**Alternate Diagnostic Approaches**

## Forms of Connective Tissue Disorders

Although connective tissue disorders affect multiple organs, the impact on the cardiovascular system is considered the most dangerous. These disorders are known to cause progressive degeneration of the integument, joints, pleura, and eyes. Potential exists for both left and right heart involvement, but clinically important pathology is typically confined to the mitral valve, aortic valve, and the aorta itself.

As opposed to other forms of cardiovascular disease, many patients come to medical attention not because of symptoms referable to the cardiovascular system but rather because of findings associated with one of the noncardiac organ systems noted previously. In addition, identification of cardiovascular pathology may be noted on screening cardiac assessment as a result of the presence of a defined or suspected connective tissue disorder in another family member. Echocardiography is the mainstay of cardiac screening for the cardiac manifestations of connective tissue disorders. As with many other cardiac disorders, transesophageal echocardiography (TEE) complements transthoracic echocardiography (TTE) in developing a thorough set of data. In addition, other noninvasive imaging modalities (i.e., computerized tomography and magnetic resonance imaging) contribute to diagnosis in selected circumstances. Although Marfan syndrome (MFS) is the most common connective tissue disorder that leads to cardiovascular compromise, a number of other inherited and congenital conditions are known to affect the cardiac structures in similar ways (Box 39-1). These conditions are elucidated in this chapter. In addition, the spectrum of disease and the methods of assessment are highlighted.

### MARFAN SYNDROME

Marfan syndrome is a well-described heritable disorder of connective tissue with a broad phenotypic spectrum. Major clinical manifestations include the cardiovascular, ocular, and skeletal systems. The diagnosis is based on the Ghent nosology, which was recently revised by an international expert panel (Boxes 39-2 and 39-3).[1] The revised criteria place increased importance on the cardinal clinical features of aortic root dilation and dissection and ectopia lentis.

The evaluation of children and adolescents for MFS requires special consideration.[1] Serial evaluations are recommended because of their potential for evolving clinical features, which could progress so that a diagnostic criterion is eventually achieved. However, the practitioner should also be judicious in conferring this diagnosis because it may cause psychosocial stress, impact career decisions, and limit insurability. Young patients (younger than 20 years of age) with a fibrillin 1 (FBN1) mutation or a family history of MFS and aortic root measurements with a Z-score of less than 3 should have a diagnosis of "potential MFS" until follow-up evaluation shows further aortic dilation.

Marfan syndrome is inherited in an autosomal dominant manner, with 25% of patients representing sporadic new mutations without a family history.[2] Once an individual is diagnosed with MFS, first-degree relatives should be screened for the condition (with physical examination, accompanied by ophthalmologic assessment and echocardiography when clinically appropriate). The age-related penetrance is high, and both interfamilial and intrafamilial variability are well described. Molecular genetic testing of the fibrillin 1 gene (locus 15q21.1) reveals a causative mutation in about 70% to 90% of individuals with the clinical diagnostic criteria for MFS.[3]

Despite a considerable effort invested in defining genotype-phenotype correlations for MFS, few if any definitive correlations have emerged. Thus far, none have been shown to be specific enough to influence clinical management. Of those that have emerged, the patients with the most severe form of MFS (also termed infantile MFS) and an identifiable fibrillin 1 mutation tend to harbor mutations in the central portion of the gene,

## REVISED GHENT CRITERIA FOR THE DIAGNOSIS OF MARFAN SYNDROME

**In the Presence of Family History, Any of the Following Confirm the Diagnosis of Marfan Syndrome:**

- Ectopia lentis
- Systemic score ≥7
- Ao sinus dilation (Z-score ≥2 above age 20 years or Z-score ≥3 below age 20 years)

**In the Absence of Family History and without Discriminating Features of Another CTD:**

- Ao sinus dilation (Z-score ≥2) and ectopia lentis = Marfan syndrome
- Ao sinus dilation (Z-score ≥2 above age 20 years or Z-score ≥3 below age 20 years) and fibrillin 1 = Marfan syndrome
- Ao sinus dilation (Z-score ≥2) and systemic score ≥7 = Marfan syndrome
- Ectopia lentis and fibrillin 1 with known aortic dilation = Marfan syndrome

From Loeys BL, Dietz HC, Braverman AC, et al: The revised Ghent nosology for the Marfan syndrome. *J Med Genet* 47:476-485, 2010.
*Ao*, Aortic; *CTD*, connective tissue disorder.

