications (morbidity and mortality) for both mother and fetus. Second, special or more intensive monitoring of the mother or fetus may be needed during pregnancy or in the peripartum period. Third, surgical or medical intervention may be needed either during or after pregnancy. Finally, the risk of congenital heart disease in the fetus may be increased, suggesting the need for fetal echocardiographic evaluation.

Several risk scores have been developed that allow stratification based not only on specific diagnosis, but on more broadly applicable clinical features such as systemic ventricular function, cyanosis, functional class, and prior history of events. Depending on the study, specific diagnoses also have been identified as risks for adverse outcomes, such as LV inflow or outflow obstruction (i.e., aortic or mitral stenosis) or tetralogy of Fallot with significant pulmonary regurgitation. A summary of the identified risks is found in Box 35-1. Echocardiography is an important component of the evaluation in such risk scores.[68,69] Recent data identified heart rate response to exercise as another important risk predictor in women with congenital heart disease who underwent cardiopulmonary exercise testing before pregnancy. There were 89 pregnancies in 83 women, with 18% suffering an adverse cardiac event such as heart failure or sustained arrhythmia during pregnancy. Peak heart rate and percentage of maximal heart rate were predictors of maternal cardiac events.[70]

Data such as this emphasize that although echocardiography and anatomic data are important in assessing risk, other data are necessary to provide a comprehensive preconceptional evaluation.

Additionally, there is data that events during pregnancy predict events in the years following pregnancy.[71] This group followed 318 women who had 405 pregnancies had found that 12% had cardiac events in the 5 years following delivery. Events before and during pregnancy predicted late events, with anatomic and functional risks similar to those identified in the risk scores developed to assess preconceptional risk (see Box 35-1).

The ACC/AHA Guidelines for the Management of Adults with Congenital Heart Disease[72] and the ACC/AHA Guidelines for the Management of Patients with Valvular Heart Disease[73] provide guidance on risk assessment, management, and the use of echocardiography in women with heart disease and are invaluable resources.

**Box 35-1**

**PREDICTORS OF CARDIAC EVENTS DURING PREGNANCY**

- Cardiac event before pregnancy
  - Heart failure, arrhythmia
- Functional status
  - NYHA class >2
- Cyanosis
- Left heart obstruction
  - Symptomatic or severe mitral stenosis
  - Severe aortic stenosis (aortic valve area <1.0 $cm^2$, aortic velocity >4.0 m/s)
  - Hypertrophic cardiomyopathy with LVOT ΔP >30 mm Hg
- Systemic ventricular dysfunction
  - Ejection fraction <40%
- Pulmonary hypertension
  - Systolic pressure >50% systemic
- Severe aortic or mitral regurgitation
  - NYHA class III or IV symptoms
- Smoking

## PULMONARY VASCULAR DISEASE

Elevated pulmonary artery pressures may be the result of primary pulmonary hypertension, pulmonary emboli, chronic lung disease, left-sided heart disease, or congenital heart disease with systemic-to-pulmonary shunting. Elevated pulmonary pressures of any cause are associated with poor maternal and fetal outcomes.

Initial concerns regarding the risk of pulmonary hypertension in pregnancy were raised by studies of women with Eisenmenger syndrome. Eisenmenger syndrome develops when a left-to-right shunt causes equalization of pulmonary and systemic vascular resistance, resulting in right-to-left shunting and cyanosis.[74] Women with Eisenmenger syndrome have cyanosis, arterial oxygen desaturation, and polycythemia. One of the largest single-center studies reported 70 pregnancies in 44 women with a maternal mortality of 52%. Over half of pregnancies delivered prematurely, and neonatal mortality was nearly 30%.[75] In a review of pulmonary vascular disease in pregnancy, 73 women with Eisenmenger syndrome had a maternal mortality of 36%, 27 with primary pulmonary hypertension had a mortality of 30%, and 25 with secondary pulmonary hypertension had a maternal mortality of 56%.[76] The neonatal survival was 88% in all groups, with all maternal deaths occurring within 35 days after delivery. Effective therapies for these conditions during pregnancy are not currently available, although small case reports describe pregnancies in patients receiving epoprostenol, sildenafil, or nitric oxide.[77,78] Despite the appeal of novel pulmonary vasodilators, maternal death is nonetheless reported following pregnancy treated with these medications.[79,80]

One series reported 9 women with 10 pregnancies who chose to continue pregnancy despite the increased risk and were managed with current pulmonary vasodilators and multidisciplinary pregnancy and delivery management. One woman who self-discontinued pulmonary vasodilators died 4 weeks after delivery, but the other women and their infants were alive after a median of 3.2 years.[81]

These data suggest that there may be mortality benefit to current pulmonary hypertension therapies combined with careful multidisciplinary management, although more data are needed to change current recommendations regarding the safety of pregnancy in these patients.

Doppler echocardiographic measurement of pulmonary pressures allows identification of women with pulmonary hypertension, quantitation of disease severity, and evaluation of the response to therapy. Doppler data are limited to assessment of pressures, not vascular resistance, and therefore may incompletely assess the extent of the underlying pathology.

## CONGENITAL HEART DISEASE

### *Acyanotic Patients with No Prior Surgical Procedures*[82]

The most common congenital defect newly diagnosed during pregnancy is an atrial septal defect (ASD). These patients are usually asymptomatic but have a prominent "flow murmur" prompting a request for echocardiography. 2D echocardiographic and Doppler diagnosis of atrial septal defects in pregnancy is straightforward (Fig. 35-7). Contrast echocardiography is not needed for detection of significant interatrial shunt and should be avoided to minimize embolic risks. Given the increased CO and ventricular volumes of pregnancy, evaluation of the shunt ratio can be problematic in borderline cases At least in theory the decreased systemic vascular resistance of pregnancy might result in increased systemic blood flow without affecting pulmonary blood flow, decreasing the pulmonic-to-systemic shunt ratio and leading to underestimation of the true magnitude of the atrial septal defect. However, accurate definition of the shunt ratio is not necessary during pregnancy because pregnancy is well tolerated if pulmonary pressures are normal, regardless of the size of the left-to-right shunt.[83]

Ventricular septal defects in acyanotic adults are typically small and associated with a loud systolic murmur. On Doppler examination, a high-velocity jet from LV to RV is seen with normal chamber dimensions and function. This lesion is also well tolerated, though one study suggests an increased risk of preeclampsia with unrepaired ventricular septal defect. The mechanism is not well understood.[84] Pregnancy does not significantly alter the echocardiographic findings. Large unrestrictive ventricular septal defects are uncommon in adulthood and almost always associated with Eisenmenger syndrome.

Occasionally, a previously undiagnosed patent ductus arteriosus becomes noticeable during pregnancy. The classic continuous machinery-like murmur may or may not be appreciated on auscultation if the murmur is soft. When a patent ductus arteriosus is not suspected a priori, findings of LA or LV enlargement in excess of the expected changes of pregnancy, diastolic flow reversal in the descending thoracic aorta in the absence of significant aortic regurgitation, or unexplained pulmonary hypertension should prompt a careful search for this possible diagnosis. On 2D imaging, the patent ductus is often difficult to visualize in adults, so that a directed Doppler examination is essential when this diagnosis is suspected. Diastolic flow reversal in the pulmonary artery is seen with both color flow imaging and pulsed Doppler techniques. The hemodynamic impact of a patent ductus arteriosus is similar to that of a ventricular septal defect and is also associated with Eisenmenger syndrome when large.

Other types of unoperated acyanotic congenital heart disease seen in pregnant patients include mild pulmonic stenosis and Ebstein's anomaly of the tricuspid valve. Both are well tolerated, provided there is no associated cyanosis.[85] Ebstein's anomaly may occur as an isolated anomaly with varying degrees of tricuspid regurgitation or may be associated with an atrial septal defect. The regurgitant jet may be directed at the atrial septum and in combination with impaired diastolic function may cause right-to-left shunting and cyanosis. In women with acyanotic Ebstein's anomaly, pregnancy is well tolerated.[86] Despite varying degrees of tricuspid regurgitation, no maternal deaths, strokes, heart failure, or arrhythmias were reported in 111 pregnancies in 44 women with Ebstein's anomaly.[87]

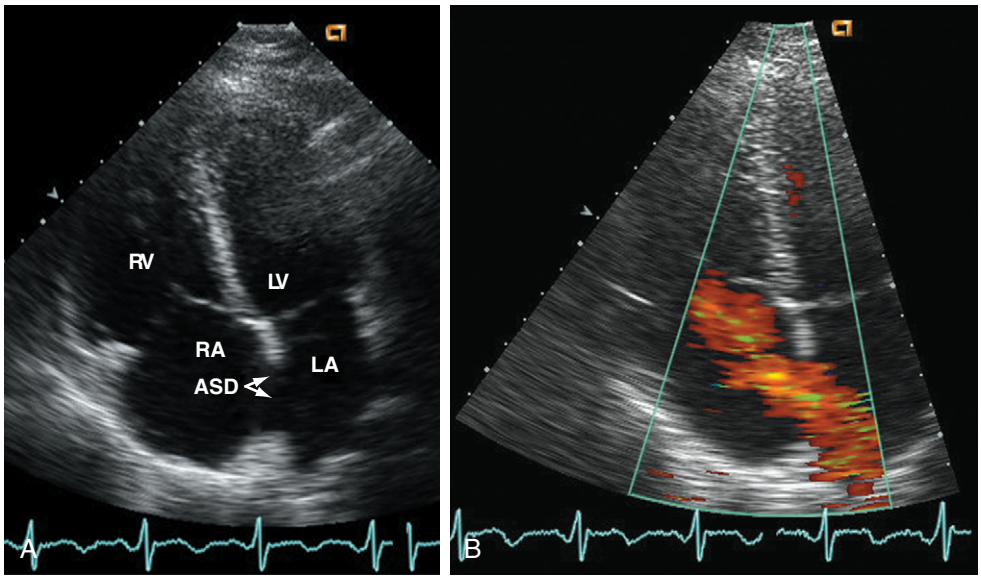

**Figure 35-7 A 24-year-old $G_1P_0$ woman at 14 weeks gestation is referred for echocardiography in evaluation of palpitations and a murmur.** Key findings from an apical four-chamber view included a secundum atrial septal defect (*ASD*) by 2D (**A**) imaging, left-to-right shunt by color Doppler (**B**), and RV and RV enlargement (**A**). Also found were normal pulmonary pressures and a 1.8:1 estimated left-to-right shunt . She was asymptomatic aside from the palpitations and went on to have an uneventful pregnancy with closure of her ASD via a percutaneous approach 4 months after delivery.

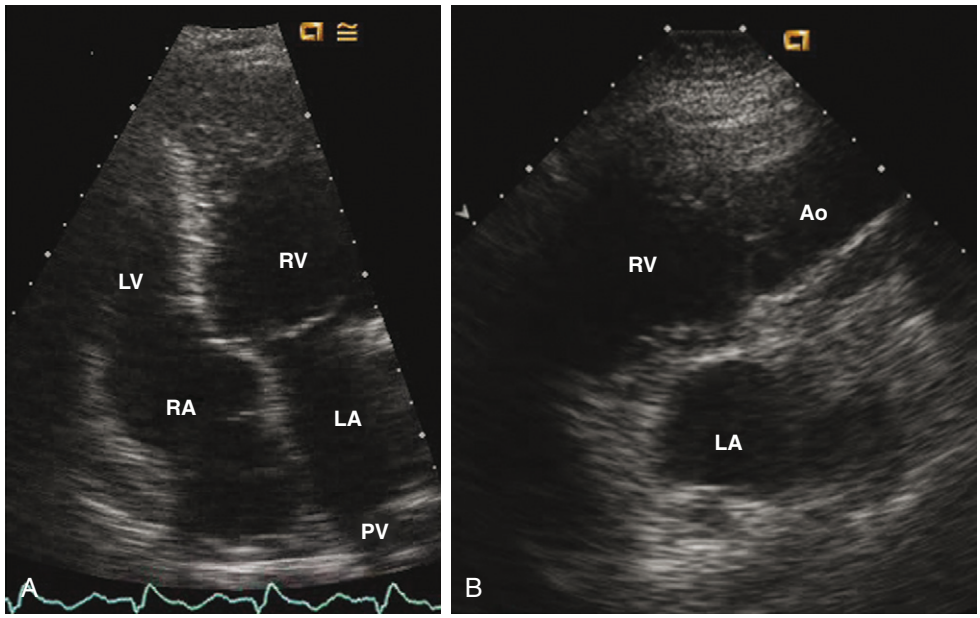

**Figure 35-8 A 34-year-old $G_3P_3$ woman with a history of congenitally corrected transposition of the great vessels returns for routine follow-up.** Her pregnancies had all been uneventful, and she has done well since her last delivery 2 years ago with minimal decrease in ventricular function. She required a pacemaker for complete heart block 1 year ago. On echocardiography, apical views demonstrate a hypertrophied anatomic RV that is rightward of the anatomic LV (**A**). An anterior aorta, typical of transposition of the great vessels, is seen on parasternal images (**B**). *Ao*, Aorta; *PV*, pulmonary vein.

Congenitally corrected transposition of the great arteries (CCTGA), also known as L-transposition with ventricular inversion (Fig. 35-8), is most often is associated with a normal physiologic pattern of blood flow through the heart and may first be recognized during pregnancy. Although there is physiologic blood flow through the heart, the anatomic RV is the systemic ventricle, and the tricuspid valve is the systemic atrioventricular valve. Associated defects are common, including ventricular septal defects, pulmonic stenosis, complete heart block, and regurgitation of the systemic atrioventricular valve, at times the result of Ebstein's anomaly of the tricuspid valve.

Outcome during pregnancy depends on the associated defects and systemic ventricular function in patients with CCTGA. Published summaries in a total of 87 women with 118 pregnancies demonstrated a live birth rate of 83%.[85,88,89] Complications during pregnancy included heart failure, increased cyanosis, endocarditis, stroke, and myocardial infarction (MI). Although there are few data regarding the fate of the systemic RV following pregnancy in CCTGA, studies of the systemic RV in patients with transposition of the great arteries corrected with an atrial-level switch (Mustard or Senning repair) may provide some insight. A study with longitudinal echocardiographic data of 16 women with 24 pregnancies demonstrated decline in systemic RV dysfunction during pregnancy in four patients (25%) with return to baseline in only one of those patients.[90] Patients with systemic RVs, including CCTGA, should have echocardiographic assessment during and after pregnancy.

### *Acyanotic Patients with Prior Surgical Procedures*

As medical therapy and cardiac surgery for congenital heart disease have advanced, the number of patients reaching adulthood has markedly increased. The majority of patients with complex congenital heart disease will have had at least one surgical repair in childhood. Additionally, the favored surgical repair of certain defects, such as transposition of the great arteries, has evolved over time and results in different anatomy and physiology depending on the era in which the repair was performed. When these patients become pregnant, echocardiographic evaluation can detect any residual structural or functional cardiac abnormalities, evaluate for long-term complications of the surgical procedure, and optimize patient management during pregnancy and in the peripartum period. Data on maternal and fetal outcomes in these patient populations are based on case series, with many series including multiple congenital abnormalities. As a consequence, although our understanding of pregnancy in congenital heart disease is increasing, recommendations based on large clinical trials are not available and recommendations must be tailored on an individual basis.

In patients with previous surgical procedures that completely correct the congenital abnormality, outcome in pregnancy is similar to that in normal women. For example, closure of an uncomplicated atrial or ventricular septal defect or patent ductus arteriosus ligation often result in normal cardiac anatomy and function, with a corresponding normal echocardiographic examination.[83] When mild abnormalities remain after corrective surgery for congenital heart disease, maternal outcome is also likely to be similar to that in women without heart disease, with the proviso that the echocardiographic examination should be directed toward potential residual abnormalities or late complications. With complex congenital heart disease and palliative or partially corrective surgical procedures, residual or recurrent anatomic/functional cardiac abnormalities occur commonly, resulting in an increased maternal risk. Echocardiographic evaluation is especially valuable in these patients both before pregnancy to assess the potential risk and during pregnancy to monitor cardiovascular function. In pregnant patients with complex congenital heart

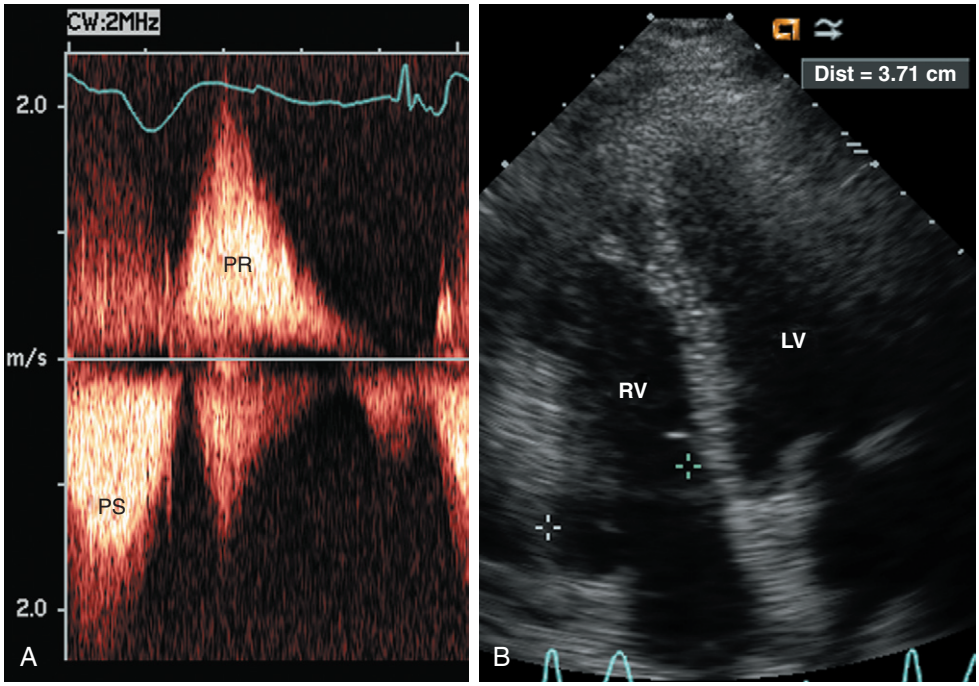

**Figure 35-9 A $G_0P_0$ 25-year-old woman with tetralogy of Fallot presents for preconception counseling.** She underwent initial Blalock-Taussig shunt palliation as an infant and subsequent complete repair with takedown of the Blalock-Taussig shunt at age 4. She is asymptomatic. An echocardiogram and cardiopulmonary exercise test are obtained. Key findings on echocardiography include significant pulmonic regurgitation (**A**), mild pulmonic stenosis (**A**), mild to moderate RV enlargement (**B**), and normal biventricular systolic function. Exercise testing demonstrated a mild reduction in exercise capacity. She was advised that pregnancy was likely to be well tolerated, and regular reassessment of her cardiac status during pregnancy was recommended. *PR*, Pulmonic regurgitation; *PS*, pulmonic stenosis.

disease, arrhythmias are a frequent cause of morbidity and mortality.[91]

## Tetralogy of Fallot

Patients with surgical repair of tetralogy of Fallot often have pulmonic regurgitation, recurrent or residual RV outflow tract obstruction, ventricular septal defect, or aneurysm of the RV outflow tract[92] (Fig. 35-9). Multiple series of pregnancies in patients with tetralogy of Fallot have been reported. Two series describe 92 women with 175 pregnancies. Cardiac complications included arrhythmias and symptomatic heart failure, which occurred in 8% of women and 4.5% of pregnancies.[93,94] There were no reported maternal deaths, but fetal complications included a high rate of spontaneous abortion. In one study, the risk of maternal and fetal complications was associated with LV dysfunction, severe pulmonary hypertension, and severe pulmonic regurgitation and RV dilation.[94]

Another more recent study evaluated 74 women with 157 pregnancies, with cardiovascular events in 8.1%, primarily supraventricular arrhythmias, with risks predicted by the use of cardiac medications before pregnancy.[95]

An echocardiographic evaluation of LV size and function during pregnancy in patients with tetralogy of Fallot followed 11 women with 17 pregnancies. An increase in LV end-diastolic diameter was noted in controls but not seen in patients with tetralogy of Fallot. A progressive increase in the Tei index as the pregnancy progressed was seen in patients with tetralogy of Fallot. Although this returned to normal postpartum, the progressive increase in Tei index was not seen in normal women.[96] This suggests that some of the normal echocardiographic findings in women without heart disease may not manifest in patients with congenital heart disease.

## Coarctation of the Aorta

Patients with a previous aortic coarctation repair may have residual or recurrent stenosis[97,98] (Fig. 35-10). Even in the absence of restenosis, these patients are at risk for late systemic hypertension, which may present initially as exercise-induced hypertension.[101] Women with a repaired coarctation and a residual gradient less than 20 mm Hg can have successful pregnancies, with one study reporting 29 births for 36 pregnancies.[90] A study of 50 women with coarctation found no significant maternal cardiovascular complications in 118 pregnancies. Thirty percent of women were hypertensive during pregnancy, and of those, 75% had a hemodynamically significant coarctation. The rate of spontaneous abortion and preeclampsia was similar to that of the general population.[102] Another series demonstrated that 24% of women with coarctation had hypertensive complications compared with 8% of women without coarctation. Women with coarctation had longer hospital stays and were more likely to have adverse cardiac outcomes.[103] These studies and other case reports suggest that hypertension during pregnancy is more common and needs to be controlled. Additionally, aneurysm in the area of prior repair or in the ascending aorta can be seen in patients with coarctation. These patients represent a higher risk group and consideration to aneurysm repair before pregnancy may be warranted. Echocardiographic evaluation may be insufficient to fully evaluate for aortic aneurysm in these patients, and other imaging modalities, such as magnetic resonance imaging or computed tomography, may be needed.[104]

## Fontan Repair

Following the initial description by Fontan and Baudet[105] of surgical atriopulmonary connection to alleviate cyanosis in

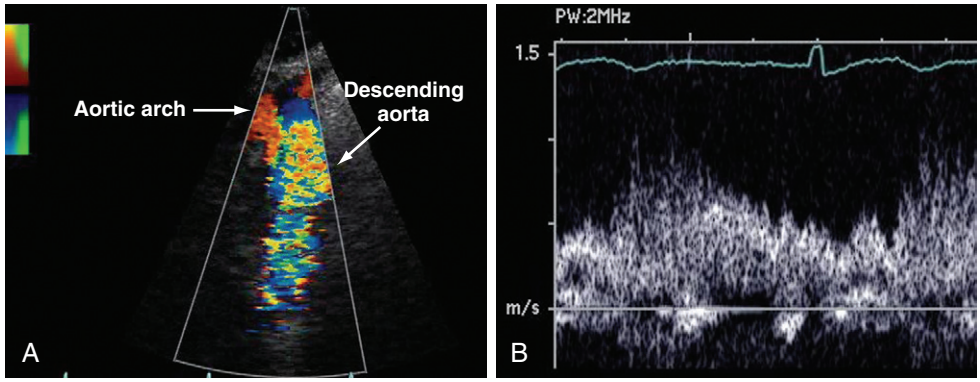

**Figure 35-10 A $G_1P_0$ 19-year-old woman underwent coarctation repair at age 6 months with subsequent repair of recoarctation at age 2 years.** She has a known mild residual coarctation and is now 7 weeks pregnant. By clinical examination, her right arm blood pressure is normal and she has a 10 mm Hg gradient by blood pressure measurements in the arms and legs. Key findings on echocardiography include narrowing by 2D and color Doppler (**A**) in the aortic arch and evidence of diastolic runoff in the abdominal aorta (**B**). CW Doppler is often an inaccurate measure of coarctation severity when using the Bernoulli equation; however, the finding of continuous forward flow is a better predictor of coarctation severity.[99,100] Further evaluation with computed tomography or gadolinium magnetic resonance imaging at 7 weeks gestation was not thought warranted, given the patient's normal blood pressure and attendant risks of radiation and gadolinium. She was followed closely during her pregnancy, and although her blood pressure and gradient increased minimally, fetal growth remained normal and she delivered a healthy girl by assisted vaginal delivery.

tricuspid atresia, modifications of the original repair have evolved, as have the underlying defects treated with a Fontan-type repair. The goal of the repair is to alleviate cyanosis in congenital defects that result in essentially single ventricle physiology. In this circulation, there is not a subpulmonic ventricle. Survival after Fontan repair is now 60% at 10 years, so that some women undergoing this procedure will reach childbearing age and may become pregnant.[91] Maternal survival has been documented, but fetal outcome is uncertain. In a series of 33 pregnancies in women with a Fontan repair, there were only 15 (45%) live births. However, there were no significant maternal complications and no deaths.[106] Another study of 38 women with Fontan repair identified 6 women with 10 pregnancies. They found a 50% spontaneous abortion rate, and of the 4 completed pregnancies, 50% of women had cardiac complications during the pregnancy including atrial arrhythmias and decline in New York Heart Association (NYHA) class. Fetal outcome of the live births was uniformly complicated, with all live infants delivered prematurely or small for gestational age, and there was one neonatal death.[107]

Another series of 6 women with 10 pregnancies had similar findings, with a high rate of miscarriage (50%) and cardiac events including a decline in functional status and atrial fibrillation.[108] Based on the limited data available, women with Fontan repairs may carry pregnancies to term. Maternal complications are generally related to supraventricular arrhythmias, especially in women with atriopulmonary anastomoses. However, the high rate of fetal loss and neonatal complications should be considered when counseling these patients.

## Transposition of the Great Arteries

Complete transposition of the great vessels (Fig. 35-11) requires surgical repair in childhood for survival and resolution of cyanosis. Initial repairs redirected blood flow at the atrial level, such that systemic venous return was directed to the LV and then the pulmonary artery and pulmonary venous return was directed to the RV and then the aorta (see Fig. 45-10). In the early and mid-1960s, Mustard and Senning each described a different surgical approach to atrial level switch procedures that bear their names.[109,110] By redirecting blood flow at the atrial level, these repairs leave the morphologic RV as the systemic ventricle.

Pregnancy in patients with a previous Mustard or Senning interatrial baffle repair (Fig. 35-12) for transposition of the great arteries has been reported in multiple series. One series of 28 women with 69 pregnancies found a decline in NYHA class during pregnancy in approximately one third of pregnancies.[111] Another reported 70 pregnancies in 40 women, with arrhythmias and heart failure complicating pregnancy and the postpartum period.[112] Multiple series have demonstrated a decline in systemic ventricular function that is permanent in some cases.[90,111,113] No maternal deaths were reported, but there was an increased rate of spontaneous abortion. In a study of asymptomatic patients who had excellent baseline prepregnancy functional status, none had significant maternal complications.[113] Specifically, none had significant baffle leaks or obstruction, significant systemic atrioventricular valve regurgitation, or systemic ventricular systolic dysfunction.

The available data suggest that in patients with significant functional cardiac abnormalities, maternal outcome is dependent on the specific underlying abnormalities (e.g., patients with systemic ventricular dysfunction are at risk for heart failure during pregnancy). Thus, echocardiographic evaluation is directed toward evaluation of the interatrial baffle (which may require transesophageal imaging), evaluation of systemic and venous ventricular function, detection and quantitation of systemic atrioventricular (tricuspid) valve regurgitation, and assessment of any other residual or acquired abnormalities.

Patients with transposition of the great arteries and ventricular septal defect may undergo a Rastelli repair, which baffles LV flow to the aorta through the ventricular septal defect and uses an RV-to-pulmonary artery conduit.[114] There are few data on pregnancy in the setting of Rastelli repair of transposition of the great arteries, and a series of 6 patients reports a 50% incidence of progressive LVOT obstruction during pregnancy.[115] Echocardiographic evaluation of these patients must focus on LVOT obstruction and dysfunction of the RV-to-pulmonary-artery conduit.

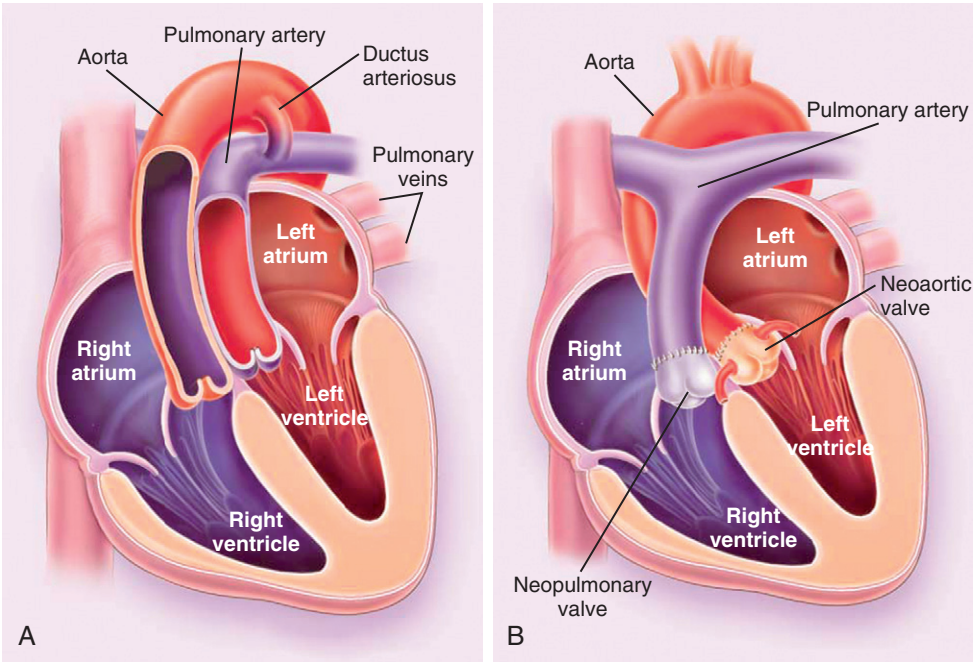

**Figure 35-11** Sketches of complete transposition of the great vessels (**A**) and an arterial switch repair (**B**). *(From Brickner EM, Hillis LD, Lange RA: Congenital heart disease in adults. Second of two parts.* N Engl J Med *342:334-342, 2000.)*

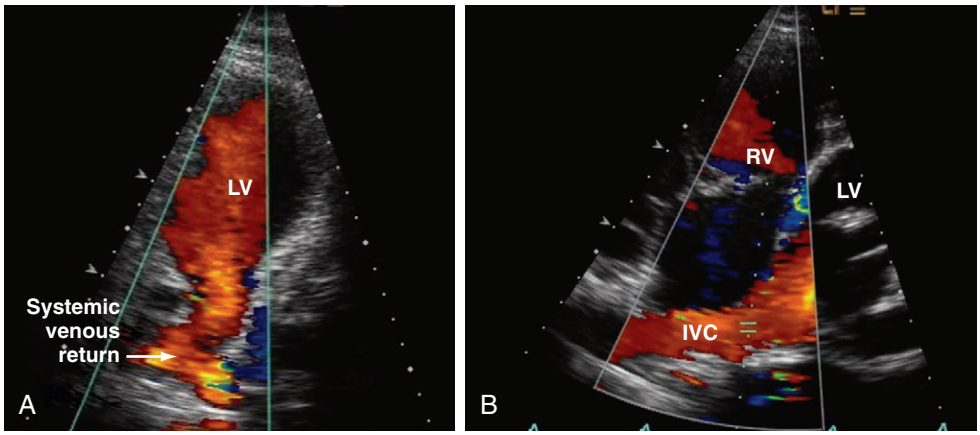

**Figure 35-12 A 28-year-old $G_2P_1$ woman with a history of transposition of the great vessels who underwent a Mustard repair in infancy presents at 10 weeks gestation.** Before pregnancy she was asymptomatic with normal exercise tolerance. Echocardiography demonstrated significant RV enlargement with mildly reduced systolic function. Long-standing, well-tolerated subpulmonic obstruction, in part as a result of systolic anterior motion of the mitral apparatus, was evident in parasternal views. Systemic (**A**) and pulmonary venous return (**B**) were unobstructed by 2D color flow, and PW Doppler. No baffle leaks were identified. Long-standing, mild tricuspid regurgitation was present. Her pregnancy was uneventful, and she delivered a healthy girl by an assisted vaginal delivery. Ventricular function remained unchanged following delivery. *IVC*, Inferior vena cava.

Currently, the preferred correction of transposition of the great arteries is the arterial switch operation as described by Jatene and colleagues[116] and later modified by LeCompte and associates[117] (see Fig. 35-11, *B*). This operation did not replace the Mustard and Senning repair until the early 1990s, and so the first patients with the arterial switch repair are just entering their reproductive years. Because the LV is the systemic ventricle, the anticipated problems relate less to ventricular function than issues related to the surgical repair, including ostial coronary stenoses, supravalvular and branch pulmonary stenosis, and supraaortic stenosis.

One series reports successful pregnancies in 9 women with 17 pregnancies with 2 pregnancy-related complications, 1 in a woman with LV dysfunction and 1 with a mechanical mitral valve. The series emphasized the importance of residua or other cardiac abnormalities in risks for adverse events.[118]

### *Cyanotic Heart Disease*

Eisenmenger physiology (Fig. 35-13) is characterized by equalization of pulmonary and systemic vascular pressures in association with a large systemic-to-pulmonary communication, such as a ventricular septal defect or atrioventricular canal defect.[119] During pregnancy and in the peripartum period, the decrease in systemic vascular resistance, in the setting of irreversible pulmonary hypertension, can result in increased right-to-left shunting and decreased pulmonary blood flow, with

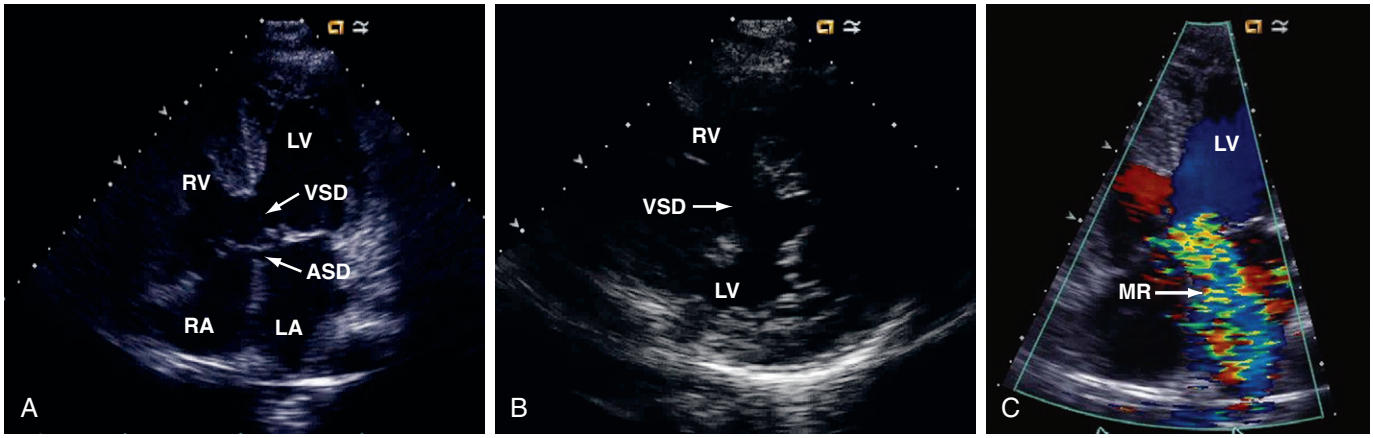

**Figure 35-13 Endocardial cushion defect with a large ventricular septal defect (*VSD*), atrial septal defect (*ASD*), and Eisenmenger physiology in a 19-year-old $G_1P_0$ pregnant woman with no previous cardiac diagnosis.** Apical four-chamber view (**A**) shows the ASD and VSD (*arrows*), and parasternal short-axis view shows the VSD (**B**). Color flow imaging (**C**) shows severe "mitral" (left-sided atrioventricular valve) regurgitation (*MR*). Despite relatively stable hemodynamics during pregnancy and delivery with careful hemodynamic monitoring, the patient had abrupt hemodynamic collapse 48 hours postpartum and died.

subsequent cardiovascular collapse resulting from hypoxia and hypotension.[120] Death usually occurs in the peripartum period, including cases reported 3 to 4 weeks postpartum. Maternal mortality is extremely high (between 30% and 70% in various series), and only 15% of infants are born at term, so pregnancy should be avoided in these patients.[74,121]

Pulmonary artery systolic pressure may be difficult to estimate in patients with Eisenmenger physiology as a result of an inadequate tricuspid regurgitation jet. The presence of pulmonary hypertension must therefore be inferred from findings of a large, nonrestrictive intracardiac communication or large systemic-to-pulmonary artery shunt, such as a patent ductus arteriosus, a short time to peak velocity in the pulmonary artery, midsystolic notching on the pulmonic valve M-mode, and the pattern of ventricular septal motion. If severe pulmonary hypertension is not clearly established, other confirmatory diagnostic tests should be considered in view of the grave prognosis associated with this condition. Rarely, a patient with previously unevaluated congenital heart disease is diagnosed during pregnancy with Eisenmenger physiology.

Cyanotic congenital heart disease without Eisenmenger physiology also connotes high maternal mortality and morbidity.[120,122] In 822 pregnancies in 416 cyanotic women, the rate of maternal cardiovascular complications was 32%, with one maternal death. Fetal outcome was also suboptimal; only 43% of pregnancies resulted in live births, 37% of which were premature. Factors that predict a poor outcome include functional status before pregnancy, arterial oxygen saturation, and blood hemoglobin. Other studies suggest that maternal outcome is also strongly related to the degree of RV pressure overload.[123] Thus, echocardiographic evaluation should include estimates of pulmonary systolic pressure and definition of the anatomic abnormalities and ventricular function.

For congenital heart disease with decreased pulmonary blood flow that cannot be physiologically repaired, palliative shunts to increase pulmonary blood flow are often used. These patients are cyanotic resulting from intracardiac shunting and decreased pulmonary blood flow, rather than from pulmonary hypertension and Eisenmenger syndrome. Few data exist on pregnancy in these patients. However, in a series of 41 pregnancies in 15 women with cyanosis after partial repair for complex pulmonary atresia, there were only 8 healthy children. Although there were no maternal deaths in this series or in a smaller study, maternal complications were high, including pulmonary embolism, heart failure, and arrhythmias.[107,109,123]

## VALVULAR HEART DISEASE

### *Valvular Stenosis*

In a pregnant patient, stenosis of a semilunar valve is usually the result of a congenitally abnormal valve.[110] Mild to moderate stenosis of the pulmonic valve is well tolerated, whereas severe pulmonic stenosis is rare in adults.[124] In contrast to patients with pulmonic valve stenosis, those with aortic valve stenosis, even if asymptomatic before pregnancy, may decompensate during pregnancy. In clinical series, the majority of pregnant patients with aortic stenosis have bicuspid valves.[125] Patients with a previous surgical commissurotomy may have significant restenosis[126]; one study estimated that about 20% of such patients require reoperation at a mean interval of 13 (range 3 to 26) years after the initial procedure.[127] Thus, depending on the patient's age at the initial commissurotomy, restenosis may be diagnosed during pregnancy.

As stroke volume increases across the stenotic valve with pregnancy, an increase in the pressure gradient measured by Doppler echocardiography is seen. Calculation of valve area with the continuity equation still provides accurate assessment of stenosis severity (Fig. 35-14). Some patients may become symptomatic during pregnancy as a result of increased metabolic demands in the setting of a limited ability to increase stroke volume across the valve.[126,128] These patients may develop angina or dyspnea during pregnancy even though they were asymptomatic before pregnancy. Reduced diastolic ventricular compliance secondary to LV hypertrophy can also lead to heart failure. Even when patients with aortic stenosis remain physiologically compensated during pregnancy, any superimposed hemodynamic alteration can lead to acute decompensation. For example, the high CO and heart rate associated with an infection or anemia may result in acute pulmonary edema resulting from a combination of an increased valve gradient and a shortened diastolic filling time.

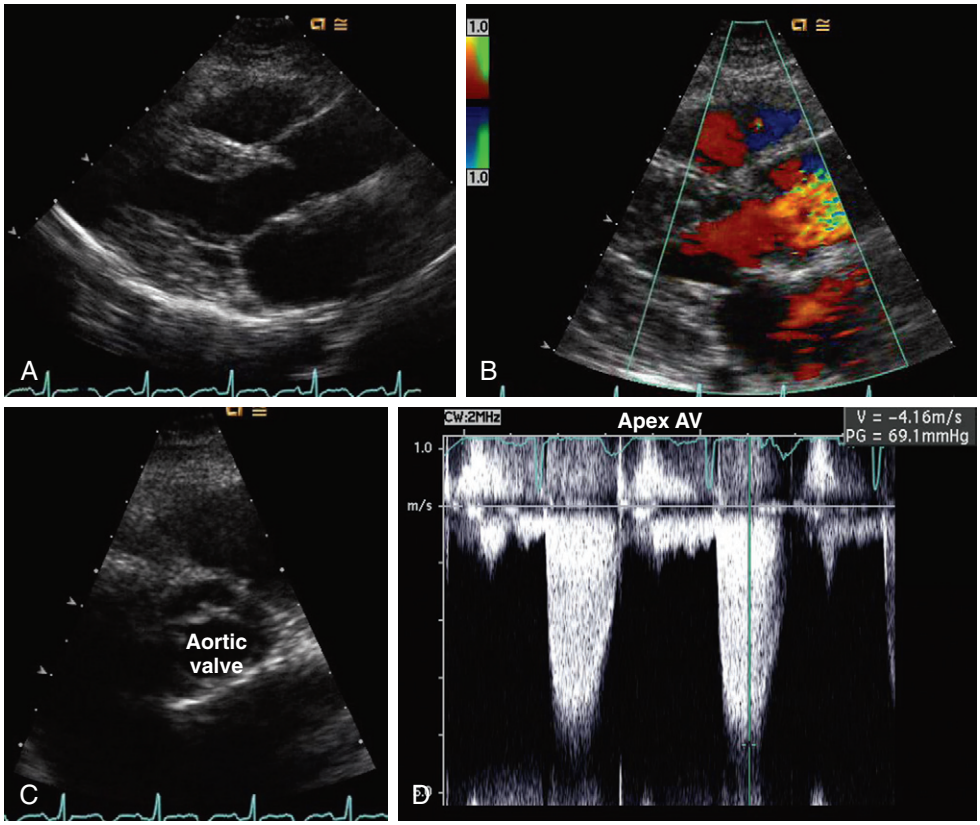

**Figure 35-14 Valvular aortic stenosis in a 25-year-old $G_1P_0$ pregnant woman who underwent an aortic valve commissurotomy 10 years previously.** The parasternal long-axis view (**A**) shows a congenitally abnormal aortic valve with reduced systolic opening. Color Doppler in this view (**B**) shows turbulent flow across the valve. Short-axis views confirm congenital aortic stenosis (**C**). The maximum jet across the aortic valve, recorded with CW Doppler from a high right parasternal position, shows maximum velocity of 4.1 m/s (**D**). There was mild coexisting aortic regurgitation. Aortic valve area, calculated by the continuity equation, was 1 $cm^2$. This patient was managed with placement of a pulmonary artery catheter and arterial line at the time of delivery. Because of fetal presentation, she underwent a cesarean section with epidural anesthesia, which was tolerated well.

The role of echocardiography in pregnant patients with aortic stenosis is to accurately delineate disease severity so that monitoring and therapy during pregnancy and in the peripartum period can be optimized (Fig. 35-15). In some patients the severity of stenosis may worsen during pregnancy, possibly related to the hormonal and metabolic changes. Most pregnant women with aortic stenosis can be managed medically, but balloon aortic valvuloplasty or valve replacement during pregnancy has been required in rare cases.[128-132] A series of 39 patients with 49 pregnancies divided groups based on stenosis severity. The mild to moderate stenosis group had no maternal complications, whereas pulmonary edema or arrhythmias occurred in 10% of pregnancies complicated by severe aortic stenosis. Interestingly, fetal complications, such as small for gestational age and prematurity, were found in both groups of patients, but more often in the mild to moderate stenosis group. Patients with severe stenosis were more likely to require valve replacement in the peripartum period than those with mild to moderate aortic stenosis, and a separate study by the same group showed that the likelihood of needing cardiac intervention was higher in those women who had undergone pregnancy than in those who had not.[128,133]

Some data exist using more novel echocardiographic modalities to identify patients at risk for adverse events. LV twist was increased in pregnant patients with aortic stenosis. Two of 10 women with aortic stenosis did not have an increase in LV twist, and both had symptomatic decline during pregnancy requiring balloon valvuloplasty.[134] As experience with novel echocardiographic modalities increases, there may be a role for some of these indices in assessing pregnant women and preconceptional risk.

Rheumatic mitral valve stenosis is often diagnosed during pregnancy (Fig. 35-16). If mitral stenosis is moderate in severity or if disease progression has been gradual, the patient may not have noted symptoms or exercise limitation before the pregnancy. Early in pregnancy the increased transmitral volume flow rate and the shortened diastolic filling time resulting from the increase in heart rate result in further elevation of LA pressures. This may result in pulmonary edema, depending on the severity of mitral valve obstruction. Because it is often difficult to appreciate the diastolic murmur of mitral stenosis in pregnant dyspneic patients, mitral stenosis should be considered in the differential diagnosis of all pregnant patients with heart failure or pulmonary congestion. Echocardiography reliably differentiates mitral stenosis from other causes of heart failure (e.g., cardiomyopathy or diastolic dysfunction) and will distinguish cardiac from noncardiac causes of respiratory distress. Echocardiographic measures of mitral stenosis severity, including 2D valve area, Doppler gradients, and pressure half-time valve area, remain valid in pregnancy, so that echocardiographic evaluation allows optimization of patient monitoring and therapy.

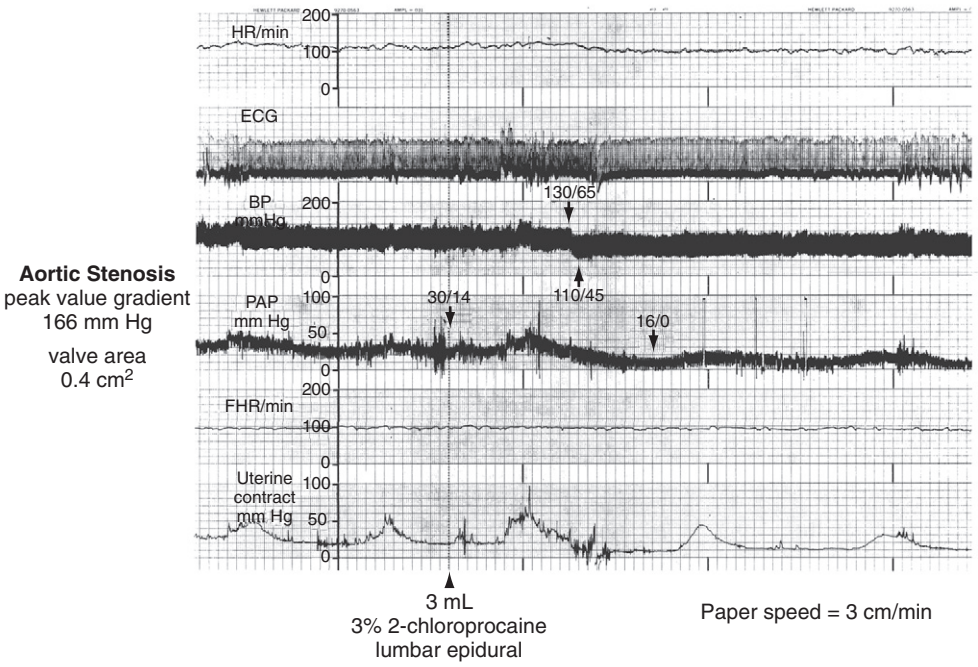

**Figure 35-15 Hemodynamic responses in a patient with severe valvular aortic stenosis showing increased vascular return associated with uterine contractions.** *BP*, Blood pressure; *ECG*, electrocardiogram; *FHR*, fetal heart rate; *HR*, heart rate; *PAP*, pulmonary artery pressure. *(From Easterling TR, Chadwick HS, Otto CM, Benedetti TJ: Aortic stenosis in pregnancy.* Obstet Gynecol *72:113-118, 1988. Reprinted with permission from The American College of Obstetricians and Gynecologists.)*

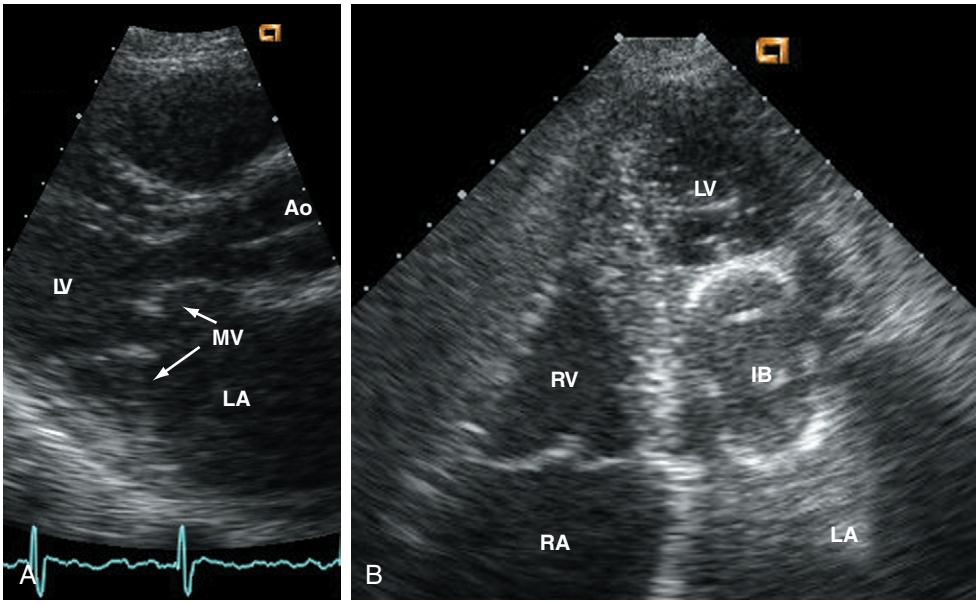

**Figure 35-16 A 35-year-old $G_2P_1$ woman presented with respiratory distress at 26 weeks gestation.** She was found to be in atrial fibrillation, and echocardiography demonstrated severe rheumatic mitral stenosis. 2D imaging is shown from a parasternal view (**A**). Despite efforts at medical stabilization, she remained in pulmonary edema. Balloon mitral valvuloplasty was performed using an Inoue balloon, seen from an apical view (**B**), and she symptomatically improved. She delivered at 35 weeks and required intravenous diuretics in the 48 hours after delivery to alleviate pulmonary edema. She subsequently recovered uneventfully. *Ao*, Aorta; *IB*, Inoue balloon; *MV*, mitral valve.

Usually, patients can be managed medically during pregnancy using beta-blockers to improve diastolic filling, even with severe mitral stenosis, although decompensation may require invasive monitoring in an intensive care unit setting.[135] In some severe cases, maternal or fetal complications may necessitate mechanical relief of stenosis during pregnancy, preferably with percutaneous balloon valvotomy.[136,137] Concerns regarding balloon angioplasty and pregnancy include both maternal risks of the procedure and the effects of radiation exposure on the fetus. One group reported 5-year follow-up of 22 women who underwent valvotomy during pregnancy at a mean gestation of 25 weeks. They demonstrated excellent maternal outcomes and no evidence of any clinical abnormalities in the children.[138] Echocardiography clearly plays a valuable role in assessing the

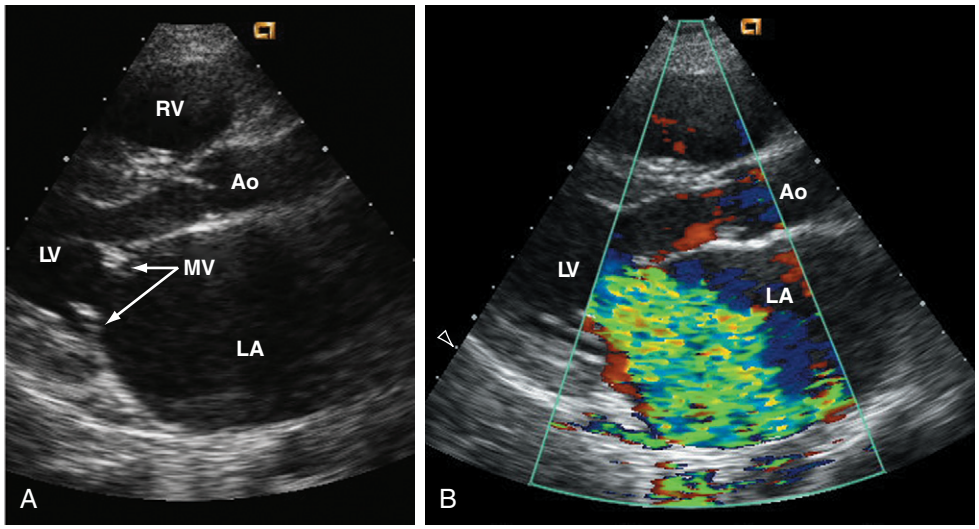

**Figure 35-17 A 34-year-old $G_3P_2$ woman presented at 28 weeks gestation with dyspnea with minimal exertion.** Failure of coaptation is seen on 2D imaging (**A**), and color Doppler shows severe mitral regurgitation (**B**). She was managed with diuretics and bedrest and delivered a healthy baby boy. After delivery she underwent mitral valve repair. *Ao*, Aorta; *MV*, mitral valve.

likelihood of complications and the expected result of percutaneous mitral valvotomy.[139] Echocardiographic monitoring also minimizes fluoroscopy time.[140]

### *Valvular Regurgitation*

Pathologic valvular regurgitation in pregnancy may be the result of a congenital abnormality (bicuspid aortic valve), previous bacterial endocarditis, rheumatic disease, or myxomatous valve disease (Fig. 35-17) or may be associated with more complex congenital heart disease. Standard 2D and Doppler echocardiographic methods for detection and evaluation of valvular regurgitation are applicable in the pregnant patient. Physiologically, it is plausible that pregnancy may result in a decrease in regurgitant severity as a result of the pregnancy-related afterload reduction. This potentially beneficial physiologic effect may be counterbalanced, to some extent, by the hormonal and vascular changes of pregnancy. Increased aortic root dimensions may increase aortic regurgitant severity, whereas increased laxity of valve tissues may lead to an increase in mitral regurgitant severity.

Valvular regurgitation is well tolerated during pregnancy by some patients. Others develop signs and symptoms of heart failure with pulmonary congestion, decreased exercise tolerance, orthopnea, and paroxysmal nocturnal dyspnea. Decompensation can occur in patients with chronic valvular regurgitation because of either (1) the increased CO demands of pregnancy or (2) worsening of the underlying valvular abnormality (e.g., chordal rupture in a patient with myxomatous mitral valve disease). Echocardiographic evaluation can distinguish between these possibilities and aid in optimizing therapy in the decompensated patient.

Quantitation of valvular regurgitant severity and evaluation of LV systolic function may be confounded by the anatomic and hemodynamic changes of pregnancy. In patients with severe aortic or mitral regurgitation, decreased systemic vascular resistance resulting from pregnancy can result in an apparent decrease in regurgitant severity and improvement in LV systolic function. In these patients, surgical intervention may be inappropriately delayed. Conversely, LV dimensions may be slightly larger than in the nonpregnant state, resulting in misdiagnosis in a patient with only moderate regurgitation. In either case, postpartum reevaluation of regurgitant severity and ventricular function will provide accurate data for clinical decision making.

### *Prosthetic Heart Valves*

The outcome of pregnancy is significantly affected by the presence of a prosthetic heart valve.[141-144] With mechanical valves, the risks of valve thrombosis (8% to 9%), embolic events (3% to 5%), serious bleeding (5%), heart failure (28%), and maternal death (4% to 8%) are high,[145] even with careful monitoring of anticoagulation.[146,147] With a bioprosthetic valve, there is less risk of maternal death (0% to 5%), but accelerated valve degeneration during pregnancy may occur and results in a high rate of heart failure (35%) and urgent repeat replacement of the valve in the early postpartum period (35%).[142] The effect of pregnancy in accelerating valve degeneration is controversial. Initial studies made the observation that women with prosthetic heart valves and more than one pregnancy have a lower 10-year graft survival rate for bioprosthetic valves (17%) than women with only one pregnancy (55%).[148] However, another study demonstrated no change in durability of bovine pericardial valves in women who bore children compared with a population who did not.[149] An evaluation of women who underwent pulmonic allograft replacement in the setting of a Ross repair for aortic valve disease did not demonstrate valvular degeneration of the pulmonic allograft.[150]

Echocardiography plays a critical role in identifying valve dysfunction and in assessing valve degeneration during pregnancy (Fig. 35-18). Assessment of prosthetic valves in women who are pregnant may be confounded by the normal hemodynamic changes of pregnancy. The increased heart rate and stroke volume affect Doppler evaluation of velocities and pressure gradients across prosthetic valves. Thus, the volume flow rate should be taken into consideration when evaluating prosthetic valves in pregnant women. The alterations in loading conditions may also affect the accuracy of the pressure half-time method.[151] Ideally, a baseline Doppler echocardiographic study in the prepartum period or early in pregnancy can be used to accurately assess changes later in pregnancy.

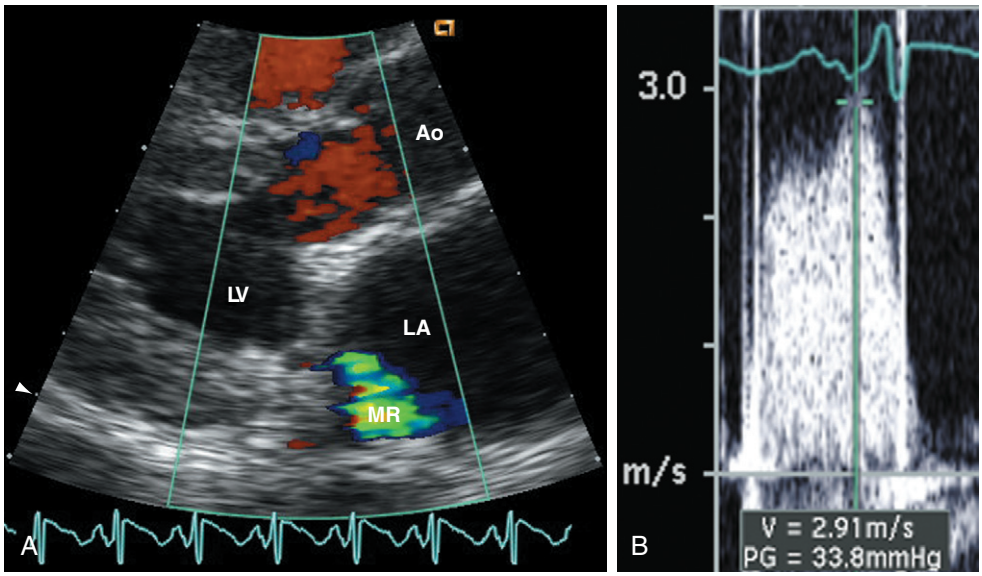

**Figure 35-18 A 24-year-old $G_1P_0$ woman with a St. Jude's mitral prosthesis placed at age 20 presented at 12 weeks gestation with dyspnea and exertional chest pain.** Her anticoagulation had been subtherapeutic. Echocardiography demonstrated more than the expected amount of mitral regurgitation (**A**) for this type of prosthesis by color Doppler and a peak gradient of 33 mm Hg and mean gradient of 20 mm Hg (**B**) by PW and CW Doppler. Despite aggressive anticoagulation and medical therapy, she did not improve. After discussion of the relative risks and benefits of thrombolytic therapy versus surgery, she was taken to the operating room for emergent valve replacement. She recovered uneventfully; however, the fetus did not survive. A subsequent pregnancy managed with therapeutic anticoagulation was uneventful, and she delivered a healthy baby. *Ao*, Aorta; *MR*, mitral regurgitation.

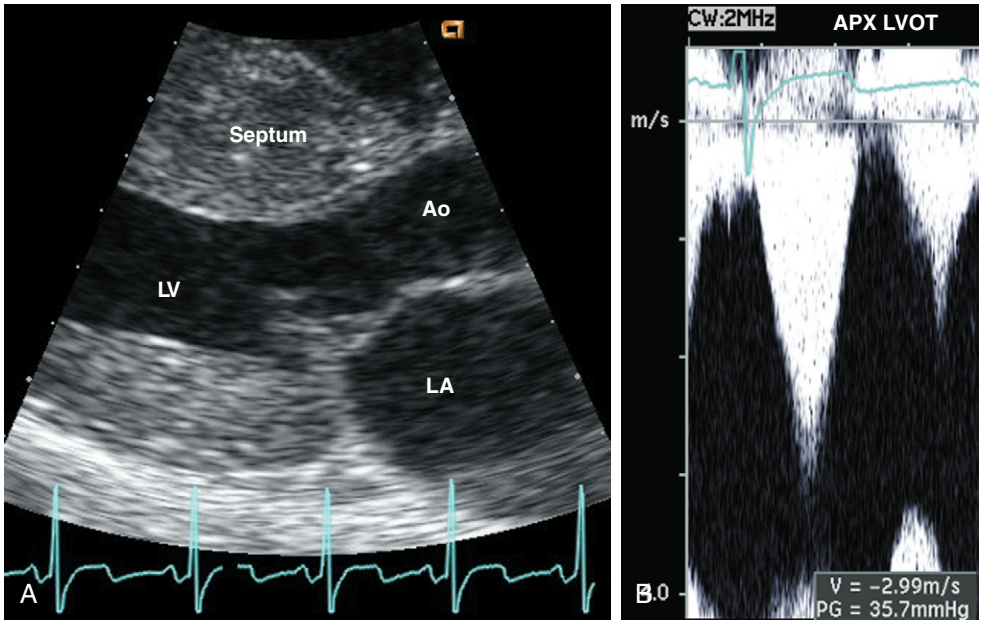

**Figure 35-19 A 21-year-old $G_1P_0$ woman with hypertrophic cardiomyopathy was seen throughout pregnancy. Before pregnancy, she had minimal symptoms of chest pain and exertional dyspnea.** Echocardiography demonstrated marked septal hypertrophy with posterior hypertrophy (**A**). Post-PVC peak gradient was approximately 3.0 m/s (**B**) and was stable from prior studies. Pulmonary pressures were normal. Her symptoms worsened during pregnancy but were controlled with diuretics and continued beta-blockers. She had an uneventful delivery and subsequently returned to her prepregnancy baseline. *Ao*, Aorta; *PVC*, premature ventricular contraction.

## CARDIOMYOPATHIES

The risk of pregnancy in a patient with a known cardiomyopathy is related to the severity of the underlying disease.[152] In familial types of cardiomyopathy, including hypertrophic (Fig. 35-19) and some forms of dilated cardiomyopathy, the genetic implications of the diagnosis also need to be taken into consideration. Echocardiography is used to confirm or exclude the diagnosis in patients considering pregnancy who are at risk for an inherited cardiomyopathy and to assess disease severity in patients with a known cardiomyopathy.[153]

Peripartum cardiomyopathy[152,154] was initially defined as heart failure presenting in the last month of pregnancy or

within 6 months of delivery, without other reason for cardiomyopathy.[155] More recently authors have suggested that the definition include LV dysfunction with an echocardiographic ejection fraction of less than 45%.[156] Others argue that the disease can be found earlier in pregnancy and that the "traditional" presentations represent a spectrum of disease that includes those patients with the earlier onset of cardiomyopathy. The diagnosis typically is established by echocardiography in the appropriate clinical setting. Despite overall improvement in therapy of heart failure, the mortality of peripartum cardiomyopathy remains greater than 20%.[157] The risk to women in subsequent pregnancies is high, particularly if the ejection fraction did not return to normal.[158] Dilated cardiomyopathy carries similarly high risks of adverse cardiac events, predicted by LV dysfunction and NYHA functional class.[159] Echocardiographic monitoring of disease severity, especially LV systolic function, helps optimize patient management.

Pregnancy in patients after cardiac transplantation has been described.[160,161] In one series of 29 organ recipients (26 heart and 3 heart-lung), 21% of women experienced a rejection episode during pregnancy, although only 3% had graft loss within 2 years of delivery. Fetal outcomes were notable for an 18% spontaneous abortion rate, higher than expected in the general population. Of live-born infants, 40% were premature and 40% had low birth weight.[162] As medical therapy for transplant patients evolves and the population requiring transplant includes more young women as a result of the increase in adults with congenital heart disease, one would expect an increase in the number of women bearing children following cardiac transplantation. Echocardiography can be used to evaluate for evidence of rejection during and after pregnancy.

## OTHER HEART DISEASES

### *Marfan Syndrome*

Pregnancy in patients with Marfan syndrome is associated with an increased risk of aortic dissection (Fig. 35-20). The mechanism of aortic dissection in pregnant women with Marfan syndrome presumably relates to (1) the underlying defect in aortic wall structure, (2) normal structural changes in the aortic wall with pregnancy, and (3) the increased stroke volume and LV *dP/dt* of pregnancy. Gestational hypertension may further aggravate the risk of dissection.[163]

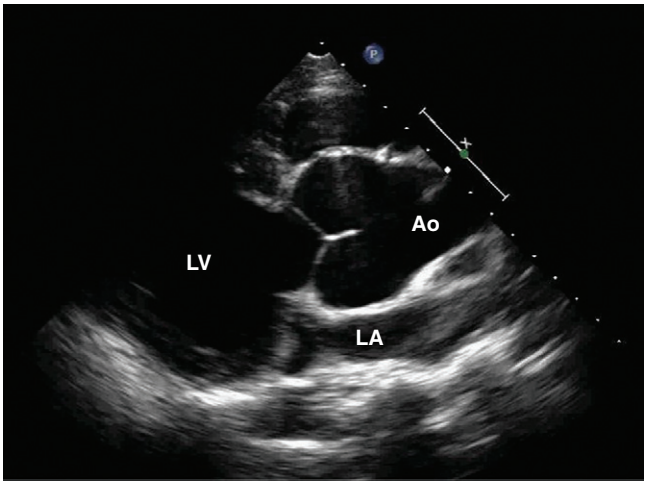

**Figure 35-20 A 23-year-old $G_1P_0$ woman with a history of Marfan syndrome presented at 6 weeks gestation with stable significant aortic enlargement with a maximal dimension of approximately 4.5 cm at the sinuses of Valsalva.** She was followed through pregnancy with serial echocardiograms with stable aortic dimensions. She had an assisted vaginal delivery and delivered a healthy baby girl who was noted to have some features suggestive of Marfan syndrome. *Ao*, Aorta.

As is the case with many cardiac disorders in pregnancy, there are difficulties in gleaning appropriate care recommendations based on the available literature. Initial series suggested a high risk of dissection: Of 35 women with Marfan syndrome and at least one pregnancy, 20 (63%) suffered an acute aortic dissection and 16 (50%) died during pregnancy.[164] Subsequent series suggested a maternal mortality rate of only 1%, especially when aortic diameter is only mildly increased.[165-169] However, in a study of 91 pregnancies in 36 women with Marfan syndrome, 4 of 36 (11%) had dissection related to pregnancy and 2 others required aortic surgery following delivery for a total aortic complication rate of 17%.[170]

As in nonpregnant patients, risk of aortic dissection increases with the degree of aortic dilation. Several studies have demonstrated an increase in the risk of dissection in women with aortic diameter greater than 4 cm.[167,168] One study evaluated 61 women, of whom 23 had had 31 pregnancies with known aortic root dimensions.[169] In this group, there were no complications in women with aortic diameters of 25 to 45 mm, with the only complication in a woman with a prior dissection. In addition to absolute diameter, change in aortic size during pregnancy has also been identified as a risk for dissection. Some patients with Marfan syndrome suffer aortic dissection with only mildly increased aortic root dimensions,[170,171] although a case report describes a woman with an aortic diameter of 8 cm who did not dissect during pregnancy.[172]

Echocardiography is extremely valuable in the preconceptional assessment of women with Marfan syndrome, as several authors have recommended prophylactic aortic root replacement when pregnancy is planned, if aortic root dilation is present.[173,174] Echocardiographic monitoring during pregnancy allows risk stratification by assessing both initial aortic diameter and progression in size increase over time. With careful echocardiographic evaluation of aortic root dimensions and geometry, review of the patient's family history, and consultation between the cardiologist and geneticist,[175] women with Marfan syndrome can be counseled about the potential risks before pregnancy, especially because the risk of dissection during pregnancy appears to be directly related to the degree of aortic root dilation. Treatment with beta-blockers[176,177] and careful peripartum anesthetic management[178] may improve the prognosis in pregnant patients with Marfan syndrome. Successful surgical repair during pregnancy of aortic dissection in Marfan syndrome has been reported.[179]

### *Aortic Dissection*

There is an increased risk of aortic dissection during pregnancy even in women without Marfan syndrome. Patients with connective tissue disorders such as Ehlers-Danlos syndrome are at higher risk, as are women with bicuspid aortic valve and dilated aortic root,[167] Turner syndrome,[180] and severe hypertension. Echocardiography is often the initial diagnostic test requested in these patients. Prompt recognition and surgical intervention can be lifesaving.[181]

### *Ischemic Heart Disease*

Acute coronary events and MI are rare in pregnancy, resulting from the low prevalence of coronary artery disease in women

of childbearing age. In women aged 15 to 44 years, the incidence of MI unrelated to pregnancy is 5 per 100,000 woman-years, and the rate of cerebrovascular events is 10.7 per 100,000 woman-years.[182] However, coronary dissection and thromboembolic events are unusual causes of MI disproportionately represented in pregnancy. A literature review of 125 cases of MI in pregnancy found the highest incidence in multigravid women over age 33 years. MI tended to occur in the third trimester, often during labor and delivery. Of the MIs, 43% were the result of atherosclerosis, 21% were thrombotic without evidence of underlying atherosclerosis, 16% were the result of coronary dissection, and in 29% coronary anatomy was normal, suggesting the possibility of coronary spasm.[182]

Another study identified 859 MIs related to pregnancy, which was a case event rate of 6.2 per 100,000. The case fatality rate was 5.1%, demonstrating that although rare, MI related to pregnancy carries a significant risk of mortality. In this study, classic risk factors for coronary artery disease, including hypertension, diabetes mellitus, and smoking, were significant. In addition, the risk was 30 times higher for women older than 40 years compared with women younger than 20 years.[183] As women delay childbirth, the incidence of MI in pregnancy may rise.[184] Though uncommon, rates of severe complications related to MI during pregnancy are high.[185] The usual criteria for MI apply in pregnancy and the puerperium, with the exception of myoglobin and creatinine kinase myocardial band, which may increase twofold in normal women within 30 minutes of delivery.[186] Troponin I is a more accurate marker in this setting. Segmental wall motion abnormalities on echocardiography should raise the possibility of ischemic heart disease.

Data regarding therapy of MI during pregnancy are limited. Thrombolytic therapy is contraindicated in pregnancy and the early postpartum period, so the optimal clinical approach to revascularization is percutaneous balloon angioplasty with or without placement of an intracoronary stent, although coronary bypass grafting surgery during pregnancy also has been described.[187] The use of clopidogrel can complicate delivery; therefore, stent selection is based on the anticipated delivery date and duration of clopidogrel therapy to protect from stent thrombosis.[188] Little is known about the risk of subsequent pregnancy for women with a pregnancy complicated by MI.

## Echocardiographic Monitoring in Pregnant Patients

In addition to monitoring disease severity and cardiovascular hemodynamics in pregnant patients, both transthoracic echocardiography (TTE) and transesophageal[140] echocardiography (TEE) have been used to monitor diagnostic and therapeutic procedures. One of the advantages of echocardiographic monitoring during pregnancy is the avoidance of exposure to ionizing radiation. Echocardiographic monitoring in pregnant women has been reported for electrophysiologic testing,[148] pacer implantation, and percutaneous balloon mitral valvotomy.[189]

## Common Clinical Presentations

### PULMONARY EDEMA AND HEART FAILURE

In the pregnant patient with acute respiratory distress, the initial differential diagnosis is cardiac and noncardiac causes, such as acute pulmonary embolism, pneumonia, or an acute viral syndrome. An echocardiographic study in these situations helps demonstrate normal cardiac anatomy and function, allowing attention to be focused on potential noncardiac causes of the illness. Conversely, a cardiac etiology can be quickly identified and evaluated, permitting appropriate therapeutic interventions.

**TABLE 35-6 Respiratory Distress in Pregnancy: Echocardiographic Differential Diagnosis**

| *Pathophysiology* | *Examples* |
|---|---|
| **Cardiac** | |
| ↓ LV (or systemic ventricle) systolic function | Peripartum cardiomyopathy |
| | Congenital heart disease |
| | Dilated cardiomyopathy |
| LV diastolic function | Hypertension |
| | Aortic stenosis |
| LV pressure overload | Aortic stenosis |
| | Hypertension |
| Impaired cardiac filling | Mitral stenosis |
| | Pericardial disease |
| LV (or systemic ventricle) volume overload | Aortic regurgitation |
| | Mitral regurgitation |
| | Tricuspid regurgitation in systemic RV |
| ↓ Pulmonary blood flow | Eisenmenger physiology |
| | Palliative systemic-to-pulmonary shunts |
| **Noncardiac** | |
| Capillary "leak" | Preeclampsia |
| | Adult respiratory distress syndrome |
| Infection | Pneumonia |
| | Viral syndrome |
| Pulmonary vascular obstruction | Pulmonary embolus |

From Vered Z, Poler SM, Gibson P, et al: Non-invasive detection of the morphologic and hemodynamic changes during normal pregnancy. *Clin Cardiol* 14:327-334, 1991.

Of the cardiac conditions presenting with pulmonary edema in the third trimester or in the peripartum period (Table 35-6), the most prevalent are mitral valve stenosis and peripartum cardiomyopathy. On physical examination, the diastolic rumbling murmur of mitral stenosis is difficult to appreciate and the patient herself is often unaware of a heart condition. The added hemodynamic burden of pregnancy may result in a previously asymptomatic patient being diagnosed with "sudden" and "unexplained" pulmonary edema. It is not unusual for the echocardiogram (ordered for other reasons) to be the first clue that valvular obstruction is present.

Peripartum cardiomyopathy may present with the insidious onset of heart failure symptoms or may be more abrupt in onset. In the latter case, it is likely that the patient has unrecognized heart failure symptoms that can be elicited in retrospect. The degree of LV systolic dysfunction is variable. Typically, clinical symptoms are first noted between 1 month antepartum and 1 month postpartum.[152,190] Echocardiographically, peripartum cardiomyopathy is indistinguishable from other forms of dilated cardiomyopathy.

### THE PREGNANT PATIENT WITH A CARDIAC MURMUR

A systolic murmur is a common finding during pregnancy, being reported in as many as 80% of women in some series.[191] This murmur typically is a "flow" murmur resulting from the increased volume flow rate of pregnancy. Depending on its location and timing, it most often originates from the pulmonic

valve, although some flow murmurs of pregnancy may be the result of high flow across the aortic valve. With the normal murmur of pregnancy, Doppler echocardiography shows no abnormal flow patterns, although antegrade velocities are increased, as expected in pregnancy.

One study of 103 women with no previous cardiac history referred for evaluation of a murmur during pregnancy found that 79% had a benign murmur on physical examination, and all of these individuals had normal results on Doppler echocardiography.[191] Benign ejection murmurs were soft and midsystolic. Even in the 14% with a loud or long ejection murmur, most had normal Doppler study results, with abnormalities seen in only 3 patients (1 mitral valve prolapse with mild mitral regurgitation, 1 nonobstructive hypertrophic cardiomyopathy, 1 bicuspid aortic valve). In contrast, in the 7% of patients with a pansystolic, late systolic, or diastolic murmur all had abnormal echocardiographic results. This group included 3 ventricular septal defects, 1 large atrial septal defect, one atrial septal defect in conjunction with rheumatic mitral regurgitation, 1 mitral valve prolapse, and 1 nonobstructive hypertrophic cardiomyopathy.

Although it is likely that the prevalence of specific cardiac diagnoses will vary with the population, this series clearly demonstrates the importance of careful patient selection in requesting echocardiography for evaluation of a murmur in pregnancy. To minimize the inappropriate use of echocardiography in pregnant women, one approach is to limit echocardiographic evaluation to pregnant women with a murmur only if they have (1) a history of underlying heart disease, (2) definite cardiac symptoms, (3) a grade 3/6 or greater systolic murmur, or (4) a diastolic murmur. Use of these criteria will avoid unnecessary echocardiography.

Conversely, it is critically important to perform an echocardiographic examination in patients with pathologic or possibly pathologic murmurs. Many cases of previously undiagnosed congenital heart disease, valvular stenosis, and valvular regurgitation are recognized during pregnancy. In addition to the prognostic information obtained by having the correct cardiac diagnosis, the echocardiographic data resulted in significant changes in patient management. Such changes included recommendation of endocarditis prophylaxis at delivery for structural heart disease, surgical closure of an atrial septal defect postpartum, and genetic counseling in patients with inherited diseases in the study described previously.[191]

Like other clinical guidelines, these criteria are not absolute, and given the negligible risk of echocardiography, it is preferable to err on the side of performing echocardiographic studies in normal women than to miss a case of significant heart disease in a pregnant patient. When a pathologic murmur is present, it is incumbent on the echocardiographer to make sure the referring physician is aware of the significance of this finding and to ensure appropriate assessment of maternal and fetal risk. In view of the multidisciplinary nature of care for pregnant women with heart disease and the impact of maternal heart disease on both mother and fetus, referral to a maternal-fetal specialist in a high-risk obstetrics clinic is needed for optimal care, particularly in patients with hemodynamically significant lesions. This consideration also applies to nonpregnant women with heart disease in whom appropriate counseling regarding the risks of pregnancy and contraceptive options is needed either to avoid unnecessary anxiety and delay in starting a family (if the maternal-fetal risk is low) or to avoid a high-risk complicated pregnancy (when the maternal-fetal risk is high). The echocardiographer often initiates communication with the maternal-fetal specialist.

### MITRAL VALVE PROLAPSE

Because a diagnosis of mitral valve prolapse is common in young women, concern is often raised that this diagnosis may affect the risk or management of pregnancy. Some series report a history of mitral valve prolapse in as many as 1.2% of all pregnancies.[192] No echocardiographic changes in the presence or degree of mitral prolapse[169] and no increase in maternal risk have been seen in pregnant patients with this diagnosis.[193,194] Many of these women have only minor abnormalities of leaflet anatomy or motion without significant valvular dysfunction. Thus, echocardiography plays an important role in reassuring both patient and referring physician that the risk of pregnancy is not affected by this diagnosis and that the management of pregnancy and the peripartum period can be considered routine, other than the need for endocarditis prophylaxis. In the patient with significant functional mitral valve disease—myxomatous leaflets and mitral regurgitation—echocardiography allows assessment of the degree of regurgitation and the LV response to chronic volume overload.

### PALPITATIONS AND ARRHYTHMIAS IN PREGNANCY

Most women experience an increased awareness of their heartbeat with occasional premature ventricular and atrial beats during pregnancy. Significant arrhythmias, associated with hypotension, dizziness, or shortness of breath, most often occur in patients with known underlying heart disease or a history of arrhythmias. The onset of symptomatic arrhythmia during pregnancy warrants echocardiographic evaluation, as in the nonpregnant patient, to evaluate for structural heart disease.

## Limitations of Echocardiography and Alternative Approaches

Echocardiography often provides all the information needed for patient management in pregnant women with heart disease, but in some situations other diagnostic approaches or imaging modalities may be needed. If TTE is inadequate because of poor ultrasound tissue penetration, TEE is appropriate and can be safely performed during pregnancy. Other useful imaging procedures in patients with congenital heart disease and valvular heart disease include radionuclide ventriculography, magnetic resonance imaging, computed tomographic imaging, and angiographic evaluation in the catheterization laboratory. In pregnant patients, the use of ionizing radiation with some of these techniques needs to be considered in the overall risk-benefit analysis of whether evaluation is needed during pregnancy or can be safely postponed to the postpartum period.

When direct and repeated measurements of pulmonary pressures, LV filling pressures, and CO are needed, invasive monitoring with an indwelling right-sided heart catheter is the procedure of choice. In patients with significant heart disease, invasive monitoring may be needed in the peripartum period to allow maintenance of optimal loading conditions under the changing volume and hemodynamic conditions of labor, delivery, and anesthesia.

## KEY POINTS

- Hemodynamic changes of pregnancy include increased cardiac output, increased heart rate, decreased systemic vascular resistance, and increased blood volume.
- Normal echocardiographic changes of pregnancy include an increased LV end-diastolic dimension with preserved systolic dimension, slight increase in aortic and LVOT diameters, and increased LA size.
- The most common cardiac conditions seen in pregnancy are valvular heart disease and congenital heart disease.
- Residual cardiac defects after surgical treatment of congenital heart disease may increase the risk of pregnancy, including:
  - Severe pulmonic regurgitation in patients with tetralogy of Fallot
  - Systemic ventricular systolic dysfunction after an interatrial baffle repair for transposition of the great arteries
- There is a higher risk of maternal and fetal complications with pregnancy in patients with:
  - Eisenmenger syndrome or severe pulmonary hypertension
  - Severe left-sided valvular stenosis (aortic stenosis or mitral stenosis)
  - Decreased systemic ventricular function (ejection fraction less than 40%)
  - Cyanotic heart disease including palliated complex congenital heart disease and Fontan repairs
  - Mechanical valve prostheses
  - Marfan syndrome, especially with a dilated ascending aorta
- Echocardiography before planned pregnancy is recommended in all women with congenital heart disease or valvular heart disease to assess prognosis, consider repair of any high-risk lesions, and optimize medical management.

**Conclusions**

The mortality of acute type A aortic dissection escalates hourly,[1] reaching 50% by 48 hours. Immediate diagnosis and therapy are critical for survival. Two thousand new cases of acute dissection are reported in the United States per year[2]; the true incidence, including the large numbers of patients who die from unrecognized dissection, has been estimated at more than 10,000 per year.[3] Further, 10% to 30% of acute dissections occurring in the hospital may be misdiagnosed. It is a great clinical challenge that patients' presenting symptoms may be nonspecific or even misleading. Aortic dissection must be included in the differential diagnosis of chest pain in many patients at risk for dissection, and also when simultaneous acute involvement of multiple organ systems does not have a ready explanation.

Acute dissection of the aorta can create myocardial ischemia via compromise of the coronary arteries; Hirst and colleagues[4] found involvement of the coronary arteries on pathologic examination in 39 of 505 cases of acute dissection (7.7%). Many clinical signs of that coronary impairment are also seen in acute myocardial infarction due to acute coronary syndrome: pain (related to the dissection itself or to myocardial ischemia), electrocardiographic abnormalities consistent with ischemia (resulting from involvement of the coronary ostia in proximal dissection),[5] and elevated serum creatinine kinase levels.[6] Confusion of acute dissection with myocardial infarction not only delays appropriate treatment, but increases the risk of disastrous consequences from thrombolytics, aggressive antiplatelet regimens, or passage of coronary catheters in the course of left heart catheterization.[7] Given that the incidence of aortic dissection is far less than that of myocardial infarction and that ST segment elevation is a relatively rare finding in patients with aortic dissection, electrocardiographic changes without physical findings suggesting dissection will rarely mislead clinicians.[8] Maintenance of a high suspicion for dissection must be paired with highly reliable tests to avoid such infrequent but catastrophic misdiagnoses.

The optimal diagnostic test for acute aortic dissection, therefore, must be accurate, safe, and immediately applicable in a broad range of medical environments. The limited sensitivity of echocardiography for dissection from the transthoracic approach has been greatly improved by transesophageal echocardiography (TEE). Transesophageal examinations can be performed within minutes in the emergency department, operating room, or intensive care unit and provide high-quality images of the thoracic aorta as well as of other cardiac and vascular structures at risk. Time to transesophageal images often exceeds the time required for emergent computed tomography (CT) scanning in emergency departments, however, and the role of TEE in the immediate diagnosis of acute aortic syndromes has diminished. The specific advantages and limitations of TEE use in the management of patients with suspected aortic dissection or trauma have been carefully investigated at many centers and have refined TEE's ongoing role in the diagnosis, repair, and follow-up of acute aortic syndromes and trauma.

## Pathophysiology of Aortic Dissection

### ANATOMY AND HISTOLOGY

The diameter of the adult aorta tapers from a size of less than 2.1 cm/$m^2$ in the ascending aorta to less than 1.6 cm/ $m^2$ at the level of the aortic arch.[9] The size of aorta increases with age during adulthood at a rate of 1 to 2 mm/ year; aging is associated with a loss of compliance and increased wall stiffness.

The aortic wall comprises three layers: the intima, which is a single layer of vascular endothelium; the media, with concentric layers of smooth muscle cells, collagen, elastin, and extracellular matrix proteoglycans; and the peripheral adventitia, consisting of loose connective tissue that anchors the aorta in surrounding tissues. The vasa vasorum, which perfuse the aortic wall, are contained within the adventitia. Of the three layers of the aortic wall, the structure of the media dominates the wall's mechanical properties.[10] Medial smooth muscle directly influences wall stiffness by contraction. In addition, smooth muscle cells are the major source of the extracellular matrix components. These include the elastin fibers, which can be stretched to 300% of their resting length without rupturing[11] and are important contributors to the normal pulsatile behavior of the vessel. Elastin is less important to the overall strength of the aorta than collagen, however, which is both stiffer and much stronger than elastin.

The components of the media vary from vessel to vessel and change with age. In the aortas of older patients, the elastin content decreases and collagen increases, resulting in increased vascular stiffness.[12] The mechanical properties of the vasculature are also almost always disturbed in cases of systemic hypertension.[13]

### MECHANICAL AND SHEAR STRESSES

The aortic wall is subjected to mechanical stresses of several forms. Stress, which is expressed as force per unit area, may occur in radial, circumferential, or longitudinal directions. The normal intima bears little of the aorta's stress load. It is exposed to shear stresses, however, which are forces applied parallel to the vessel wall as a result of the viscous effects of blood flow. The amount of these shear stresses varies with the distribution of velocity across the vessel lumen and with local vessel geometry.

Circumferential stress predominantly affects the media. This type of stress ($\delta$) increases with the radial pressure from the aortic lumen (P) and the aortic radius (r) and decreases with increasing wall thickness (h):

$$\delta = Pr/2\,h$$

The danger of aortic dilation can therefore be understood: In dilated, thin-walled aortas, the circumferential stresses may be increased many times above normal. In addition, the geometry of the dilating aorta changes progressively from the normal cylinder to an ellipsoidal or even spherical shape. This slowly increases the circumferential stress but quickly exacerbates longitudinal stress. Most atraumatic aortic tears are caused by longitudinal stress, which explains why they are generally transverse in orientation.[14] The ascending aorta experiences additional longitudinal stress owing to the motion of the aortic annulus. Finally, dilated or aneurysmal vessels demonstrate marked stiffness, in part because of loss of elastin.[15] Combined aortic dilation, wall thinning, and shape change sets the stage for intimal rupture and the initiation of dissection.

Intimal and/or medial abnormalities of the aorta increase the resistance to both shear and circumferential stresses. Stress failures of both types may play a role in aortic dissection. Circumferential stress failure can occur when the stresses caused by intraluminal pressure are greatly magnified in the thin fibrous cap of an atheromatous lesion. If the lesion fractures and a small crack develops, the circumferential stress will cause it to extend through the wall.[10] Shear stress failure is due to inhomogeneity in the properties of the vessel wall. Even under normal conditions, mural stresses are greater on the inner than on the outer wall.[16] In the presence of atherosclerosis, incremental variations in the shear resistance between contiguous regions of diseased and normal wall occur. The progression of aortic dissection probably represents an example of shear failure, where the interface between two such aortic segments with different stiffness leads to separation of medial and intimal layers: the two layers slide relative to one another because the "glue" of the extracellular matrix cannot withstand the shear stress.[10]

Once initiated, dissections behave like a two-ply tube. The intima and the internal elastic lamina of the media form the inner layer, while the outer layer consists of the external elastic lamina and the adventitia. A velocity-dependent shear force will then further separate the two layers, creating a false lumen separated from the true lumen by the intima and internal elastic lamina (Fig. 36-1). Experimentally, it has been demonstrated that the work per unit area of tissue required to propagate a tear in the aorta is small ($15.9 \pm 0.9$ mJ $cm^{-2}$) and independent of the depth of the tear.[16]

Increasing recognition of intramural hematoma as one of the acute aortic syndromes has expanded our understanding of the precursors of dissection. In the case of hematoma formation, the inciting event is hemorrhage into the media from the vasa vasorum. This lesion may expand and rupture into the aortic lumen, creating what we recognize as an entry tear and allowing progression of the intimal detachment along the arterial tree. In other cases, the hematoma is contained but creates a risk of external rupture.

These concepts of shear and tensile failure are the basis for understanding why different patient populations are at increased

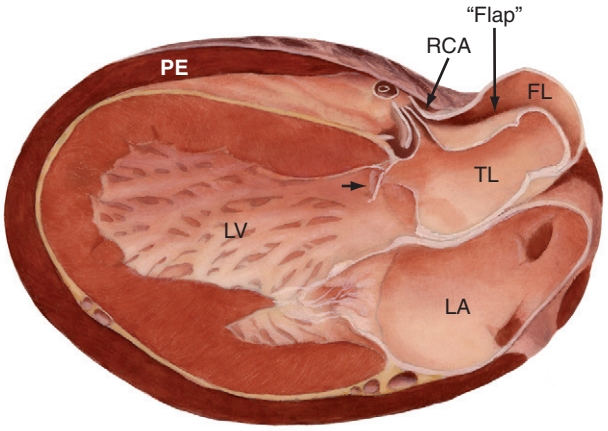

**Figure 36-1 Complications of aortic dissection.** The intimal flap is seen in the ascending aorta separating the true lumen (*TL*) from the false lumen (*FL*). The flap may extend into the right coronary artery (*RCA*), resulting in myocardial ischemia; may rupture into the pericardial space with a hemorrhagic pericardial effusion (*PE*) and tamponade physiology; or may disrupt the valve leaflet attachment with a flail leaflet (*small arrow*) and aortic regurgitation.

risk for aortic dissection. Medial elastic tissue degeneration resulting from hereditary defects of the arterial wall creates the substrate for dissection in patients with Marfan syndrome, Turner syndrome,[17] Noonan disease, Ehlers-Danlos syndrome, and osteogenesis imperfecta.[14,18] In these patients, as well as in other groups, dilation of the aorta is an important source of tensile failure and a precursor to dissection.

Both wall abnormalities (shear failure) and increased wall stress (tensile failure) owing to dilation are important in nonhereditary risk groups. Dissection occurring in hypertensive patients is generally based on high blood pressure, moderate aortic dilation, and medial muscular degeneration predisposing the internal layer to tear.[14] The contribution of shear stress in those patients is infrequent and unpredictable.

## RISK FACTORS

Hypertension and atherosclerosis are the predominant conditions that result in dissection. More infrequently, pregnancy, inflammatory disorders such as giant cell arteritis and Takayasu disease, or congenital collagen disorders such as Marfan syndrome, Turner syndrome, or Ehlers-Danlos are etiologic. Bicuspid aortic valve and/or aortic coarctation are other congenital causes.

Cocaine use, trauma, and iatrogenic disruption of the arterial structures during surgery or cardiac catheterization can also be the initiator (Box 36-1).[19-25]

### *Atherosclerosis*

Atherosclerosis is a highly prevalent disorder whose generalized and focal manifestations can predispose to dissection. True aortic aneurysms are due to atherosclerotic degeneration of the media and progress to involve all three layers of the vessel wall and to gradual dilation. Increasing risk accompanies enlarged diameters, rapid expansion, or symptoms. Formation of laminar thrombus within the aneurysm does not decrease the wall stress. The 1-year survival rate in patients with thoracic aortic aneurysms is less than 60%, and the 5-year survival rate approximately 20%. Up to 14% of patients presenting with dissection in the International Registry of Acute Aortic Dissection had preexisting aortic aneurysm.[26]

### *Trauma*

Trauma may create a spectrum of aortic injuries (see later discussion). Aortic dissection may occur in external, accidental trauma and be difficult to assess in the setting of major multisystem injuries. The region most prone to traumatic injury is the aortic isthmus, where relative tethering by the spinal arteries and ligamentum arteriosum resists abrupt deceleration more than the more mobile transverse arch.[27] Other vulnerable sites include the origin of the right brachiocephalic artery, particularly with vertical forces from falls, and the ascending aorta above the sinus of Valsalva.[28] Traumatic injuries to the aorta may result in intimal tears, recognizable on TEE as mobile flaps. Thrombus may be seen protruding into the lumen; in other cases, intramural hematoma without apparent intimal discontinuity is seen. Whereas very minor lesions such as minimal hematomas may regress spontaneously, the prognosis of significant aortic trauma is grave. Without repair, there is 30% mortality within the first 24 hours. Within 1 week, mortality is greater than 50%.[29] Prompt recognition is therefore critical to patient outcome. TEE has been shown to be safe and highly sensitive for aortic trauma after motor vehicle accidents, equivalent to angiography and more expeditiously applied.[30] TEE may also detect other signs of cardiac trauma, including wall motion abnormalities, pericardial effusion, and valvular regurgitation. When the suspicion of aortic rupture in the territory of the transverse arch remains high, CT may provide better images of those territories.

Other sources of trauma include the Heimlich maneuver for respiratory obstruction, and cardiovascular procedures. Operative sources of tears in the aorta include cannulation sites for cardiopulmonary bypass, aortic transections for valve or aortic segment replacement, and proximal anastomotic sites for coronary bypass grafts.[31,32] Very uncommonly, aortic catheterization for angiography may traumatize an atherosclerotic region and

Cocaine use
Discontinuation of beta blockers
Polycystic kidney disease

prompt dissection.[33] Angioplasty procedures of coronary or renal vessels can also initiate the process.[34] A history of these procedures may be important in alerting the clinician to the possibility of dissection in these patients.

### *Cocaine and Methamphetamine*

Cocaine stimulates central neural sympathetic outflow and blocks reuptake of catecholamines in the synaptic clefts. The resulting intense vasoconstriction; prothrombosis; and increase in heart rate, blood pressure, and myocardial contractility increase the risk of aortic dissection. In one series, 14 of 38 cases of aortic dissection were associated with cocaine use during the preceding 24 hours (average, 2 hours). The proportion of types A and B dissection was similar to than in nonusers of cocaine.[35] Methamphetamine use is increasing, and users may also experience a significant increase in their risk for acute aortic dissection. One retrospective series found that 20% of acute aortic dissections in patients under age 50 years were associated with methamphetamine.[36]

### *Pregnancy*

Although aortic dissection is mostly a disease of middle-aged or elderly males, women and children can also experience dissection. It has been claimed that half of all aortic dissections occurring in women younger than 40 years of age are associated with pregnancy, particularly during the third trimester, or the postpartum period.[37-39] This has been disputed by Oskoui and Lindsay,[40] who reviewed their own experience and published a series of 1253 dissections in consecutive patients (868 males and 385 females), with no cases occurring in pregnancy. They concluded that most women experiencing aortic dissection in pregnancy had other risk factors such as hypertension or Marfan syndrome, and that the apparent association could result from selective reporting and coincidental occurrence of dissection with the very common condition of pregnancy.