## SYSTEMIC SCORE IN MARFAN SYNDROME

- Wrist and thumb sign, 3 (wrist or thumb sign, 1)
- Pectus carinatum deformity, 2 (pectus excavatum or chest asymmetry, 1)
- Hind foot deformity, 2 (plain pes planus, 1)
- Pneumothorax, 2
- Dural ectasia, 2
- Protrusio acetabuli, 2
- Reduced upper segment/lower segment ratio and increased arm/height and no severe scoliosis, 1
- Reduced elbow extension, 1
- Scoliosis or thoracolumbar kyphosis, 1
- Facial feature (3/5), 1 (dolichocephaly, enophthalmos, downslanting palpebral fissures, malar hypoplasia, retrognathia)
- Skin stria, 1
- Myopia >3 diopters, 1
- Mitral valve prolapsed, 1

between exons 24 to 32.[4-6] Interestingly, mutations have been also found in this region in other patients with classic, atypically severe, and milder forms of MFS and other fibrillinopathies.[6-8] By way of contrast, mutations in fibrillin 1 that result in milder forms of a type 1 fibrillinopathy have also been described. These include mutations in the C-terminus region of fibrillin 1 that result in only the skeletal manifestations of MFS.[9] Mutations in exons 59 to 65 of fibrillin 1[10] and exons 1 to 10[11] have been associated with phenotypes that lack significant aortic involvement or with only late onset and relatively mild cardiovascular features.

## EHLERS-DANLOS SYNDROME

The multiple forms of Ehlers-Danlos syndrome (EDS) are each manifested by particular phenotypic features. The most common forms are type III, otherwise termed benign hypermobility syndrome; and the classic form, previously designated as types I and II but now recognized as forming a clinical continuum (involving hyperextensibility, fragile "cigarette paper" skin that heals poorly, scoliosis, and hernias). Between one quarter and one third of individuals with these types of Ehlers-Danlos syndrome have aortic dilation, but usually only to a mild degree. Aortic dissection is rare absent significant preexisting dilation.[12-14] The long-term prognosis regarding progression or development of aortic dilation is the subject of ongoing investigations.[12,13] Mitral valve prolapse is also encountered in these patients. Classic and type III Ehlers-Danlos syndrome are inherited in an autosomal dominant fashion and are caused by a disorder in synthesis of collagen.

Type IV or vascular form is considered the malignant form of Ehlers-Danlos syndrome in that there is an increased susceptibility to spontaneous vascular dissection. The median age of death is 48 years. Large vessel dissections can involve the aorta, but the cerebral and abdominal large arteries are also at risk.[15,16] The sites of arterial rupture are the thorax and abdomen (50%), head and neck (25%), and extremities (25%). Although uncommon, the vascular type of Ehlers-Danlos syndrome is a cause of stroke in young adults. The mean age of intracranial aneurysmal rupture, spontaneous carotid-cavernous sinus fistula, and cervical artery aneurysm is 28 years.[17] Hyperelastic tissues and hyperextensible joints are less frequent manifestations, but easy bruising, poor wound healing, and rupture of the gastrointestinal tract are commonly seen. Inheritance is autosomal dominant, with the defect occurring in the type III collagen gene *COL3A1*.[18]

All patients with Ehlers-Danlos syndrome (irrespective of particular type) should undergo screening echocardiographic assessment. Patients with types I, II, and IV (more commonly associated with cardiovascular manifestations) should be evaluated annually with echocardiography for a serial assessment of aortic dilation and mitral valve disease. Aortic regurgitation may also develop. The indications for surgical repair in classic and type III syndromes are similar to MFS and are discussed subsequently in the chapter. The fragile nature of the large vessels in the vascular form of Ehlers-Danlos syndrome increases surgical morbidity and mortality. Therefore, whether there is a role for early prophylactic repair of unruptured aneurysms in the vascular form of Ehlers-Danlos syndrome is unclear.[19] However, successful repairs of aneurysms and dissections can be achieved with careful surgical technique.[20] TEE should be approached with caution because of the potential for gastrointestinal involvement.