The most up-to-date information on acute aortic dissection in women from the International Registry of Acute Aortic Dissection implies that dissection generally affects women at a more advanced age than men and that they fare worse than their male counterparts with respect to rupture, hypotension, and surgical mortality.[26]

### *Genetic Diseases*

#### Marfan Syndrome

Of the genetic causes of aortic medial disease and aortic dissection, Marfan syndrome is the most common and best studied. Although a clinical diagnosis, Marfan syndrome may be confirmed by linkage to the dominantly inherited gene MFS-1 on 15q21 or by determination of the specific family mutation.[41] Histologic examination of the aortic wall in Marfan syndrome patients reveals fragmentation of aortic components, especially the elastic fibers,[42] and abnormal accumulation of collagenous and mucoid materials in the media.[43] Fragmentation of elastin-associated microfibrils also occurs in aortic valve leaflets.[44] The disruption and loss of elastic tissue of the media is attributed to a deficiency of fibrillin, a microfibrillar protein that scaffolds the elastic lamellae in the aortic wall.[45,46] These changes are greatest in the ascending aorta, which is subject to the greatest pulsatile expansion and therefore the highest stress in systole.[14] The alterations in aortic wall components are associated with abnormal functional properties: aortic elasticity is abnormal in patients with Marfan syndrome, irrespective of the aortic diameter.[47] A comparative study of aortic wall dynamics between Marfan syndrome patients and normal controls confirmed that in both groups, stiffness of the wall increases with age and aortic diameter, but at all ages the Marfan syndrome group exhibits a stiffer aorta than controls for a given diameter.[48] Furthermore, Marfan syndrome patients have large ascending aortic diameters, but not abdominal aortic size, after correction for body surface area.[47] Dissection occurs in Marfan syndrome patients because of this dilation in combination with wall weakness; mural stress increases dramatically with increasing radius and becomes self-perpetuating.[14]

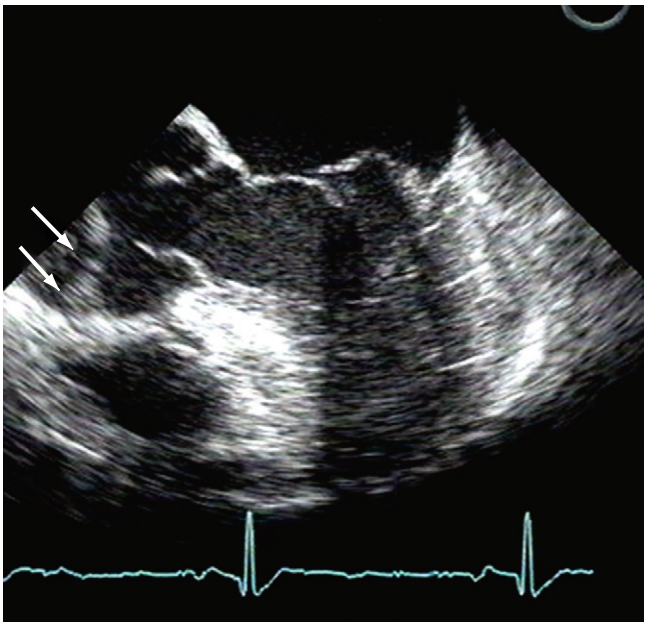

**Figure 36-2 Type A aortic dissection (*arrows* indicate intimal flap) in a patient with Marfan syndrome on transesophageal imaging.** Enlargement of the proximal aortic root and prolapse of the posterior mitral valve leaflet are also noted.

Echocardiographic evidence of aortic root dilation is present in 60% to 80% of Marfan syndrome patients (Fig. 36-2).[49] In one series, aortic dilation was generalized in 51% and localized in 28%.[50] Localized dilation did not appear to represent an earlier stage of aortic involvement, as the patient ages in both groups were identical, as was the duration of follow-up. It could not be determined whether generalized dilation reflected more severe underlying cystic medial necrosis from different specific mutations in fibrillin. Generalized dilation, however, was associated with higher rates of expansion as well as aortic regurgitation. In Marfan syndrome patients, aortic regurgitation has been associated with decreased survival.[25] The existence of mitral valve prolapse does not appear to be an independent predictor of outcome. The clinical course of Marfan syndrome patients with respect to progressive aortic dilation and dissection is variable.[50] Increased risk has been associated with older age,[51,52] male gender, aortic root diameters exceeding 60 mm,[50] aortic growth rate,[49,50] and a family history of dissection.[53] In one study, two groups of Marfan patients were identified according to the speed of their aortic root dilatation.[54] The speed of dilatation was not related to the use of beta blockers or the family history. The fast-growing group had significantly more type A dissection, as well as more elective root replacement, compared to subjects with slower dilatation. Of great

concern is the observation that aortic dissection can occur in Marfan syndrome patients even in the absence of aortic root dilation.[55]

Medical management of Marfan patients with aortic dilatation involves beta-blockers and observation of aortic root diameter to determine timing of elective surgery aimed at preventing aortic dissection. (See Chapter 39.) Long-term fatality rates are improved with prophylactic aortic root replacement; 5-year survival is approximately 97% for elective surgery versus only 51% with emergency surgery for dissection.[56] Operative mortality in experienced centers for elective surgery in Marfan patients is low (1.3% to 1.5% 30-day mortality versus 11.7% for emergency surgery).[57,58] In patients with normal aortic valve leaflets, elective aortic valve–sparing surgery may provide better clinical outcomes than aortic root replacement.[59] In this retrospective review, however, those undergoing aortic root replacement with aortic valve replacement had more cardiac comorbidities than the group in which valve-sparing surgery was possible. The size of aneurysm often determines the feasibility of valve-sparing surgery; hence, some centers recommend elective surgery when the aortic root reaches 50 mm.

### Bicuspid Aortic Valve

Bicuspid aortic valve is the most common congenital heart anomaly, with a prevalence of 1% to 2%. It has been estimated that patients with bicuspid valves have a ninefold increase in the risk of dissection compared to those with normal valves, and up to a 5% lifetime risk of dissection.[60] As with Marfan syndrome, aortic histology in bicuspid aortic valve patients demonstrates cystic medial necrosis, with significantly increased expression of metalloproteinase MMP2 and MMP9. It is important to remember that replacement of the malformed valve does not correct the patient's progressive aortic root dilatation or elevated dissection risk. Ascending aorta replacement is indicated when the aortic diameter exceeds 50 mm.[61]

### Turner Syndrome

The most common cause of aortic dissection in young women is Turner syndrome. This relatively common disorder is associated with short stature and congenital cardiovascular defects. These patients are at significantly increased risk for dissection at every age (1.4 in 100 patients with Turner syndrome, more than 100-fold increased from normal), but the risk appears highest during young adulthood and pregnancy.[62] The dissection risk is associated with ascending aortic dilation and is thought to be similar in etiology to the cystic medial necrosis of Marfan syndrome. Although bicuspid aortic valve and coarctation may also occur, their absence does not preclude dissection.[63]

### Familial Aortic Dissection

Twenty percent of patients with aortic dissection have a first-degree relative with a history of thoracic aneurysm or aortic aneurysm. The inherited risk for dissection appears to follow an autosomal dominant pattern, and surveillance of family members is warranted. [61]

## Spectrum of Acute Aortic Syndromes

It is now recognized that aortic dissection is part of a larger collection of acute aortic disorders (Box 36-2) which can share features of acuity, prognosis, treatment options, and etiology. Their separation is often temporal rather than etiologic: intramural hematoma and penetrating ulcer may progress to aortic dissection during their course.

## AORTIC DISSECTION

Aortic dissection is defined by separation of the intima and internal media from the external media and adventitia of the aorta, with creation of an intimal flap that separates the true aortic lumen from a false lumen where active flow or thrombus can be seen. The etiologic event for dissection is a medial lesion that creates a hematoma in the aortic wall; a subsequent tear in the overlying tissue allows pulsatile aortic flow entry into the medial tissues. The primary entry tear is usually transverse and involves more than half of the circumference of the aorta. In 65% of cases it occurs within 3 cm of the coronary ostia. Ten percent of tears occur in the descending thoracic aorta and another 10% in the arch. Primary tears are rare in the abdominal aorta.[64] Whatever the location of the initial tear, dissections may progress distally, proximally, or occasionally in both directions.

### *Anatomic Classification*

There are several widely used classification systems for dissection (Table 36-1). The DeBakey classification divides dissections with involvement of the ascending aorta into type I, which extends into the transverse arch and distal aorta, and type II, which is confined to the ascending aorta. DeBakey type III dissections involve the descending aorta only.[65] The Stanford classification[66] was developed from a functional approach based on whether the ascending aorta is involved, regardless of the site of primary intimal tear and irrespective of the extent of distal propagation. This reflects clinical observations that the biologic behavior of the dissection, the clinical prognosis, and how the patient should be managed pivot almost exclusively on whether the ascending aorta is involved.[67-69] This system of nomenclature describes type A dissections as any with involvement of the ascending aorta (including DeBakey types I and II), and type B dissections as dissection limited to the descending aorta (DeBakey type III).

The clinical classification schemes just described do not emphasize the location of the primary entry tear or the extent of the distal propagation of the dissection. These two factors are

of less prognostic value and can be technically difficult to determine.[70,71] When identification of the entry site is possible, the culprit primary intimal tear is more easily resected. Although successful resection of the primary tear does not appear to affect early or late survival rates, it may decrease the incidence of late reoperation.[72]

Some cases of aortic dissection will present with multiple *primary* tears. Two separate dissections in the same patient may be more common than previously reported. Roberts and Roberts[73] reported that 3 of 40 necropsy patients had separate proximal and distal thoracic dissections. Although all fatal events were caused by rupture of the acute proximal dissections, a separate distal dissection may still pose a risk for late complications, and therefore recognizing two separate dissections may have important implications regarding follow-up and therapy.[74] Multiple distal *exit* tears, which decompress the false lumen, are extremely common.

### *Time Course*

Dissections are also differentiated with respect to their time course. Acute dissections are detected within 14 days of the onset of initial symptoms. Chronic dissections present more than 2 weeks after onset.[69,75] This division is arbitrary; it may primarily reflect the fact that the majority of type A dissection patients will die within 2 weeks if untreated. Chronic dissections may be detected because of symptoms or may be an incidental finding. They are differentiated from aortic aneurysms by the presence of an intimal flap and false lumen. These may not be easy to recognize when the false lumen is largely thrombosed. Pronounced atherosclerotic changes may be present in the false lumen in chronic dissections, even when the true lumen walls appear normal and hyperlipidemia is absent.[76]

### *Sequelae*

The sequelae of aortic dissection are many and varied. Obstruction of branch vessels may explain acute myocardial ischemia and infarction of cerebral, spinal, bowel, and renal territories. Aortic valve dehiscence with regurgitation, cardiac tamponade from retrograde extension into the pericardium, and frank aortic rupture are all highly morbid consequences.

## INTRAMURAL HEMATOMA

A small number of aortic dissections, estimated at 3% to 5%, occur without apparent intimal disruption.[6,77] The pathologic process in these cases of aortic intramural hematoma is rupture of the vasa vasorum into a region of medial degeneration, or possibly rupture of atherosclerotic plaque without an intimal tear. Patients with this form of disease tend to be older (mean age 70 years, versus 56 years for communicating dissection) and have frequently had long-term hypertension.

The clinical course of aortic intramural hematoma is similar to that of aortic dissection, with a high incidence of aortic dilation due to expansion of the false lumen, pleural and pericardial effusions, aortic regurgitation, aortic rupture, and progression to classical dissection. The early prognosis in aortic intramural hematoma patients may be slightly better than in those with acute "communicating" dissections; this may reflect the tendency for the noncommunicating medial space to heal with complete thrombus formation.[78] Many aortic intramural hematomas progress to typical dissection (in 33%) or to rupture (in 27%), however, and therefore usually require surgical rather than medical management.[79]

About half of patients progress despite medical treatment. Predictors of disease progression include involvement of the ascending aorta, a maximum aortic diameter of 50 mm or more, persistent pain, progressive thickening of the aortic wall, or expanding aortic diameter. The treatment of aortic intramural hematoma is similar to that of aortic dissection. If the aortic intramural hematoma is located in the ascending aorta, early surgical intervention with aortic graft replacement is often recommended. Mortality after surgery ranges from 10% to 50% at 30 days.[80,81,82] Another strategy that has been advocated is initial medical therapy with aggressive antihypertensive treatment and frequent imaging follow-up, with elective surgery for patients who develop complications.[83]

Early prognosis in those patients was somewhat better than in those with acute *communicating* dissections; this may reflect the tendency for the noncommunicating medial space to heal with complete thrombus formation.[84] These intramural hematomas may progress to typical dissection (in 33%) or to rupture (in 27%) and therefore usually require surgical rather than medical management.[79]

## PENETRATING AORTIC ULCER

Ulceration of an atheromatous plaque into the internal elastic lamina of the aorta creates a penetrating atheromatous ulcer.[85] Patients with such ulcers are typically older and have more cardiovascular risk factors and diffuse atherosclerosis. The ulcers are predominately located in the descending aorta, where atherosclerosis tends to be more severe. They can progress to aneurysm formation, intramural hematoma, dissection, or rupture. Controversy remains regarding medical versus surgical therapy for these lesions.[86,87]

## AORTIC TRAUMA

The intrathoracic aorta may be injured during penetrating or blunt trauma, particularly episodes that involve high-energy and/or marked deceleration, such as falls from over 10 feet or motor vehicle crashes at speeds over 40 miles per hour. The site most often affected is the aortic isthmus. The mechanism of injury is primarily rupture of the adventitia. This creates a high risk of lethal hemorrhage, which occurs in nearly 80% of blunt aortic injuries. In some cases mediastinal structures temporarily contain the rupture, but these will almost all rupture within 24 hours if untreated.[88,89]

Contrast-enhanced spiral CT of the chest is usually obtained early in trauma resuscitations. Its accuracy in diagnosis and exclusion of aortic injury generally places it ahead of TEE as an emergent modality. TEE is contraindicated with unstable injuries of the cervical spine or in the setting of suspected esophageal injury. TEE more often is applied in the operating room and during the intensive care unit course, where it can be performed serially if necessary.

TEE in patients with traumatic rupture of the aortic subadventitia will demonstrate flow on both sides of the wall. [90] The flap that is seen on TEE comprises the intima and media in separation from the adventitia. It may be limited to a few centimeters only, in contrast to the intimal flap of dissection which can extend longer distances in both directions.

Other aortic manifestations of trauma include dissection, intramural hematoma, and thrombus formation. False aneurysm originating at the site of the rupture may be seen.[90,91] Mediastinal hematomas can also be recognized[92,93] by noting an

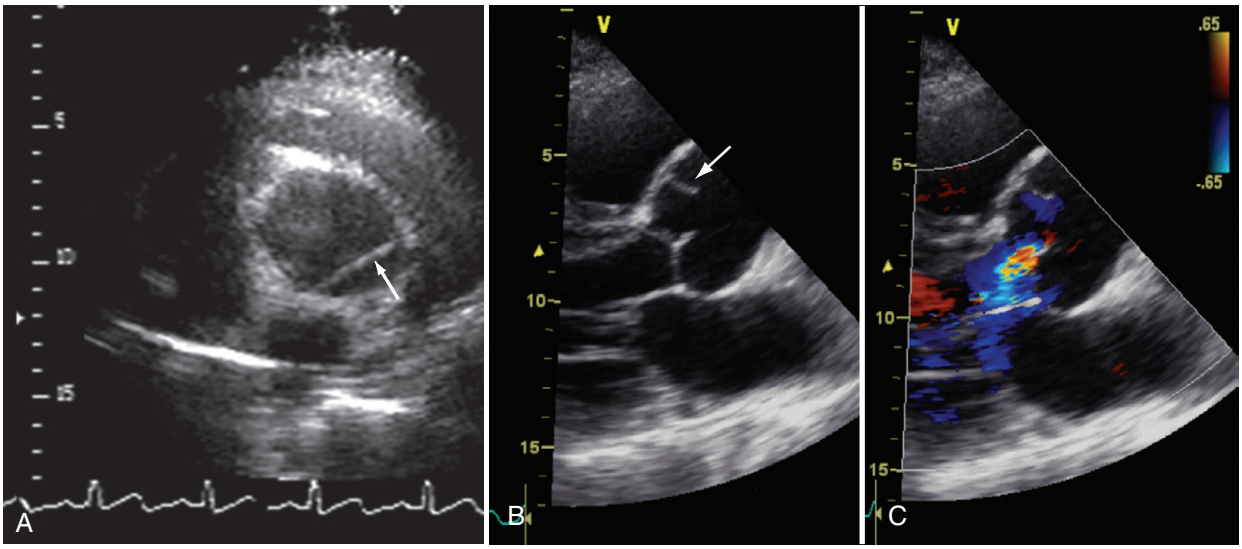

**Figure 36-3 Conventional transthoracic views are often the first clue to diagnosis of aortic dissection.** Parasternal short-axis views (**A**) demonstrate intimal flap in proximal aortic root (*arrow*). Long-axis views show the mobile flap (**B**) as well as the associated aortic regurgitation (**C**).

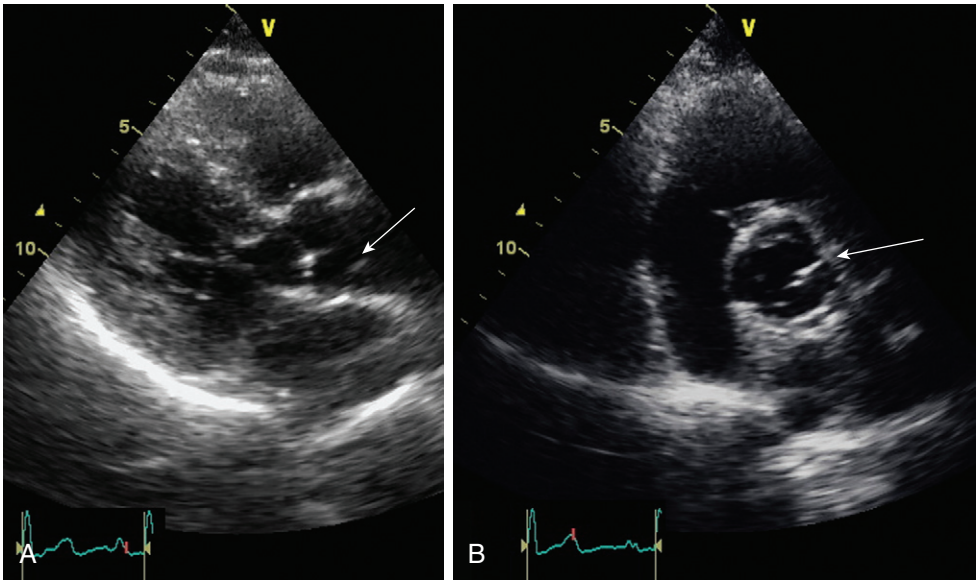

**Figure 36-4 Recognition of aortic dissection from transthoracic views often requires a high level of suspicion.** Linear structure near the posterior sinotubular ridge might be an artifact (**A,** *arrow*) but is more clearly seen on short-axis views (**B**). These inconclusive findings in a patient with clinical features of dissection merit clear communication to other care providers and rapid progression to another modality such as computed tomography or TEE. This patient had a type A dissection.

increased distance from the TEE probe face and the aortic lumen.

## Imaging Approaches to the Diagnosis of Acute Aortic Syndromes

### TRANSTHORACIC ECHOCARDIOGRAPHY

Time is of the essence when aortic dissection is suspected. Most emergency departments have ultrasound equipment that can be used by staff to quickly determine the presence of pericardial effusion using the standard FAST (Focused Assessment with Sonography for Trauma) examination. More expert users and dedicated echocardiography equipment can also be utilized to perform emergent transthoracic echocardiography (TTE) to rapidly define aortic valve competence, ventricular dysfunction, and regional wall motion abnormalities. Though these immediate scans are inherently restricted to available windows and have limited sensitivity, they can often provide the first images of mobile intimal flaps in the aortic root, arch or descending aorta (Figs. 36-3 through 36-6) that can guide earliest therapy and mobilize other resources.

### TRANSESOPHAGEAL ECHOCARDIOGRAPHY

The intrathoracic aorta is well visualized from esophageal windows (Fig. 36-7), with the exception of a well-recognized *blind spot* created by the interposition of the trachea between the esophagus and the heart, obscuring portions of the distal ascending aorta, superior transverse arch, and origins of the great vessels. As a result, a dissection limited to these areas could be missed by transesophageal imaging alone. This is of concern

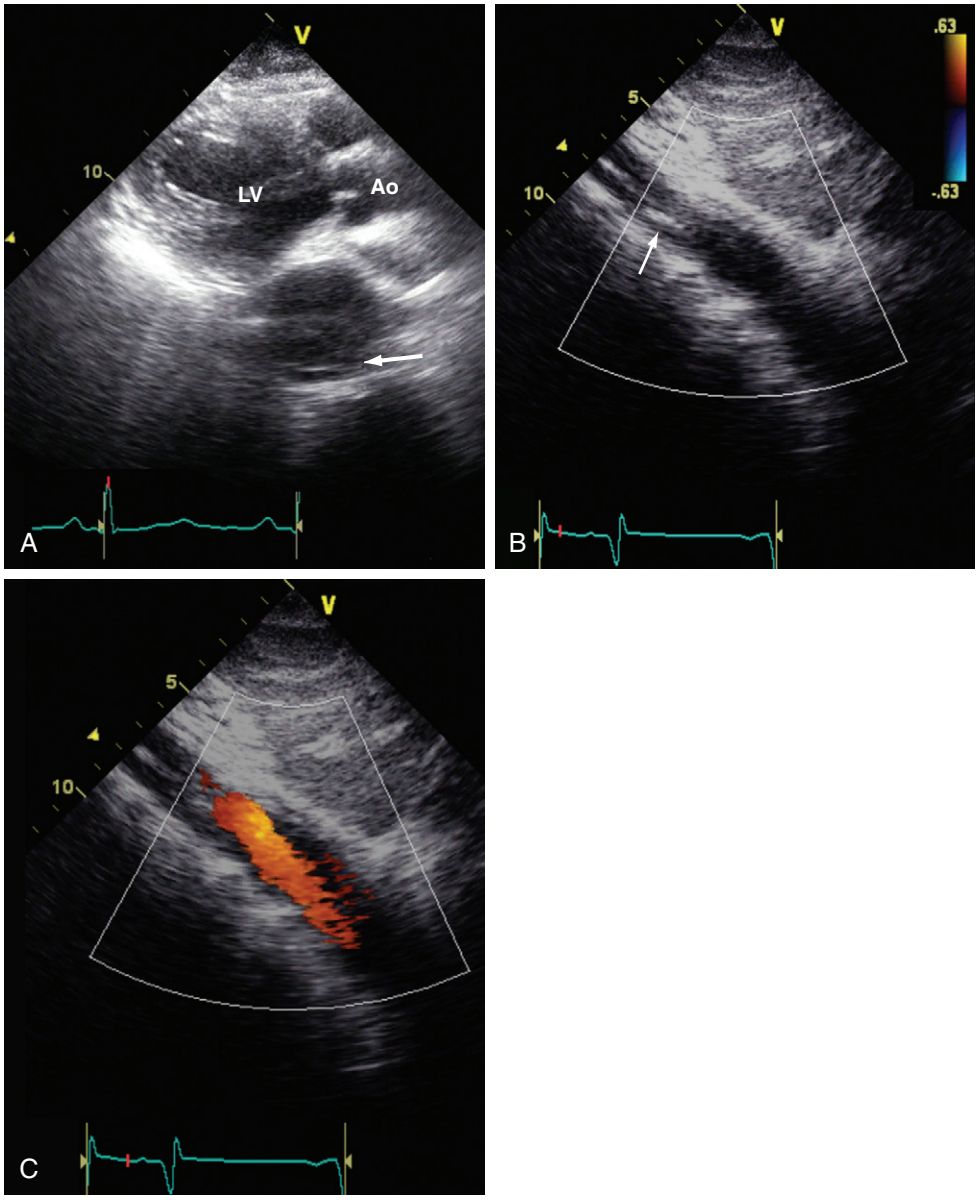

**Figure 36-5 Descending aortic dissection.** Transthoracic views can be helpful in some patients as shown by a parasternal long-axis view (**A**) showing enlarged descending thoracic aorta posterior to and compressing LA with a linear echo suggestive of a dissection flap (*arrow*). Subcostal view shows the flap (**B**) and flow in the true lumen (**C**). *Ao*, Aorta.

because the clinical behavior and therapeutic approach to the patient depend largely on whether the proximal aorta is involved in the dissection.[94] Despite this, the sensitivity and specificity of TEE for acute aortic dissection are high and well documented. More relevant considerations regarding emergent TEE for acute aortic syndromes are the delay to implementation (many sites will not have the personnel immediately available to perform this study, particularly off hours) and the conscious sedation that is required for alert patients. The potential for incomplete visualization of all thoracic aortic segments and therefore inconclusive results limits the use of emergent TEE where other highly reliable options are more readily available.

## COMPUTED TOMOGRAPHY

CT is a powerful and rapid tool for acute aortic syndromes (Fig. 36-8).The use of TEE in emergency departments for these cases has fallen well behind that of CT in centers where CT is immediately available. Extensive trauma where possible aortic involvement is the concern may often be better evaluated during the comprehensive CT scanning that those patients undergo. A concerted imaging strategy may well rely on more than one imaging modality, as the unique strengths of one method may offset the limitations of another. TEE may be the initial choice in patients with contraindications to CT contrast or magnetic resonance scanning, or be a subsequent choice when imaging artifacts in those tests render results inconclusive.

CT scans may demonstrate extension of dissection into great vessels that TEE views would not confirm. More often, CT is particularly useful in confirming that there is no demonstrable involvement of the distal ascending aorta. Another important role for CT is in clarifying inconclusive TEE results (see False Positives, later). The incidence of false-negative TEE studies has been minimal in large series,[76] and positive angiographic or CT results are rare when the initial TEE results are negative.

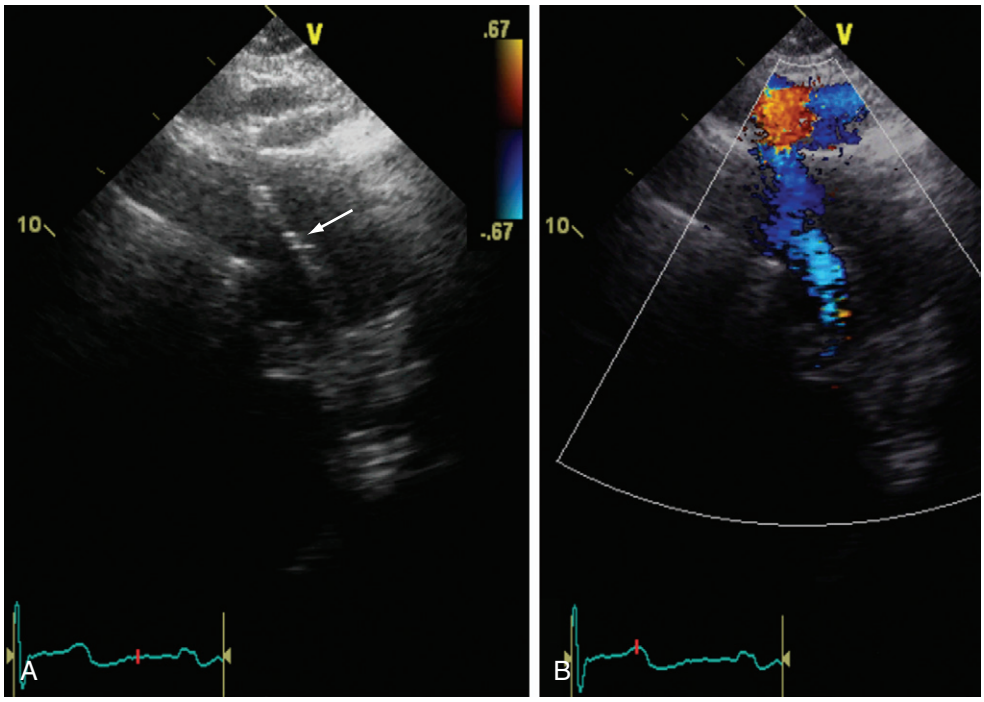

**Figure 36-6** **Aortic arch dissection flap.** Transthoracic suprasternal view (**A**) shows a clear intimal flap (*arrow*); there is no alternative diagnosis as its course does not mimic other surrounding structures. Color flow Doppler (**B**) shows systolic flow confined to the smaller true lumen, increasing confidence in the diagnosis.

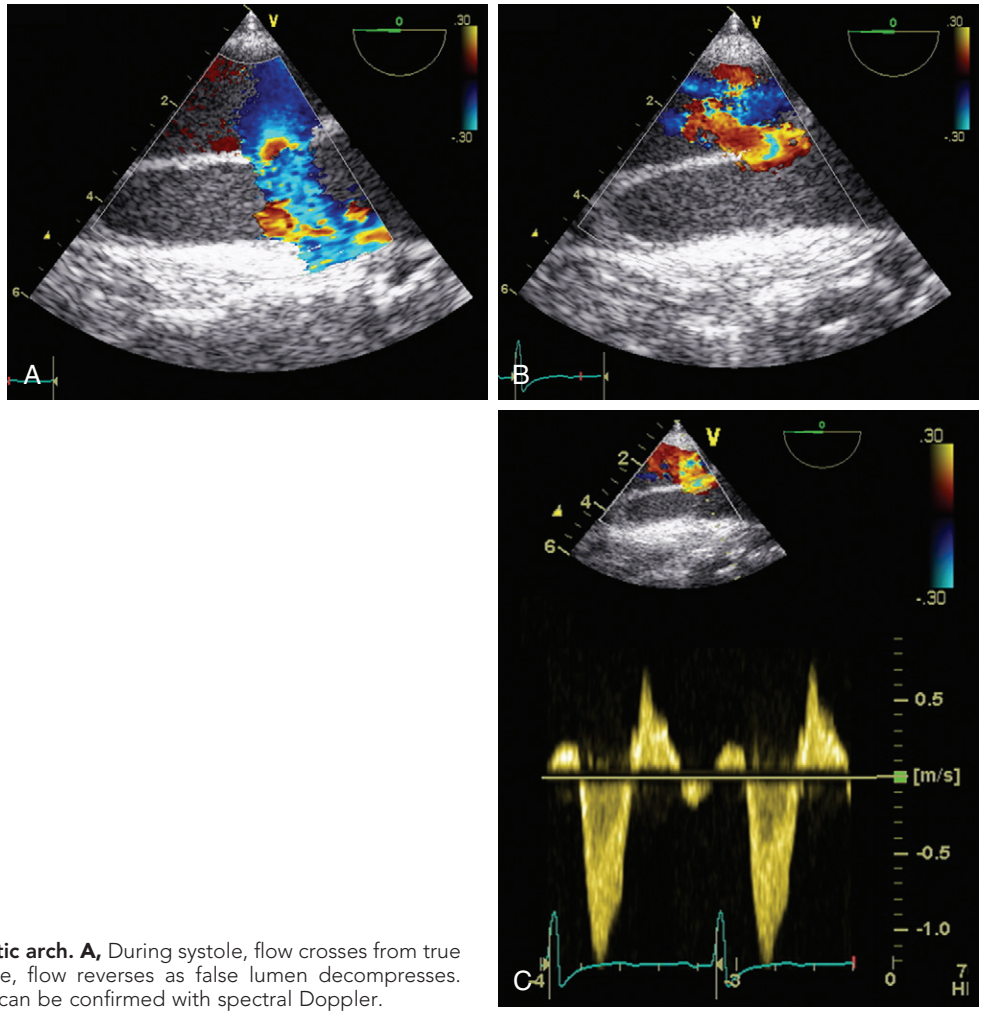

**Figure 36-7** **Entry tear in transverse aortic arch. A,** During systole, flow crosses from true lumen into false lumen. **B,** During diastole, flow reverses as false lumen decompresses. **C,** Alternating direction and timing of flow can be confirmed with spectral Doppler.

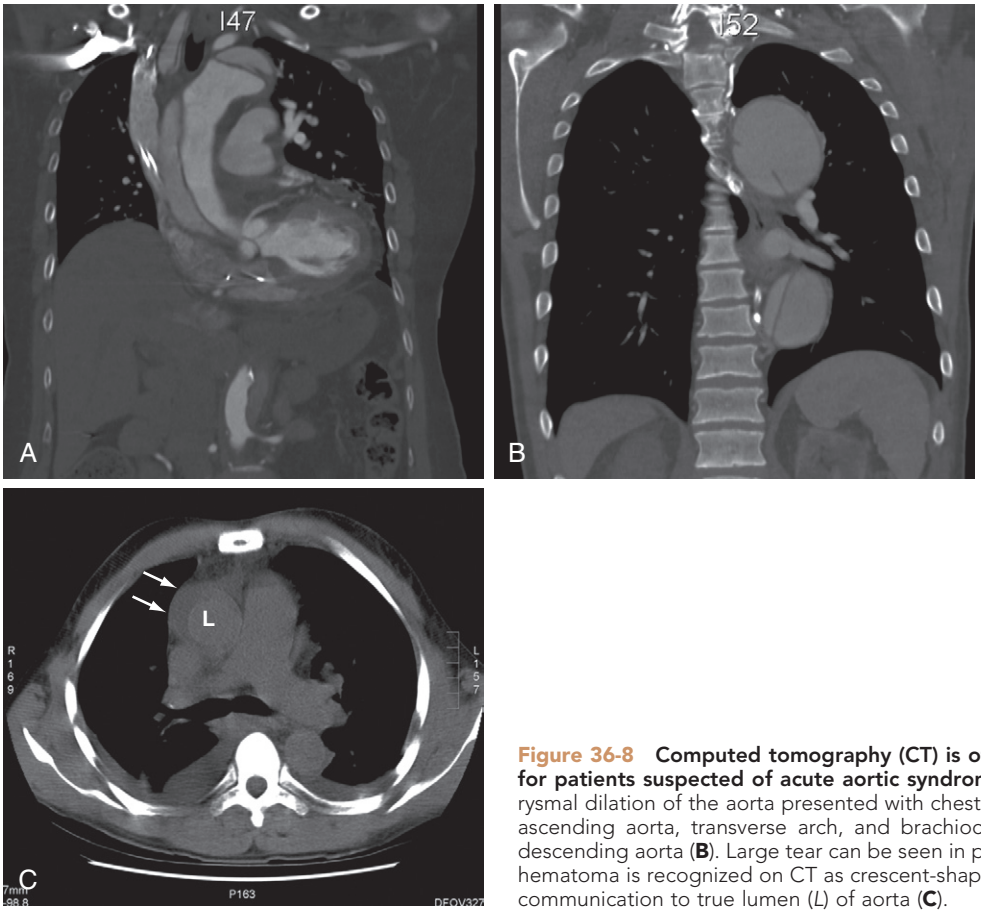

**Figure 36-8 Computed tomography (CT) is often used as an early diagnostic modality for patients suspected of acute aortic syndromes.** A patient with hypertension and aneurysmal dilation of the aorta presented with chest pain. Extensive dissection is seen involving ascending aorta, transverse arch, and brachiocephalic artery (**A**) and spiraling down the descending aorta (**B**). Large tear can be seen in proximal descending aorta. Aortic intramural hematoma is recognized on CT as crescent-shaped thickening of aortic wall (*arrows*) without communication to true lumen (*L*) of aorta (**C**).

## MAGNETIC RESONANCE IMAGING

The sensitivity of magnetic resonance imaging (MRI) for aortic dissection approaches 100% (Fig. 36-9).[95] However, pragmatic issues of imaging such acutely ill patients with trauma or need for hemodynamic monitoring or infusion of medications or those at risk for hemodynamic collapse continue to make CT or TEE preferable in acute settings unless the clinical suspicion is low or the patient is stable.

## CHOICE OF IMAGING

Echocardiography is only one of several diagnostic tests for acute aortic syndromes. The choice of one over the other, as well as the clinical confidence in positive or negative results, needs to be gauged relative to each test's performance (Table 36-2). A meta-analysis of 16 studies involving a total of 1139 patients reviewed the reliability of TEE, helical CT, and MRI.[96] The sensitivity and specificity of the three modalities were equivalent. After stratifying the patients for pretest likelihood of dissection (high-risk features included typical tearing chest pain in the back, hypotension, and pulse disparities), the positive likelihood ratio was highest for MRI, suggesting that this is the most powerful modality to confirm dissection in a patient with a high pretest likelihood of dissection. Helical CT had the lowest negative likelihood ratio of the three tests, suggesting that it is best at ruling out dissection in patients at lower risk. Angiography is a time-honored diagnostic method for aortic dissection that may identify the intimal flap and false lumen, as well as coronary and great vessel involvement. However, its sensitivity and specificity for dissection (88% and

**Figure 36-9 Gadolinium-enhanced magnetic resonance angiography (MRA) can be used to create 3D images of aorta and branches.** Follow-up of patients after acute dissection requires careful comparison of aortic dimensions; MRA is particularly useful for this. This demonstrates chronic dissection (*arrow* indicates intimal flap) that extends to level of renal arteries.

*CT*, Computed tomography; *MRI*, magnetic resonance imaging.

94%, respectively[97]) are limited by false lumen thrombosis, intramural hematomas, and equal flow in true and false lumens.[98,99] The last case is also an important limitation for CT studies, where differential flow may not be detectable even with dynamic CT imaging.[100] Ongoing improvements with multidetector, helical CT methods have improved the CT performance compared to early methods with lesser spatial and temporal resolution in assessing patients for aortic dissection.[101] Nevertheless, despite CT's high specificity (up to 100% in some series), a negative CT result in the presence of high clinical suspicion of dissection requires a second confirmatory test. This is also true for clinically discordant results from TEE or MRI as well.

## Transesophageal Echocardiography in Acute Aortic Syndromes

Multiple studies have documented that the specificity and sensitivity of TEE in the range of 98% and 99%, respectively. The recognized blind spot of TEE, involving the distal ascending aorta and superior aspect of the arch, is an important limitation, especially because entry tears in this region are important to clinical management. The goal of imaging the entire thoracic aorta may therefore require a combination of modalities and approaches, including transthoracic views (often from the suprasternal notch), transesophageal windows, and often direct epiaortic or epicardial views at the time of surgery (Fig. 36-10).

TEE has many discrete advantages in the diagnosis of acute aortic dissection, the most important of which is its documented accuracy. Erbel and colleagues,[102] reporting for the European Cooperative Study Group for Echocardiography on a series of 164 patients suspected of acute dissection, demonstrated sensitivity and specificity rates of 99% and 98%, respectively. Another large study by Nienaber and co-workers[103] compared TEE with MRI. Both TEE and MRI had perfect sensitivity; the 100% specificity of MRI exceeded the 68% specificity of TEE. The authors suggested that TEE's limited visualization of common ascending aorta pathology might have accounted for the higher rate of false-positive studies. In that study, strict criteria for diagnosing dissection were not applied (see later discussion); more stringent criteria could minimize false-positive results. TTE from the suprasternal notch provides additional views of this vulnerable area. The sequential use of TEE and CT, aortography, or MRI is clearly extremely powerful in clarifying suspicious or clinically incongruous results.[104,105]

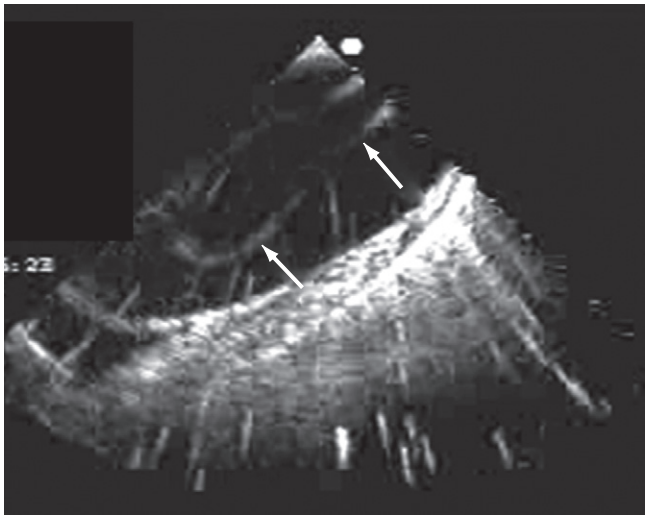

**Figure 36-10 Intraoperative epiaortic view of transverse aortic arch in patient with acute proximal aortic dissection.** Intima is widely dissected and highly mobile (*arrows*). Note linear streaking artifact from electrocautery.

TEE provides additional information about left and right ventricular wall motion and global function, and aortic and mitral valve competence. Importantly, with acute type A dissections, TEE is able to detect and determine the severity and mechanism of aortic valve regurgitation[106] and may influence the decision to replace or repair the valve.

An important advantage of TEE in cases of dissection is its rapid and safe performance in a wide range of clinical environments, including emergency departments, intensive care units, and the operating room. TEE requires minimal patient preparation, avoids the contrast and x-ray exposure associated with CT and angiography, and eliminates the time delays and practical encumbrances of MRI. Choice of a *best test* must always take into account the individual center's track record with each modality, as well as access issues.

## SAFETY OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Safety of transesophageal examinations depends on adequate patient preparation with respect to pain, anxiety, and airway protection. (See Chapter 1.) Careful monitoring of the electrocardiogram and blood pressure is critical to avoiding adverse affects of TEE. In a study of 54 ambulatory patients, TEE was accompanied by an increase in systolic pressure in 77% of patients. This elevation was moderate (average increase of 16 mm Hg) in most patients, but some patients had acute increases of as much as 51 mm Hg.[107] Abrupt increases of blood pressure must clearly be avoided in any patient suspected of dissection. Serial blood pressure monitoring, pulse oximetry, intravenous sedation, topical anesthesia, and control of blood pressure with intravenous vasodilators and beta-blockers, if needed, are important to patient safety. With these precautions, the majority of patients can undergo esophageal intubation with minimal distress and good hemodynamic stability. Despite this, there has been a reported case of aortic rupture occurring during TEE in a patient with an acute dissection, which might have been elicited by retching and elevated blood pressure.[108] Other commonly reported adverse events during transesophageal studies that must be anticipated and avoided are nonsustained atrial and ventricular arrhythmias, excessive vagotonia with transient atrioventricular block, and arterial hypoxemia.[109]

## DIAGNOSTIC FEATURES

### *Dissection*

The diagnosis of aortic dissection is most secure when very specific criteria are met. Identification of an intimal flap, seen as a mobile, linear echo within the vascular lumen, and flow in the true and false channels on either side of the flap are highly sensitive features of dissection. The motion of the intimal flap toward the false lumen during systole may be a helpful feature. A thickening of the aortic wall in excess of 15 mm has also been used as a sign of dissection, suggesting thrombosis of a false channel, which makes the intimal flap difficult to recognize.[110] Strict adherence to these criteria can avoid confusion from imaging artifacts and manifestations of other types of disease and minimize false-positive results.[111] This is particularly important because most patients suspected of having an aortic dissection have evidence of vascular disease involving the thoracic aorta (Fig. 36-11). In one series of 40 patients evaluated for dissection, abnormal aortic findings (including atherosclerotic plaques, intravascular and extravascular masses, thrombi, and dilation) were found in 16 of 17 patients in whom aortic dissection and coronary artery disease were excluded as explanations for their chest pain.[112] Other underlying aortic abnormalities such as coarctation or prior surgical repair may affect clinical management, but they are also important potential sources of misdiagnosis.

### *Intramural Hematoma*

Transesophageal images demonstrate a thickened aortic wall with intramural echo-free spaces, an increased distance from the TEE probe to the inner aortic wall, and focal distortion of the transverse circular configuration of the aorta. Proposed echocardiographic criteria for aortic intramural hematoma include a crescent-shaped or circular thickening of the aortic wall 7 mm or more in thickness, extending 1 to 20 cm longitudinally, without an intimal flap or evidence of flow in the thickened aortic wall. TEE has a reported sensitivity of 100% and a specificity of 91% for the diagnosis of aortic intramural hematoma.[84]

### *Penetrating Ulcer*

Echocardiographic features of penetrating ulcers of the aorta include a crater-like outpouching of the aorta with jagged edges, associated with complex atheromatous plaque.

## DOPPLER FINDINGS

Color Doppler flow imaging during TEE is an excellent descriptor of the abnormal aortic flow patterns associated with acute dissection. Flow in the false channel is variable and complicated; the true lumen, which is often dwarfed by the false channel, is identified by forward systolic flow. With large proximal entry tears, flow in the nearby segments of the false lumen may have the same direction and timing as the true lumen flow and may reverse in diastole.[113,114] With smaller or more distal tears, false lumen flow is less similar to true lumen flow: It may be directed in the opposite direction, and peak velocity may occur later in the cardiac cycle, representing delay of flow into the false lumen. Many areas will show extremely slow, swirling flow with

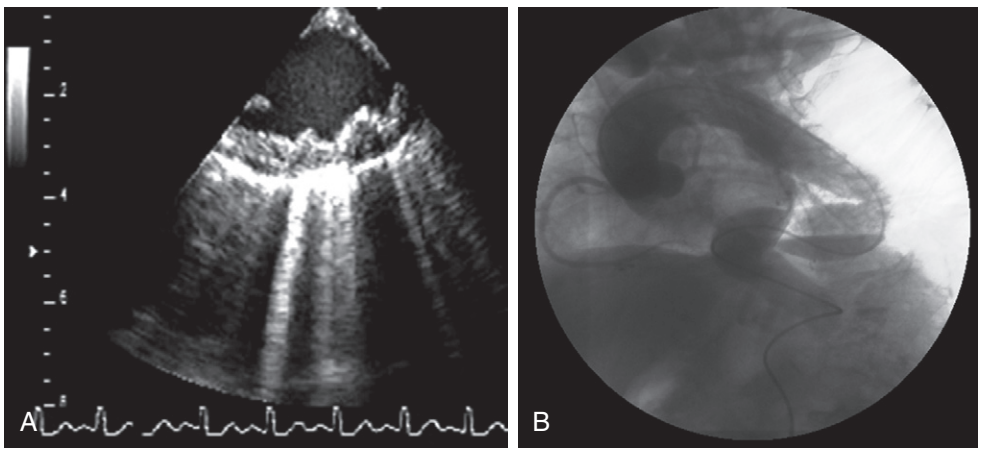

**Figure 36-11 Imaging artifacts and difficult views can be expected in the setting of severe atherosclerosis (A) and aortic tortuosity and/or ectasia (B).** Complementary methods such as computed tomography and magnetic resonance imaging may assist in difficult cases with low-confidence images.

spontaneous echo contrast or partial thrombosis. These segments tend to be remote from large entry or exit sites where high-velocity flow keeps these changes from occurring. Finally, areas of complete thrombosis are also seen, and care must be taken to ascertain that the hematoma is entirely intravascular and not actually the result of adventitial rupture, pseudoaneurysm formation, or intramural hematoma.

Multiple communications between the true and false lumens are often identified on careful scanning of the entire thoracic aorta. Some will represent entry sites with flow from the true toward the false channel, and others will be exit sites or have bidirectional flow (see Fig. 36-7). Exit tears, where flow reenters the true lumen from the false lumen, may occur at one or multiple sites. The exact location of a given tear can be estimated from the depth of probe insertion from the incisors, an arbitrary but convenient reference point. Recording this information at the time of the procedure and on the written report not only is helpful in the surgical correction of dissection, but also is extremely important for comparison with postoperative follow-up TEE studies, where many of the original tears may still be detectable.

Identification of the primary entry site must be deduced from location, size, and flow patterns. In some cases the primary tear cannot clearly be assigned to any one tear, either because of multiple tears as described earlier or, in some cases, because of the TEE blind spot. Adachi and associates[115] were able to identify the entry site in 50 of 57 patients with acute dissection. They were more successful in this with type B dissections (90%) than with type A (83%). As mentioned previously, identification of the primary tear is mostly important because ensuring that the surgical repair resects the primary entry site may decrease the incidence of late reoperation.

## COMPLICATIONS OF DISSECTION

An important goal of echocardiographic imaging in aortic dissection is identifying associated complications. Type A dissections may produce acute aortic regurgitation due to annular dilation or disruption of leaflet suspension. TEE can provide detailed morphologic information regarding the quality of the leaflet tissue and the mechanism of aortic regurgitation; these can help in the decision regarding valve resuspension versus replacement (see Chapter 20). This is a clear advantage and complementary feature to CT and MRI. Pericardial effusion and tamponade are manifestations of aortic rupture with dissection and are often readily identified on transthoracic views (Fig. 36-12). The Doppler manifestations of pericardial tamponade may be best obtained from external apical views and may obviate preoperative TEE in the interest of moving the patient emergently to the operating room (see Chapter 29). Other rupture syndromes can occur at different sites (Fig. 36-13). Uncontained rupture into the mediastinum or pleural space causes sudden death. Some ruptures are contained by the aortic adventitia, resulting in pseudoaneurysm formation or hematoma. In these cases TEE can detect the intimal breach as well as the extension of the hematoma into the surrounding tissues. An important proviso is to image the aorta at an adequate imaging depth so that such a hematoma can be recognized. These extravasations can be missed if the imaging field is restricted to the expected aortic contours; disastrous consequences can ensue if the site of the extravasation is not corrected along with the proximal aortic repair. Contrast may be useful in ruling out extravasation (Fig. 36-14).

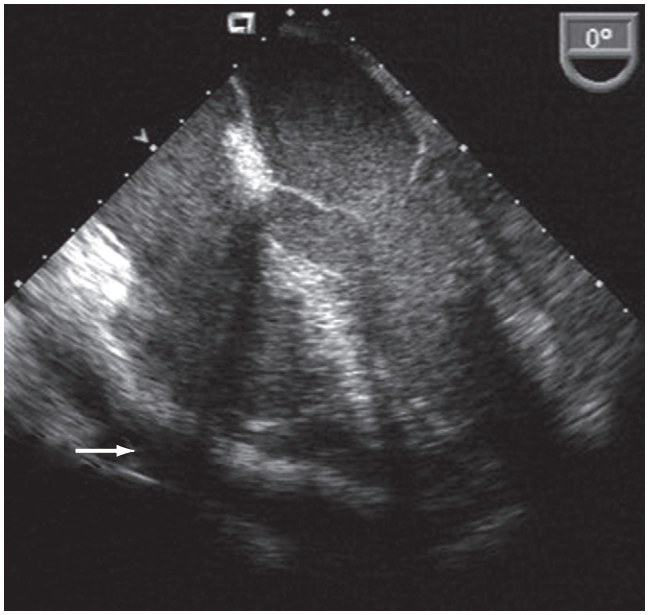

**Figure 36-12 Four-chamber TEE view in patient with type A dissection and pericardial effusion.** Contrast injection was performed and shows contrast in cardiac chambers, but not in the small pericardial effusion (*arrow*). This suggests that there is no active extravasation, which would have implied dissection with rupture. No tamponade physiology was detected.

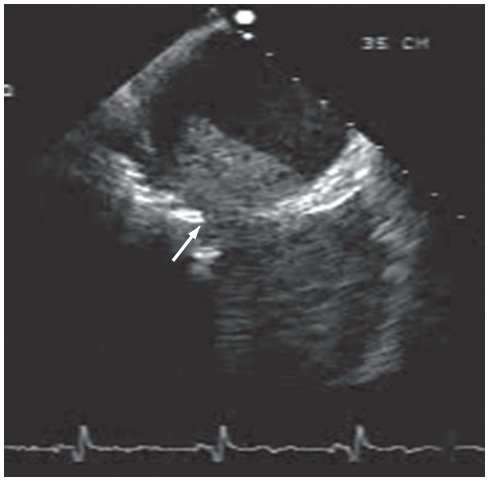

**Figure 36-13 Transesophageal view of descending aorta in patient after high-speed motor vehicle accident shows large thrombus in aortic lumen.** There is discontinuity of the posterior aortic wall (*arrow*) underlying the thrombus and extension of clot into periaortic tissues. This was confirmed to be a descending thoracic aortic rupture at emergent surgery.

### *Coronary Artery Involvement*

Involvement of coronary arteries by aortic dissection is an important issue, and one that raises the question of whether preoperative coronary angiography is mandatory. Involvement of one or both coronary arteries by acute aortic dissection has been estimated to occur in 10% to 20% of cases (Fig. 36-15).[116] In a series of 34 aortic dissection patients, Ballal and colleagues[117] detected coronary involvement with TEE in 6 of 7 surgically documented dissected coronaries. Of note, electrocardiographic changes were demonstrated in only 2 of the 6 patients with coronary involvement. Adequate views of the ostia and proximal vessel were obtained for 88% of left main arteries

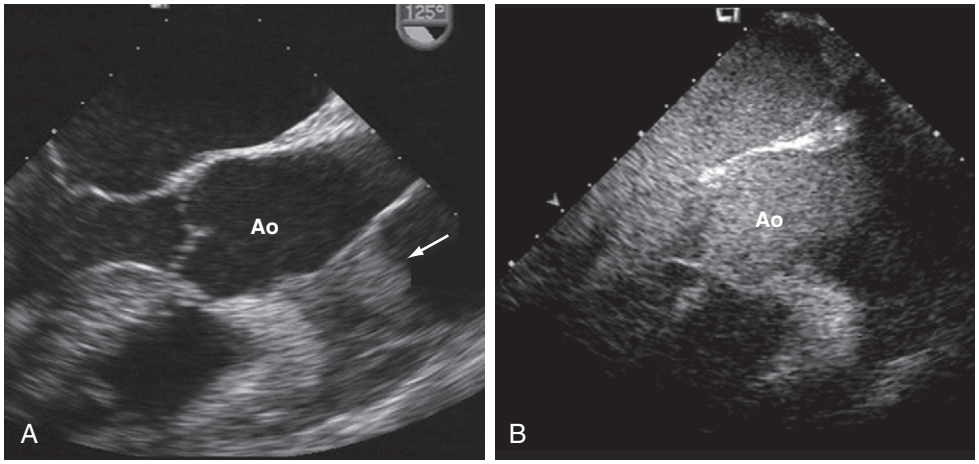

**Figure 36-14** **TEE view of the ascending aorta suggests an intimal flap with possible lumen rupture (A,** *arrow*). Contrast injection does not confirm extravasation outside aorta (**B**). *Ao*, Aorta.

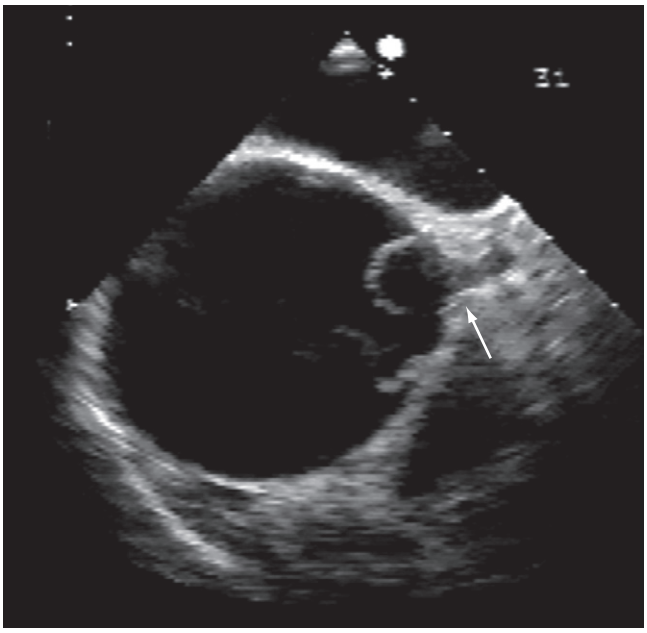

**Figure 36-15** **Short-axis TEE view of aortic root demonstrates an intimal flap in proximity to left coronary ostium (*arrow*).**

and 50% of right coronary arteries overall. Visualization of the ostia and proximal coronaries with TEE continues to improve. A separate but related issue is whether possible concomitant coronary artery disease, independent of coronary dissection, should prompt routine angiography. Given the underlying vascular disease that affects many patients with dissection, it is not surprising that coronary disease has been found in up to 43% of patients with aortic dissection. The benefits of addressing potentially important coronary stenoses must be weighed against the risk of delays and aortic manipulation during acute dissection and adjusted for the patient's baseline likelihood of coronary disease. A series of 122 patients from the Cleveland Clinic found no difference in the in-hospital mortality between patients who had emergency coronary arteriography before dissection repair and those who did not. Three-fourths of all coronary artery bypass grafting procedures performed in that series were done because of coronary dissection rather than obstruction due to coronary artery disease.[118]

### INCONCLUSIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHIC RESULTS

The path of ultrasound through the esophageal wall and surrounding tissues may generate near-field artifacts that are often disconcertingly linear and run parallel to the aortic wall, mimicking an intimal flap. In patients with severe atherosclerotic disease, calcification in the wall can present similar artifacts and shadows. Abrupt aortic dilation can create a *shelf*, which can resemble a flap as well. Determining that these do not represent true intimal flaps depends on recognizing the minimal mobility of these structures and the homogeneity of flow on both sides of the line. The ability to change to a second imaging plane, as is possible with biplane or multiple-plane TEE probes, is extremely helpful in resolving the issue of artifactual flaps.[111,119] Multiple-plane imaging also allows better visualization of the proximal ascending aorta, where atherosclerosis and ectasia can be misinterpreted as dissection.[102]

Aneurysmal dilation of the aorta is another source of false-positive TEE studies for dissection.[120] Flow in aneurysmal areas is often low-velocity and swirling, similar to the flow in false channels. The absence of an intimal flap is important in avoiding misdiagnosis in this situation. The possibility that the intimal flap is not seen because the false channel has thrombosed must be excluded by carefully scanning up and down the aorta from the abnormal site. An intimal layer identified proximally or distally may be followed back to the suspicious dilated segment to suggest dissection.

## Surgical Considerations

The planning of surgical correction of aortic dissection is heavily influenced by many of the features discussed earlier. The extent of the dissection, the location of primary tears, and concomitant valvular regurgitation and coronary disease are all critically important to the surgical team. In addition, intraoperative ultrasound can address safe cannulation sites, aortic valve repair strategies, need for coronary reimplantation with root replacement, and confirmation of adequate cardiopulmonary bypass and even intraaortic balloon function (Box 36-3). Transesophageal imaging during surgery has the advantage of being unobtrusive (at least for the surgeon, if not for the anesthesiologist) and is commonly also used as an accurate monitor of left ventricular wall motion and volume status. The

long-term outcomes for surgery are very promising; a recent review found 96% and 90% survival at 1 and 3 years after surgery, respectively, for type A dissection.[121]

## INTRAOPERATIVE ECHOCARDIOGRAPHIC MONITORING

An additional tool for completing the scan of the aorta is intraoperative imaging from the epicardium or surface of the aorta (see Chapter 2). The unlimited number of acoustic windows from this approach allows careful interrogation of the aortic root, origins of the great vessels, cardiac valves, and left ventricular wall motion. The transesophageal blind spots in the ascending aorta and transverse arch can be thoroughly inspected from the epicardium, and potential aortic cannulation sites can be evaluated from the exterior aortic surface. Epicardial views give much greater freedom of visualization and measurement of the aortic valve and allow precise annular sizing before cardiopulmonary bypass to expedite selection of the valvular prosthesis. The position of the coronary ostia relative to the dissection and the annulus can be defined precisely with epicardial views, which may also aid in surgical decisions regarding valve-graft conduit placement or coronary ostial reimplantation.

The amount of time required for imaging in the surgical field can be limited to a few minutes, but this requires an experienced team with a surgeon or cardiologist familiar with the epicardial techniques and views. The combination of epicardial and transesophageal techniques ensures that a high-quality ultrasound image is acquired of all segments of the aorta above the diaphragm and eliminates any uncertainty regarding involvement of the ascending aorta. Post–cardiopulmonary bypass images from the epicardium can also be extremely helpful in reassessing proximal tears and interrogating suture lines between aorta and conduit.

Transesophageal views at the conclusion of cardiac surgery confirm aortic valve or prosthetic valve competency and allow prompt reinstitution of support if significant aortic regurgitation demands surgical revision. Intraaortic balloon pump position can be assessed with TEE; accidental placement of the balloon in the false lumen can be disastrous if not immediately recognized.[122] Finally, postoperative TEE images of the graft and native aorta create a baseline for subsequent follow-up studies.

## AORTIC REGURGITATION

Aortic valve regurgitation complicating aortic dissection has negative effects on outcome and may dictate important issues in surgical approach. Preservation of the native aortic valve is possible in 86% of type A dissection with excellent results.[123] If the aortic annulus is abnormal due to Marfan syndrome or annuloaortic ectasia, aortic valve replacement is preferred because of the limited long-term durability of aortic valve reconstruction in these patients. Initiation of cardioplegia for cardiopulmonary bypass usually depends on a competent aortic valve to allow antegrade perfusion of the coronaries; in the presence of significant aortic regurgitation, therefore, individual ostial cannulation or coronary sinus retroperfusion may be indicated. The specific causes of aortic regurgitation are also important[106]: Normal-appearing leaflets with a prolapsing cusp owing to avulsion of the leaflet base may be amenable to aortic repair with resuspension. Other cases may require aortic valve replacement. The specific involvement of the adjacent aortic root is also critical and may require a variable extent of prosthetic conduit. In some cases human aortic allografts are used, which have the advantage of supplying both natural aortic valve and root.

In proximal aortic involvement, the position and involvement of the coronary ostia are important. Ostial reimplantation

may be necessary; coronary bypass grafting may be unavoidable if the coronaries are dissected. Coronaries may be reattached by direct reimplantation with or without a surrounding button of aortic tissue, reattached to a piece of prosthetic conduit, or completely bypassed with saphenous vein or internal mammary artery grafts.

### MITRAL REGURGITATION

Mitral regurgitation is a different example of a valvular abnormality associated with aortic dissection. New regurgitation may result from wall motion abnormalities induced by coronary involvement in the dissection, or from acute left ventricular dilation induced by aortic regurgitation. In other cases mitral regurgitation is part of the underlying disorder, as is the case with Marfan syndrome with mitral valve prolapse. Identification of the etiologic factors in the mitral regurgitation (e.g., leaflet degeneration, ventricular dilation, or papillary muscle ischemia) will influence the need for repair or prosthetic replacement. Confirmation of results on early post–cardiopulmonary bypass images is important, especially when the decision is made to leave the mitral valve alone despite some regurgitation in hopes that correction of acute ischemia or dilation will remedy it.

### PERFUSION OF DISTAL VASCULAR BEDS

In the throes of acute aortic dissection, organs may be perfused by either the true or the false lumen flow. Organ underperfusion may occur if flow to the source lumen is compromised. During surgery, malperfusion may be caused by flow reversal when cardiopulmonary bypass is established by cannulation of the femoral artery, with obliteration of major communications between the two lumens from cross clamping, or with repair of the dissection itself. Neustein and colleagues[124] describe a case in which femoral cardiopulmonary bypass compressed the true lumen and created severe malperfusion once the dissection was repaired. Perfusion through the new ascending aortic graft allowed immediate reinstitution of forward flow.

## Endovascular Repair Considerations

Endovascular stenting is an important option and alternative to open surgery in selected patients with aortic trauma and dissection.[125] In traumatic rupture, it may be associated with lower mortality and incidence of complications such as spinal cord ischemia.[126] TEE may help guide endovascular stent placement[127] and detection of complications due to device deployment.[128] Echocardiography offers the best detection and delineation of endoleaks and is an important addition to angiography and intravascular ultrasound at the time of stent placement and at follow-up.[129] Intravascular ultrasound has also proved to be a valuable tool in this situation.

## Follow-up of Patients after Aortic Dissection

### PERSISTENT INTIMAL FLAPS

Despite successful surgical repair of aortic dissection, the aorta retains many abnormalities of structure and flow. Distal to the repair, the intimal flap and false lumen persist. The false lumen may fill with thrombus, or it may retain flow along with entry and exit flow through multiple fenestrations. One study detected persistent flap and false lumen in 100% of postrepair patients by MRI.[130] Persistent flow in the false lumen can be detected with TEE in the majority of patients after surgical repair. Mohr-Kahaly and co-workers[114] found persistence of the false lumen in 71% of their postoperative patients at a follow-up interval of 1 to 41 months, and in 82% of their medically treated patients. Dinsmore and Willerson[71] have suggested that long-term survival is poorer in patients with persistent flow in the false lumen. Thrombosis of the false channel seems to be protective, a "natural buttress against future or further extension of the dissection." TEE confirms that sites without communications develop low-velocity flow and thrombus, whereas healing changes are less likely to occur in regions with significant tears and persistent flow. TEE also demonstrates aggressive atherosclerotic changes and calcification of the neointima lining the false channel.

### PROGRESSION OF DISEASE

Patients with previous dissection may develop progressive abnormalities of both operated and nonoperated aortic segments. Of original dissections, 25% to 40% will enlarge over time, and the rate and extent of enlargement are primary factors driving the need for reoperation.[116] In addition, dilation of noncontiguous, nonoperated aortic segments develops in 17% of patients with prior acute type A dissections. Early recognition of this progressive downstream aortic pathology allows reoperation in hopes of preventing rupture or redissection.[131] The concern regarding disease progression commits these patients to routine follow-up studies indefinitely.

### PSEUDOANEURYSM FORMATION

Pseudoaneurysms form in 7% to 25% of patients with composite grafts, such as a Bentall procedure, secondary to hemorrhage at a suture line dehiscence.[132] Blood between the graft and aortic wall can create supravalvular aortic stenosis.[133] Both of these complications can be detected and completely delineated by TEE,[134] as well as by CT, angiography, and MRI.[135,136] Color flow Doppler will demonstrate blood flow into the echo-free space between the graft and the aortic wall. Other postoperative complications include endocarditis and development of a sinus of Valsalva aneurysm.[137]

### RECURRENT DISSECTION

Because the symptoms of acute redissection or expansion of a chronic dissection are nonspecific, the ability to reassess rapidly and compare the current findings with previous images is extremely important. Younger patients, those with Marfan syndrome, and those with primary tears involving the transverse arch are particularly prone to progression of their disease.[138] Because TEE may not be able to reproducibly measure the true transverse diameter of an ectactic aorta, suspicion of chronic expansion usually requires additional confirmatory tests such as CT or MRI. Excellent definition of the intimal flap, false channel thrombi and flow patterns, and consistent reference landmarks for serial sizing over time make MRI a highly reliable method. When recurrent chest pain or hemodynamic instability suggests acute redissection, TEE can rapidly define the new pathologic abnormality and its extent. Changes from baseline postoperative or postdissection images can be extremely helpful in clarifying the etiologic site and event.

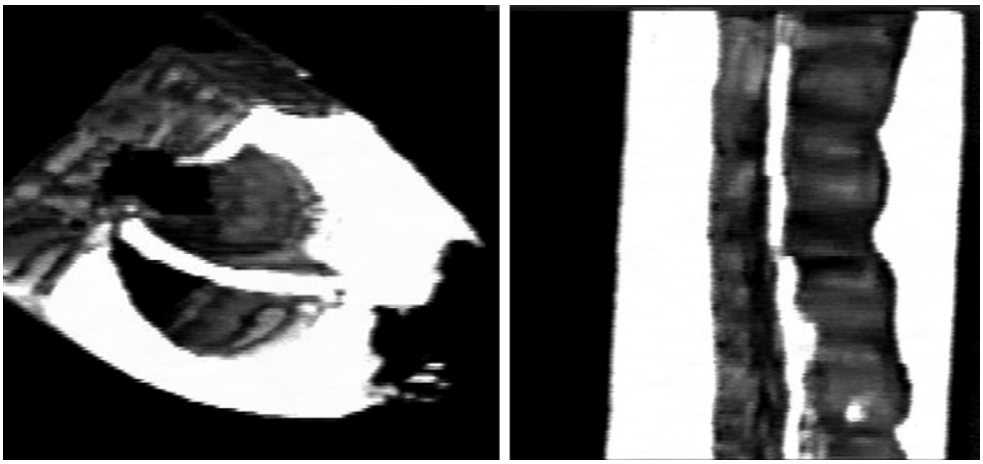

**Figure 36-16** 3D reconstructed views of the aorta in short-axis (*left*) and long-axis (*right*) orientations demonstrate intimal flap separating true and false lumens.

## Research Applications and Future Directions

TEE images provide excellent spatial resolution, and in combination with the high temporal resolution of M-mode methods they allow investigation of aortic distensibility in normal patients, in patients at risk for vascular disease, and after repair of aneurysms or dissection. These types of methods have documented decreases in elastic aortic properties after aortic surgery, which predispose patients to redissection.[139] Two-dimensional echocardiographic assessments of aortic distensibility have been shown to estimate changes in aortic mechanical properties resulting from increasing age[140]; Doppler estimates of pulse wave velocity are also being investigated as measures of aortic compliance.[141] Animal models for validation of these parameters include chronic models of accelerated atherogenesis, as well as acute aortic ischemia and decreased distensibility generated by removal of the vasa vasorum.[142] Multidimensional TEE images continue to inform regarding diagnosis and surgical planning (Fig. 36-16).

High-frequency ultrasonic integrated backscatter methods are also being applied to the aortic wall. Recchia and associates[143] detected sixfold decreases in backscatter and 15-fold decreases in anisotropy, suggesting marked disorganization of the three-dimensional (3D) aortic architecture in Marfan syndrome patients' aortas compared to those of normal patients. Tissue strain analysis based on speckle tracking and tissue Doppler are also being actively investigated alongside tonometry and peripheral vascular evaluations for the detection of aortic pathology. These types of functional and structural investigations may improve our recognition of aortic disease of many stages and refine our prediction of risk of dissection.

## Conclusions

The grim prognosis of patients with acute aortic dissection or traumatic aortic injury demands a rapid, highly sensitive, and efficient diagnostic approach. The use of imaging in the earliest minutes of patient evaluation continues to shift toward CT scanning. Echocardiography remains a mainstay in the emergent diagnosis, treatment, and follow-up of patients with acute aortic syndromes.

### KEY POINTS

- The immediate management and prognosis of acute aortic syndromes including dissection and intramural hematoma hinge on whether the ascending aorta is involved.
- Any dissection involving the ascending aorta is type A, irrespective of the site of the entry tear or direction of propagation.
- Mortality of type A aortic dissection is 1% per hour for the first 48 hours.
- TEE, MRI, and CT have similar clinical performance in assessing aortic dissection:
  - To rule out aortic dissection in a patient with low pretest probability, CT may be best but requires contrast and radiation exposure.
  - To confirm aortic dissection in a patient with high pretest probability, MRI may be best but is often inappropriate for unstable patients.
  - TEE can rapidly diagnose dissection and identify high-risk features, including pericardial effusion, aortic regurgitation, and wall motion abnormalities.
- Aortic intramural hematoma has the same prognosis and urgency as aortic dissection.
- Aortic dissection can occur without significant root enlargement in a patient with Marfan syndrome.
- Patients with bicuspid aortic valve remain at risk for progressive aortic dilation and dissection even after aortic valve replacement.
- After surgery for dissection, the intimal flap and false lumen usually persist distal to the graft, and multiple entry and exit tears may be seen.
- Aortic injury from severe blunt trauma or deceleration is usually rupture confined only by adventitia.

Associated Cardiovascular Involvement

Rheumatologic diseases are chronic inflammatory states caused by autoimmunity. These diseases are more common in women than in men (with the exception of ankylosing spondylitis), usually manifest from the second through the fifth decade, and cause significant morbidity and mortality.

Although the heart is not the principal target organ of rheumatologic diseases, cardiovascular involvement is common and has serious consequences. The heart valves, myocardium, pericardium, coronary arteries, great vessels, and conduction system may be involved. Estimates of the prevalence of cardiac involvement vary widely because of differences in study design, study populations, and methods of cardiac evaluation.

Echocardiography plays a major role in the better understanding of the prevalence, incidence, characteristics, severity, evolution, and response to therapy of the cardiovascular diseases associated with rheumatologic diseases. The increasing application of real-time three-dimensional (3D) transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE); tissue Doppler imaging, including myocardial strain; and contrast echocardiography will result in upward revision of prevalence and incidence rates, characterization, prognosis, and therapy of heart disease in patients with rheumatologic diseases. Also, echocardiography will play a major role in guiding and assessing the results of future pharmacotherapeutic trials and of percutaneous or surgical valve repair in these high-risk surgical candidates.

## Systemic Lupus Erythematosus

### BACKGROUND

Systemic lupus erythematosus (SLE) is a rheumatologic disease that affects predominantly the musculoskeletal and mucocutaneous systems. However, cardiovascular disease is the third most common cause of death in these patients, after infections and renal disease.

The most important forms of cardiac involvement in SLE are Libman-Sacks endocarditis, intracardiac thrombosis and thromboembolism, premature atherosclerosis, pericarditis, myocardial disease, and pulmonary hypertension.[1]

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Valve Disease*

Valve disease in SLE is subdivided into Libman-Sacks (inflammatory and thrombotic) or thrombotic vegetations, leaflet thickening with or without fibrosis, and valve regurgitation.[2,3] Mitral valve prolapse is more prevalent (up to 22%) in patients with lupus than in age-matched and gender-matched controls (5%).[4] About one third to half of patients with SLE may have valve vegetations or thickening, but the degree of associated valve regurgitation is usually mild to moderate and therefore clinically silent.[2,3] However, subclinical valve disease is

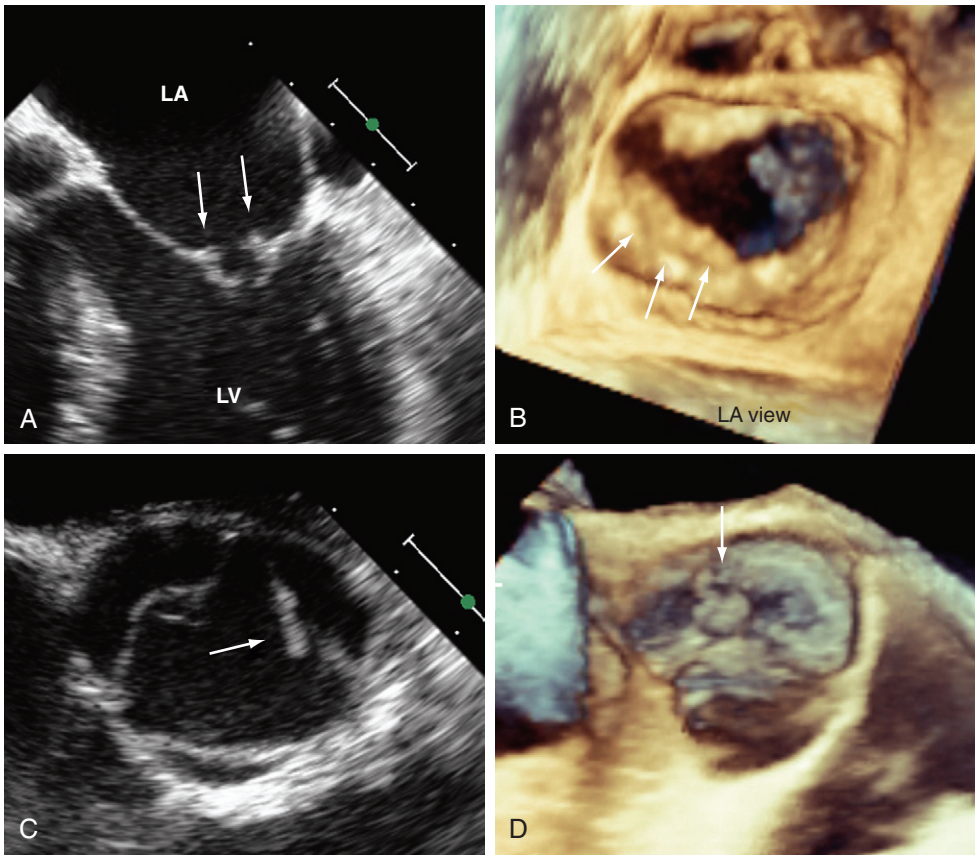

**Figure 37-1 Libman-Sacks vegetations of the mitral and aortic valves in a 27-year-old man with systemic lupus erythematosus. A,** This 2D TEE shows small, irregular-shaped, sessile, and soft tissue echoreflectant vegetations on the atrial side and coaptation point of the anterior and posterior mitral leaflets (*arrows*). Associated mild thickening of the leaflet tip is noted. Only mild mitral regurgitation was detected. **B,** This real-time 3D TEE of the mitral valve viewed from the atria and during diastole illustrates the tubular-shaped and sessile vegetation of the posterior mitral leaflet extending from P2 to P1 scallops (*arrows*). Similar characteristics of the anterior leaflet vegetation were best noted during systole. **C,** This 2D TEE shows a small, tubular-shaped, and homogeneously echo reflectant vegetation located at the tip on either the aortic or ventricular side of the left coronary cusp (*arrow*). **D,** This real-time 3D TEE of the aortic valve viewed from the aorta and during diastole shows the oval-shaped and soft tissue echoreflectant vegetation located on the tip and aortic side of the left coronary cusp (*arrow*). The aortic cusps are otherwise normal. No aortic regurgitation was shown.

commonly complicated by either subclinical or clinical cardioembolism and uncommonly by significant regurgitation from recurrent immune-mediated valvulitis or superimposed infective endocarditis.[3,5,6]

The pathogenesis of valve disease in SLE includes an immune-complex–mediated inflammation exacerbated by a commonly associated increased systemic and local thrombogenesis mediated by antiphospholipid antibodies, which include immunoglobulin G or immunoglobulin M anticardiolipin antibodies, lupus anticoagulant, and antibodies to plasma phospholipid-binding B2-glycoprotein I.[7,8] However, the temporal association of valve disease with activity and severity of SLE and the presence and levels of antiphospholipid antibodies is variable.[2,3,8,9] Libman-Sacks vegetations were originally described as cauliflower-like fibrous masses 2 to 4 mm in diameter that are located on any of the four cardiac valves. Active vegetations have central fibrinoid necrosis with fibroblastic proliferation and fibrosis surrounded by mononuclear and polymorphonuclear cellular infiltration, small hemorrhages, and platelet and fibrin thrombus.[10,11] Healed masses have central fibrosis, minimal or no inflammatory cell deposition, and no or hyalinized and endothelialized thrombus. Active, healed, and mixed masses can be seen in the same valve. Almost all patients with Libman-Sacks vegetations have a variable degree of leaflet fibrosis, but fibrosis is more prevalent than Libman-Sacks vegetations among unselected patients with SLE.

Echocardiographic studies have shown that Libman-Sacks vegetations are commonly less than 1 cm in diameter, vary in shape, have irregular borders, and have heterogeneous echodensity. The broad-based growths rarely move independently of the underlying valve structure. Lesions are more common on the mitral valve, are more commonly attached at the leaflet or cusp coaptation point, and typically are seen on the atrial side of the mitral valve and on either side of the aortic cusps (Figs. 37-1 to 37-4).[2,3,5,12] Rarely, vegetations are seen on the right-sided heart valves, atrial or ventricular endocardium, mitral or tricuspid subvalvular apparatus, or aortic root (see Question 37-1, Fig. 1, at ExpertConsult.com).[13] Echocardiographic studies estimate the prevalence rate of Libman-Sacks vegetations as less than 11% with TTE and 35% to 45% with TEE.[2,3,5,12,14] With TEE as the standard, TTE has a very low sensitivity and a low negative predictive value for detection of vegetations (11% and 57%, respectively).[15,16] The low detection of vegetations with TTE precludes assessment of its specificity and positive predictive value. Although real-time 3D TTE and TEE may improve the detection and characterization of Libman-Sacks vegetations, limited data are currently available.[17,18]

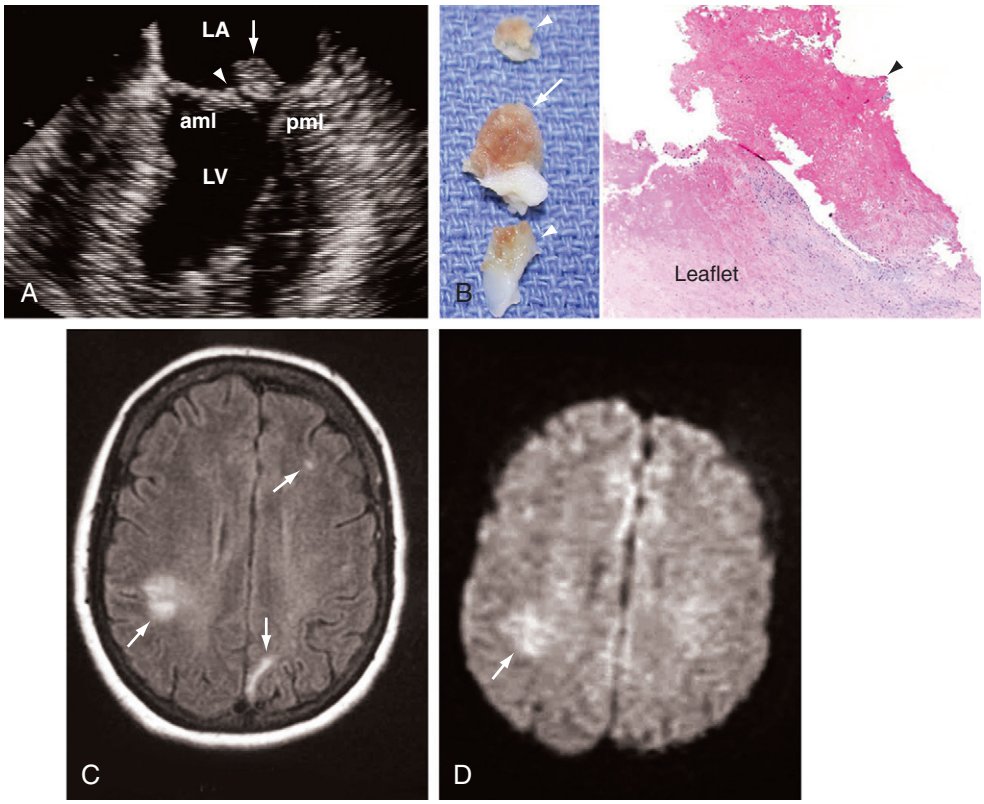

**Figure 37-2 Mitral valve Libman-Sacks vegetations in a 31-year-old woman with systemic lupus erythematosus and recurrent transient ischemic attacks. A,** This TEE shows a large vegetation on the atrial side and basal portion of the posterior mitral leaflet (*pml; arrow*) and a small vegetation on the atrial side of the anterior mitral leaflet (*aml; arrowhead*). Both leaflets had diffuse moderate thickening. Only mild mitral regurgitation was detected. The patient underwent mitral valve replacement as a result of recurrent transient ischemic attacks despite anticoagulation. **B,** Large vegetation (*arrow*) from the posterior leaflet and small vegetations (*arrowheads*) from the anterior leaflet. Histology of the leaflet revealed inflammation with mononuclear cells and fibrosis. Vegetations of predominant fibrinous material well adhered to the leaflet were shown (*arrowhead*). **C,** This fluid-attenuated inversion recovery magnetic resonance image shows a recent cerebral infarct in the right occipitoparietal white matter (*arrow on left*). Left occipital and frontal lobe small cerebral infarcts (*arrows on right*) are also shown. **D,** This diffusion-weighted image shows a large area of hyperintensity (focally restricted diffusion) and confirms a recent infarct in the right occipitoparietal white matter (*arrow*). The cerebral infarcts in the left occipital and frontal hyperintense lesions are not visible by diffusion-weighted image, indicating they are old infarcts.

Libman-Sacks vegetations and leaflet fibrosis are frequently accompanied by only mild to moderate valve regurgitation and therefore are usually clinically silent. However, significant complications, such as subclinical and clinical cardioembolism, commonly occur. Valve vegetations or thickening are more common in patients with asymptomatic or symptomatic focal ischemic brain injury on magnetic resonance imaging, in those with stroke or transient ischemic attack, and in those with nonfocal neurologic manifestations of cognitive dysfunction, acute confusional state, or seizures (Figs. 37-2 to 37-5).[3,5,19,20,21] Left-sided vegetations rarely embolize to the coronary arteries, and right-sided valve vegetations rarely embolize to the lungs or paradoxically embolize.[22,23] Also, transcranial Doppler imaging studies show higher rates of microembolic events in patients with valve disease and neurologic events.[24,25] In addition, in a series that correlated brain magnetic resonance imaging with pathology, a high association of valve vegetations or thickening with thromboembolic cerebrovascular injury was found.[26] Furthermore, Libman-Sacks endocarditis can be complicated with severe regurgitation that results from recurrent or acute valvulitis; noninfective valvulitic perforations, including bioprosthetic leaflets; noninfective mitral valve chordal rupture; or infective endocarditis in at least 20% of patients.[3,6,27,28] Infective endocarditis can mimic, accompany, or trigger a flare of SLE and can lead to severe valve dysfunction, congestive heart failure, and septic death. Similarly, a flare of SLE can mimic endocarditis (pseudoinfective endocarditis). The leaflet fibrosis (increased thickness and echoreflectance) that accompanies Libman-Sacks vegetations may cause reduced leaflet mobility, but valve stenosis is rare (less than 3%). In a TEE study, 48% of unselected patients with lupus younger than 60 years of age had abnormal leaflet thickness, defined as more than 3 mm.[2,3,12,16] With TEE as the standard, TTE has low sensitivity (53%), low specificity (50%), low negative predictive value (31%), and moderate positive predictive value (71%) for detection of valve thickening.[15,16] This limited diagnostic accuracy may explain the highly variable rates of valve thickening reported in studies with TTE. Shadowing caused by leaflet scarring is observed in 12% of patients. Annular, subvalvular, and right-sided heart involvement is rare.

The natural history of SLE-associated valve disease parallels that of the primary disease. With serial TEE, valve disease, especially valve vegetations, may appear de novo, resolve, change appearance, or progress (see Fig. 37-5).[3,12] Chronic inflammation may accelerate the progression of valve sclerosis into stenosis.[29] Also, patients with valve vegetations or with moderate to severe valve dysfunction have a threefold to fourfold higher combined incidence rate of stroke, peripheral embolism, need for valve surgery or repair, and death in a 2-year to 8-year follow-up period as compared with those without valve disease

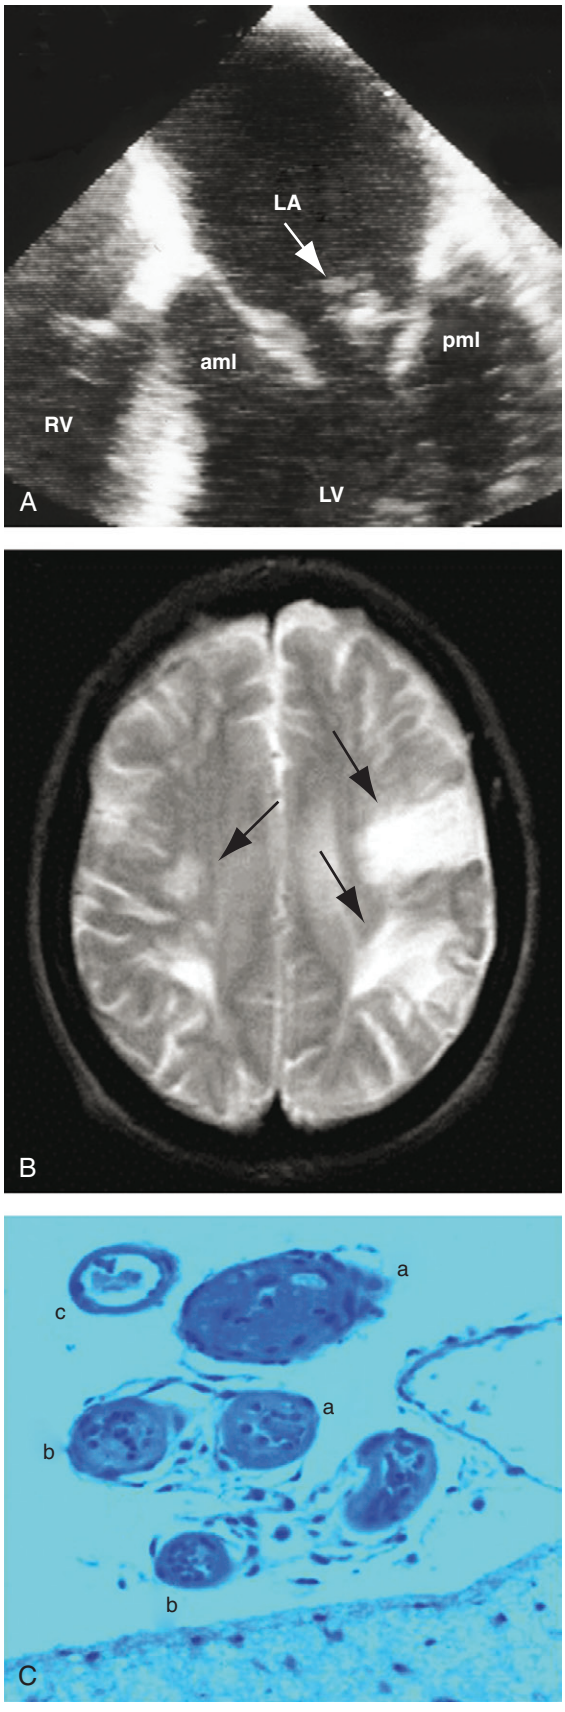

**Figure 37-3 Mitral valve Libman-Sacks vegetation in a 47-year-old woman with systemic lupus erythematosus and recurrent fatal stroke. A,** This TEE shows thickening of the mid and tip portions of the anterior (*aml*) and posterior (*pml*) mitral leaflets with a large vegetation on the midportion and atrial side of the posterior leaflet (*arrow*). **B,** This T2-weighted magnetic resonance imaging in the patient shows generalized cortical atrophy, multiple areas of old cerebral infarcts characterized by loss of both gray and white matter (large areas of hyperintensity; *arrows*) in a cortical or subcortical pattern, and multiple areas of deep white matter abnormality consistent with widespread ischemic cerebrovascular disease. **C,** Histopathology of the brain shows cerebral vessel occlusion by fibrin thrombi (*a*); intimal hyperplasia, vessel wall thickening, and platelet thrombi (*b*); and an occasional patent blood vessel (*c*).

or with mild valve disease.[3,5,6,28,30] The effect on valve vegetations of immunosuppressive therapy or long-term anticoagulation therapy is likely favorable but have not been tested in large controlled longitudinal series.

Rheumatic and SLE valve disease may have similar clinical, serologic, and echocardiographic findings.[31] In their chronic states, the echocardiographic characteristics of these two conditions may overlap. In patients greater than 60 years of age, the pattern of valve scarring characteristic of SLE may be obscured by changes that result from aging or atherosclerosis.[29] The echocardiographic appearances of Libman-Sacks, thrombotic, and infective vegetations also overlap (see Case 37-1 at Expert Consult.com).[3,11,32,33]

### *Intracardiac Thrombosis and Thromboembolism*

Patients with SLE are subject to intracardiac thrombosis and cerebral, peripheral arterial, and coronary artery thromboembolism. Pulmonary thromboembolism or rarely paradoxical embolism may occur in those with right heart lesions. These events occur independently of or are exacerbated by antiphospholipid antibody–induced thrombogenesis.[2,3,5,8,19,22,23,34] The most common substrates of high embolic potential are Libman-Sacks or thrombotic vegetations and less often intracardiac thrombi. Mitral valve vegetations are two to four times more common and are strong independent predictors of focal ischemic brain injury on magnetic resonance imaging, stroke or transient ischemic attack, and nonfocal neuropsychiatric manifestations.[5,19,20] Also, microembolism with transcranial Doppler ultrasound scan has been shown in patients with cerebral ischemic events.[24,25] In addition, postmortem series of patients with lupus frequently identify Libman-Sacks vegetations and thromboembolic ischemic brain injury.[26] Other uncommon embolic substrates in these patients are acute anterior myocardial infarction, more commonly resulting from coronary embolism or in situ thrombosis than from atherosclerotic disease; reduced left ventricular (LV) ejection fraction (less than 35%); and atrial fibrillation. Although paradoxical embolism has been reported, the prevalence and impact of patent foramen ovale have not been prospectively studied.[23] If substrates of high embolic potential are not identified on TTE, TEE should be performed.

### *Atherosclerotic Disease*

Controlled studies have shown that after controlling for traditional atherosclerotic risk factors, the prevalence rates of subclinical atherosclerosis in patients with lupus are two to four times higher than in matched controls.[1,35-37] Functional atherosclerosis in these patients is manifested as decreased coronary flow reserve with dipyridamole or adenosine echocardiography,

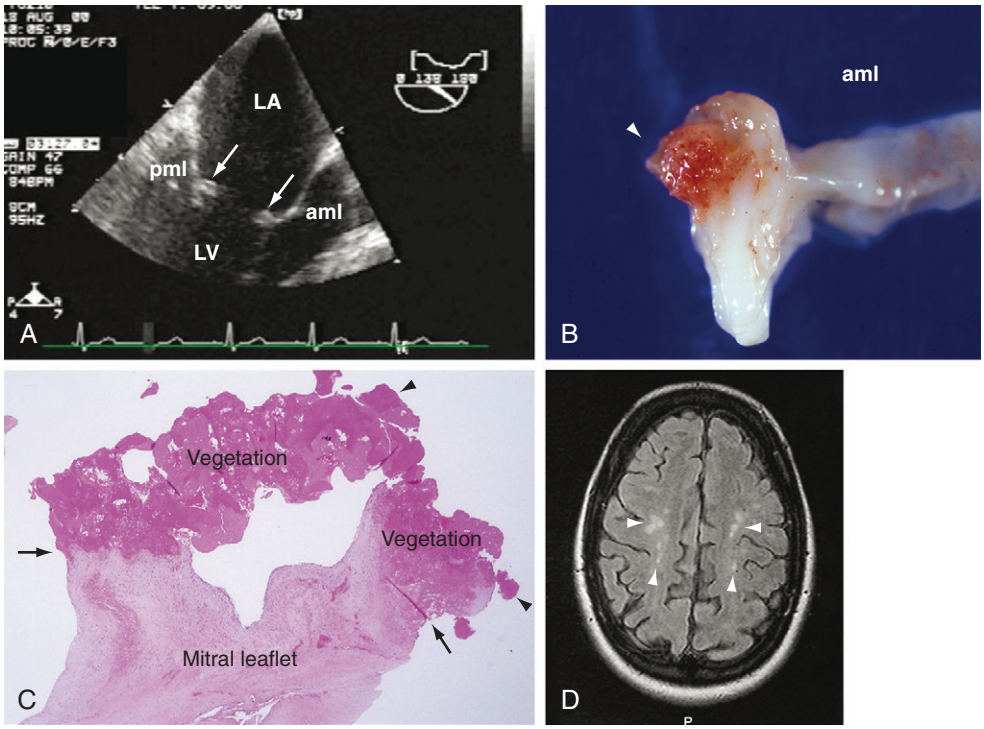

**Figure 37-4 Mitral valve Libman-Sacks vegetations in a 28-year-old woman with systemic lupus erythematosus and acute confusional state and cognitive dysfunction. A,** This TEE view shows small vegetations (*arrows*) on the atrial side and tip portions of the anterior (*aml*) and posterior (*pml*) mitral leaflets with associated leaflet thickening and decreased mobility. Patient underwent valve replacement because of associated symptomatic severe mitral regurgitation. **B,** Diffuse thickening with a Libman-Sacks vegetation on the atrial side and tip portion of the anterior leaflet is noted (*arrowhead*). **C,** Vegetation attached to the leaflets (*arrows*) shows amorphous eosinophilic fibrinous to granular deposits admixed with histiocytes, inflammatory cells, and superficial microthrombi (*arrowheads*). The mitral leaflet shows focal areas of myxoid degeneration and fibrinoid necrosis but no inflammation. **D,** This fluid-attenuated inversion recovery image shows multifocal hyperintensities in the subcortical white matter typical of small infarcts (*arrowheads*).

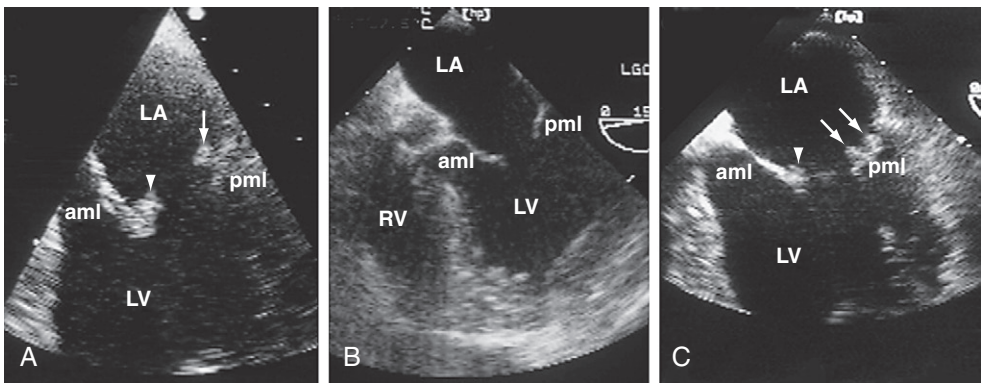

**Figure 37-5 Resolution and reappearance of mitral valve Libman-Sacks vegetations in a 37-year-old woman with systemic lupus erythematosus and a stroke. A,** This initial TEE shows two mitral valve vegetations: one on the atrial side of the tip of the anterior mitral leaflet (*aml; arrowhead*) and another on the midportion of the posterior leaflet (*pml; arrow*). Diffuse thickening of both mitral leaflets is also visible. Moderate mitral regurgitation is detected. **B,** Follow-up TEE obtained 2 months later shows resolution of both mitral valve vegetations and improvement in leaflet thickening. Mitral regurgitation was only mild. **C,** This TEE obtained 20 months later, when the patient had inactive systemic lupus erythematosus, shows reappearance of three mitral valve vegetations: one on the anterior mitral leaflet (*arrowhead*) and two on the posterior mitral leaflet (*arrows*). The thickening of both mitral leaflets has also worsened.

decreased peripheral arterial vasodilation, or increased carotid arteries and aortic stiffness. Premature subclinical atherosclerosis is also manifested as increased prevalence of coronary artery calcifications on computed tomography (31%) and increased carotid and aortic intima media thickening and plaques on carotid ultrasound scan (37%) and TEE (43%), respectively (Fig. 37-6).[35-40] Atherosclerotic aortic aneurysms have also been described.[41] Also, aortic and mitral valve sclerosis or calcification may be a manifestation of premature atherosclerosis.[29]

Clinically evident atherosclerosis is found in at least 10% of patients. Autopsy studies show a 25% prevalence rate of significant epicardial coronary atherosclerosis in patients with SLE. The proposed pathogenesis of atherosclerosis includes:

1. Activation of cellular and humoral immunity that causes cytotoxicity to the endothelium and vascular wall and results in increased vasoconstriction, thrombosis, neointimal and smooth muscle cell proliferation, medial hypertrophy, and ultimately plaque formation.

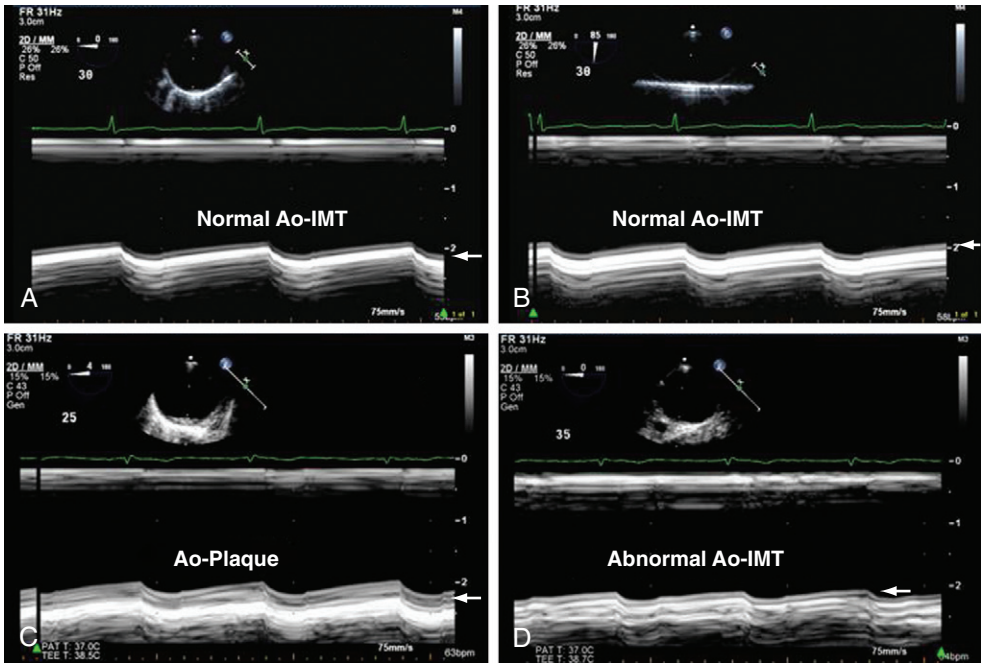

**Figure 37-6 Aortic atherosclerosis with TEE in patients with systemic lupus erythematosus.** Two-dimensional guided M-mode short-axis (**A**) and long-axis (**B**) TEE views of the anterior wall at the mid level (30 cm) of the descending thoracic aorta show normal intima media thickness (*IMT*) of less than 8 mm (*arrows*) in a 50-year-old woman with systemic lupus erythematosus. **C** and **D,** Two-dimensional guided M-mode short-axis TEE views of a 48-year-old woman with systemic lupus erythematosus show an aortic plaque of 3.3 mm at the proximal (25 cm; **C;** *arrow*) and abnormal intima media thickness of 1.2 mm at the distal (35 cm; **D;** *arrow*) descending thoracic aorta. *(Adapted from Roldan CA, Joson J, Sharrar J, Qualls CR, Sibbitt WL Jr: Premature aortic atherosclerosis in systemic lupus erythematosus: a controlled transesophageal echocardiographic study.* J Rheumatol *37:71-78, 2010.)*

2. Increased production of inflammatory cytokines and chemokines, which recruit inflammatory cells and promote vascular smooth cell proliferation, oxidative stress, endothelial apoptosis, and upregulation of adhesion molecules and chemokines.
3. Exacerbation of dyslipidemia, homocysteinemia, and insulin resistance by the disease itself and steroid therapy.

In patients with active SLE and vasculitis that affect other organs, angina and myocardial infarction may also rarely result from coronary arteritis.[22] In these patients, standard therapy for acute coronary syndrome, including percutaneous coronary interventions, and aggressive antiinflammatory therapy are beneficial.[42] Coronary embolism from a valve vegetation or in situ thrombosis warrants consideration when acute coronary syndrome occurs in a young patient with a cardioembolic substrate or antiphospholipid antibodies.

In patients with chest pain syndrome and regional wall motion abnormalities on echocardiography, coronary angiography most commonly reveals normal coronaries or nonobstructive coronary artery disease. In these patients frequently unable to exercise, stress echocardiography yields a low rate of abnormal results. Also, the clinical, electrocardiographic, serologic, and echocardiographic features of lupus myopericarditis or myocarditis mimic acute coronary syndrome. Therefore, coronary angiography may be warranted in patients with SLE with a suspected acute coronary syndrome.

### *Myocardial Disease*

Myocardial disease, manifested predominantly in the form of subclinical ventricular diastolic dysfunction, is common in patients with lupus and has multifactorial pathogenesis. One predominant cause is endothelial dysfunction–mediated microvascular coronary artery disease as determined by a decrease in coronary flow reserve by dipyridamole or adenosine Doppler TTE.[35] A highly prevalent (25% to 35%) arterial hypertension is the second most common cause.[35-40] In addition, premature peripheral arterial stiffness independent of hypertension may cause increased left ventricular (LV) afterload, LV mass, and diastolic dysfunction.[37,40,43,44] Small vessel vasculitis, coronary arteritis, and primary myocarditis are uncommon causes.[45] Rarely, acute lupus myocarditis manifested as clinical congestive heart failure with global or segmental LV dysfunction may be the initial manifestation of active SLE.[45] Finally, a chloroquine sulfate-induced dilated or restrictive cardiomyopathy has been recently reported.[46,47] Many controlled Doppler echocardiography series in asymptomatic patients without systemic or pulmonary hypertension and normal LV systolic function have shown a high prevalence rate (15% to 35%) of variable degrees of LV and right ventricular (RV) diastolic dysfunction.[48-50] Tissue-Doppler parameters and myocardial strain and strain rate are more sensitive than mitral inflow Doppler parameters in detection of early stages of ventricular diastolic and systolic dysfunction.[48-53] Subclinical LV diastolic and systolic dysfunction occur more frequently in patients with longer disease duration and in those with higher disease activity and severity.[49,53] Indicative of microvascular coronary artery disease, LV diastolic dysfunction has been associated with reversible, fixed, and mixed myocardial perfusion defects in young patients with active SLE and normal coronary arteries. In contrast to ventricular diastolic dysfunction, the prevalence rate of systolic dysfunction is less than 20% in unselected patients.[2,3,48,51-54] In summary, Doppler echocardiography is important in the detection of subclinical LV and RV diastolic and systolic dysfunction in patients with lupus. However, the clinical and prognostic implications of these findings need to be determined in longitudinal studies.

### *Pericarditis*

As many as 50% of patients with SLE have at least one episode of symptomatic pericarditis.[55] Most episodes are acute and frequently associated with active SLE. Cardiac tamponade and constrictive pericarditis are uncommon (less than 2%).[55-57] Rarely, acute pericarditis and cardiac tamponade can be the initial manifestation of SLE.[58] Because an effusion is not always present, the diagnosis of pericarditis rests on clinical manifestations, not the echocardiogram. However, echocardiography is of diagnostic value in these patients because pericardial chest pain can be mistaken as musculoskeletal or pleural pain.

An effusion without accompanying signs and symptoms of pericarditis in a patient with lupus results from mild pericarditis, hypoalbuminemia, or pulmonary hypertension with or without cor pulmonale.[59] Asymptomatic effusions are common incidental finding (~20%) in hospitalized patients with active SLE.

Echocardiography is the standard method for the evaluation of suspected SLE pericarditis to assess the size of an effusion and look for signs of tamponade. Tamponade is uncommon in SLE pericarditis, but the high morbidity rate of this complication and the potential for an atypical clinical presentation mandate careful evaluation. Echocardiographic indicators of tamponade should prompt intensive antiinflammatory and immunosuppressive therapy and pericardiocentesis. Echocardiographically guided diagnostic or therapeutic pericardiocentesis has been successfully performed in series of patients with lupus.

Rarely, constrictive or infectious pericarditis may complicate SLE pericarditis. Echocardiography is an effective screening method when constriction is under consideration. However, echocardiography is insensitive for the detection of mild or moderate pericardial thickening. Cardiac magnetic resonance imaging or computed tomography (CT) are preferred methods for assessment of pericardial thickness and are important confirmatory tests when the echocardiogram suggests constriction.

### *Pulmonary Hypertension*

Pulmonary hypertension occurs in at least 15% of patients with SLE. The most common causes include interstitial lung disease, vasculitis, and thromboembolism.[60,61] The association of pulmonary hypertension with Raynaud phenomenon also suggests a vasospastic etiology.[62] In fact, endothelin-1 receptor antagonists improve pulmonary arterial hypertension.[63] Resting and, in selected cases, exercise Doppler echocardiography is commonly used in the diagnosis and assessment of severity, causes, response to therapy, and follow-up of SLE-associated pulmonary hypertension.[60-62]

## Primary Antiphospholipid Syndrome

### BACKGROUND

Primary antiphospholipid syndrome (PAPS) is defined by:

1. Presence of antiphospholipid antibodies;
2. Venous or arterial thrombosis or complicated pregnancy (fetal loss, preeclampsia, and eclampsia); and
3. Lack of diagnostic criteria for other rheumatologic disease.

The diagnosis is established with one or more clinical criteria and one type of antiphospholipid antibodies on two or more occasions at least 6 weeks apart.[8] The pathogenesis of cardiovascular disease associated with PAPS may result from antiphospholipid antibody–induced functional and structural endothelial dysfunction, increased platelet aggregation, increased intrinsic and extrinsic coagulation pathways, and decreased fibrinolysis.[8,64] Cardiovascular disease occurs in 50% to 75% of patients with PAPS and is manifest as valve disease, intracardiac thrombosis and thromboembolism, pulmonary hypertension, nonobstructive coronary disease, and myocardial disease.[64-66]

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Valve Disease*

Valve disease is the most common cardiac manifestation of PAPS. The prevalence, distribution, characteristics, and clinical implications of valve disease in PAPS mimic those of SLE.[11,64-69] Valve disease manifests as valve vegetations, valve thickening, and less commonly, valve regurgitation. In controlled series with TTE, the prevalence rate of left-sided valve disease ranges from 30% to 40%, as compared with less than 5% in controls. With TEE, an even higher prevalence rate of valve disease (60% to 80%) is seen.[70,71] Echocardiographically, and probably histopathologically, vegetations associated with PAPS are indistinguishable from those associated with SLE (Fig. 37-7).[2,3,5,15,16,69-72] As in patients with SLE, valve lesions frequently persist unchanged (50% to 60%), appear de novo (20% to 30%), resolve (20%), uncommonly progress (less than 20%), or need valve replacement (less than 10%) during a 1- to 5-year follow-up period.[71,72] Left-sided valve lesions are associated with thromboembolism to the brain (50%), peripheral and coronary arteries (20% to 25%), and intraabdominal visceras.[70-72] The effect of anticoagulation therapy on valve lesions is generally beneficial, but the effect of antiinflammatory therapy is undefined. However, large controlled longitudinal therapeutic series are not available.[72,73]

#### *Intracardiac Thrombosis and Thromboembolism*

Patients with PAPS have a high prevalence rate (~60%) of left-sided and right-sided thrombotic valve vegetations and intracavitary thrombi.[64-72] Intracardiac thrombi include:

1. Thrombotic valve vegetations that consist of platelet or fibrin thrombi formed on structurally abnormal or rarely normal valves[64-73];
2. Left atrial (LA) appendage thrombi[74];
3. Atrial or ventricular wall or free-floating intracavitary thrombi[75,76];
4. Obstructive thrombi that create a functional tricuspid or mitral stenosis[77,78]; and
5. Thrombi associated with cardiac catheters, wires, or valve prosthesis.[78]

Right-sided heart thrombi are associated with deep venous thrombosis or pulmonary embolism and with right heart catheters or wires. Intracardiac thrombosis in patients with PAPS is predominantly associated with cerebral and peripheral arterial embolism, including the coronary arteries, and is uncommonly associated with pulmonary thromboembolism and rarely with paradoxical embolism. Valve vegetations and intracardiac thrombi are best detected with TEE. Expectedly, real-time 3D TEE may provide superior detection and characterization of valve vegetations and intracardiac thrombi in these patients, but limited data are currently available (see Fig. 37-7).

#### *Pulmonary Hypertension*

The prevalence rate of pulmonary hypertension on prospective echocardiographic series of patients with PAPS is at least 20% to 25% and results predominantly from chronic and recurrent

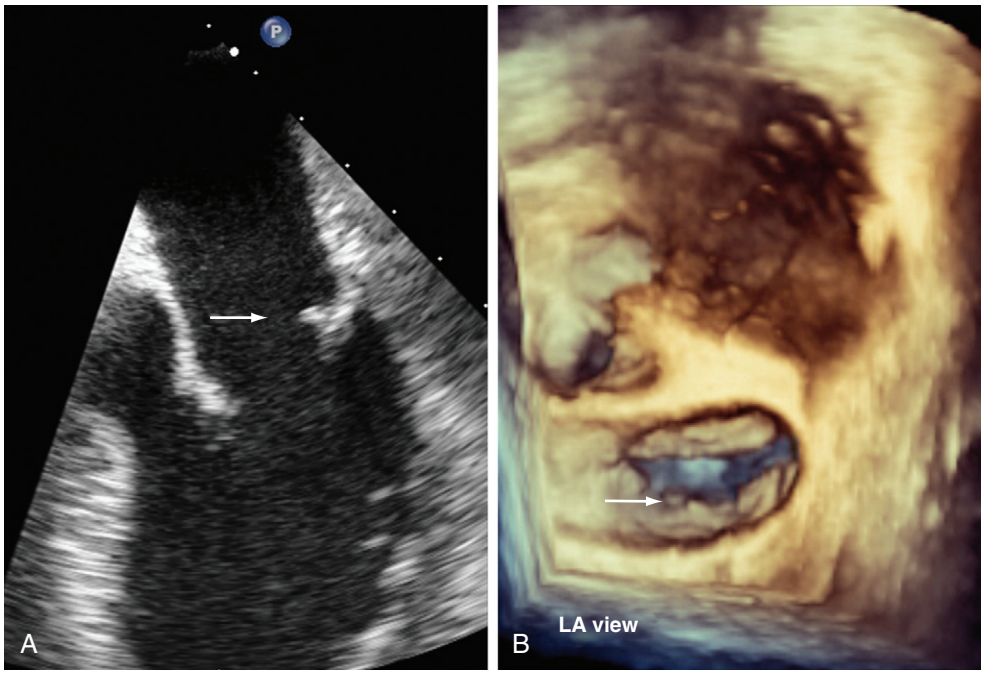

**Figure 37-7** **Mitral valve thrombotic vegetation in a 43-year-old man with primary antiphospholipid antibody syndrome and a stroke.** **A,** This 2D TEE shows a small, oval-shaped, sessile, heterogeneous echoreflectant vegetation with well-defined borders that is located on the mid to distal portions of the posterior mitral leaflet (*arrow*). Diffuse thickening of the posterior leaflet and thickening of the distal portion of the anterior leaflet is also noted. **B,** This real-time 3D TEE of the mitral valve viewed from the atria confirmed the characteristics of the vegetation as seen with 2D images and defined better the exact location of the vegetation at the tip and middle scallop of the posterior leaflet (*arrow*). The mitral valve vegetation resolved completely after several months of warfarin therapy.

pulmonary embolism and uncommonly from an abnormal vasospastic or in situ thrombotic vasculopathy.[72,75,78] Doppler echocardiography has an important role in the diagnosis, assessment of severity, response to therapy, and follow-up of PAPS-associated pulmonary hypertension.

### *Coronary Artery Disease*

Hemostatic abnormalities, possibly inflammation, and increased intake of oxidized low-density lipoprotein by activated macrophages in the coronary vessel wall cause endothelial damage and dysfunction, vasoconstriction, thrombosis, and atherosclerosis.[8,79,80] High prevalence rates of increased intima media thickness but no plaques of the carotid arteries are reported in these patients.[80,81] A high prevalence rate (20% to 35%) of myocardial infarction has been reported in patients with PAPS and results from microvascular disease, in situ coronary thrombosis, or coronary thromboembolism.[70,72,82,83] No series are found that systematically use resting or stress echocardiography for detection of epicardial coronary artery disease in patients with PAPS, but the sensitivity of these techniques is likely low given the low prevalence of epicardial atherosclerosis.

### *Myocardial Disease*

In small controlled cross-sectional studies of asymptomatic patients with PAPS, a high prevalence of LV diastolic dysfunction, predominantly impaired relaxation, is reported.[84] The mechanisms of diastolic dysfunction include microvascular coronary artery disease, thrombotic microangiopathy, and rarely, primary myocardial disease. Rarely, catastrophic PAPS may manifest as dilated cardiomyopathy with LV thrombus. RV diastolic dysfunction, predominantly impaired relaxation, is also common in patients with PAPS with pulmonary hypertension.[49]

## Rheumatoid Arthritis

### BACKGROUND

Rheumatoid arthritis is characterized by symmetric arthritis that involves any synovial joint but usually affects the metacarpophalangeal and proximal interphalangeal joints and wrists. Other manifestations of rheumatoid arthritis include rheumatoid nodules, systemic vasculitis, glomerulonephritis, pulmonary fibrosis, and cardiovascular disease.[85] Clinically apparent heart disease occurs in 25% to 40% of patients with rheumatoid arthritis. Heart disease is the third leading cause of death in patients with rheumatoid arthritis and accounts for nearly 40% of deaths.[86]

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Coronary Artery Disease*

After controlling for traditional atherogenic risk factors, the prevalence of coronary artery disease in patients with rheumatoid arthritis is two to three times higher than in matched controls.[87] Coronary arteritis is rare, whereas typical atherosclerotic epicardial coronary artery disease is common, often symptomatic, and associated with increased morbidity and mortality.[88] Estimates are that by age 65 to 70 years, 75% to 80% of patients with rheumatoid arthritis have angiographic evidence of coronary artery disease (30% with three vessels of coronary artery disease) and a high incidence of myocardial infarction (4.8 to 5.9 events per 1000 person-years). In addition, microvascular disease is common and correlates with levels of asymmetric dimethylarginine (an endogenous inhibitor of nitric oxide synthase).[89-91] Coronary artery disease accounts for at least 40% of the mortality of patients with rheumatoid arthritis.[88]

The pathogenesis of coronary artery disease in patients with rheumatoid arthritis is similar to that described for patients with SLE.[85,87,89-93] The rheumatoid arthritis–related clinical predictors of epicardial, microvascular, and inflammatory coronary artery disease include older age at onset of rheumatoid arthritis, longer duration of corticosteroid therapy, and long-standing disease (more than 10 years); active extraarticular, erosive polyarticular, and nodular disease; vasculitis; high titers of rheumatoid factor; high levels of haptoglobin, Von Willebrand factor, and plasminogen activator inhibitor; high levels of interleukins 1 and 6; and an erythrocyte sedimentation rate of more than 55 mm Hg. Compared with matched controls, a twofold increased risk is found for myocardial infarction, congestive heart failure, stroke, and cardiovascular mortality in patients with rheumatoid arthritis with elevated markers of inflammation and in those with reduced small and large arteries elasticity.[94-96] Patients with rheumatoid arthritis with an acute coronary syndrome have a higher recurrence rate of events and mortality than matched controls (58% versus 30% and 40% versus 15%, respectively).[97] Also, coronary artery bypass grafting surgical morbidity and mortality rates of patients with rheumatoid arthritis are two to four times higher than those of matched controls. In addition, a high prevalence rate (up to 61%) of subclinical coronary artery disease as determined with coronary artery calcification on computed tomography is seen in patients with established disease as compared with those with recent onset of the disease (43%) and matched controls (38%).[98] Furthermore, cyclooxygenase-2 selective inhibitors (which inhibit prostaglandin I-2, a vasodilator and inhibitor of platelet aggregation) and nonsteroidal anti-inflammatory drugs increase the risk of acute coronary syndromes in patients with rheumatoid arthritis.[99] Amelioration of inflammation with corticosteroids, cytotoxics, and disease-modifying antirheumatic drugs such as tumor necrosis factor–α blockers, inhibitors of interleukin 6, and statins decreases vascular inflammation and dysfunction and consequently the risk of adverse cardiovascular outcomes.[91,100,101]

Although rare, coronary vasculitis can affect small or medium-sized intramyocardial arteries. In patients with rheumatoid arthritis with an acute coronary syndrome from coronary arteritis, aggressive antiinflammatory and immunosuppressive therapy in conjunction with standard therapy, including coronary stents and surgical revascularization, has been successful (see Case 37-2 at ExpertConsult.com).

As in the general population, resting and stress echocardiography are useful in the detection of wall motion abnormalities in those with obstructive coronary artery disease but have decreased sensitivity for microvascular disease. Symptomatic patients with rheumatoid arthritis often have evidence of ischemia on resting and exercise echocardiography, and the presence of ischemia on exercise echocardiography portends a three times higher mortality rate than in matched controls with negative resting or exercise studies.[102] Also, dipyridamole or adenosine TTE can be used to assess coronary flow reserve in those with microvascular disease.

### *Pericarditis*

Echocardiographic studies have shown pericardial effusions in as many as 50% of patients with rheumatoid arthritis, but symptomatic pericarditis is less common. Pericarditis occurs in patients with active disease with similar clinical and serologic characteristics of those with coronary artery disease. Immunofluorescent staining of the pericardium reveals deposits of immunoglobulin G, immunoglobulin M, C3, and C1q, which indicates autoimmune injury. The pericardial effusion is exudative and bloody with a low glucose level, and it may contain rheumatoid factor. As in SLE pericarditis, tamponade and constriction are rarely reported. Also, asymptomatic pericardial effusions are seen in about 25% of patients and are associated with renal disease, hypoalbuminemia, and pulmonary hypertension.[103] The role of echocardiography in the diagnosis, management, and follow-up of rheumatoid effusions parallels its role in SLE pericarditis.[104]

### *Valve Disease*

Estimates of the clinical prevalence of valve disease in rheumatoid arthritis are undefined. The reported prevalence rate of valve abnormalities in unselected patients less than 60 years old is as low as 30% with TTE and nearly 60% with TEE.[85,105] Valve disease occur in five forms:

1. Valve nodules;
2. Healed valvulitis with residual leaflet fibrosis and regurgitation and rarely stenosis;
3. Acute chronic valvulitis;
4. Rarely acute valvulitis with Libman-Sacks–like vegetations; and
5. superimposed infective endocarditis.[85,105-107]

Acute and chronic valvulitis with resulting leaflet thickening or fibrosis is indistinguishable from that seen in SLE. Chronic inflammation may also promote accelerated leaflet fibrosis, calcification, and valve stenosis.[108] In contrast, valve nodules appear to be unique to rheumatoid arthritis. These nodules can also be seen on valve rings, papillary muscle tips, and atrial or ventricular endocardium.[109] Histologically, the valve nodules resemble subcutaneous nodules and may result from a process of focal vasculitis.

On TEE, rheumatoid valve nodules are detected in one third of patients; they usually appear as small (less than 0.5 $cm^2$) spheroid masses with homogeneous reflectance, typically appearing singly and on any portion of the leaflet.[105] The adjacent leaflet appears normal or shows mild sclerosis. This picture is unlike that of Libman-Sacks vegetations (compare Fig. 37-1 with Fig. 37-5 with Fig. 37-8). Acute valvulitis with superimposed Libman-Sacks–like vegetations can occur (Fig. 37-9). Valve thickening is detected in half of patients and is equally diffuse or localized (when localized affects any leaflet portion), is usually mild, involves equally the mitral and aortic valves, and involves rarely the annulus and subvalvular apparatus. Mild or worse valve regurgitation is seen in 20% to 25% of patients, but stenosis is rare (Fig. 37-10). However, in severe single or multiple acute valvulitis, diffuse leaflets thickening and moderate to severe valve regurgitation can occur (see Question 37-3 at ExpertConsult.com).

Rheumatoid valve disease is generally mild and asymptomatic, and it is less likely than SLE valve disease to result in clinically significant valve dysfunction. However, several uncommon severe manifestations of the disease have been described:

1. Valve thrombus overimposed on a valve nodule, Libman-Sacks–like vegetations, or superimposed valve strands complicated with systemic embolism (see Fig. 37-9)[105,110];
2. Acute or recurrent valvulitis that results in severe valve regurgitation and rarely stenosis (see Fig. 37-10)[109];
3. Acute severe valve regurgitation from rupture of a single or coalescent nodule or a large nodule that affects leaflet coapation[111];
4. Aortitis with aortic root dilation and aortic regurgitation; and
5. Superimposed infective endocarditis.[107]

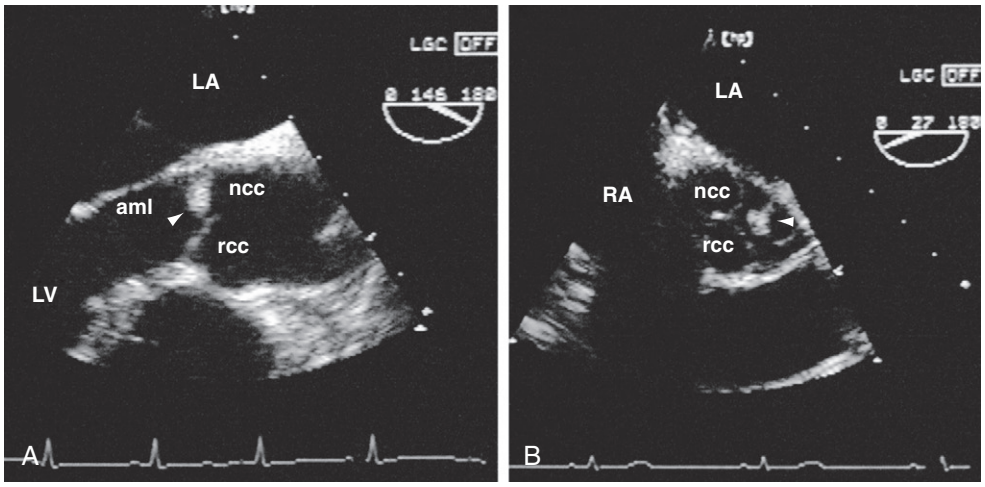

**Figure 37-8** **Rheumatoid aortic valve nodules in young asymptomatic patients. A,** This TEE view longitudinal to the outflow tract in a 48-year-old woman with rheumatoid arthritis shows an oval-shaped nodule with well-defined borders and homogeneous soft tissue echoreflectance within the midportion of the aortic noncoronary cusp (*ncc; arrowhead*). The appearance of the right coronary cusps is normal. Aortic valve regurgitation was not shown. **B,** This TEE short-axis view of the aortic valve in a 43-year-old man with rheumatoid arthritis shows a well-defined nodule with homogeneously increased echoreflectance within the tip and midportion of the left coronary cusp (*arrowhead*). Note the normal appearance of the uninvolved portions of the cusp and that of the noncoronary cusp and right coronary cusp (*rcc*). Mild aortic valve regurgitation was detected. *aml*, Anterior mitral leaflet.

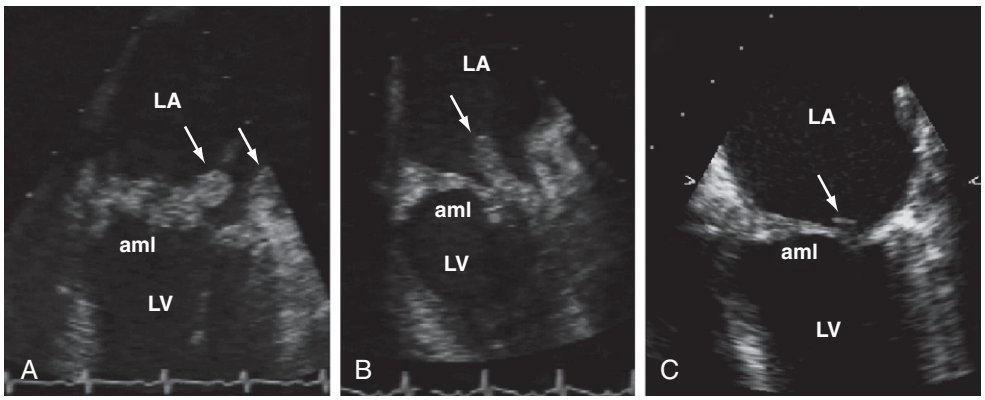

**Figure 37-9** **Severe mitral valvulitis with Libman-Sacks–like vegetations in a 52-year-old woman with severe rheumatoid arthritis and recurrent transient ischemic attacks. A,** This close-up four-chamber TEE view when patient presented with a transient ischemic attack shows severe and irregular thickening with soft tissue echoreflectance of the anterior and posterior mitral leaflets. Two large, multilobed masses, with irregular borders and with soft tissue echoreflectant, are noted on the atrial side of the anterior (*aml*) and posterior mitral leaflets (*arrows*). **B,** Close-up four-chamber TEE view after 3 months of warfarin, steroids, and tumor necrosis factor–α receptor inhibitors shows remarkable improvement of the thickening of the mitral leaflets, complete resolution of the anterior mitral leaflet vegetation, and reduction in size of the posterior mitral leaflet (*arrow*). **C,** Close-up four-chamber TEE view after 6 months of therapy shows further improvement in the thickening of the mitral leaflets and a very small residual vegetation on the atrial side and tip of the posterior mitral leaflet (*arrow*). Also, mitral regurgitation improved from moderate to trivial.

The short-term and long-term mortality rates of patients with rheumatoid arthritis with valve disease are significantly higher than those of matched controls. In small case series, the 30-day and 1-year morbidity and mortality rates of patients with rheumatoid arthritis undergoing valve replacement or rarely valve repair are two to three times higher than those of patients without rheumatoid arthritis.[109] Early diagnosis and aggressive antiinflammatory or immunosuppressive therapy may decrease the progression of the disease and improve patient survival. Therefore, TTE and TEE continue to play an important role in the diagnosis, characterization, management, and follow-up of rheumatoid valve disease.

### *Myocardial Disease*

Patients with rheumatoid arthritis have a high prevalence rate of subclinical and clinical LV and RV diastolic dysfunction as compared with matched controls (30% to 76% versus less than 20%, respectively) in multiple Doppler echocardiography series.[112-116] The pathogenetic factors for ventricular diastolic dysfunction are similar to those described in SLE.[90,91,113] Lower E′ and A′ velocities and increased E/E′ ratio with tissue Doppler imaging, lower color flow propagation velocity, decreased longitudinal myocardial strain and strain rate, and increased myocardial performance index are more sensitive than mitral or tricuspid inflow Doppler parameters. The clinical predictors of myocardial disease are similar to those described for coronary artery disease and valve disease. Also, large longitudinal series have shown a high incidence rate (35% to 40%) of clinical diastolic congestive heart failure independent of traditional risk factors for diastolic dysfunction. In these patients, diastolic congestive heart failure doubles the mortality risk as compared with matched controls with diastolic congestive heart failure but no

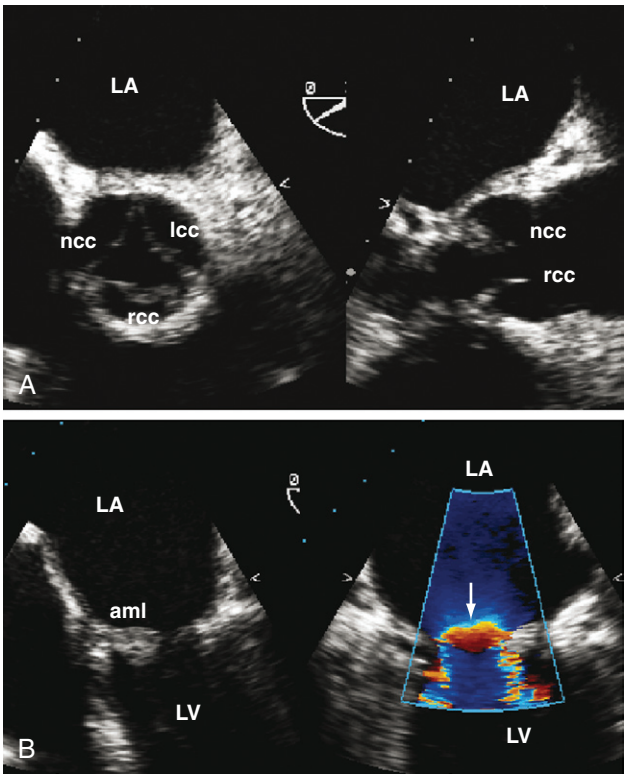

**Figure 37-10 Aortic and mitral stenosis in a patient with severe rheumatoid arthritis. A,** The short-axis and longitudinal TEE views of the aortic valve show diffuse soft tissue thickening and decreased mobility of the aortic cusps. An associated peak aortic valve gradient of 19 mm Hg consistent with mild aortic stenosis and mild aortic regurgitation was shown with continuous wave Doppler imaging. **B,** These close-up four-chamber TEE views of the mitral valve show severe soft-tissue thickening predominantly of the base and midportion of the mitral leaflets with significantly decreased mobility. Note the large acceleration zone with color Doppler imaging (*arrow*) of the mitral inflow that suggests mitral valve stenosis. Continuous wave Doppler imaging confirmed the presence of moderate mitral stenosis. Associated mild mitral regurgitation was also seen. This TEE was performed several months after patient had a flare of her disease associated with pancarditis. *aml,* Anterior mitral leaflet; *lcc,* left coronary cusp; *ncc,* noncoronary cusp; *rcc,* right coronary cusp.

rheumatoid arthritis.[117,118] The incidence rate of congestive heart failure decreases with tumor necrosis factor–α blocker therapy.[118] Pulmonary hypertension is the most common cause of RV diastolic dysfunction in patients with rheumatoid arthritis, but microvascular coronary artery disease and autoimmune mediated myocardial disease also play a role. Some patients with rheumatoid arthritis have myocarditis, myocardial nodules, or cardiac amyloidosis. Evidence of present or past myocarditis is revealed at autopsy in as many as 30% of patients, but decreased LV ejection fraction with echocardiography is less common. Myocarditis, associated with SS-A/SS-B autoantibodies can mimic non-ST and ST elevation myocardial infarction clinically, electrocardiographically, serologically, and echocardiographically.[119] Recently, a dilated or restrictive cardiomyopathy from chloroquine therapy has been reported.[120] Finally, rarely rheumatoid arthritis–associated myocardial amyloidosis can occur.

### *Pulmonary Hypertension*

Pulmonary hypertension with normal pulmonary venous pressure resulting from interstitial fibrosis, pulmonary vasculitis, or obliterative bronchiolitis is more common than left heart disease. In controlled series of asymptomatic patients, the prevalence rate of pulmonary hypertension by echocardiography is five times higher in patients with rheumatoid arthritis than in controls (21% versus 4%) and is even higher in those with symptoms or evidence of pulmonary disease.[121] The mortality rate is high within 1 year of diagnosis. Prompt diagnosis is vital because these conditions are responsive to immunosuppressive therapy.

Therefore, if pulmonary hypertension is identified, LA hypertension should be excluded and then the search for a treatable pulmonary cause should be pursued. When pulmonary hypertension is diagnosed in asymptomatic or symptomatic patients, echocardiography is useful not only for assessment of its severity and associated RV diastolic or systolic dysfunction and tricuspid regurgitation but also for assessment of the short-term and long-term response to therapy.

## Ankylosing Spondylitis

### BACKGROUND

Ankylosing spondylitis and other human leukocyte antigen-B27–related arthropathies are characterized by inflammation of the vertebral and sacroiliac joints. Arthritis of other joints, uveitis, and proximal aortitis and aortic valvulitis are common. Although arthritis may be disabling, the overall prognosis is good.

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Aortitis and Valve Disease*

Aortic root and valve disease in patients with ankylosing spondylitis is categorized as:

1. Proximal aortitis that leads to aortic root thickening, stiffness, dilation, and rarely aneurysm formation, all of which contribute to aortic regurgitation;
2. Aortic valvulitis that results in cusp thickening and retraction and also leads to aortic regurgitation;
3. Thickening of the aortomitral junction or "subaortic bump" that causes anterior mitral leaflet retraction with decreased mobility and asymmetric or incomplete mitral leaflet coaptation that leads to mitral regurgitation; and
4. Extension of the subaortic fibrotic process into the basal septum, atrioventricular node, proximal bundle of His, and bundle branches or fascicles that causes conduction disturbances.[122]

The reason for selective injury of the proximal aorta by this human leukocyte antigen-B27–mediated mononuclear cellular inflammatory process is unknown.

The prevalence of clinically manifested ascending aorta and aortic and mitral valve disease varies widely but is probably about 20%. Aortic or mitral regurgitation is generally mild to moderate. However, acute or healed aortitis, acute or healed aortic valvulitis, and superimposed infective endocarditis can lead to severe aortic regurgitation.[122-124]

In several echocardiographic studies, including TEE series, aortic root thickening or sclerosis (predominantly of the posterior wall), increased stiffness, and dilation range from 20% to 60%, 60%, and 25% to 50% of patients, respectively.[122,125,126] Aortic valve thickening seen in 40% of patients is manifested mainly as nodularities of the aortic cusps. Mitral valve thickening seen in one third of patients is manifested as basal thickening of the anterior mitral leaflet, forming the characteristic

subaortic bump. Valve regurgitation seen in almost half of patients was moderate in one third of them. Aortic root disease and valve disease are related to duration of the disease but are not temporally related to its activity, severity, or therapy (Figs. 37-11 and 37-12).[122,127] Mitral valve prolapse or myxomatous mitral leaflets with mild or moderate regurgitation is reported in 10% to 15% of patients.

The effect of corticosteroids or disease-modifying antirheumatic drug therapy on aortic root, valve disease, and conduction disturbances is uncertain. Because of the absence of multiorgan disease and infrequent use of corticosteroids or cytotoxics in patients with ankylosing spondylitis, the mortality rate during valve replacement is probably similar to that of the general population.

### *Conduction Abnormalities*

Atrioventricular and intraventricular conduction blocks occur in 20% or more of patients with ankylosing spondylitis.[128] Echocardiographic studies have shown an association of conduction abnormalities with aortic root thickening and subaortic bump, suggesting a role for extension of aortic root fibrosis into the proximal septum and atrioventricular node.[122,125,128] In a controlled tissue-Doppler echocardiography series, an increase in interatrial and intraatrial electromechanical coupling intervals has been demonstrated.[129] However, the clinical significance of these findings is uncertain.

### *Myocardial and Pericardial Disease*

Although the frequency of myocardial disease in patients with ankylosing spondylitis is higher than in the general population, it is generally subclinical and therefore more commonly incidentally detected. Patients with ankylosing spondylitis also have microvascular disease, which is associated with subclinical diastolic dysfunction.[130] In addition, the associated aortic stiffness may lead to increased LV afterload, LV mass, and diastolic dysfunction.[131] Few controlled Doppler echocardiography series in patients less than 50 years old with no clinical heart disease have uncommonly reported LV systolic dysfunction. In contrast, a 20% to 30% prevalence rate of diastolic dysfunction, predominantly impaired relaxation, has been reported. The prevalence rates of diastolic dysfunction are higher (up to 50%) with tissue-Doppler echocardiography.[129,132] In these studies, diastolic dysfunction was temporally unrelated to age, disease duration, or disease activity. Rarely, cardiac amyloidosis with diastolic congestive heart failure has been reported.

The prevalence of pericardial disease in patients with ankylosing spondylitis is rare, and the rate is probably similar to that of the general population (less than 2%). Echocardiographic studies report incidentally detected small pericardial effusions.

## Scleroderma

### BACKGROUND

In scleroderma, excessive connective tissue overproduction and accumulation, structural and functional microvascular disease, and immune-complex deposition affect the blood vessels, skin, joints, skeletal muscle, and multiple organs, including all structures of the heart. Thickening of the skin and Raynaud phenomenon affect more than 90% of patients. In the diffuse type, symmetric fibrosis of the skin of the face, trunk, and extremities is seen, with frequent involvement of internal organs. In the limited cutaneous type, the skin changes are limited to the extremities and face; internal organs are generally spared. This latter type is associated with the calcinosis, Raynaud phenomenon, esophageal hypomotility, sclerodactyly, and telangiectasia syndrome.

Cardiovascular disease occurs in as many as 50% of patients with scleroderma.[133] The predominant findings are functional and structural microvascular coronary artery disease, myocarditis, pulmonary and systemic hypertension-related heart disease, and pericarditis.[133-136] Atrial and ventricular arrhythmias and conduction abnormalities are less common but clinically relevant. Overall, pulmonary fibrosis and pulmonary arterial hypertension with or without cor pulmonale, congestive heart failure, and arrhythmias are the leading causes of death in patients with scleroderma.[137]

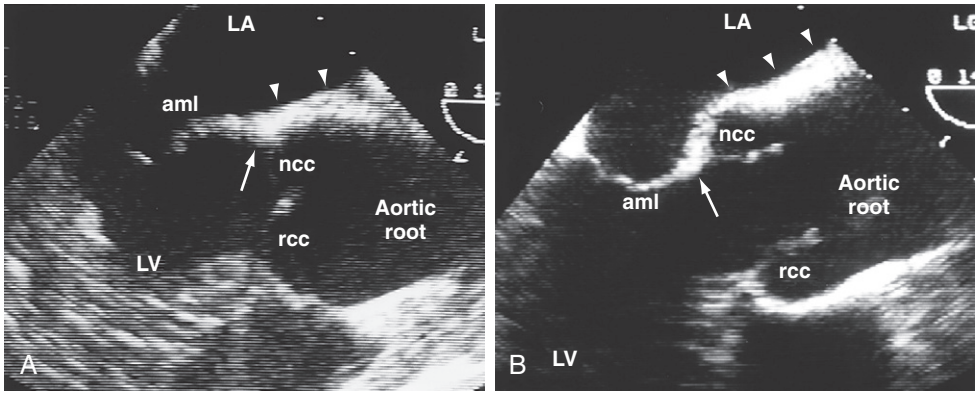

**Figure 37-11 Aortic root and aortic and mitral valves disease in patients with ankylosing spondylitis. A,** This TEE view longitudinal to the outflow tract in a 31-year-old man with progressive dyspnea of exertion and a diastolic murmur shows marked thickening of the posteromedial aortic root (*arrowheads*) extending to the basal portion of the noncoronary cusp (*ncc*) and into the base and midportions of the anterior mitral leaflet (subaortic bump; *arrow*). Mild thickening of the right coronary cusp (*rcc*) tip and mild aortic root dilation are also noted. Moderate to severe aortic regurgitation was shown. Therefore, the patient underwent an uncomplicated aortic valve replacement. **B,** This TEE view longitudinal to the outflow tract in a 43-year-old man shows severe sclerosis of the aortic root predominantly of the posteromedial wall (*arrowheads*) extending to the base of the anterior mitral leaflet (*aml*) to form the subaortic bump (*arrow*). Moderate aortic root dilation is present. The noncoronary (*ncc*) and right coronary cusp (*rcc*) show mild localized thickening of the middle and tip portions. Moderate aortic regurgitation was shown.

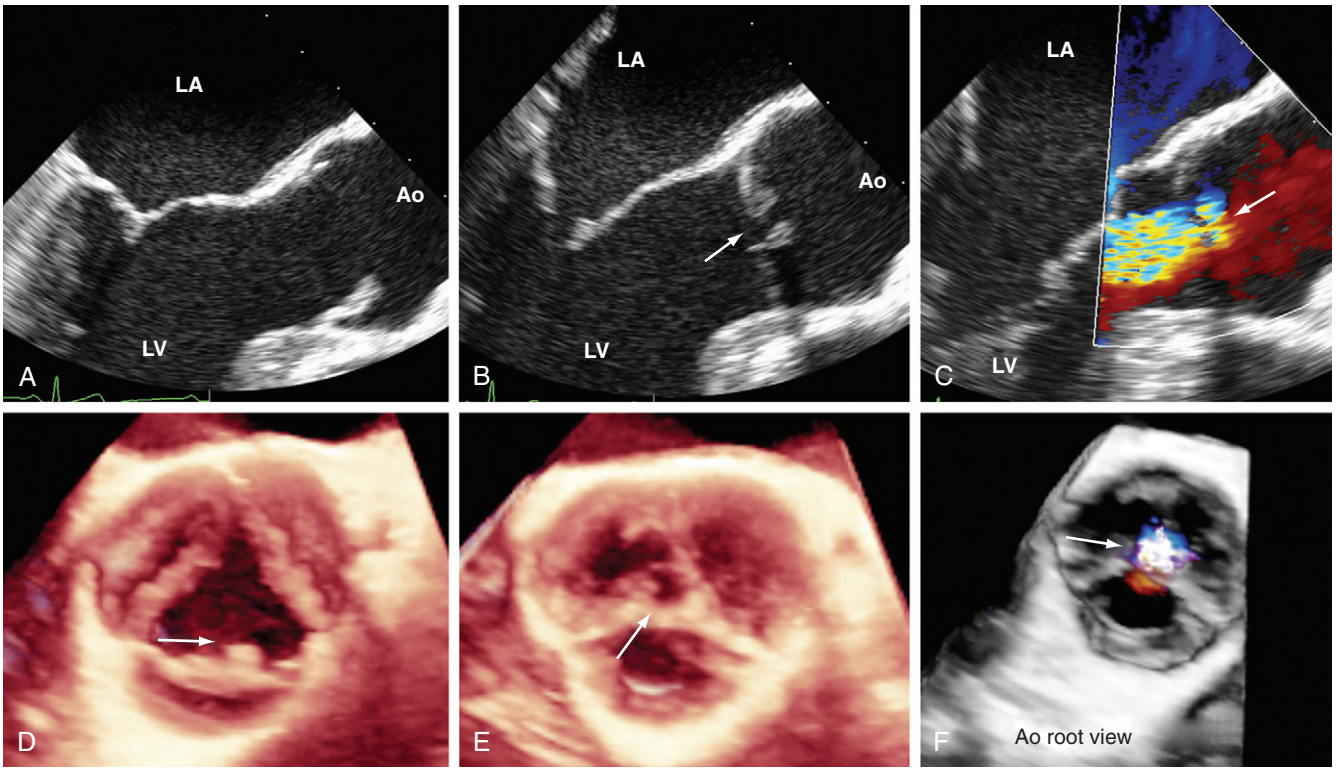

**Figure 37-12 Aortic valvulitis in a 37-year-old man with ankylosing spondylitis. A,** Two-dimensional TEE long-axis view during systole shows cusps thickening, retraction, and decreased doming mobility predominantly of the right coronary cusp. Also note aortic root sclerosis and mild thickening extending to the base of the anterior mitral leaflet (subaortic bump; *arrow*). **B,** Two-dimensional TEE long-axis view during diastole shows thickening predominantly of the tip portions and retraction of the aortic cusps leading to an incomplete coaptation (*arrow*). **C,** Two-dimensional TEE long-axis view with color Doppler imaging shows moderate aortic regurgitation based on a flow convergence zone of 3 mm (*arrow*), a vena contracta of 4 mm, and a jet height to LV outflow tract height ratio of 40%. **D,** Real-time 3D TEE of the aortic valve viewed from the aortic root and during systole defines better the moderate and diffuse thickening of the cusp tips and decreased mobility of all three cusps. Also a well-defined oval nodularity at the tip and ventricular side of the right coronary cusp is noted (*arrow*). **E,** During diastole, note the cusps retraction that leads to an incomplete central coaptation (*arrow*). **F,** With real-time 3D TEE of the aortic valve viewed from the aorta, the effective regurgitant orifice area and vena contracta area were 0.18 $cm^2$ and 0.19 $cm^2$ (*arrows*), respectively, confirming the severity of aortic regurgitation as moderate.

## ASSOCIATED CARDIOVASCULAR INVOLVEMENT

### *Coronary Artery Disease*

In scleroderma, the intramyocardial coronary arteries and arterioles are predominantly affected by two main mechanisms. The first is abnormally increased vasoconstriction that results from an immune-mediated inflammatory endothelial dysfunction. In these patients, high levels of asymmetric dimethylarginine, an endogenous inhibitor of nitric oxide synthase, have been reported, and intramyocardial coronary arterial spasm is highly associated with peripheral Raynaud phenomenon.[134,135,138] The second mechanism is obstructive microvascular disease that results from endothelial proliferation, intimal hypertrophy, intimal smooth muscle cell migration, fibrinoid necrosis, fibrosis, and ultimately, vessel narrowing. Consequently, focal or diffuse contraction band necrosis (from ischemia and reperfusion) and myocardial fibrosis occur. The prevalence of epicardial atherosclerotic disease is of less clinical relevance than microvascular disease. In fact, coronary angiography in asymptomatic patients with diffuse scleroderma shows normal or ectatic coronary arteries with slow flow indicative of increased intramyocardial coronary resistance; in those with typical or atypical angina, epicardial coronary artery disease is seen in more than 50% of patients, and in patients with myocardial infarction, normal epicardial arteries are seen in more than 30% of patients. Therefore, typical acute coronary syndrome, including myocardial infarction, is uncommon in these patients (less than 2%). Ischemic heart disease is most commonly manifested as subacute or chronic diastolic and uncommonly systolic congestive heart failure. However, acute ischemic congestive heart failure and sudden death rarely occur.

Because of predominant microvascular disease, echocardiographic findings typical of transmural ischemia or myocardial infarction are uncommon. In several prospective controlled series with Doppler TTE in asymptomatic young patients, reduction in coronary flow reserve (less than 2.5) during dipyridamole or adenosine infusion was detected in up to 50% of patients as compared with less than 5% of matched controls.[134,135] Reduction in coronary flow reserve is more common in the diffuse form of scleroderma and is related to the severity and duration of peripheral Raynaud phenomenon and duration and severity of the disease. As a result of microvascular disease, LV and RV diastolic and uncommonly systolic dysfunction can occur.[133,136,138] In contrast to typical atherosclerotic disease, areas of ischemic necrosis and fibrosis do not correspond to the regional distribution of a coronary artery and myocardial fibrosis is predominantly subendocardial and at the base and mid portions of both the LV and the RV. Occasionally, a transmural myocardial infarction from epicardial coronary vasospasm can occur, and its echocardiographic diagnosis relies on the same findings as those of atherosclerotic disease. The

cold pressor test with myocardial perfusion scanning and echocardiography shows transient wall motion abnormalities that correspond to reversible, fixed, or mixed perfusion abnormalities in patients with angiographically unremarkable epicardial coronary arteries. Symptoms and myocardial perfusion abnormalities improve with coronary vasodilator therapy.[139]

### *Myocardial Disease*

Myocardial disease is more common in patients with diffuse cutaneous involvement, anti-Scl70 and anticentromere antibodies, peripheral myopathy, and Raynaud phenomenon and in those with microvascular coronary artery disease.[133-137] Patchy myocyte contraction band necrosis (typical of ischemia and reperfusion) with myocardial fibrosis is characteristic of the disease and is reported in up to 80% in postmortem series. These data suggest that microvascular coronary artery disease is a common cause of scleroderma-associated myocardial disease. Also, patients with scleroderma commonly have septal infarction pattern, ventricular arrhythmias, or conduction abnormalities on electrocardiography, which are associated with fixed septal or anteroseptal perfusion abnormalities and correspond to areas of myocardial fibrosis on gadolinium-enhanced myocardial magnetic resonance imaging. Therefore, myocardial dysfunction in patients with scleroderma is also related to increased interstitial collagen deposition and fibrosis. Autoimmune-mediated myocarditis is uncommon. Independently of the pathogenesis, systolic congestive heart failure is associated with a high mortality rate (up to 80% at 1 year).[137]

In multiple controlled cross-sectional and longitudinal series with Doppler echocardiography, a high prevalence rate (30% to 50%) of LV and RV diastolic dysfunction is seen in unselected middle-aged patients with either diffuse or limited cutaneous disease as compared with less than 10% in controls.[135,136,138-144] Tissue-Doppler and myocardial strain and strain rate are more sensitive than mitral and tricuspid inflow patterns (60% versus 30%, respectively). Ventricular diastolic dysfunction correlates with higher levels of inflammatory markers and with the duration and severity of Raynaud phenomenon.[134,135,138,145] Right ventricular diastolic dysfunction is more common in those with pulmonary hypertension but also occurs in those without pulmonary or LA hypertension. A RV tissue-Doppler E velocity of less than 11 cm/s is found in select patients with pulmonary artery pressure greater than 35 mm Hg. Also, controlled Doppler echocardiographic series in middle-aged patients with normal LV ejection fraction, RV ejection fraction, and pulmonary artery pressure have shown significantly decreased tissue-Doppler systolic velocities of the mitral and tricuspid annulus in 15% to 20% of patients.[142-144] These findings also suggest subclinical LV and RV systolic dysfunction in these patients. Of clinical relevance, LV and RV diastolic dysfunction improve with vasodilators, including endothelin antagonists.[139] Finally, the short-term and long-term implications of subclinical diastolic and systolic dysfunction are still undefined.

### *Pulmonary Hypertension and Cor Pulmonale*

Interstitial lung disease and pulmonary arterial hypertension are major features and causes of mortality in scleroderma.[137] Pulmonary fibrosis can occur in as many as 80% and pulmonary hypertension in as many as 35% to 50% of patients in series with resting and exercise Doppler echocardiography and right heart catheterization.[146-148] The incidence of pulmonary hypertension is also high during a 3-year follow-up period of these patients.[149] Pulmonary arterial hypertension from inflammatory vasculopathy or pulmonary vasospasm is less common and is more often associated with the limited cutaneous type, Raynaud phenomenon, parameters of endothelial dysfunction, and anticentromere antibodies.[148,150,151] Abnormal pulmonary function tests, abnormal lung uptake of gallium and technetium-99 m sestamibi, and radiographic abnormalities often precede cor pulmonale on echocardiography. Patients with pulmonary hypertension have a decreased survival rate of 81%, 63%, and 56% at 1, 2, and 3 years, respectively, from the diagnosis and independent of the etiology of pulmonary hypertension.[137,152] Resting or exercise Doppler echocardiography are of important value in the detection and assessment of severity, pathogenesis, and response to therapy of pulmonary hypertension (see Question 37-4 at ExpertConsult.com).[146-148] A significant increase (20 mm Hg or more) from resting to peak exercise echocardiography is seen in up to 40% of patients with scleroderma with dyspnea of exertion or abnormal pulmonary function tests.[147,153] However, the sensitivity of Doppler echocardiography for detection of pulmonary hypertension as compared with right heart catheterization is moderate (about 60%) but highly specific (98%). Therefore, in patients with suspected symptomatic pulmonary hypertension, the ultimate diagnosis and therapeutic decisions may be best determined with right heart catheterization.

### *Pericarditis*

Clinically evident or symptomatic pericardial disease occurs in 4% to 17% of patients with scleroderma and manifests as acute pericarditis and rarely as cardiac tamponade or pericardial constriction.[154] This low clinical prevalence contrasts with that of postmortem and echocardiographic series, especially of asymptomatic pericardial effusions (30% to 50%). Asymptomatic pericardial effusions on echocardiography or computed tomography are common (up to 50%) in patients with pulmonary hypertension and hypoalbuminemia.[154] Symptomatic pericardial disease is two to four times more common in patients with the diffuse form than with the limited cutaneous form of the disease. Pericardial disease is rarely the initial manifestation of scleroderma.

### *Valve Disease*

Published data suggest that scleroderma rarely cause primary valve disease. Reports have described small masses similar to Libman-Sacks vegetations, aortitis, and aortic regurgitation and an unexplained increased frequency of mitral valve prolapse.[146,155,156] Because of the high prevalence of pulmonary hypertension and cor pulmonale, functional tricuspid regurgitation is common and predominantly of mild to moderate degree.

## Polymyositis and Dermatomyositis

### BACKGROUND

Polymyositis and dermatomyositis are clinically similar diseases characterized by autoimmune-mediated skeletal muscle inflammation that leads to symmetric proximal muscle weakness. Unlike polymyositis, dermatomyositis is accompanied by a rash on the face, neck, chest, and extensor surfaces of the extremities. Overlap syndromes frequently occur, in which features of

dermatomyositis or polymyositis are combined with those of SLE, rheumatoid arthritis, and scleroderma. Rarely, polymyositis or dermatomyositis can be associated with antiphospholipid antibody syndrome.

Myocarditis, pericarditis, and functional or structural microvascular coronary artery disease are the most common cardiac manifestations of polymyositis and dermatomyositis.[157] Epicardial atherosclerotic coronary artery disease, conduction disorders, valve dysfunction, and pulmonary hypertension are uncommon. As a result of the lack of controlled cross-sectional and longitudinal studies, reported prevalence rates of cardiovascular disease are highly variable. Although clinically manifested heart disease may occur in less than 25% of patients, it accounts for at least 10% of mortality.

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Myocardial Disease*

Myocardial disease is the result of a direct autoimmune myocardial inflammatory process and less likely of a functional microvascular coronary artery disease.[158] In postmortem series, as many as 50% of patients with polymyositis or dermatomyositis show histologic evidence of active or healed myocarditis. Although the clinical prevalence of myocarditis is unknown, approximately 10% to 20% of those who have myocarditis may have cardiomyopathy develop. Patients with myocarditis frequently have active skeletal myositis; as many as 50% of those with peripheral myositis, as indicated by uptake of technetium-99m pyrophosphate, also have myocardial uptake.[159] Rarely, a fulminant myocarditis with severe LV systolic dysfunction may be the initial manifestation of the disease. Also, acute myocarditis can mimic an acute coronary syndrome based on symptoms, non-ST and ST elevation, elevation of CPK-MB and troponin T from regenerating chronically inflamed muscles, and echocardiographic wall motion abnormalities.[160] Limited prospective echocardiographic studies suggest that few patients with polymyositis or dermatomyositis manifest wall motion abnormalities or a decreased LV ejection fraction during the course of their disease. In noncontrolled small series and a recent controlled Doppler echocardiography series, subclinical LV diastolic dysfunction as impaired relaxation was reported in 12% to 40% of patients.[158]

#### *Pericarditis*

The prevalence rate of clinically apparent pericardial disease in patients with polymyositis and dermatomyositis is low (~10%). Pericarditis is more frequent in patients with the overlap syndrome and in children. Pericarditis and cardiac tamponade can rarely be the initial manifestation of the disease.[161] Echocardiographic series have shown an up to a 25% prevalence rate of small and asymptomatic pericardial effusions. Cardiac tamponade and constriction are rare.

#### *Coronary Artery Disease, Valve Disease, and Pulmonary Hypertension*

Epicardial coronary artery disease with angina has been reported in 20% to 25% of patients. Microvascular disease may be as prevalent, but coronary arteritis is rare.[157]

Noninfective valve vegetations similar to those seen in SLE have been rarely reported.[162]

Pulmonary hypertension is uncommon, and its clinical and echocardiographic manifestations, treatment, and prognosis are similar to that of other rheumatologic diseases.

## Mixed Connective Tissue Disease

### BACKGROUND

Mixed connective tissue disease is an overlap syndrome with features of SLE, rheumatoid arthritis, scleroderma, and polymyositis. This disease is characterized by high titers of antibodies to nuclear ribonucleoprotein; patients also have speckled antinuclear antibodies and rheumatoid factor. Typical clinical features of this disease include Raynaud phenomenon, hand edema, polyarthritis, sclerodactyly, interstitial pulmonary fibrosis, myositis, and esophageal hypomotility. The true prevalence rate of heart disease in this disease is unknown, but it is highly variable (10% to 80%), with the highest rates of asymptomatic disease reported in echocardiographic series.[157] As for other rheumatologic diseases, the temporal correlation of heart disease with the severity and activity of the disease is variable.

### ASSOCIATED CARDIOVASCULAR INVOLVEMENT

#### *Pulmonary Hypertension*

Pulmonary hypertension is a common complication of mixed connective tissue disease and most frequently affects patients with features of scleroderma.[163] Proliferative vasculitis of the small and medium-sized pulmonary arteries and pulmonary fibrosis are the most common causes. Pulmonary arterial vasospasm and thromboembolism are uncommon. In those with a vasospastic etiology, a favorable short and long response to endothelin antagonists has been reported.[163] Echocardiography is essential in the diagnosis, stratification, and follow-up of these patients.

#### *Pericarditis*

Pericardial disease is common, but most patients have asymptomatic, small pericardial effusions on echocardiography. Clinical pericarditis has been reported in 25% to 30% of patients and rarely can be the initial manifestation of the disease.[164] Large pericardial effusion with tamponade rarely occurs and responds favorably to steroid or other immunosuppressive therapy (see Question 37-5 at ExpertConsult.com).[164,165]

#### *Valve Disease and Myocardial Disease*

No data associating specific forms of valve disease with mixed connective tissue disease have been reported. However, mitral valve prolapse has been reported in 20% to 25% of patients.[157] Myocarditis is uncommon and, when detected early, can be reversible with steroids and pulse cyclophosphamide therapy. On echocardiography, the spectrum of the disease ranges from diastolic dysfunction to global or regional LV systolic dysfunction and congestive heart failure.[166]

#### *Coronary Artery Disease*

As in other rheumatologic diseases, coronary artery disease in patients with mixed connective tissue disease is predominantly related to microvascular disease. Acute coronary syndromes may result from microvascular disease, coronary vasospasm, in situ thrombosis, coronary embolism from a valve vegetation, and rarely, arteritis.[167] Finally, acute myocarditis may mimic an acute coronary syndrome (Table 37-1).

**TABLE 37-1 Cardiovascular Involvement in Rheumatologic Diseases**

| *Disease* | *Type of Involvement* | *Frequency (%)** | *Key Characteristics* |
|---|---|---|---|
| Systemic lupus erythematosus (SLE) | Libman-Sacks vegetations | 10-35 | Characteristic, but not exclusive of systemic lupus erythematosus. Can be inflammatory, thrombotic, or mixed vegetations. Vegetations frequently change in appearance, resolve, appear de novo, or reappear. |
| | Leaflet fibrosis | 30-50 | Frequently diffuse. Associated calcification is uncommon. |
| | Valve regurgitation (mild or worse) | 30-50 | Can be severe with acute valvulitis or with overimposed infection. Valve stenosis is rare (<3%). |
| | Intracardiac thrombosis and cardioembolism | 15-20 | More commonly to the brain (50%-80%). |
| | Pericarditis | 10-50 | Antinuclear antibodies in pericardial fluid are diagnostic but not always present. Tamponade or constriction is rare. |
| | Asymptomatic effusion | 2-20 | Primary myocarditis is associated with cellular antigen Ro (SS-A) and La (SS-B) antibody. |
| | Myocarditis/cardiomyopathy | 1-20 | Most commonly nonobstructive. |
| | Coronary disease | | |
| | *Atherosclerotic* | 10-30 | Abnormal coronary vasodilation or microvascular disease. Microvascular thrombosis uncommon. |
| | *Functional* | 25-30 | Involves small and medium-sized vessels. |
| | *Arteritis* | Rare | A result of epicardial atherosclerosis, vasospasm, in situ thrombosis, or embolism. Arteritis is rare. |
| | Myocardial infarction | <10 | Predominantly impaired LV relaxation. |
| | Diastolic dysfunction† | 15-35 | Caused by interstitial lung disease, vasculitis, and thromboembolism. |
| | Pulmonary hypertension | 5-15 | |
| Primary antiphospholipid syndrome (PAPS) | Valve vegetations | 10-30 | All valve abnormalities, especially valve vegetations, have similar characteristics and evolution as to those of systemic lupus erythematosus. They are predominantly thrombotic but can be inflammatory or mixed. These vegetations also change in appearance over time, resolve, or reappear over time. |
| | Valve thickening | 40-60 | |
| | Valve regurgitation | 30-40 | |
| | Intracardiac thrombosis and cardioembolism | 15-20 | Includes thrombotic vegetations, adhered or free-floating intracavitary thrombi, atrioventricular valve thrombi with inflow obstruction mimicking stenosis, and echocardiographic pseudocontrast. |
| | Pulmonary hypertension | 20-25 | More commonly the result of pulmonary emboli, but pulmonary vasoconstriction or obstructive vasculopathy can occur. |
| | Coronary artery disease | 20-30 | Predominantly functional microvascular disease. |
| | Myocardial disease | 15-30 | Rarely primary inflammatory. Most commonly diastolic dysfunction from microvascular coronary artery disease. |
| Rheumatoid arthritis | Coronary artery disease | 40-60 | |
| | *Atherosclerotic* | >40 | Predominantly subclinical as detected with electron-beam computed tomography. |
| | *Functional* | >25 | Two to four times higher than the general population; severe obstructive disease uncommon. |
| | *Arteritis* | Uncommon | Abnormal coronary vasodilation or microvascular disease. |
| | Myocardial infarction | 10-15 | Difficult to diagnose clinically. |
| | Pericarditis | ≤10 | Most commonly the result of epicardial atherosclerosis. Rarely, coronary vasospasm, in situ thrombosis, or embolism. |
| | Asymptomatic effusion | 30-50 | Occurs in patients with active disease, high rheumatoid factor level, and nodular disease; pericardial fluid can have rheumatoid factor. |
| | Leaflet fibrosis | >30 | — |
| | Valve nodules | ~10 | Leaflet fibrosis is indistinguishable from that of systemic lupus. |
| | Valve regurgitation, mild or more | >30 | Characteristic of rheumatoid arthritis. |
| | Myocarditis/cardiomyopathy | <10 | Amyloid deposition is a rare cause. |
| | Diastolic dysfunction | 30-40 | Predominantly impaired LV relaxation. |
| | Pulmonary hypertension | ~20 | — |
| Ankylosing spondylitis | Proximal aortitis/valvulitis | 20-60 | Root sclerosis extending to base of anterior mitral leaflet and root dilation are characteristic of the disease. |
| | Aortic regurgitation, mild or more | 10-40 | Decreases anterior mitral leaflet mobility and causes regurgitation. |
| | Subaortic bump | 10-40 | — |
| | Conduction system disease | >20 | Extension of aortic root/annulus sclerosis into the proximal septum and atrioventricular node. |
| | Diastolic dysfunction | 20-30 | Predominantly impaired LV relaxation. |
| | Pericarditis | <5 | Primary immune mediated is uncommon. |
| | Asymptomatic effusion | <5 | — |
| | Myocarditis/cardiomyopathy | <5 | Primary immune-mediated myocarditis is rare. |
| Scleroderma | Coronary disease | | |
| | *Atherosclerotic* | <20 | — |
| | *Functional* | ~50 | Predominantly vasospastic or coronary Raynaud phenomenon. |
| | Myocarditis/cardiomyopathy | 10-50 | Most commonly related to recurrent intramyocardial ischemia/necrosis/fibrosis. Inflammatory uncommon. |
| | Diastolic dysfunction | 30-50 | Affects the LV and RV, and predominates as impaired relaxation. |
| | Pulmonary hypertension | 35-50 | Caused by pulmonary fibrosis, less commonly by vasculitis, vasospasm, or left heart disease. |
| | Pericarditis | 5-20 | — |
| | Asymptomatic effusion | 30-40 | — |
| | Valve disease | <10 | Nonspecific. Mitral valve prolapse is common. |
| Polymyositis/ dermatomyositis | Myocarditis/cardiomyopathy | >25 | Primary myocarditis more common in patients with myositis. Diastolic dysfunction occurs in 10% to 40% of patients. |
| | Pericarditis | ~10 | More frequent in children and in overlap syndrome. |
| | Asymptomatic effusion | 5-25 | Commonly nonobstructive atherosclerotic. |
| | Coronary artery disease | ~20 | Microvascular disease also common. Arteritis is rare. |
| | Valve disease | Unknown | Is nonspecific. Libman-Sacks–like vegetations are rare. |
| Mixed connective tissue disease (MCTD) | Pulmonary hypertension | ≤80 | More often resulting from proliferative vasculitis and pulmonary fibrosis. |
| | Pericarditis | 5-30 | — |
| | Asymptomatic effusion | Unknown | — |
| | Valve disease | Unknown | Nonspecific. High prevalence rate of mitral valve prolapse (20%-25%). |
| | Myocarditis/cardiomyopathy | <5 | — |
| | Coronary artery disease | Unknown | Predominantly microvascular disease. |

*Variability of rates is related to differences in patient population characteristics, study design, and diagnostic methods.
†Defined by Doppler echocardiographic criteria.

**TABLE 37-2 Key Echocardiographic Features of Valve Lesions in Selected Conditions**

| *Disease* | *Affected Structures* | *Key Characteristics* | *Functional Sequelae* |
|---|---|---|---|
| Systemic lupus erythematosus | Mitral valve more than aortic valve leaflets; rarely chordae, tricuspid valve, and pulmonary valve; spares annuli. | Libman-Sacks vegetations: masses usually <1 cm in diameter, with heterogeneous echocardiographic reflectance (but not calcified) and with irregular borders; usually rounded shape. Attached to leaflet with a broad base. Usually no independent motion. Lesions are located at any portion of leaflets, on atrial side of mitral valve and aortic vessel or ventricular side of aortic valve. Diffuse leaflet thickening or sclerosis common; calcification uncommon and mild. | Mild to moderate mitral regurgitation or aortic regurgitation is common, but stenosis is rare. High potential embolic source. |
| Primary antiphospholipid syndrome | Mitral valve more than aortic valve leaflets; rarely chordae, tricuspid valve, and pulmonary valve; spares annuli. | Libman-Sacks–like vegetations with similar characteristic to those described for systemic lupus erythematosus. | Mild to moderate mitral regurgitation or aortic regurgitation are common. High potential embolic source. |
| Rheumatoid arthritis | Mitral valve, aortic valve leaflets; rarely annuli and chordae; spares tricuspid valve and pulmonary valve. | Rheumatoid nodules: masses usually <1 cm in diameter, with homogeneous soft-tissue echocardiographic reflectance and irregular border; usually rounded shape. Any location within the leaflet; leaflet thickening/sclerosis generally mild or absent.<br>Libman-Sacks–like vegetations. | More than mild mitral regurgitation or aortic regurgitation is rare. Rupture of a nodule may lead to severe valve regurgitation. Rarely associated with cardioembolism.<br>Associated with acute or recurrent valvulitis. Similar characteristics to those associated with systemic lupus erythematosus. High embolic potential. Postvalvulitis stenosis is rare. |
| Ankylosing spondylitis | Proximal aorta, annulus and aortic valve, base of anterior mitral leaflet; posterior mitral valve leaflet, mitral annulus, and chordae spared. | Sclerosis, stiffness, and dilation of aortic root extend to the annulus. Aortic valve leaflet sclerosis is generally mild. Subaortic bump: a localized thickening of base of anterior mitral leaflet resulting from downward extension of aortic root and annular sclerosis. | Mild to moderate aortic regurgitation or mitral regurgitation are common. Stenosis not reported. |
| Rheumatic heart disease | 90% involvement of mitral valve or aortic valve; 10% tricuspid valve or pulmonary valve; annuli of valves and aortic root spared. | Mitral valve leaflet edges and chordae are most affected, and commissural fusion is common; with severe disease, sclerosis extends toward base of leaflet and may involve papillary muscles. Extensive calcification may occur. When localized, sclerosis may appear masslike, but very high echocardiographic reflectance is unlike other lesions, except degenerative. Aortic valve cusp edges are affected in a similar pattern. | Leaflet edge fusion and chordal shortening produce a tethered mitral leaflet motion; analogous doming motion of the aortic cusps may be seen. If fusion predominates, stenosis results; if leaflet retraction predominates, regurgitation results. |
| Degenerative disorders | Mitral valve and aortic valve annuli and leaflets; uncommonly involves chordae and tip of papillary muscles. | Sclerosis is concentrated at base of leaflets and annulus, with progressive extension toward leaflet mid portion; tip uncommonly involved. When localized, sclerosis may appear masslike or as nodules. Aortic valve nodules more commonly located at the base and commissural portions. | Annular calcification predominates for mitral valve, with leaflet sclerosis less common and usually limited to posterior leaflet. Mitral regurgitation rarely more than mild, and stenosis is rare and subclinical or mild. Aortic valve leaflet sclerosis and fusion lead to stenosis, and leaflet distortion leads to aortic regurgitation, generally mild. |
| Infective endocarditis | Acute: mass with homogeneous soft tissue reflectance and irregular borders; size and shape are highly variable, usually with narrow base, often pedunculated. Lesions almost always exhibit motion independent of underlying structure and almost always oscillatory. Mitral valve and tricuspid valve lesions prolapse into atria in systole; aortic valve and pulmonary valve lesions prolapse into outflow tracts in diastole. Lesions usually attached to distal third of leaflet. With aortic valve disease, additional vegetations may occur on anterior mitral leaflet and chordae.<br>Chronic: localized thickening or increased reflectance of leaflet or chordae. Lesion is not necessarily distal on leaflet. Fibrous tissue reflectance and calcification are common. | | Valve regurgitation is common and frequently severe; stenosis involving native valves is rare. Leaflet perforation or abscess formation occurs. Cardioembolism is common. |
| Valve or Lambl excrescences[168] | Detected with TEE, rarely with TTE. Similarly high frequency rate (35% to 40%) in healthy subjects, in patients with connective tissue diseases, and in patients with suspected cardioembolism. They are thin (0.6 to 2 mm in width), elongated (4 to 16 mm), hypermobile structures seen at or near the leaflets coaptation point, on the atrial side during systole for mitral and tricuspid valves and ventricular side during diastole for the aortic valve. Multivalvular involvement seen in 20% to 25% of subjects. | | Valve excrescences are not associated or cause valvular dysfunction, persist unchanged over time, and are not associated with antiphospholipid antibodies or with an increased risk of cardioembolism. |

## KEY POINTS

- Nonbacterial valve vegetations and leaflet fibrosis are seen in many patients with SLE, PAPS, and rheumatoid arthritis.
- Intracardiac thrombi, including thrombotic vegetations, are common in patients with SLE and PAPS and frequently lead to subclinical and clinical macroembolism or microembolism, predominantly to the brain.
- An increased prevalence of early coronary, carotid, and aortic atherosclerotic disease is found in patients with systemic inflammatory diseases, independent of traditional atherogenic risk factors.
- Chronic or recurrent systemic and local immune-mediated inflammation causes endothelial dysfunction that leads to abnormal coronary vasodilation or functional microvascular disease in patients with SLE, PAPS, and rheumatoid arthritis and especially in those with scleroderma.
- Subclinical LV and RV diastolic dysfunction is common in patients with rheumatologic disease and is predominantly the result of microvascular coronary artery disease.
- LV systolic dysfunction is uncommon in patients with systemic inflammatory disease and is usually multifactorial (microvascular or epicardial coronary artery disease, myocarditis, hypertension, or valve disease).
- Pericarditis is common in patients with SLE, rheumatoid arthritis, polymyositis, dermatomyositis, and mixed connective tissue disease.
- Pulmonary hypertension more commonly results from thromboembolism or vasculitis in SLE; from thromboembolism in PAPS; from interstitial lung disease or vasculitis in rheumatoid arthritis; and from interstitial lung disease, vasculitis, or vasospastic disease in scleroderma and mixed connective tissue disease.
- Libman-Sacks or thrombotic vegetations in SLE and PAPS, valve nodules in rheumatoid arthritis, and aortic root in association with aortic and mitral valve disease have distinctive echocardiographic features (Table 37-2).
- Although advances in echocardiography have upgraded the prevalence rates and characteristics of cardiovascular disease in rheumatologic diseases, the short-term and long-term clinical, prognostic, and therapeutic implications of common subclinical cardiovascular abnormalities are still uncertain and await large controlled cross-sectional and longitudinal studies.

# 38 Echocardiography in the Evaluation of Cardiac Disease Resulting from Endocrinopathies, Renal Disease, Obesity, and Nutritional Deficiencies

MARCUS F. STODDARD, MD

**Endocrinopathies**
- Diabetic Heart Disease
- Metabolic Syndrome
- Hypothyroidism
- Hyperthyroidism
- Acromegalic Heart Disease
- Primary Hyperparathyroidism
- Adrenal Diseases and Heart Disease

**Chronic Kidney Disease**
- Uremic Cardiomyopathy, Systolic Dysfunction, and LV Hypertrophy
- Diastolic Dysfunction
- Structural and Valvular Heart Disease
- Clinical Utility

**Obesity**
- Systolic Function
- Diastolic Function
- Structural Abnormalities
- Anorexigen Use, Valvulopathy, and Pulmonary Hypertension
- Clinical Utility

**Nutritional Deficiencies and Heart Disease**
- Vitamin and Trace Element Deficiencies
- Protein and Calorie Malnutrition

Endocrinopathies, renal diseases, nutritional deficiencies, and obesity have an adverse impact on cardiac function and structure and affect cardiovascular morbidity and mortality. These disorders may impair systolic and diastolic function, cause valvular regurgitation or stenosis, and lead to ventricular hypertrophy and dilation. Although the cardiac manifestations of these disorders are nonspecific, their detection has clinical relevance and significantly affects patient management. The emergence of strain imaging and tissue-Doppler echocardiography has allowed for early detection of myocardial disease. Conventional echocardiography and newer modalities play an important role in the timely detection of cardiac abnormalities from these diverse disease entities, particularly in asymptomatic patients.

## Endocrinopathies

### DIABETIC HEART DISEASE

Diabetes mellitus may cause a diabetic cardiomyopathy by impairing diastolic and systolic myocardial function via incompletely understood mechanisms independent of coronary artery disease or hypertension.[1] The mechanisms that cause diabetic cardiomyopathy are likely multifactorial and may relate to hyperglycemia, insulin resistance, diabetic microangiopathy of the coronary circulation, reduction in myocardial glucose supply and oxidation, impaired myocardial free fatty acid metabolism, abnormal regulation of intracellular calcium homeostasis, duration of diabetes, and type of diabetes. Diabetes is a major contributor to heart failure and occurs in 15% to 35% of heart failure patients.[2] In diabetic subjects, the risk of heart failure is higher in women than men. Cardiovascular prognosis is worse in heart failure patients with diabetes. Meta-analyses show that the relative risk for mortality is 28% higher in diabetic subjects with heart failure and systolic dysfunction as compared to their nondiabetic counterparts.[3] The impact of diabetes on outcome in patients with heart failure from diastolic dysfunction is less clear. In diabetic patients with diastolic dysfunction compared to those without, the cumulative probability of death at 5 years has been reported to be 30.8% versus 12.1%.[4] Diabetic cardiomyopathy begins in a preclinical phase as regional myocardial systolic and diastolic dysfunction that leads to global diastolic dysfunction, and progresses to left ventricular hypertrophy (LVH), fibrosis, dilatation, and global systolic dysfunction or reduced left ventricular (LV) ejection fraction. Detection of myocardial disease potentially on the basis of diabetes in its early stages, before structural changes such as hypertrophy or fibrosis occur, may affect intensity of treatment and disease progression.

#### *LV Systolic Dysfunction*

Regional impairment of LV myocardial systolic function is an early manifestation of diabetic heart disease assessed by strain, strain rate, and peak myocardial tissue-Doppler velocity imaging. It occurs before the onset of symptoms.[5-10] Regional contractility reserve is decreased in patients with diabetes as

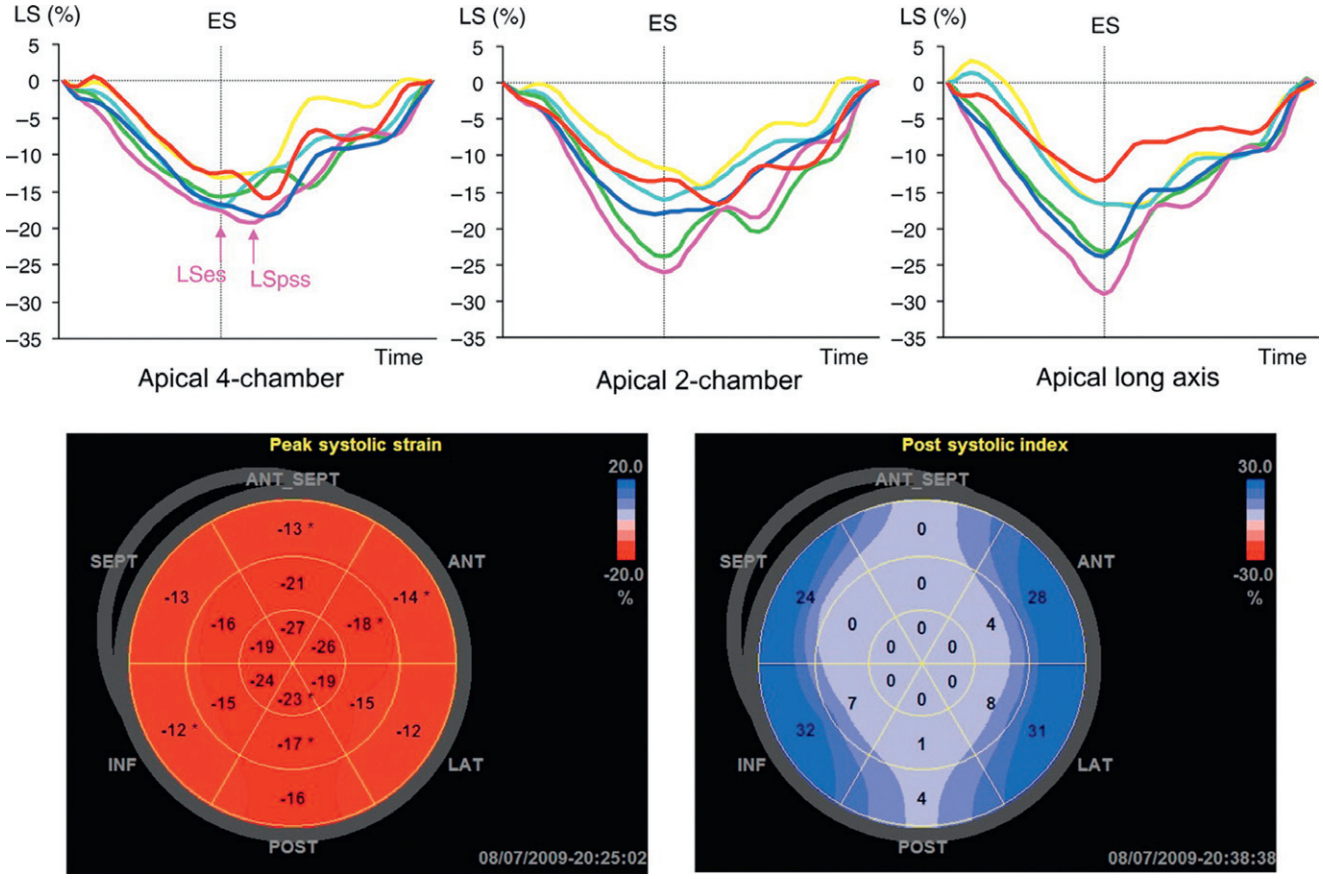

**Figure 38-1 Measurements of strain and post-systolic index in a diabetic patient.** *Upper three panels* show longitudinal regional strain curve of six segments from the apical four-chamber, two-chamber, and long-axis views. The *vertical line* denotes end-systole (*ES*). In addition to longitudinal strain values at end-systole (*LSes*), post-systolic peak longitudinal strain (*LSpss*) was measured, if the regional strain curve reached its peak after the aortic valve closure. *Lower panels* show parametric image of end-systolic strain and post-systolic index. Note that post-systolic index was observed in the basal part of the myocardium. *(Modified from Nakai H, Takeuchi M, Nishikage T, et al: Subclinical left ventricular dysfunction in asymptomatic diabetic patients assessed by two-dimensional speckle tracking echocardiography—correlation with diabetic duration.* Eur J Echocardiogr *10:926-932, 2009.)*

assessed by strain and peak strain rate imaging during dobutamine stress echocardiography.[11] Exercise may unmask potential abnormalities of systolic function unrelated to coronary artery disease that were not apparent at rest in diabetes.[12] Regional myocardial systolic dysfunction progresses to global impairment in systolic function as manifested by a reduced LV ejection fraction and associated remodeling.

LV longitudinal systolic strain and peak systolic tissue-Doppler velocity may be reduced in patients with diabetes, representing an early stage of systolic dysfunction that precedes abnormalities of more conventional echocardiographic indexes of systolic function (e.g., LV ejection fraction, ratio of preejection period to LV ejection time, or shortening fraction.[5-10,13] Nakai and co-workers[6] reported LV longitudinal systolic strain obtained as the average of 18 myocardial segments from apical four-, two-, and three-chamber views (Fig. 38-1) to be reduced in asymptomatic diabetic patients compared to controls (−17.6 ± 2.6% versus −20.8 ± 1.8%, $p < 0.001$). Ng and associates[7] noted similar findings, and that longitudinal systolic strain rate was lower in asymptomatic diabetic patients versus healthy subjects (−0.99 ± 0.17 $s^{-1}$ versus −1.07 ± 0.3 $s^{-1}$, $p = 0.009$). The influence of diabetes on radial systolic strain of the mid left ventricle (LV) is less consistent: Some investigators note normal systolic strain[6,7] and/or strain rates,[7] whereas other researchers report a decrease in systolic strain.[5] The myocardial performance index derived from conventional Doppler echocardiography may be abnormal during the early course of type 2 diabetes. Echocardiographic-based measurement of LV systolic torsion and contractile dyssynchrony offer promise in detection of diabetic myocardium in its early stages, but future studies validating their role are needed.[14]

In diabetic patients with long-term, complicated disease, systolic time intervals are frequently abnormal and include prolongation of LV preejection period and shortening of ejection time. Shortening fraction derived by M-mode echocardiography may be decreased in diabetic patients with long-standing disease. In young asymptomatic diabetic patients, abnormalities of LV shortening fraction and velocity of circumferential fiber shortening ($V_{cf}$) measured by M-mode echocardiography may become evident immediately after exercise. Divergent results have been reported in diabetic subjects on the response of peak systolic myocardial tissue velocity to dobutamine, with findings of a blunted increase[13] versus normal increase.[15]

Diabetes is a cause of LVH and concentric remodeling, which can be assessed for by M-mode and two-dimensional (2D) echocardiography.[16] Abnormal myocardial acoustic properties characterized by a reduction in the cyclic variation of ultrasound-integrated back-scatter and abnormal acoustic densitometry

can be detected in asymptomatic diabetic patients and reflect subclinical cardiomyopathic changes potentially attributable to collagen deposition or myocardial fibrosis in the heart.[10,17]

### *Right Ventricular Dysfunction*

Although data regarding the effect of diabetes on LV function and structure are robust, information is scant in regard to the right ventricle (RV). Studies show that diabetic patients have impaired regional and global relaxation (grade 1) of the RV, as evidenced by tricuspid valve peak early to atrial inflow velocity ratio less than 1.0, lateral tricuspid annular tissue-Doppler peak early to atrial velocity ratio less than 1.0,[18] and reduced peak early diastolic strain rate of base and apical RV free wall.[19] The potential influence of diabetes on RV systolic function is less well studied. Some studies support diabetes as a cause of impairment of RV systolic function,[19,20] whereas others do not.[18]

### *Valvular Function and Aortic Elastic Properties*

Type 2 diabetes accelerates the rate of progression in patients with moderate (i.e., valve area 1.0 to 1.5 $cm^2$) aortic stenosis.[21] Diabetic patients as compared to nondiabetic subjects showed a more rapid decrease in aortic valve area of $0.25 \pm 0.20$ versus $0.14 \pm 0.13$ $cm^2$/year ($p = 0.0016$).[21] In patients with severe aortic stenosis, the presence of diabetes leads to more adverse remodeling of the LV as characterized by greater LV mass and end-diastolic dimension than explained by afterload.[22] Elastic properties of the aorta are impaired in asymptomatic type 2 diabetic patients.[23] Aortic stiffness is increased and distensibility decreased as measured at the proximal ascending aorta using M-mode echocardiography.[23] Impaired aortic elastic function is associated with diastolic dysfunction in asymptomatic diabetic patients.[23]

### *Diastolic Dysfunction*

Conventional echocardiographic parameters of diastolic function (e.g., peak early filling velocity, peak early to atrial velocity ratio, deceleration time, inflow propagation rate, pulmonic vein systolic to diastolic peak velocity ratio, or isovolumetric relaxation time) largely reflect the impact of diabetes on diastolic function of the LV and/or RV chambers and as such are "global indexes" of diastolic function (Table 38-1). In well-controlled type 2 diabetic patients, 60% showed global diastolic dysfunction, with a pattern of impaired LV relaxation (grade 1) in 32% and pseudonormal (grade 2) in 28%.[24] Boyer et al.[25] reported grade 1 diastolic dysfunction in 46% of well-controlled type 2 diabetic patients. Pseudonormal diastolic function can be unmasked in diabetic patients with normal diastolic filling at rest by performance of Valsalva maneuver or isometric handgrip exercise Doppler echocardiography.[15] Restrictive diastolic filling in the absence of reduced LV ejection fraction (i.e., dilated cardiomyopathy) has not been convincingly shown as a feature of diabetic myocardial disease. However, before global diastolic function is impacted, a cumulative amount of regional myocardial diastolic dysfunction and/or dyssynchrony must occur.

**TABLE 38-1 Echocardiographic Findings in Diabetic Cardiomyopathy**

| *Myocardial Disease Stage* | *Diastolic Function* | *Systolic Function* | *Structure* |
|---|---|---|---|
| Early | **Strain/tissue-Doppler imaging:**<br>↓Peak global early LV diastolic SR (<1.0 $s^{-1}$)<br>↓MV annular E′ (<8 cm/s)<br>↓MV annular E′/A′ ratio (<1.0)<br>↓Diastolic reserve (i.e., blunted rise in annular E′ with supine bicycle exercise)<br>**Conventional Doppler indexes:**<br>Normal (E, E/A, IVRT, %AC, $V_p$) | **Strain/tissue-Doppler imaging:**<br>↓Global LV longitudinal strain (<–18%)<br>↓Peak global LV longitudinal systolic SR (<0.90 $s^{-1}$)<br>↓Systolic reserve (i.e., Blunted rise in annular S′ with supine bicycle exercise)<br>Possible ↓MV annular S′<br>Conventional 2D/3D echocardiography<br>Normal (rest LVEF, SF, $V_{cf}$)<br>**Conventional Doppler indexes:**<br>Normal (PEP/LVET) | **M-mode/2D echocardiography:**<br>Normal (LVM index, LV volume, LV wall thickness) |

*DT*, Transmitral early diastolic deceleration time; *E*, peak transmitral early diastolic filling velocity; *E/A*, E/peak transmitral late diastolic filling velocity ratio; *E′*, peak early diastolic tissue-Doppler velocity; *E′/A′*, E′ to peak late diastolic tissue-Doppler velocity; *E/E′*, E to E′ ratio; *IVRT*, isovolumic relaxation time; *LVEF*, LV ejection fraction; *LVM*, LV mass; *MV*, mitral valve; *PEP/LVET*, LV preejection to LV ejection time ratio; *SF*, LV shortening fraction; *SR*, strain rate; *S′*, peak LV systolic tissue-Doppler velocity; $V_{cf}$, LV velocity of circumferential fiber shortening; $V_p$, LV inflow propagation rate; *%AC*, percent atrial contribution to LV filling.

Subclinical regional myocardial impairment of LV diastolic function is an early manifestation of diabetic cardiomyopathy independent of associated diseases, such as hypertension or coronary artery disease.[4] Studies using myocardial tissue-Doppler imaging have shown regional impairment of LV diastolic function at early stages in diabetes with a prevalence as high as 75%.[8,9,13,15,25,26] Importantly, progression to impaired global LV diastolic function as determined by Doppler echocardiography may occur after only a few years of diabetes. Although global LV diastolic function is more likely to be abnormal in diabetic patients with advanced disease manifestations, such as overt nephropathy, autonomic neuropathy, or retinopathy, it does occur in these patients with uncomplicated disease. Impairment of regional RV diastolic function is an early manifestation of diabetic heart disease and can be subclinical.[20]

Augmentation of regional myocardial relaxation (i.e., diastolic functional reserve) during dobutamine infusion[11] or exercise[27,28] as assessed by tissue-Doppler velocities, strain, and/or strain rate imaging is blunted in subjects with diabetes and occurs before the development of abnormalities in diastolic function at rest. Global or regional LV diastolic dysfunction determined by pulsed Doppler echocardiography or tissue-Doppler myocardial imaging, respectively, in type 2 diabetic subjects adversely reduces maximal exercise capacity and tolerance.[29-31]

Tissue-Doppler and strain imaging allow for a more direct appraisal of diastolic function at the regional myocardial level. As a result, these approaches are more sensitive for detection of diastolic dysfunction from diabetes and allow for its detection at a preclinical stage that precedes the earliest stage of global diastolic dysfunction (grade 1), that is, a "preglobal" (or pre–grade 1) diastolic dysfunction (Fig. 38-2). Supporting this concept is the study of Di Bonito and colleagues,[26] who showed that 50% of type 2 diabetics with uncomplicated and short-term (4 years or less) disease had a reduced (i.e., less than 1.0) ratio of peak early to atrial mitral annular tissue-Doppler (E′/A′), in the face of normal global indexes of diastolic function (see Chapter 11). The detection of diastolic dysfunction is enhanced by the addition of tissue-Doppler imaging parameters to that of conventional Doppler indexes (see Chapter 10). Individual diabetic patients may show an isolated abnormality in conventional or tissue-Doppler imaging indexes, which emphasizes the need for a comprehensive echocardiographic evaluation in the assessment of diastolic function. Tissue-Doppler echocardiography of peak septal mitral annular early diastolic velocity (E′) shows a blunted increase with supine bicycle exercise and may allow for early detection of diabetic myocardial disease.[27] Similarly, diabetes patients have a blunted decrease from rest to exercise in the time to onset of regional LV relaxation derived by strain imaging, a promising method to detect early diabetic myocardial disease.[28]

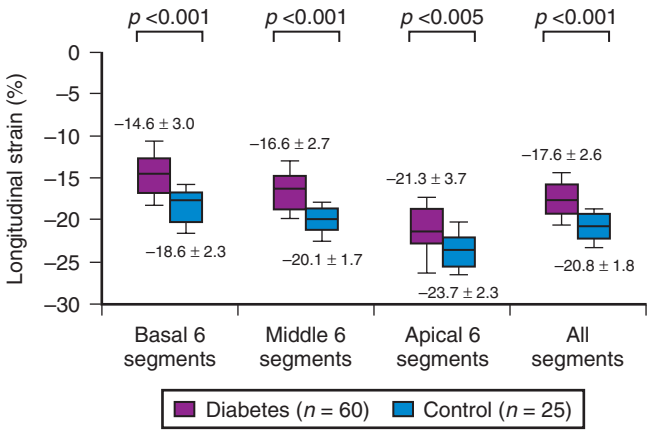

**Figure 38-2 LV longitudinal systolic strain values in diabetic patients (*purple boxes*) and control subjects (*blue boxes*) from basal, middle, and apical segments, and all segments averaged.** Systolic strain was reduced at each segment in diabetic patients. Numerical values are mean ± SD. *In each box, line in middle* equals median value, and *top and bottom of box* represent the 75th and 25th percentiles, respectively. *Upper and lower bars of each box* plot show the 90th and 10th percentiles, respectively. *(Modified from Nakai H, Takeuchi M, Nishikage T, et al: Subclinical left ventricular dysfunction in asymptomatic diabetic patients assessed by two-dimensional speckle tracking echocardiography—correlation with diabetic duration.* Eur J Echocardiogr *10:926-932, 2009.)*

2D speckle tracking has made echocardiographic strain imaging practical by eliminating many of the inherent limitations of color Doppler–based strain, such as dependency on angle of insonation, inability to correct for cardiac translational motion, and inability to measure radial or circumferential strain. Strain imaging is an important modality in the evaluation of diabetic patients with normal conventional indexes and tissue-Doppler parameters of diastolic function for early detection of diabetic myocardial disease.[7] Longitudinal early diastolic LV strain rate is decreased in asymptomatic patients with type 2 diabetes[7] (Fig. 38-3).

### *Interaction of Diabetes with Hypertension, Renal Insufficiency, Obesity, Aging, and Gender*

Diabetes and systemic hypertension are both independently associated with concentric LVH and concentric remodeling. The prevalence of concentric LVH and magnitude of relative wall thicknesses is greater in patients when these two diseases coexist as compared to when either exists in isolation.[32] Importantly, type 2 diabetes attenuates regression of LVH in patients treated for hypertension (Fig. 38-4).[33] LV diastolic function is more impaired in patients with coexisting diabetes and hypertension as compared to those subjects with only one of these diseases.[8] A novel application of strain rate imaging is assessment of left atrial (LA) function. In diabetic patients, hypertension augments impairment of LA conduit and booster function as assessed by peak early and late diastolic atrial strain rates, respectively.[33] LV diastolic dysfunction, independent of LVH, may markedly progress in patients with chronic kidney disease and diabetes.[34] LV diastolic dysfunction is significantly more prevalent in obese patients with as compared to those without diabetes.[35] Diabetes in the presence of obesity augments the increase in LV mass corrected for height.[36] The interaction of diabetes and obesity on increasing LV mass is further amplified by aging in women, but not in men.[36] Aging is an independent contributor to diastolic dysfunction in the normotensive type 2 diabetic patient.[37] There are gender differences in LV diastolic stiffness in diabetic patients.[2] Diabetes in women compared to men is associated with increased LV stiffness during supine bicycle exercise at 50 watts using a novel noninvasive echocardiographically derived index of elastance calculated as the ratio of peak mitral inflow to annular velocities divided by LV stroke volume.

### *Clinical Utility*

Echocardiography has emerged as an important, practical, and reliable modality for the early detection of diabetic myocardial

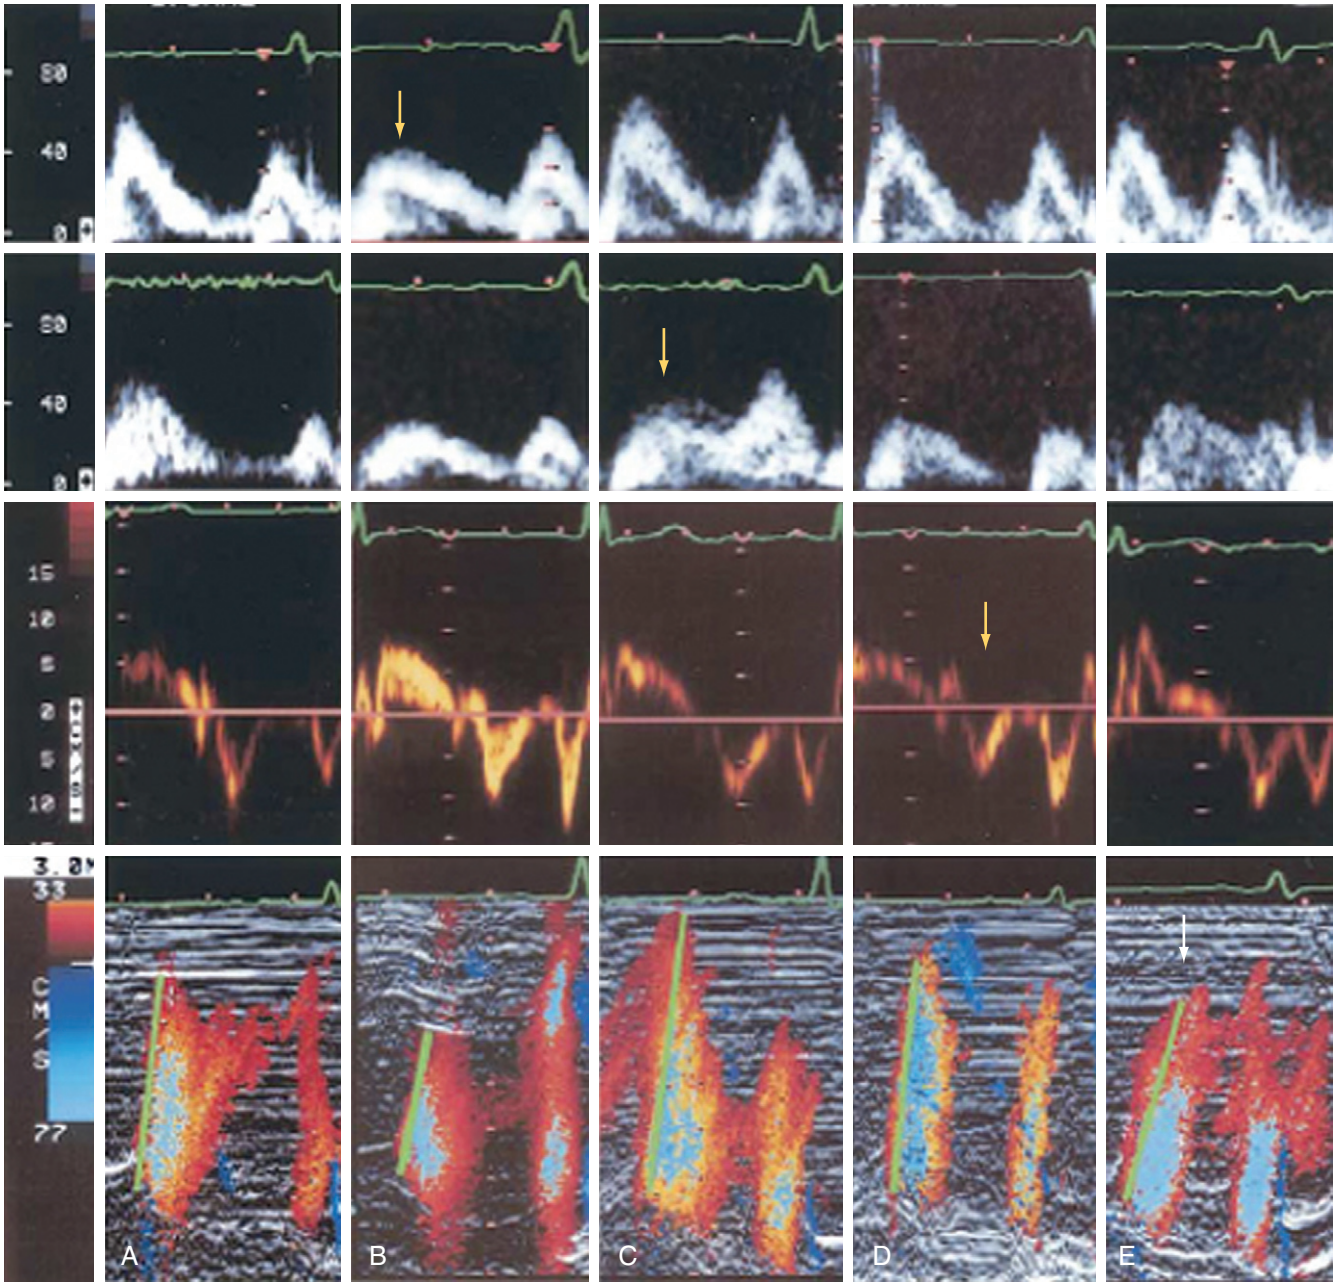

**Figure 38-3 Echocardiographic findings of diastolic function in five different patients with diabetes mellitus, designated as A, B, C, D, and E.** In order from *top*, rows represent resting pulsed Doppler mitral inflow, mitral inflow during the Valsalva maneuver, early diastolic tissue-Doppler velocity, and color M-mode inflow propagation rate, respectively. Patient A shows no diastolic dysfunction abnormalities. In patients B through E, only one of the diastolic parameters (*arrow*) was abnormal when the remaining measurements were normal. *(From Boyer JK, Thanigaraj S, Schechtman KB, Perez JE: Prevalence of ventricular diastolic dysfunction in asymptomatic, normotensive patients with diabetes mellitus.* Am J Cardiol *93:870-875, 2004.)*

disease, particularly when using tissue-Doppler and strain imaging,[5-9,13,15,25,26] and, when necessary, dobutamine or stress echocardiography.[11,27,28] Echocardiographic characterization of diastolic function yields insight into the status of myocardial pathology. It is proposed that in diabetic cardiomyopathy impaired relaxation (grade 1), pseudonormal (grade 2), or restrictive (grade 3) forms of diastolic dysfunction represent predominantly deranged myocardial metabolism with only mild fibrosis, a moderate degree of fibrosis, or severe fibrosis, respectively.[38] Preglobal diastolic dysfunction characterized by diastolic and/or systolic impairment of myocardium detectable by strain or tissue-Doppler imaging that precedes abnormalities of early diastolic filling (grade 1), or other global indexes such as isovolumic relaxation time or LV inflow propagation rate ($V_p$), may represent altered myocardial metabolism without fibrosis.[39] Diastolic dysfunction assessed by peak early mitral inflow velocity to early annular tissue-Doppler velocity (E/E′) ratio correlates with worsening glycemic control (Fig. 38-5).[40] Importantly, echocardiography is useful in demonstrating that therapeutic approaches may prevent or delay the progression of early diabetic myocardial disease. Diastolic and systolic dysfunction in diabetes improves with glycemic control as assessed

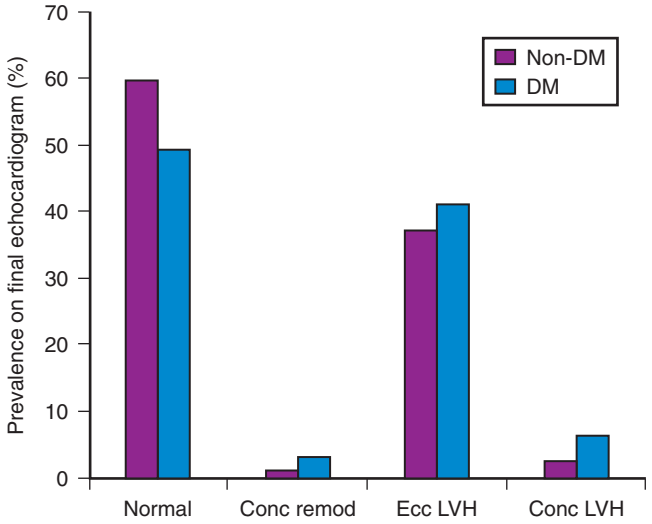

**Figure 38-4 LV geometry at time of final echocardiography in diabetic (*DM, blue bars*) and nondiabetic (*Non-DM, purple bars*) hypertensive patients in the LIFE study.** LV hypertrophy persisted at more than 3.5 years of follow-up more commonly in diabetic versus nondiabetic patients (47% versus 39%, $p$ <0.05) because of greater prevalence of concentric and eccentric LV hypertrophy. *Conc remod*, Concentric LV remodeling; *Ecc LVH*, eccentric LV hypertrophy; *Conc LVH*, concentric LV hypertrophy. *(From Gerdts E, Okin PM, Wachtell K, et al: Impact of diabetes on treatment-induced changes in left ventricular structure and function in hypertensive patients with left ventricular hypertrophy.* Nutr Metab Cardiovasc Dis *19:306-312, 2009.)*

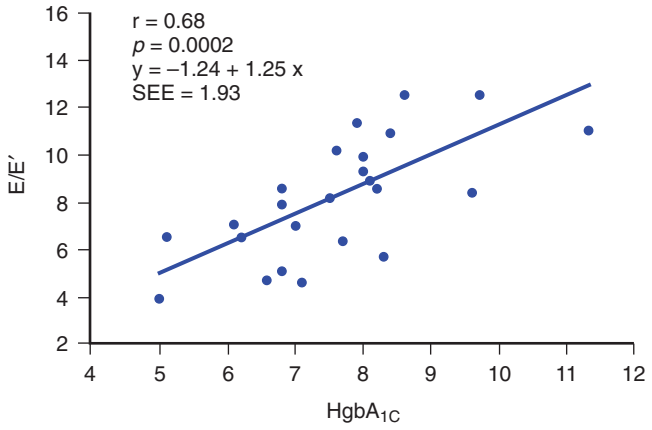

**Figure 38-5 Relation of hemoglobin $A_{1c}$ (*$HgbA_{1c}$*) to LV peak early mitral inflow velocity to early annular tissue-Doppler velocity ratio (*E/E′*) in type 1 diabetic patients.** Improved glycemic control is associated with better diastolic function. *SEE*, Standard error of estimate. *(Modified from Shishehbor MH, Hoogwerf BJ, Schoenhagen P, et al: Relation of hemoglobin A1c to left ventricular relaxation in patients with type 1 diabetes mellitus and without overt heart disease.* Am J Cardiol *91:1514-1517, 2003.)*

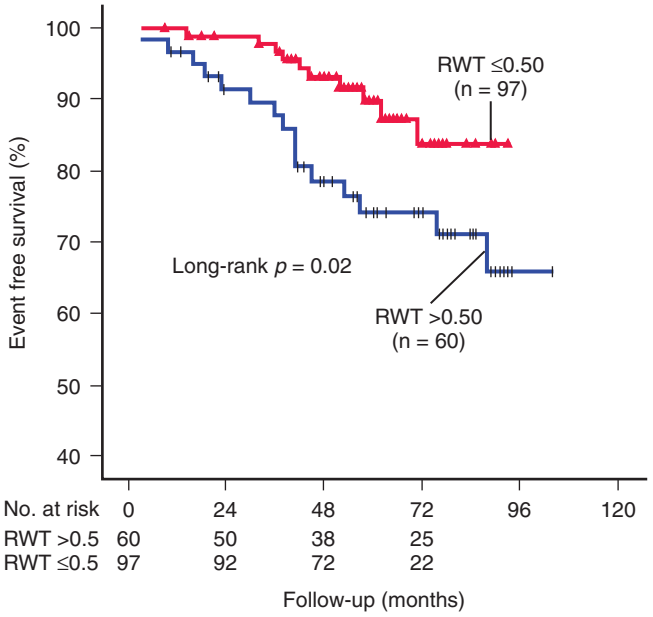

**Figure 38-6 Event-free survival curves without a cardiovascular event by relative wall thickness (*RWT*) >0.50 (4th quartile) or ≤0.50 (1st to 3rd quartiles) in nonobese type 2 diabetic patients.** Relative wall thickness greater than 0.50 was associated with greater events ($p$ = 0.18). *(Modified from Eguchi K, Ishikawa J, Hoshide S, et al: Differential impact of left ventricular mass and relative wall thickness on cardiovascular prognosis in diabetic and nondiabetic hypertensive subjects.* Am Heart J *154:79.e9-79.e15, 2007.)*

by early annular E′ and longitudinal systolic strain rate, respectively.[41,42] The potential benefits for cardiac function of individual treatments to achieve glycemic control in diabetes patients are not uniform. Metformin and rosiglitazone appear beneficial,[43,44] but pioglitazone does not.[45] Although vigorous training aiding in glycemic control may improve myocardial disease in diabetes patients as assessed by tissue-Doppler and strain,[46] conventional exercise training does not.[47] A randomized trial failed to demonstrate the benefit of glycemic control in diabetes on myocardial diastolic function, but studied only 39 patients.[48] Once diabetic myocardial disease is advanced or systolic heart failure ensues, the effectiveness of treatment for reversing the cardiomyopathic state is unproven.[49,50] In type 2 diabetes patients with hypertension, echocardiography determination of LV mass index greater than 142 g/m$^2$ in women, or greater than 164 g/m$^2$ in men, or a relative wall thickness greater than 0.50 is a predictor of cardiovascular events (Fig. 38-6).[51] The Framingham Heart Study estimates that in type 2 diabetes and no clinical coronary artery disease, each 50-g increase in LV mass index increases risk of cardiovascular disease in women by 57% and in men by 49%. Treatment may regress LVH in diabetes patients.[52] Fang and colleagues[53] reported that in unselected asymptomatic patients (n = 101) with diabetes, 22% had LVH, and in a subgroup (n = 66) without coronary artery disease or hypertrophy, 56% had myocardial diastolic or systolic dysfunction, or both as determined by tissue-Doppler velocities or strain. Brain natriuretic peptide was insensitive for detection of diabetic myocardial disease.[53] Echocardiographic screening of asymptomatic diabetic subjects for abnormalities in regional and global systolic and diastolic function, or LVH is advisable, particularly if there is the coexistence of diseases that potentiate the adverse effects of diabetes on cardiac structure and function, such as hypertension, chronic kidney disease, or obesity. Serial echocardiography would appear useful to gauge potential benefit of treatment.

## METABOLIC SYNDROME

The metabolic syndrome is a combination of three or more disorders that include fasting glucose level of 110 mg/dL or greater, central obesity, triglyceride level greater than 150 mg/

dL, high-density lipoprotein cholesterol level <40 mg/dL, and blood pressure at or above 130/80 mm Hg. It has an estimated prevalence of 75 million adults in the United States. It is not surprising that the metabolic syndrome is a risk factor for adverse cardiovascular complications, such as heart failure. Akin to diabetes, over the past 5 years substantial data has emerged confirming that abnormalities of LV diastolic and systolic function and structure occur with the metabolic syndrome.[54-61] It has not been completely determined whether these abnormalities are due to the metabolic syndrome per se, or due to specific individual components of the syndrome. Female compared to male gender in patients with metabolic syndrome is a greater risk factor for concentric remodeling or hypertrophy.[57,59] Dyssynchronous systolic contraction and impaired diastolic relaxation occur in the metabolic syndrome, and hypertension is not the most prominent determinant.[62] Briand and co-workers[63] have shown that metabolic syndrome doubles the rate of progression of aortic stenosis (−0.14 ± 0.13 $cm^2$/year versus −0.08 ± 0.08 $cm^2$/year, $p = 0.008$) and is associated with a substantially lower 3-year event-free survival (44 ± 8% versus 69 ± 6%, $p = 0.002$). In a separate study, these investigators have reported that metabolic syndrome is associated with a significantly faster rate of deterioration of bioprosthetic aortic valves.[64]

Abnormal echocardiography parameters of early LV myocardial disease that occur in subjects with metabolic syndrome include a reduced myocardial E′ or annular E′, decreased regional and global systolic and early diastolic strain rates, and regional systolic strain.[55,56] Grade 1 LV diastolic dysfunction characterized by a reduced transmitral E/A ratio may occur in 29% of subjects with metabolic syndrome.[54,55] The myocardial performance index or Tei index is adversely affected by metabolic syndrome and progressively worsens with more components of the disease (Fig. 38-7).[54,60]

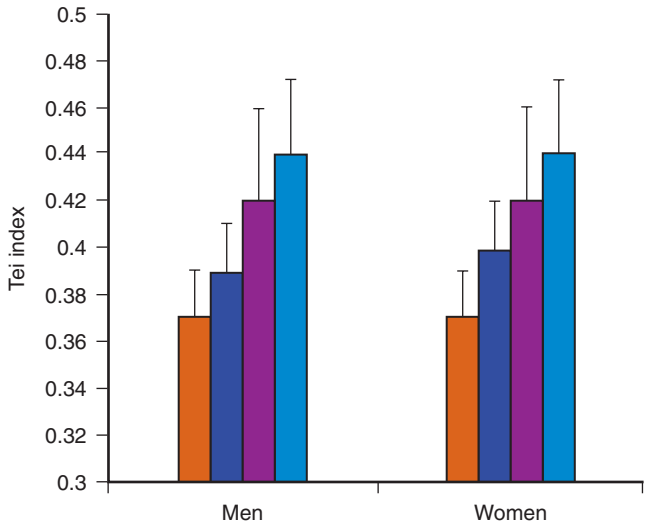

**Figure 38-7 The Tei index (mean ± SD) in men and women without (*orange bars*) metabolic syndrome, and with three (*dark blue bars*), four (*purple bars*), or five (*royal blue bars*) components of the metabolic syndrome.** Myocardial performance progressively worsens with increasing components of the metabolic syndrome. *(From Voulgari C, Moyssakis I, Papazafiropoulou A, et al: The impact of metabolic syndrome on left ventricular myocardial performance.* Diabetes Metab Rev *26:121-127, 2010.)*

## HYPOTHYROIDISM

Hypothyroidism occurs in 4.6% of adults in the United States and is subclinical in the vast majority of these individuals, whereby circulating free thyroid hormone concentrations are normal but thyroid stimulating hormone level is elevated. The Framingham Heart Study has shown hypothyroidism in 10.3% of individuals over age 60 years, and that it is over 2 times more common in women.[65] Thyroid dysfunction adversely affects LV function and structure and the pericardium (Table 38-2), with effects ranging from a subclinical level to frank heart failure.[66] RV systolic function may also be impaired in patients with overt hypothyroidism.[67] However, restoring normal thyroid homeostasis will often reverse adverse affects of thyroid disease, emphasizing the importance of detecting thyroid-induced heart disease.[68]

### *Systolic Dysfunction*

LV systolic dysfunction is a well-recognized feature of overt chronic hypothyroidism using conventional echocardiography measures, with signs including prolongation of the LV preejection period and a reduced ejection fraction, $V_{cf}$, and systolic ejection. More recently, Tiryakioglu and colleagues[69] reported that untreated patients with overt hypothyroidism compared to control subjects have reduced longitudinal systolic strain (16.4 ± 1.4% versus 20.6 ± 1.5%, $p < 0.001$) and peak strain rate (1.0 ± 0.1 $s^{-1}$ versus 1.4 ± 0.1 $s^{-1}$, $p < 0.001$) as determined from the average of all myocardial segments. Kaplan and co-workers[70] have used color Doppler–based tissue imaging to show that LV systolic dyssynchrony occurs more commonly in overt hypothyroidism compared to controls (84% versus 27%, $p < 0.001$) as defined when the standard deviation of time to peak myocardial velocity of the six basal and six midventricular segments exceeds 40 ms.

With subclinical hypothyroidism, LV systolic dysfunction, as evidenced by a reduced peak myocardial systolic velocity, is seen during exercise.[71-75] More sensitive measures of strain also show myocardial systolic dysfunction at rest in patients with subclinical hypothyroidism.[76] Aghini-Lombardi and associates[77] reported reduced systolic longitudinal strain of midseptal wall (−19.2 ± 4.2% versus −23.3 ± 5.4%, $p = 0.05$) and midlateral wall (−18.4 ± 3,7% versus −23.1 ± 5.6%, $p = 0.02$), as well as decreased peak strain rate of midseptal wall (−0.7 ± 0.2 $s^{-1}$ versus −1.2 ± 0.4 $s^{-1}$, $p = 0.05$) and midlateral wall (−1.05 ± 0.2 $s^{-1}$ versus −1.25 ± 0.2 $s^{-1}$, $p = 0.05$), in patients with subclinical hypothyroidism versus controls. The cyclic variation index, a measure of intrinsic contractility derived by integrated backscatter, is reduced in subclinical hypothyroidism.[78,77] The cyclic variation index of regional myocardial segments (e.g., septum or posterior wall) is the percent difference in integrated backscatter from end-diastole to end-systole. The cyclic variation index of the septum of less than 31% correctly discriminates subjects with subclinical hypothyroidism from controls in 86%, significantly better than conventional echocardiographic indexes.[77] Peak systolic tissue-Doppler velocity of the lateral or septal annulus at rest appears insensitive for myocardial dysfunction in subclinical hypothyroidism, as it may be normal despite abnormalities in global indexes of LV systolic (i.e., preejection period or increased preejection to LV ejection time ratio)[74,77] or diastolic (i.e., peak) function.[74,75,77,79]

The adverse effect of subclinical hypothyroidism on left and RV myocardial contractile function can be reversed or improved with thyroid replacement therapy.[79-81]

### *Diastolic Dysfunction*

Overt hypothyroidism is typically associated with grade 1 diastolic dysfunction,[82-84] but grade 2 or pseudonormal diastolic dysfunction also may be seen.[69] Overt hypothyroidism impairs early and late regional and global diastolic peak longitudinal LV strain rates.[69,76,] In addition, tissue Doppler–derived E′ and the E′/A′ ratio are reduced,[84] and the myocardial performance index may be prolonged.[85]

In subclinical hypothyroidism, regional LV diastolic dysfunction has been consistently shown, as evidenced by a decrease in E′, or E′/A′ ratio as derived from pulsed-wave (PW) tissue-Doppler of the septal or lateral annulus.[73-75,77,79,81] Grade 1 global diastolic dysfunction may occur as shown by a decreased transmitral E and E/A ratio, or prolongation of isovolumic relaxation time derived from Doppler echocardiography.[73-75,77-79]

Importantly, impaired relaxation in subclinical and overt hypothyroidism may be reversed by thyroid hormone replacement.[72,78,80,83]

### *Pericardial and Structural Disease*

Echocardiographic[78] or ultrasonic tissue back-scatter[77,78,86,87] indexes of myocardial texture in adults with hypothyroidism are abnormal, consistent with histologic studies showing interstitial edema and fibrosis, and myofibril swelling.[77,78,86,87] These abnormalities of myocardial texture and septal hypertrophy may reverse with thyroid hormone treatment (Fig. 38-8).[86]

The incidence of pericardial effusion in hypothyroidism varies with severity of disease and occurs in 30% to 80% of patients with advanced disease and in 3% to 6% of patients with mild disease. However, cardiac tamponade due to pericardial effusion from hypothyroidism is rare.[88]

### *Clinical Utility*

Cardiac abnormalities of function and structure caused by subclinical hypothyroidism portend development of overt cardiac disease but are reversible with thyroid hormone replacement treatment.[80,79,81] Thus, early diagnosis is important and supports the need for thyroid hormone, although effective screening for myocardial dysfunction in these patients likely requires sophisticated echocardiographic techniques, such as strain, strain rate imaging, and tissue-Doppler imaging. This is particularly the case when conventional but less sensitive echocardiography methods for LV dysfunction are unremarkable. Otherwise, occult and reversible myocardial disease may go unrecognized.

Overt hypothyroidism causes diastolic and systolic heart failure, which is partially reversible.[82,83] However, making an accurate diagnosis of heart failure in the setting of overt hypothyroidism may be difficult because symptoms of heart failure are easily misdiagnosed as being attributable to hypothyroidism. Conventional echocardiographic findings of cardiac dysfunction support the diagnosis of heart failure and potentially affect the specific selection of medical therapy. Tissue-Doppler velocities and strain and strain rate imaging complement conventional echocardiography for these purposes, particularly for abnormalities in regional ventricular diastolic and systolic function.

Pericardial tamponade in overt hypothyroidism can easily be misdiagnosed as heart failure.[88] Both may present with dyspnea, jugular venous distention, enlarged cardiac silhouette, and peripheral edema. The diagnosis of cardiac tamponade is facilitated by the use of echocardiography.

## HYPERTHYROIDISM

### *Systolic Function*

Echocardiographic findings of systolic function in overt hyperthyroidism typically show increased LV ejection fraction or $V_{cf}$[89,90]; however, these findings are not uniform[91,92] (Table 38-3). Explanation for this difference in findings is unclear. Patients in these studies were untreated, newly diagnosed, and predominantly of female gender. However, etiologies of hyperthyroidism did differ (i.e., Graves disease, autonomous goiter, multinodular goiter, thyroid carcinoma). In addition, ejection fraction and $V_{cf}$ are load-dependent indexes. The increase in preload and decrease in afterload associated with

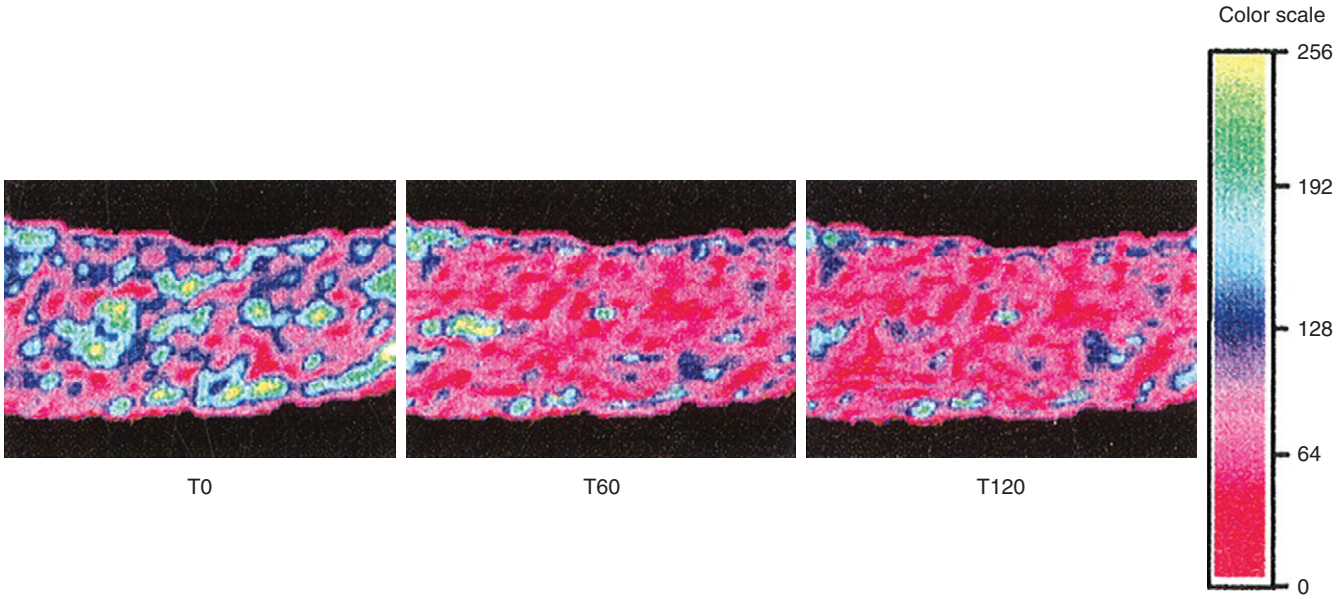

**Figure 38-8 Echocardiographic images from interventricular septum in representative patient with hypothyroidism obtained before (*T0*), 60 (*T60*), and 120 (*T120*) days after levothyroxine treatment.** An arbitrary color scale enhancing the changes in echoreflectivity was used. Abnormal amount of yellow before treatment denotes increased echoreflectivity, which progressively decreases after 60 and 120 days of treatment. *(From Ciulla MM, Paliotti R, Cortelazzi D, et al: Effects of thyroid hormones on cardiac structure: a tissue characterization study in patients with thyroid disorders before and after treatment.* Thyroid *11:613-619, 2001.)*

hyperthyroidism varies between patients, potentially contributing to divergence in results of studies.

During exercise patients with hyperthyroidism may display a decline or blunted increase in LV ejection fraction, stroke volume, heart rate, and cardiac output. Overt hyperthyroidism impairs cardiopulmonary exercise capacity, which is reversible by achieving a euthyroid state. Cardiomegaly, impaired global systolic function, and heart failure may ensue from overt hyperthyroidism, which can reverse after induction of a euthyroid state.[93] However, dilated cardiomyopathy persists in one third of these patients.[93] Takotsubo cardiomyopathy may occur from thyroid storm.[94] Although overt hyperthyroidism may enhance

RV systolic function,[68] in rare cases it may lead to RV volume overload and heart failure.[95] LV dyssynchronous systolic contraction occurs in overt hyperthyroidism.[96]

Subclinical hyperthyroidism is defined as normal free thyroid hormone levels in the face of lower than normal thyroid stimulating hormone concentration. It may be caused by endogenous thyroid disease or induced by thyroid hormone treatment (i.e., exogenous). Studies on the impact of subclinical hyperthyroidism on LV global and regional systolic function have shown seemingly divergent results. Several studies have shown exogenous or endogenous subclinical hyperthyroidism to increase global LV systolic function, but other researchers have reported no effect.[89,97,98] Similarly divergent results of regional systolic function have been reported.[99,100] Di Bello and colleagues[99] found enhanced longitudinal strain and systolic strain rate of the midseptal and lateral wall in patients with recently diagnosed and untreated endogenous subclinical hypothyroidism. However, Abdulrahman and co-workers[100] reported reduced longitudinal strain in patients with exogenous subclinical hyperthyroidism treated with suppressive therapy for at least 10 years. It is possible that the discrepancies in global and regional LV systolic function reported in patients with subclinical hyperthyroidism are partly explained by the duration of the illness, with early disease characterized by enhanced function that later normalizes and progresses to impaired systolic function.

### *Diastolic Function*

Most studies have shown that overt hyperthyroidism is associated with an increased transmitral E and/or shortened isovolumic relaxation time, findings that suggest enhanced global diastolic function.[89,90,101] However, limited data exist on less load-dependent indexes of diastolic function (e.g., diastolic strain rate or E′) in patients with overt hyperthyroidism.[101] It is unclear whether augmentation of myocardial diastolic function accounts for the enhanced early filling seen in these studies, because such changes could be on the basis of a decrease in systemic vascular resistance and/or increase in cardiac output, which also were reported to occur in these patients.[90] Others have reported a decrease transmitral E/A ratio[89] and reduced myocardial E′,[101] which suggests that overt hyperthyroidism is a cause of LV diastolic dysfunction in some patients. Yue and associates[101] noted a diagnosis of diastolic dysfunction in 31% (22 of 70) of patients with overt hyperthyroidism.

Exogenous[100,102] and endogenous[99] subclinical hyperthyroidism causes LV regional myocardial diastolic dysfunction as assessed by diastolic strain rate and tissue-Doppler velocity imaging. In patients with subclinical hyperthyroidism compared to controls, peak early diastolic strain rate derived by color Doppler tissue imaging is reduced of the midseptum ($0.8 \pm 0.4\ s^{-1}$ versus $1.4 \pm 0.6\ s^{-1}$, $p$ 0.001) and midlateral wall ($0.91 \pm 0.4\ s^{-1}$ versus $1.17 \pm 0.54\ s^{-1}$ $p$ 0.01).[99] Similarly, myocardial E′ obtained as the average of four basilar LV segments is reduced in subclinical hyperthyroidism ($5.7 \pm 1.3$ cm/s versus $9.0 \pm 1.6$ cm/s, $p$ <0.001).[99] Echocardiographic findings of global diastolic dysfunction in subclinical hyperthyroidism have been shown on the basis of conventional Doppler echocardiographic indexes, namely prolongation of isovolumic relaxation time and deceleration time of early filling and/or reduced peak transmitral E/A ratio.[99,100,102] For example, Smit and colleagues[102] reported in patients with subclinical hyperthyroidism compared to controls a decreased E/A ratio ($0.87 \pm 0.13$ versus $1.29 \pm 0.18$, $p$ <0.001), and prolonged deceleration time ($234 \pm 34$ ms versus $188 \pm 33$ ms, $p$ <0.001) and isovolumic relaxation time ($121 \pm 15$ ms versus $77 \pm 10$ ms, $p$ <0.001). Diastolic dysfunction, when present in exogenous subclinical hyperthyroidism, is partially reversible with achievement of a euthyroid state after medication titration.[102]

### *Structural Disease*

Increased LV mass and LVH, features of subclinical and overt hyperthyroidism, can be diagnosed by M-mode and 2D echocardiography.[89,98,102] Coexisting subclinical hyperthyroidism and hypertension are associated with substantially higher LV mass than when either disease is seen in isolation.[103]

Valvular heart disease, including mitral valve prolapse and hemodynamically significant mitral or tricuspid regurgitation, associated with overt hyperthyroidism can be assessed for clinical significance and progression with echocardiography. A prevalence as high as 16.5% to 25% of mitral valve prolapse in patients with Graves disease has been reported. The basis for this association remains unclear; however, prior studies support a possible autoimmune-mediated mechanism or potential genetic linkage between Graves disease and mitral valve prolapse. Mitral regurgitation occurs in 71% of patients with Graves disease, and tricuspid regurgitation may occur in 63% of such patients. Moderate or severe tricuspid regurgitation can be seen in 29% of these patients and is associated with congestive heart failure. Echocardiography has been used to demonstrate that pulmonary hypertension defined as peak pulmonary systolic pressure greater than 35 mm Hg may occur in as many as 41% of patients with overt hyperthyroidism.[105]

### *Clinical Utility*

Adverse cardiac effects from overt or subclinical hyperthyroidism are potentially reversible or improve with treatment.[93,102] Heart failure is the initial presentation of hyperthyroidism in approximately 6% of such patients.[93] In patients with overt hyperthyroidism, attributing exercise limitations to primary cardiac disease may be challenging on the basis of resting global systolic or diastolic function echocardiography indexes, which are typically enhanced. However, exercise echocardiography may be useful in unmasking a blunted improvement in systolic function with exercise and aid in treatment. The potential clinical usefulness of tissue-Doppler imaging in this setting is promising.[101] Future studies investigating strain and strain rate imaging in overt hypothyroidism are needed and may further guide the utility of echocardiography. Subclinical hyperthyroidism has a relevant clinical impact in that it adversely affects cardiac structure and function and impairs functional capacity. Subclinical hyperthyroidism patients with any of these manifestations should be treated by treating the primary thyroid disorder (e.g., thyroidectomy, radioiodine ablation, or antithyroid medications) if endogenous, by reducing thyroid hormone dose if exogenous, or by the use of beta-blockers. Screening for cardiac abnormalities with echocardiography, particularly using global indexes as well as sophisticated measures of regional diastolic function, is advisable. Last, overt hyperthyroidism should be included in the differential diagnosis of pulmonary hypertension.[104]

## ACROMEGALIC HEART DISEASE

Acromegaly is a rare pituitary disorder with a prevalence of 40 to 60 persons per million and incidence of 3 to 4 individuals per million caused by increased secretion of growth hormone.

**TABLE 38-4 Echocardiographic Findings in Acromegaly**

*DT*, Transmitral early diastolic deceleration time; *E*, peak transmitral early diastolic filling velocity; *E/A*, E/peak transmitral late diastolic filling velocity ratio; *E′*, peak early diastolic tissue-Doppler velocity; *E′/A′*, E′ to peak late diastolic tissue-Doppler velocity; *IVRT*, isovolumic relaxation time; *LVEF*, LV ejection fraction; *MV*, mitral valve; *SR*, strain rate; *S′*, peak LV systolic tissue-Doppler velocity.

Cardiovascular complications are a major cause of morbidity and mortality from acromegaly. Initially, patients show enhanced global systolic function, but progression to diastolic dysfunction and LV hypertrophy is typical, followed by systolic dysfunction and overt heart failure. In advanced, untreated acromegaly, a dilated cardiomyopathy may ensue with about 10% of patients presenting with heart failure. Before effective therapy, nearly 80% of patients died before age 60 years from cardiovascular complications.

### *Ventricular Hypertrophy*

Echocardiography is well suited to delineate the presence and severity of structural cardiac abnormalities due to acromegaly, which include increased LV mass,[105-110] concentric LVH,[108] eccentric LVH,[111] asymmetric septal hypertrophy, LV dilation, and RV hypertrophy (Table 38-4). LVH plays a significant role in the morbidity and mortality from this disease.[112-116] LVH is partially related to hypertension, an associated condition in acromegaly,[117] but it occurs in a substantial proportion of acromegalic patients in the absence of hypertension.[112] LV mass increases with short-term growth hormone hypersecretion[118] and regresses after effective chronic pharmacologic therapy.[105,113-116,119,120] In acromegaly, LVH is typically concentric, but eccentric hypertrophy whereby the increase in LV mass is predominantly on the basis of chamber dilatation does occur.[111] The reported prevalence of asymmetric septal hypertrophy in acromegaly is highly variable: Some studies report a rare association, whereas others describe a frequent association. LV chamber enlargement develops in acromegaly and may occur in the absence of associated conditions such as hypertension, coronary artery disease, or diabetes. The reported incidence of an increased LV mass in patients with acromegaly is 38% to 81%.[88,106] RV hypertrophy also occurs from acromegaly. Echocardiography is useful in documenting regression of hypertrophy with therapy for acromegaly.[105,113-115,119]

### *Diastolic Dysfunction*

LV diastolic dysfunction is present in over 50% of patients with acromegaly,[109,112-116] even in the absence of associated LVH, hypertension, premature coronary artery disease, and diabetes. Typically, there is a reduction of transmitral E and E/A ratio, an increase in peak atrial filling velocity, and a longer early diastolic deceleration time.[109,112-116] Isovolumic relaxation time, assessed by Doppler echocardiography, is prolonged.[112,113] Tissue-Doppler imaging of LV myocardium confirms regional diastolic dysfunction in acromegaly patients as evidenced by a decrease in myocardial E′ and annular E′/A′ ratio.[107-109,116,121,123] In these patients, early diastolic strain rate and peak annular velocity are reduced,[107-109,121,122] and grade 1 diastolic dysfunction is present.[109,112-116] Regional[108] and global[109] LV myocardial performance assessed by Tei index is reduced in acromegaly. Impaired LV diastolic function in acromegaly often improves with treatment.[105,113,115,116,123] Similar to the LV, abnormal regional and global RV diastolic function[107] is a feature of acromegaly.

### *Systolic Function*

In patients with short-term acromegaly uncomplicated by hypertension, coronary artery disease, or diabetes, global LV systolic function, as assessed by shortening fraction, stroke volume, and cardiac output, typically is enhanced. Global LV systolic dysfunction in acromegalic patients appears uncommon.[108,120,121] However, regional LV systolic dysfunction may be evident.[107,112,122,123] High-output heart failure with a modest reduction in LV ejection fraction occurs in 10% of newly diagnosed acromegaly.[124] Di Bello et al.[122] have shown untreated acromegaly patients have reduced longitudinal strain of septum (−19.8 ± 2.9% versus −27.9 ± 3.8%, $p$ <0.001) and lateral wall (−17.7 ± 2.2% versus −25.3 ± 2.6%, $p$ <0.001) and decreased peak strain rate of septum and lateral wall. Importantly, abnormalities of strain virtually normalized after 6 months of treatment with somatostatin analogs.[122] Reduced peak myocardial systolic velocity by PW tissue-Doppler imaging may be evident at rest with active acromegaly[107,112] but has not been consistently reported.[108] Exercise may show a blunted increase in LV ejection fraction, unmasking occult systolic dysfunction. Ultrasonic integrated back-scatter in patients with acromegaly shows reduced cyclic variation and increased derived collagen volume fraction, an index of myocardial fibrosis.[111,115]

### *Valvular Heart Disease*

Acromegaly is a cause of potentially significant mitral and aortic regurgitation.[125,126] Uncontrolled acromegaly is associated with progressive mitral regurgitation.[110] Severe mitral regurgitation has been noted in 5% of acromegaly patients.[126] Aortic regurgitation of a mild or greater severity occurs in 18% of patients with inactive acromegaly and increases to 31% if acromegaly is active.[125] Aortic root stiffness measured by transthoracic echocardiography[127] and aortic root sinotubular junction diameter[128] are increased in acromegaly and could contribute to the aortic regurgitation frequency and severity seen in this disease. The prevalence of significant aortic regurgitation increases with duration of disease, with significant aortic valve disease in only 10% of patients with 6 to 10 years of disease but in over 35% of those with a disease duration over 15 years.[126] Successful valvular surgery has been reported in acromegaly patients.[126,129] The echocardiographic manifestations of structural valvular disease in acromegaly include aortic and mitral valve fibrosis and calcification and mitral annular calcification.[125] Valvular pathology also includes myxoid degeneration.[129]

### *Clinical Utility*

Acromegalic heart disease begins subclinically but often portends serious morbidity and mortality.[123,124,130] Clinical studies show that suppression of growth hormone release by somatostatin analogs (e.g., octreotide acetate) in acromegalic patients significantly reduces LVH and improves abnormalities of global and regional diastolic and systolic function of the LH and RH.[105,113-116,119,120,122] A comprehensive echocardiographic evaluation of cardiac size and function in patients with acromegaly is of value to assess ventricular hypertrophy and cardiac dysfunction. Echocardiographic indexes of regional myocardial function, particularly of diastolic function, derived from strain and tissue-Doppler imaging appear very sensitive and should be employed. For example, tissue Doppler–derived LV E′/A′ was able to determine a greater severity of myocardial disease in patients with active versus well-controlled acromegaly.[109] Strain and tissue-Doppler imaging are useful in the serial evaluation of treated patients with acromegaly to detect cardiac involvement.[109,112,116,122]

Regional myocardial Tei index was found to be increased in patients with acromegaly (0.49 ± 13.4 versus 0.39 ± 5.2, $p$ = 0.005) and more sensitive for detection of diastolic dysfunction compared to conventional echocardiographic indexes (48% versus 36%).[108] Similarly, global Tei index is sensitive for detection of ventricular dysfunction in acromegaly.[109] However, E′/A′ (i.e., an index of regional function) compared to global Tei index is better for differentiating active from well-controlled acromegaly.[108] Prolongation of isovolumic relaxation time is the most sensitive of the conventional echocardiographic indexes of cardiac involvement in acromegaly and is useful for evaluation in the subclinical stage of the disease (Fig. 38-9). Regional and global Tei index should be used for detection of potential acromegalic heart disease when conventional echocardiography, strain, and tissue-Doppler imaging fail to confirm potential cardiac involvement from acromegaly. Ventricular hypertrophy and/or myocardial dysfunction signal the need for aggressive treatment to control growth hormone levels to improve heart disease in patients with acromegaly.[123,124,130] The use of more sophisticated but technically challenging echocardiographic techniques such as ultrasonic integrated back-scatter to assess for myocardial fibrosis and collagen volume await future investigations but are promising.[111,115]

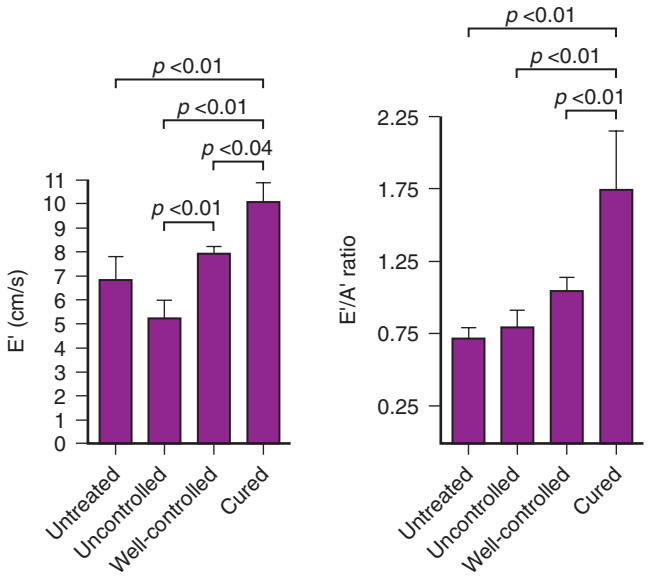

**Figure 38-9 Histogram demonstrating impact of acromegaly disease activity and treatment on LV regional diastolic function by tissue-Doppler echocardiography of peak early (*E′*) and peak early to atrial ratio (*E′/A′*) of septal annulus from four-chamber view.** Cured patients show normalized diastolic parameters, whereas untreated and uncontrolled subjects show impaired myocardial diastolic function. *(From van Thiel SW, Bax JJ, Biermasz NR, et al: Persistent diastolic dysfunction despite successful long-term octreotide treatment in acromegaly.* Eur J Endocrinol *153:231-238, 2005.)*

Acromegaly is a cause of significant mitral and/or aortic regurgitation, which can be clinically silent. Occasionally, surgical intervention is needed. Conventional color flow and spectral Doppler echocardiography are essential for the serial evaluation of patients with acromegaly and evidence of structural valvular disease, particularly with long-standing disease.[126]

## PRIMARY HYPERPARATHYROIDISM

Primary hyperparathyroidism is a recognized cause of increased cardiovascular morbidity and mortality from heart failure, stroke, and myocardial infarction in patients with moderate to severe or severe disease. The impact of milder forms of primary hyperparathyroidism on cardiovascular disease is controversial, with most studies finding no adverse effects.

### *Cardiac Calcification*

Hypercalcemia due to primary hyperparathyroidism may induce calcification of coronary arteries, valves, and myocardium. Aortic valve calcification occurs in 46% to 63% of primary hyperparathyroidism patients, and mitral valve or submitral annulus calcification has been reported in 33% to 49% of these patients. Aortic and mitral stenosis may result from primary hyperparathyroidism. Myocardial calcific deposits have been reported in 62% to 74% of patients with primary hyperparathyroidism. Myocardial calcification mainly involves the interventricular septum and may result in third-degree heart block. Successful parathyroidectomy appears to halt the progression of valvular calcification. Mild primary hyperparathyroidism appears not to show a propensity for valvular calcification.[131]

### *LV Structure and Function*

LVH is commonly associated with primary hyperparathyroidism and may be caused by excessive serum concentration of parathyroid hormone or intracellular calcium concentration[132] (Table 38-5). LVH develops independent of hypertension, a condition also associated with primary hyperparathyroidism. Partial regression of LVH may occur 6 months to 1 year after parathyroidectomy in these patients. Mild primary hyperparathyroidism appears unassociated with LVH.[131] Impaired myocardial relaxation and performance are associated with primary hyperparathyroidism as assessed by tissue-Doppler and Tei index, respectively. Grade 1 diastolic dysfunction characterized by reduced transmitral E, E/A, $V_p$, and prolonged isovolumic relaxation time are seen in primary hyperparathyroidism.[132,133] However, patients with mild primary hyperparathyroidism may display normal global and regional diastolic function.[131,134] Global LV systolic function is not impaired by primary hyperparathyroidism but may be slightly increased as assessed by LV ejection fraction or shortening fraction.[131,133,134] Similarly, regional myocardial systolic function assessed by peak myocardial systolic velocity is normal in patients with primary hyperparathyroidism.[133,134] Primary hyperparathyroidism reportedly may cause structural and function findings of hypertrophic cardiomyopathy. Alternatively, a reversible dilated cardiomyopathy and heart failure from severe hypocalcemia secondary to hypoparathyroidism is a recognized entity.[135]

### *Clinical Utility*

Echocardiography helps identify LVH, regional and global diastolic dysfunction, and valvular stenosis in patients with primary hyperparathyroidism. Parathyroidectomy may promote regression of myocardial hypertrophy, cessation of valvular calcification, and stabilization or improvement of diastolic dysfunction, all of which can be monitored by serial echocardiographic studies.[136]

## ADRENAL DISEASES AND HEART DISEASE

### *Cushing Syndrome*

Cushing syndrome is caused by excessive secretion of adrenocortical hormones, which causes hypertension, impaired glucose tolerance, diabetes, abdominal obesity, dyslipidemia, and hypercoagulability. These features of Cushing syndrome cause a fourfold increase in mortality rate from cardiovascular complications. Echocardiography shows LVH and asymmetric septal hypertrophy in 75% of patients with Cushing syndrome. LVH may be partly attributable to associated hypertension. Other findings in Cushing syndrome include the following:

- Asymmetric septal hypertrophy is common and severe, with interventricular septal thickness ranging from 1.6 to 3.2 cm and the ratio of septal to posterior wall thickness as high as 2.67.
- LV concentric remodeling occurs is independent of blood pressure.
- Regional and global LV diastolic dysfunction are seen.[137-141]
- Grade 1 global diastolic dysfunction is characterized by decreased transmitral E and E/A ratio, and prolonged deceleration time and isovolumic relaxation time.[137-140]
- Regional LV systolic dysfunction is present as demonstrated by strain measurements.[140]

LVH, regional and global diastolic dysfunction, and regional systolic dysfunction are reversible or improve with successful treatment of Cushing syndrome (Fig. 38-10).[140] A reversible dilated cardiomyopathy attributable to Cushing syndrome has been reported in a minority of patients.[142]

### *Primary Hyperaldosteronism*

Echocardiographic findings in patients with primary aldosteronism include:

- Concentric LVH
- Regional myocardial diastolic dysfunction as assessed by E′[143]
- Grade 1 global diastolic dysfunction[143]

However, LV systolic function does not appear to be impaired as assessed by LV ejection fraction or regional indexes, such as myocardial strain and peak systolic strain rate.[143] In primary hyperaldosteronism, myocardial ultrasonic integrated backscatter demonstrates decreased cyclic variation—findings consistent with greater myocardial collagen content and fibrosis.[144] Experimental data support the concept that excessive aldosterone, independent of its hypertensive effect, may induce ventricular hypertrophy and fibrosis.[145]

The frequency of concentric remodeling and diastolic dysfunction increases with longer duration of Cushing syndrome. These abnormalities may contribute to the high cardiovascular morbidity seen in patients with Cushing syndrome and suggest a role for echocardiography. Regression of LVH in Cushing syndrome after surgical treatment frequently occurs and may

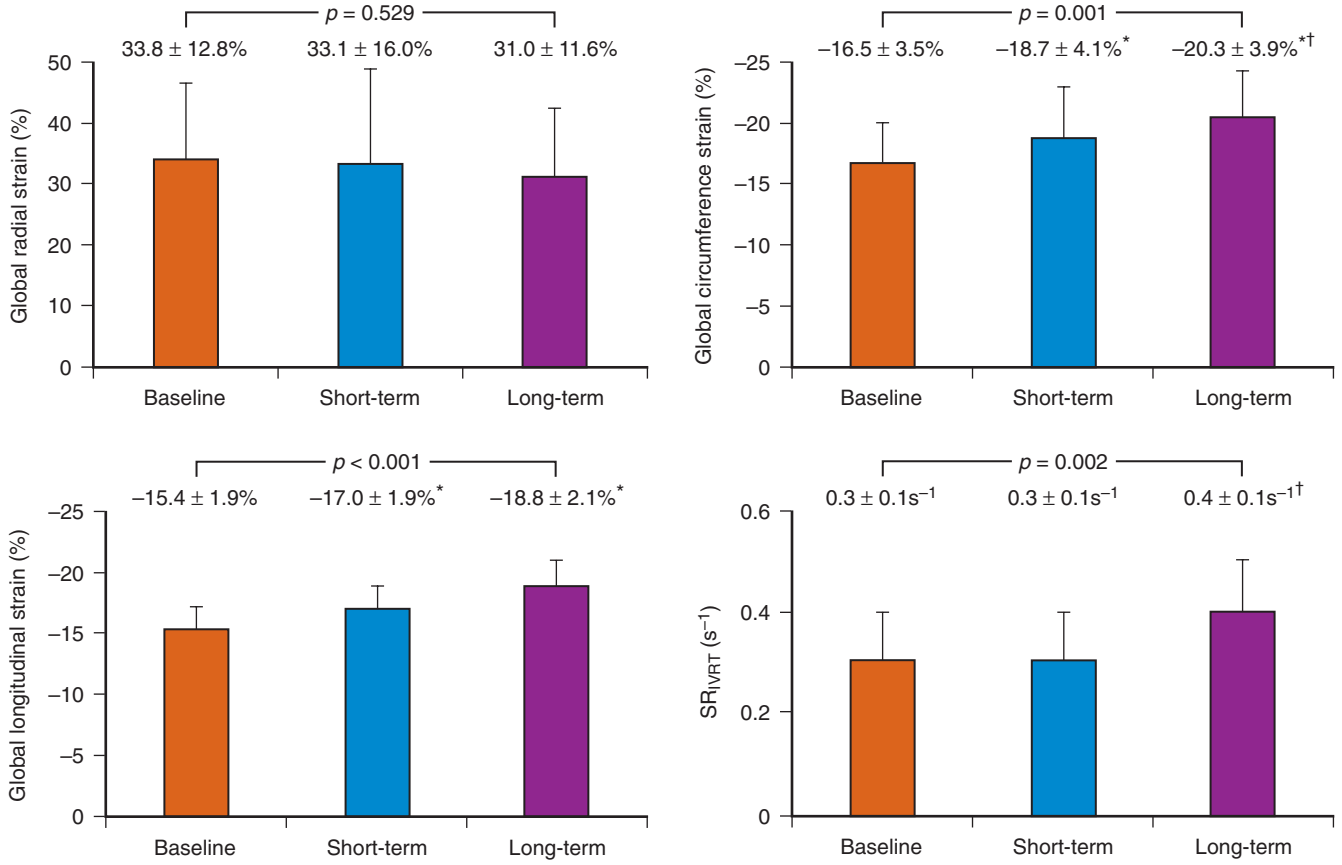

**Figure 38-10 Histograms showing reversibility of impaired LV global radial, circumferential, and longitudinal strain and strain rate at isovolumetric relaxation time ($SR_{IVRT}$) in 15 patients with Cushing syndrome after surgical treatment at short-term (median 1 month) and long-term (median 14 months) follow-up.** *(From Pereira AM, Delgado V, Romijn JA, et al: Cardiac dysfunction is reversed upon successful treatment of Cushing's syndrome.* Eur J Endocrinol *162:331-340, 2010.)*

be dramatic. Echocardiographic findings of severe LVH or hypertrophic cardiomyopathy without obvious cause should raise the clinical suspicion of glucocorticoid excess, possibly from Cushing syndrome. Regression of LVH may occur after surgical excision of an aldosterone-producing tumor in patients with primary hyperaldosteronism.

## Chronic Kidney Disease

Cardiovascular disease is a major cause of morbidity and mortality in patients with chronic kidney disease. In addition to a high prevalence of traditional risk factors, uremia-related risk factors contribute to cardiovascular disease, partly mediated from development of LVH, myocardial fibrosis, diastolic and systolic dysfunction, and valvular disease. Structural or valvular abnormalities of the heart detectable by echocardiography occur in most patients with end-stage renal disease and may include atrial or ventricular chamber enlargement; concentric or eccentric LVH; asymmetric septal hypertrophy; mitral annular calcification; valvular calcification; myocardial calcification; valvular regurgitation; aortic and mitral valve stenosis; and pericardial effusion (Table 38-6).[146-150]

## UREMIC CARDIOMYOPATHY, SYSTOLIC DYSFUNCTION, AND LV HYPERTROPHY

Chronic kidney disease contributes to and worsens structural and functional abnormalities of cardiac disease and may lead to heart failure. The multifactorial causes of heart failure from chronic kidney disease and uremia appear to include anemia, electrolyte and acid-base abnormalities, volume overload, hypertension, coronary artery disease, and uremic toxins. A specific uremic cardiomyopathy may ensue from these derangements and is characterized by cardiac enlargement, impaired LV systolic function, and ventricular hypertrophy.[151] A reduced LV ejection fraction is present in approximately one third of new dialysis patients. LVH is present in 70% of patients with end-stage renal disease and ranges from 34% to 78% in nonuremic chronic kidney disease.[146] Renal transplantation may reverse systolic dysfunction, decrease LV volume overload, and regress LVH, independent of blood pressure control.[152]

Global and regional LV myocardial systolic function is impaired in patients with early stages of chronic kidney disease,[153] moderately advanced chronic kidney disease,[154] and end-stage renal disease on hemodialysis[155] as assessed by peak longitudinal strain and strain rate. LV systolic dyssynchrony occurs with greater frequency in chronic kidney disease or end-stage renal disease patients.[156] It improves with hemodialysis.[147] Secondary hyperparathyroidism due to uremia is a cause of LV systolic dysfunction.[157] Dilated cardiomyopathy associated with advanced secondary hyperparathyroidism in patients on chronic dialysis improves 6 months after parathyroidectomy. LV myocardial systolic dysfunction occurs from mild secondary hyperparathyroidism.[157] Gender influences development of LVH in chronic kidney disease. LVH occurs 2.5 to 4 times more often in women compared to men with end-stage renal disease on hemodialysis.[158] In patients with hypertension, progression of chronic kidney disease from stage 2 to stage 5 is associated with increasing prevalences of concentric, eccentric, and "mixed" forms of LVH (Fig. 38-11).[148]

The systolic and diastolic dysfunction associated with chronic kidney disease and end-stage renal disease is detectable at a subclinical level using modern echocardiographic methods of strain, strain rate and tissue-Doppler velocity imaging. Edwards and colleagues[153] showed that in patients with early chronic kidney disease compared to controls, a reduced global LV longitudinal strain (−15 ± 4% versus −17 ± 3%, $p$ <0.01), peak systolic strain rate (0.88 ± 0.16 $s^{-1}$ versus 1.06 ± 0.31 $s^{-1}$, $p$ <0.05), and regional strain and strain rates. Gulel and associates[154] showed similar findings in patients with chronic kidney disease compared to controls as well as reduced mid-LV wall peak early diastolic strain rate (1.24 ± 0.58 $s^{-1}$ versus 2.02 ± 0.45 $s^{-1}$, $p$ <0.001).

Hemodialysis, a commonly used treatment in patients with end-stage renal disease, reduces intravascular volume and preload. The influence of preload reduction must be considered when diastolic function is being assessed in end-stage renal disease patients after dialysis. Conventional indexes (e.g., E and E/A) are sensitive to preload. E′ and myocardial Tei index appear less sensitive to preload reduction from hemodialysis, particularly when body weight postdialysis decreases by less than 2 to 3 kg.[159-162] The acute influence of hemodialysis on systolic function is complex and likely influenced by dialysate composition and temperature and by dialysis-induced changes in serum electrolytes, as well as by alteration in loading conditions. Systolic function acutely after hemodialysis, as assessed by echocardiographically derived shortening fraction, LV ejection fraction, $V_{cf}$, or ratio of fractional shortening to end-systolic stress, has shown divergent results. Systolic LV longitudinal strain decreases after hemodialysis.[163] The effect on strain rate is unclear. Hemodialysis may result in "stunned" myocardial segments, which may progress over 12 months to fixed dysfunctional segments.[164] Regional and global RV systolic dysfunction are impaired in hemodialysis patients with end-stage renal disease as assessed by tissue-Doppler indexes and ejection fraction, respectively.[165]

## DIASTOLIC DYSFUNCTION

LV regional and global diastolic dysfunction is associated with chronic kidney disease and end-stage renal disease.[154,155,166,167] In both these diseases, LVH is a common associated finding but is not a necessary feature to develop diastolic dysfunction. However, in end-stage renal disease, diastolic function worsens as LVF progresses.[167] The primary etiology of chronic kidney disease independently contributes to diastolic dysfunction, such as systemic hypertension or diabetes mellitus. Conventional Doppler indexes in chronic kidney disease patients may show grade 1 LV diastolic dysfunction with reduced transmitral E, E/A ratio, and prolonged isovolumic relaxation time,[167] as well as pseudonormal or restrictive patterns of diastolic dysfunction.

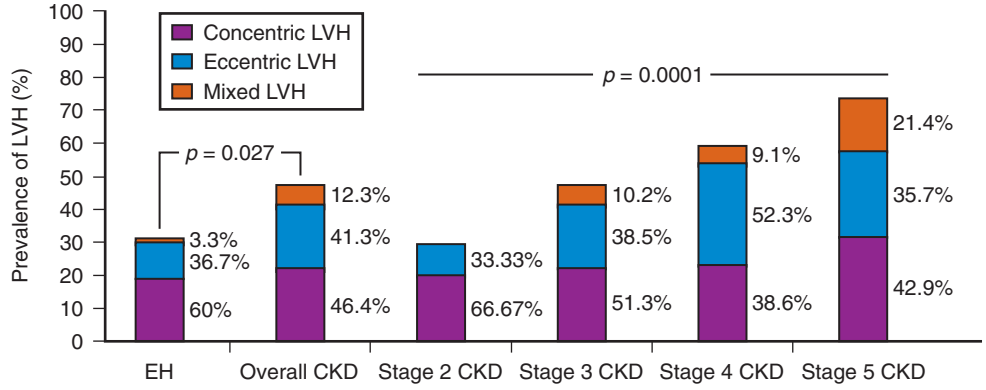

**Figure 38-11 Histograms showing prevalence of LV hypertrophy (*LVH*) in patients with essential hypertension (*EH*) and normal renal function and in patients with chronic kidney disease (*CKD*) of stages 2 to 5.** *Purple*, concentric LVH; *blue*, eccentric LVH; *orange*, "mixed" LVH. *(From Nardi E, Palermo A, Mulè G, et al: Left ventricular hypertrophy and geometry in hypertensive patients with chronic kidney disease.* J Hypertension *27:633-641, 2009.)*

## STRUCTURAL AND VALVULAR HEART DISEASE

Calcification of valves, cardiac skeleton, or myocardium is found in most patients with end-stage renal disease. It is caused by abnormalities in calcium and phosphorus metabolism.[149] Aortic valve calcification occurs in 28% to 60% of patients with end-stage renal disease.[149,150] Mitral annular calcification occurs in 10% to 36% of patients on dialysis and is associated with systemic inflammation.[168] Calcification from chronic kidney disease may occur in "atypical" areas, such as the base of both mitral leaflets and intervalvular fibrosa. Ultrasonic backscatter of myocardium in end-stage renal disease shows less homogeneity and greater reflectivity, reflecting myocardial calcification.

Aortic valve regurgitation occurs in 13% of chronic kidney disease patients, primarily due to calcification. Mitral regurgitation may occur in 38% of these patients and may be caused by mitral annular calcification or LV dilation. Tricuspid and pulmonic insufficiency occur with similar frequencies as that of mitral and aortic regurgitation, respectively, in patients with chronic kidney disease. However, tricuspid and pulmonic insufficiency occur secondary to increased pulmonary artery pressures as a consequence of significant mitral regurgitation and not valvular calcification.

Calcific aortic and mitral stenoses occur as a result of chronic kidney disease. Occasionally, they rapidly progress in patients with chronic kidney disease, possibly because of associated secondary hyperparathyroidism.[150] Chronic kidney disease may cause pericardial effusion, pericardial thickening, or cardiac tamponade.[168]

## CLINICAL UTILITY

Echocardiography is a useful noninvasive method of evaluating patients with chronic kidney disease and end-stage renal disease who present with symptoms suggestive of heart failure. An accurate clinical diagnosis of heart failure in these patients is challenging, because heart failure in such patients is often multifactorial. It could be on the basis of dilated cardiomyopathy, diastolic failure, inadequate ventricular hypertrophy, mitral or aortic valvular regurgitation, or stenosis. Pericardial effusion with secondary cardiac tamponade could mimic congestive heart failure. Conventional M-mode, 2D, and Doppler echocardiography techniques are useful in the diagnosis of the many structural and valvular abnormalities that may cause heart failure in the chronic kidney disease patient. In addition, tissue-Doppler imaging and strain rate imaging complement the conventional echocardiographic approaches in the comprehensive assessment of patients with chronic kidney disease for confirming associated myocardial disease. Myocardial tissue characterization with ultrasonic integrated back-scatter aids in the diagnosis of myocardial disease in patients with chronic kidney disease, but it has not been employed widely.

Echocardiography-derived measurements, when abnormal, are better predictors of prognosis than clinical evaluation or electrocardiographic findings in end-stage renal disease patients. These measurements include reduced LV ejection fraction and fractional shortening, increased LV volume, LVH, abnormal diastolic filling, increased E/E′ ratio, increased LA volume or diameter, and mitral annular calcification. End-stage renal disease patients with reduced LV systolic function and LV dilation have a poor prognosis, a mean survival of 7.8 months. Prospective studies in these patients show that improvement in echocardiography-derived systolic dysfunction and LVH or midwall fractional area change is associated with improved outcome over mean follow-up durations of 41 months[169] and 17 months,[170] respectively. LVH is a strong predictor of progression to dialysis in chronic kidney disease and is a major risk factor for morbidity and mortality in end-stage renal disease patients. Its complete regression may occur with intense and multifaceted therapy, making serial echocardiography useful in monitoring success of treatment.

In patients with end-stage renal disease, transmitral E/E′ ratio (an index of LV filling pressure), even when added to clinical parameters, LV mass index, and midwall fractional shortening, significantly improves prediction of overall mortality and cardiovascular death over 4 years (Fig. 38-12).[171] In chronic kidney disease patients with heart failure and systolic dysfunction, the presence of restrictive filling (grade 3 or 4) further adds to predicting cardiac death or need for urgent renal transplant over a mean follow-up duration of 16.5 months with a reported hazard ratio of 2.77 ($p = 0.019$).[172]

LA enlargement due to remodeling as determined by anterior-posterior diameter or volume is a practical and useful predictor of adverse outcome in chronic kidney disease and end-stage renal disease patients. Intuitively, it reflects the effects of multiple adverse cardiac abnormalities from chronic kidney disease, such as LVH, diastolic dysfunction, volume expansion, left-sided valvular disease, systolic dysfunction, hypertension, myocardial ischemia, and atrial fibrillation. However, even when all of these known factors are considered, LA enlargement remains an independent predictor of mortality. Chan and colleagues[173] reported in chronic kidney disease patients that an increased LA diameter indexed to body surface area independently adds to prediction of cardiovascular death. Similarly, LA volume indexed to body surface area greater than 32 mL/m$^2$ is a predictor of mortality.[174] In addition, serial monitoring for an increase in LA volume index to height by 1 mL/m$^2$ or more per year is associated with a 12% increase in relative risk for fatal and nonfatal cardiovascular events ($p < 0.001$).[175] Mitral annular calcification diagnosed by M-mode and/or 2D echocardiography is a predictor of mortality and coronary artery disease in patients with end-stage renal disease.[176]

Systemic hypotension complicating hemodialysis occurs often and is occasionally life threatening. Echocardiography is useful in identifying those patients predisposed to hemodialysis-induced hypotension. LA volume index greater than 35 mL/m$^2$ shows a 2.5-fold greater likelihood of hemodialysis-induced hypotension and was a better predictor of this occurrence as compared to LV systolic dysfunction.[177] Patients with impaired and short duration of early LV filling and/or reduced $V_p$ are at higher risk for hemodynamic instability during hemodialysis. $V_p$ less than 55 cm/s had a sensitivity of 47% and specificity of 86% for hemodialysis-induced hypotension.[178] During hemodialysis-induced hypotension refractory to conventional therapy, conventional and three-dimensional (3D) echocardiography helps assess potential causes of hypotension, such as intravascular volume depletion, impaired systolic function, or a hyperdynamic state with secondary intraventricular obstruction.[179]

Moderate or severe aortic valve calcification, as compared to none or mild, in end-stage renal disease patients identifies subjects prone to have a faster rate of progression in yearly aortic valve area diminution ($0.17 \pm 0.15$ cm$^2$/yr versus $0.04 \pm 0.07$ cm$^2$/yr, $p < 0.001$).[180] Serial echocardiography is useful to identify these high-risk patients and guide frequency of

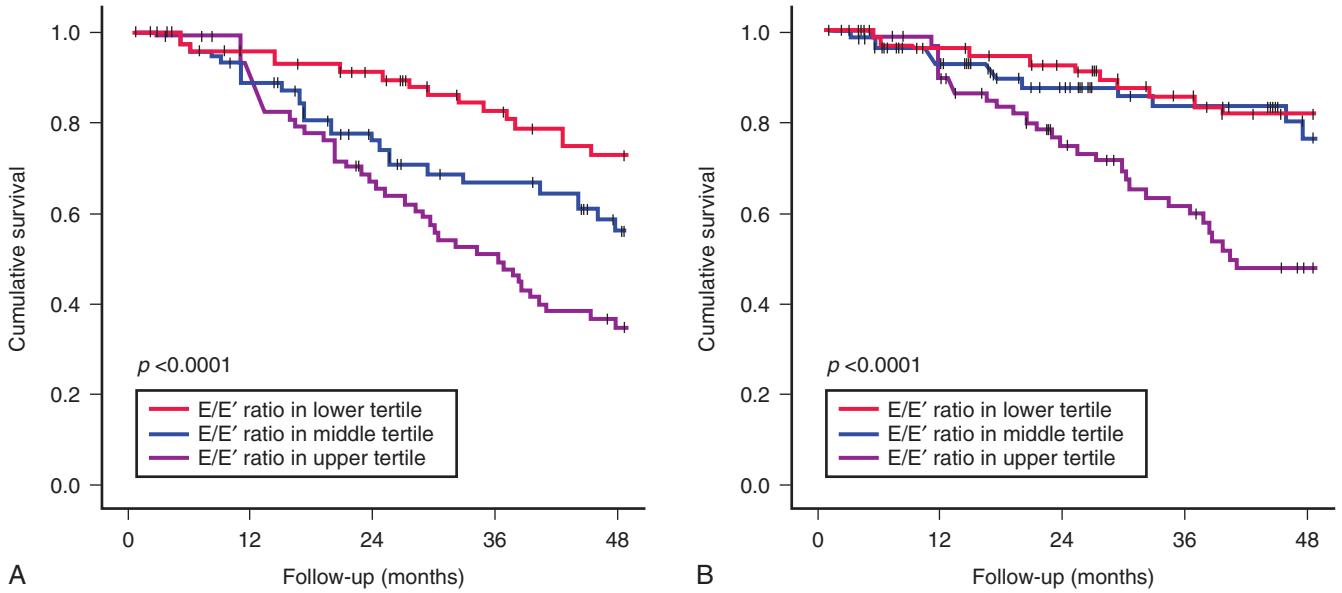

**Figure 38-12 Kaplan-Meier graphs of overall survival (A) and cardiovascular death (B) of patients with end-stage renal disease on basis of ratio of transmitral peak early filling to early diastolic tissue-Doppler velocity (*E/E′*) stratified by tertiles.** E/E′ defined as ≤14.43 for lower (*red line*), >14.43 to 21.73 for middle (*blue line*), and >21.73 for upper tertiles (*purple line*). Log-rank test showed significant differences between all tertiles for overall survival (**A**) and between upper versus middle or lower tertiles for cardiovascular death (**B**). *(From Wang AYM, Wang M, Lam CWK, et al: Left ventricular filling pressure by Doppler echocardiography in patients with end-stage renal disease.* Hypertension *52:107-114, 2008.)*

evaluation, as aortic valve replacement is an effective treatment for aortic stenosis despite the presence of end-stage renal disease.[181]

Dobutamine stress echocardiography is useful to identify coronary artery disease in patients with chronic kidney disease or end-stage renal disease, and to predict mortality. Karagiannis and co-workers[182] reported in 2292 patients with chronic kidney disease followed for over 8 years. Dobutamine stress echocardiography–induced ischemia of more than four segments portended an 80% mortality over the course of the study.[182] Normal dobutamine stress echocardiography portended a risk of 10% for cardiac events at 15 months.[182] Early identification and aggressive risk factor modification of coronary artery disease are essential in the chronic kidney disease population.

The Kidney/Disease Outcome Quality Initiative guidelines recommends that patients undergoing hemodialysis echocardiography should be monitored for changes in cardiac structure and function at initiation of dialysis and every 3 years thereafter. This recommendation is supported by prospective studies.[183]

## Obesity

Obesity increases circulatory blood volume and cardiac output as a compensatory mechanism from high metabolic demands of excessive adipose. Moderate to severe obesity may lead to LV enlargement, eccentric LVH, and diastolic dysfunction in the absence of other obesity-related diseases, such as hypertension, coronary artery disease, obstructive sleep apnea, hypoventilation syndrome, and diabetes (Table 38-7). Systolic impairment

and heart failure may ensue, giving rise to an obesity cardiomyopathy.[184] Heart failure is a frequent cause of death in morbidly overweight persons.

## SYSTOLIC FUNCTION

Obesity causes increases in circulatory blood volume and cardiac output, which are proportional to excess body weight. The high-output state of morbid obesity occurs predominantly from increases in adipose tissue blood flow. Resting heart rate is only minimally affected, but stroke volume is increased. LV ejection fraction may be augmented or normal in the early stages of obesity.[176,185] However, systolic function curves or indexes, such as the stroke work index to LV end-diastolic pressure or preejection period to LV ejection time ratio, may be reduced in obese patients, consistent with depressed myocardial systolic function. In addition, even in the face of normal global LV systolic function, abnormalities in regional myocardial systolic function have been shown to exist in persons with obesity.[186-190] Wong and colleagues[186] demonstrated in overweight, mildly obese, or severely obese subjects with normal LV ejection fraction that regional myocardial systolic function is decreased as assessed by systolic strain or tissue-Doppler velocity. Others have confirmed these findings.[187-191]

Reduced LV ejection fraction and attenuation of the normal increase in LV ejection fraction with exercise may occur in morbidly obese persons. In such individuals, increased LV mass is associated with an attenuation of the normal increase in LV ejection fraction during exercise. RV regional and global systolic function may be impaired due to obesity.[191-193] Weight reduction in subjects with obesity is associated with improvement in systolic function.[192,193]

Echocardiography is a sensitive method for detection of myocardial systolic dysfunction from obesity when applying sophisticated methods of LV strain and strain rate.[186,188,189,191] Orhan and associates[191] reported in obese persons compared to controls decreased LV global longitudinal ($-1.07 \pm 0.14$ $s^{-1}$ versus $-1.38 \pm 0.12$ $s^{-1}$, $p < 0.001$) and regional strain (Fig. 38-13).[191] RV systolic dysfunction also is present in obese persons as demonstrated by tissue Doppler–derived RV peak systolic velocity ($6.5 \pm 2.4$ cm/s versus $10.2 \pm 1.5$ cm/s, $p < 0.001$), longitudinal strain ($-21.0 \pm 4.5\%$ versus $-28.8 \pm 4.2\%$, $p < 0.001$), and peak systolic strain rate ($1.4 \pm 0.4$ $s^{-1}$ versus $2.0 \pm 0.5$ $s^{-1}$, $p = 0.001$).[192]

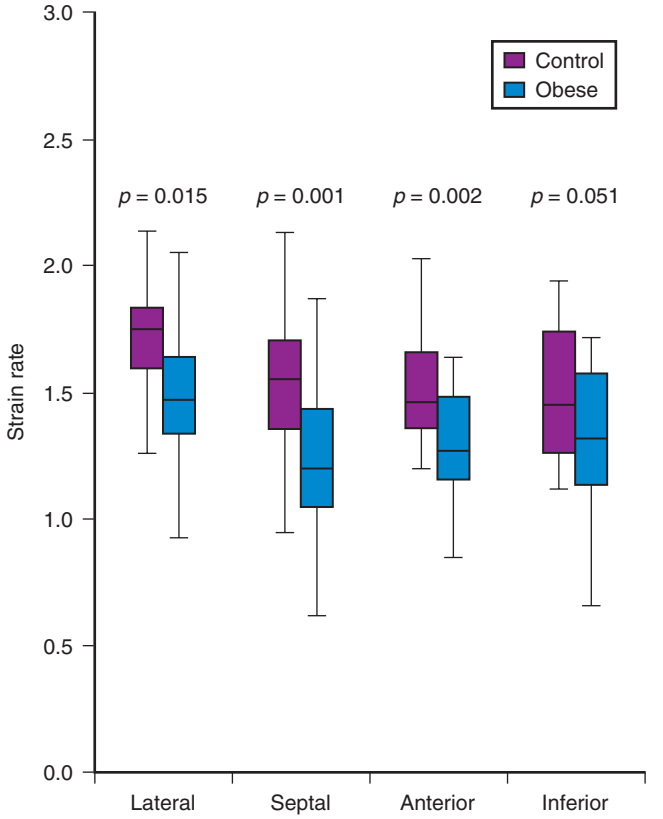

**Figure 38-13 Regional peak systolic longitudinal strain rates were lower in obese (*blue bars*) compared to controls (*purple bars*) measured from LV lateral, septal, anterior, and inferior basal walls.** *(From Orhan AL, Uslu N, Dayi SU, et al: Effects of isolated obesity on left and right ventricular function—a tissue-Doppler and strain rate imaging study.* Echocardiography *27:236-243, 2010.)*

## DIASTOLIC FUNCTION

Global LV diastolic dysfunction occurs in otherwise healthy obese persons as demonstrated by abnormalities of LV filling[185,194] and prolongation of isovolumic relaxation time.[185] LV diastolic dysfunction of at least a pseudonormal severity has been reported in 23% of obese persons without diabetes.[195] Regional myocardial diastolic function also is impaired in obese persons.[186,187,190] Findings include reduced E′ from tissue-Doppler ($10.1 \pm 1.7$ cm/s versus $8.0 \pm 2.2$ cm/s, $p < 0.01$)[191] and peak early LV diastolic strain rate. Impaired LV relaxation, compliance, or both occur in obese patients because of associated LVH. RV regional and global diastolic dysfunction occurs in obese persons, but the independent influence of coexisting diabetes and/or sleep apnea is difficult to quantify.[192,196,197] Weight reduction is associated with improvement in LV and RV diastolic dysfunction.[198]

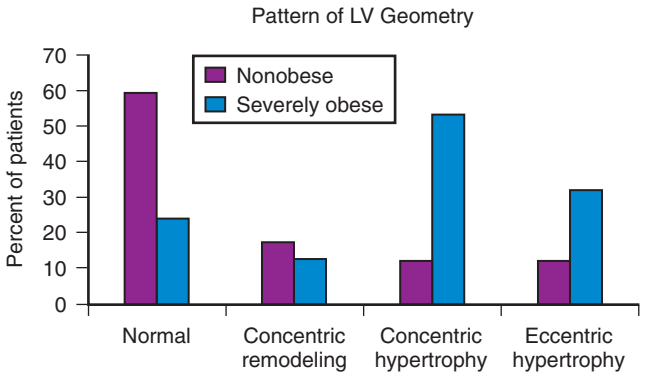
LA enlargement ideally assessed by volume derived from 2D or 3D echocardiography can be on the basis of obesity, particularly in older subjects.[199] When LA enlargement is present despite normal conventional measures of global LV diastolic function (e.g., E/A ratio, isovolumic relaxation time, or $V_p$), pseudonormal diastolic dysfunction and elevated LA pressure should be suspected. This can be confirmed by an elevated E/E′ ratio, typically greater than 13 to 15.

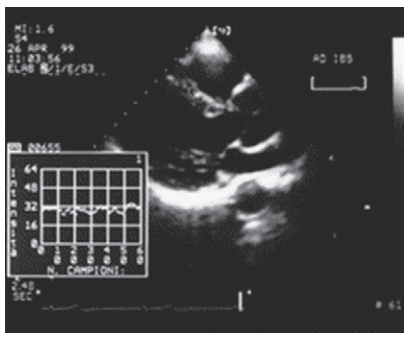
RV systolic dysfunction is present in obese persons as demonstrated by tissue Doppler–derived RV peak early diastolic velocity ($6.8 \pm 2.4$ cm/s versus $10.3 \pm 2.5$ cm/s, $p < 0.001$).[192]

## STRUCTURAL ABNORMALITIES

Compared with normal-weight controls with similar blood pressure, obese patients show an increase in LA diameter, area, and volume, aortic root diameter, LV end-diastolic diameter, septal and posterior wall thickness, and LV mass[186-188,200-202] (see Table 38-7). Obesity causes predominantly concentric LVH but is also associated with concentric remodeling and eccentric LVH (Fig. 38-14).[201] Eccentric LVH in obesity is accounted for by chronic increased intravascular volume and partially explains the association between increasing LV mass and severity of obesity. Inadequate hypertrophy of the LV wall to normalize wall stress in the face of a dilated cavity occurs in some obese persons and may account for impaired myocardial systolic function. RV enlargement occurs in obesity and is partially explained by associated sleep apnea and pulmonary

hypertension. Weight loss induces significant reductions in LV end-diastolic diameter, end-systolic wall stress, LV mass, and RV size.[198,202,203] Ultrasonic integrated back-scatter of LV septum and posterior walls is increased in obese compared to controls, potentially on the basis of increased collagen content or myocardial fibrosis (Fig. 38-15).[204] Epicardial fat on the free wall of the RV is visceral fat that correlates with obesity-related insulin resistance and more commonly seen in obese persons.[205] Aerobic exercise and weight reduction decreases epicardial fat layer thickness.[206]





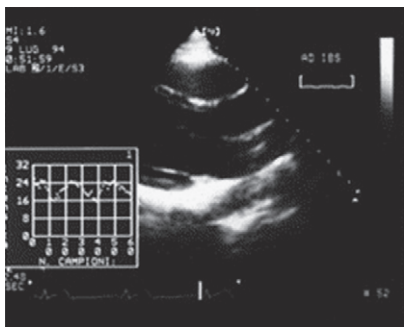


**Figure 38-14 Patterns of LV geometry in nonobese (n = 59; *purple bars*) and severely obese (n = 455; *blue bars*) subjects.** Concentric LV hypertrophy (LVH) is most frequent in obese subjects, but eccentric LVH represents a significant proportion. *(From Avelar E, Cloward TV, Walker JM, et al: Left ventricular hypertrophy in severe obesity—interactions among blood pressure, nocturnal hypoxemia, and body mass.* Hypertension *49:34-39, 2007.)*

## ANOREXIGEN USE, VALVULOPATHY, AND PULMONARY HYPERTENSION

Obesity is associated with serious cardiovascular health risks, such as heart failure, stroke, and systemic hypertension. Appetite-suppressant medications or anorexigens with diverse mechanisms of action are used in the treatment of obese subjects to promote weight reduction. Studies with matched control subjects and blinding of echocardiographic interpretations show a prevalence from 6.3% to 11.3% (unadjusted for background rates) of aortic valvular regurgitation in association with the use of anorexigens when the U.S. Food and Drug Administration (FDA) criteria (i.e., mild or greater aortic regurgitation) were met.[207] Studies have shown no association between anorexigen use and valvular heart disease when duration of treatment was less than 3 months.[208,209] Meta-analysis of four studies showed a statistically significant increase of moderate or greater mitral regurgitation in patients treated for greater than 90 days with fenfluramine or dexfenfluramine as compared to controls (i.e., 3.5% versus 1.8%). Structural abnormalities seen on echocardiography have been reported to include aortic or mitral leaflet thickening, diastolic doming of the anterior mitral leaflet and immobility of the posterior mitral leaflet, shortening and thickening of chordae tendineae, and retraction of aortic valve leaflets. Histopathologic and gross pathologic findings available in these subjects included fibrotic endocardial changes of valve leaflets and chordae tendineae with a "stuck on plaque" appearance and white glistening valves, which were indistinguishable from the features of carcinoid or ergotamine valvulopathy.

Aortic or mitral valvular regurgitation that meets the FDA criteria in severity, when present, appears far more likely to

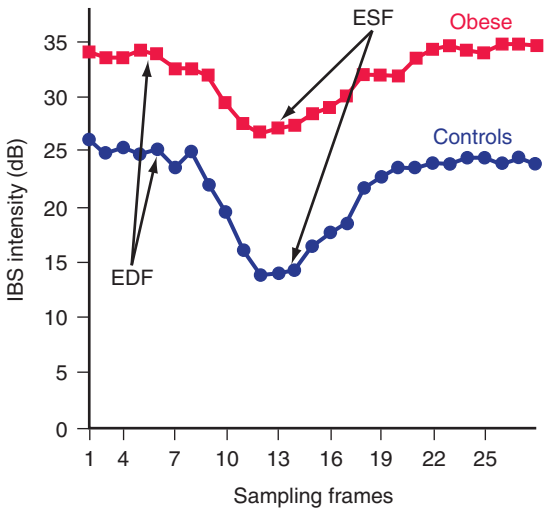

**Figure 38-15 Ultrasonic integrated back-scatter showing greater echoreflectivity of the myocardium in a representative obese patient versus healthy control person.** *EDF*, End-diastolic frames; *ESF*, end-systolic frames. *(From Di Bello V, Santini F, Cori AD, et al: Obesity cardiomyopathy—is it reality? An ultrasonic tissue characterization study.* J Am Soc Echocardiogr *19:1063-1071, 2006.)*

remain stable and/or to regress than to progress in obese subjects after cessation of the use of fenfluramine or dexfenfluramine.[210] Ideally, quantitative measures should be employed to assess regurgitation severity. The need for valve surgery from anorexigen valvulopathy is rare, particularly many years later in those not initially meeting FDA criteria of valvulopathy in proximity to fenfluramine or dexfenfluramine use.[211] The use of appetite suppressants, including dexfenfluramine or fenfluramine, for longer than 3 months showed an odds ratio of 23 (95% confidence index: 6.9 to 77) for primary pulmonary hypertension in obese individuals.[212] Echocardiography has an important role in the noninvasive estimation of pulmonary artery pressure in obese subjects when pulmonary hypertension on the basis of anorexigen use is suspected. Peak pulmonary systolic pressure, estimated by echocardiography, is greater than 35 mm Hg in nearly one third of otherwise normal obese individuals.[213] The prevalence of elevated pulmonary pressures in morbidly obese individuals living at moderate altitude may be in excess of 96%. These data suggest caution when ascribing mild elevation of pulmonary artery systolic pressure to anorexigen use in obese subjects.

### CLINICAL UTILITY

Although the echocardiographic findings of obesity are nonspecific, echocardiography is useful in the assessment of obese patients, particularly if there is long-standing heart failure or suspicion of the presence of heart failure. Appraisal of LV global and regional systolic function, diastolic function, chamber size, and hypertrophy, and RV function helps to guide medical therapy. Substantial weight reduction by the morbidly obese may improve LV and RV systolic and diastolic function, decrease LV chamber size, and reduce LV mass.[197,198,202,203]

Echocardiography is of benefit in obese subjects with suspected aortic or mitral valvulopathy on the basis of anorexigen use. The presence of aortic or mitral valvular thickening unexplained by other causes in combination with at least mild aortic regurgitation or at least greater than mild mitral regurgitation, respectively, should be present before a diagnosis of anorexigen-induced valvulopathy is entertained. Several quantitative measures should be employed to assess changes in severity of regurgitation over time, as reliance on qualitative assessments or any single method is unreliable and may lead to erroneous conclusions on the clinically relevant question of progression, stability, or regression in anorexigen-induced valvular heart disease.[214] Obesity is a cause of pulmonary hypertension and confirms a need for caution when attributing mild elevation of pulmonary artery systolic pressure as estimated by echocardiography to anorexigen use in obese subjects.[213]

## Nutritional Deficiencies and Heart Disease (Table 38-8)

### VITAMIN AND TRACE ELEMENT DEFICIENCIES

#### *Beriberi Heart Disease*

Thiamine deficiency may occur in many as 33% of patients with heart failure.[215] Diuretics increase urinary excretion of thiamine and is a cause of this deficiency. Body stores can be depleted in 2 to 3 weeks. Severe thiamine deficiency that persist for 3 months or longer may lead to beriberi. Heart disease in beriberi patients is characterized by biventricular failure and marked edema associated with a high cardiac output and arteriolar vasodilation. RV failure may predominate, but significant elevation of LV end-diastolic and pulmonary capillary wedge pressures occur. The disease has been virtually eliminated in the United States, but it can be seen in alcoholic persons who become thiamine deficient. The hemodynamic abnormalities are reversible with thiamine therapy but may not respond to inotropic agents or diuretics. The possibility of thiamine deficiency and beriberi heart disease should be considered in cases of refractory heart failure presumed to result from alcoholic cardiomyopathy.

#### *Keshan Heart Disease*

Keshan heart disease, first described in China, is a dilated cardiomyopathy characterized by myocardial fibrosis and necrosis. Selenium and vitamin E deficiency may be important in its development. Suspected cases of selenium deficiency and cardiomyopathy similar to this disease have been reported in the United States. Keshan disease is preventable by selenium supplementation in the diet.

#### *Other Vitamin Deficiencies*

Vitamin D deficiency is estimated to occur in 25% to 57% of adults in the United States. It has been linked to presence of valvular calcifications, mitral annular calcification, LV dilation, and possibly LVH.[216-218] Vitamin C deficiency may cause scurvy and heart abnormalities. The manifestations of cardiac involvement in scurvy may include dyspnea, chest pain, sudden death, PR interval prolongation, and ST-segment abnormalities. The direct effects of vitamin A or niacin deficiency on heart muscle in humans have not been established.

*LVEF*, LV ejection fraction; $V_{cf}$, LV velocity of circumferential fiber shortening.

## PROTEIN AND CALORIE MALNUTRITION

Protein-calorie malnutrition leads to kwashiorkor. Heart disease in this condition is shows atrophy of cardiac muscle fibers, interstitial edema, vacuolization of myocardial fibers, and low-output heart failure. The condition is rare in developed nations, but it contributes to heart disease in patients with chronic illnesses or anorexia nervosa. In children, LV diameter and mass assessed by M-mode echocardiography are decreased in protein-calorie malnutrition, proportional to the reduction in body size.[219] In children, LV systolic function may be decreased in protein-calorie malnutrition and manifested by a decrease in shortening fraction, mean $V_{cf}$, and systolic time interval, but these findings have not been consistently shown.[219]

## KEY POINTS

- Diabetes is associated with a cardiomyopathy characterized by impaired diastolic and systolic dysfunction, independent of coronary disease or hypertension.
  - Regional LV systolic dysfunction is an early manifestation of diabetic heart disease as measured by strain, strain rate, and tissue-Doppler velocity imaging.
  - Subclinical diastolic dysfunction also is evident by conventional Doppler and strain imaging.
  - An increased LV mass index is a predictor of adverse cardiovascular events in diabetic patients.
  - Aortic stenosis progression may be more rapid in diabetic subjects.
- Pericardial effusion may be seen in overt hypothyroidism or may be the first indication of thyroid dysfunction.
- Hyperthyroidism is associated with an increased LV ejection fraction at rest but a reduced increase in ejection fraction and stroke volume with exercise.
- Cardiovascular complications are common in patients with acromegaly, with early LV diastolic dysfunction followed by progression to systolic dysfunction and heart failure, often in associated with an increased LV mass index.
- In about 50% of patients with hyperparathyroidism, aortic valve and mitral annular calcification are present. Coronary artery calcification and myocardial calcium deposits also are common.
- Echocardiographic findings of severe LVH or hypertrophic cardiomyopathy without obvious cause should raise the clinical suspicion of glucocorticoid excess, possibly from Cushing syndrome.
- Chronic kidney disease results in impaired LV systolic and diastolic dysfunction. Concurrent hypertension leads to an increase in LV wall thickness and LV mass.
- Obesity results in increase in cardiac dimensions, LV diastolic dysfunction and RV systolic dysfunction.