## HOMOCYSTINURIA

This disorder is defined as the presence of excessive homocysteine in the urine. The most common form of homocystinuria is caused by a metabolic disorder in which a deficiency of cystathionine β synthase results in an elevation of blood methionine and subsequent deposition of its precursor homocysteine in the urine. The inheritance occurs in an autosomal recessive pattern, with variable phenotypic expression even within the same family. Clinical findings can include developmental delay, ectopia lentis, coagulopathies, and many of the same skeletal features present in MFS, including scoliosis, arachnodactyly, tall stature, and pectus deformities. As opposed to the aortic dilation seen in patients with MFS, this entity is not generally present in homocystinuria. From a cardiovascular standpoint, these patients can have arterial and venous thromboses develop, which can lead to peripheral or cerebral vascular disease in both children and adults.[21] This is complicated by vascular injury, including medial degeneration of the aorta and large arteries, with intimal hyperplasia and fibrosis. There is resultant pulmonary embolism with associated right ventricular hypertension and ischemic coronary disease with the potential for myocardial infarction.

## OTHER FIBRILLINOPATHIES

Fibrillin 1 mutations have also been reported in distinct phenotypes that have overlap with MFS, including mitral valve prolapse syndrome, the MASS phenotype (*M*yopia, *M*itral valve prolapse, borderline *A*ortic enlargement, and nonspecific *S*kin/*S*keletal signs), apparently isolated ectopia lentis, predominant or isolated skeletal features of MFS, and familial aortic aneurysm or dissection.[3] Together, MFS and the MFS-related phenotypes have been termed the type 1 fibrillinopathies.

Congenital contractural arachnodactyly (also known as Beals syndrome), another connective tissue disorder similar to MFS, is caused by fibrillin-2 mutations. Differentiation between these two syndromes can be difficult because of the similar skeletal complications that include arachnodactyly, pectus deformities, and scoliosis. However, congenital contractural arachnodactyly usually presents with multiple joint contractures and crumpled ear helices. There is the occasional finding of aortic root dilation; in addition, eye involvement can be seen.[22]

## LOEYS-DIETZ SYNDROME

Loeys-Dietz syndrome is a recently described autosomal dominant connective tissue disease associated with arterial aneurysms and dissections and other systemic involvement.[23,24] Importantly, aortic dissection can occur at diameters smaller that those observed in MFS.[23,25] The genes for the transforming growth factor–β receptors 1 and 2 are the only currently known genes involved in this disorder.[24] Loeys-Dietz syndrome is characterized by the clinical triad of arterial tortuosity and aneurysms; hypertelorism; and bifid uvula or cleft palate or uvula with a wide base or prominent ridge. Aneurysms occur in the aortic root but are also commonly found in other arteries. The arterial tortuosity most commonly affects the head and neck vessels.

Specific diagnostic criteria for Loeys-Dietz syndrome have not been established. Typically, the diagnosis is rendered when a patient has findings from some of the commonly affected organ systems in addition to identification of a disease-causing mutation on genetic testing. The four main groups of clinical findings are vascular, skeletal, craniofacial, and cutaneous (Box 39-4).[23] We recommend genetic testing on patients with aortic root dilation who have any features from the other main groups of clinical findings. Some patients with aortic dilation and dissection have mutations in the transforming growth factor–β receptor 1 and 2 genes without other features of Loeys-Dietz syndrome. These patients fall in the category of thoracic aortic aneurysms and dissections and are discussed subsequently. Consideration should be given for genetic testing in families with multiple members with only aortic or other arterial dilation. Finally, it is reasonable also to consider genetic testing for transforming growth factor–β receptor 1 and 2 mutations in patients who have had aortic dissection at diameters less than 5 cm, unless another causative condition is identified.

Loeys-Dietz syndrome is often divided into two subtypes. Patients with Loeys-Dietz syndrome type I (around 75% of patients with Loeys-Dietz syndrome) do not typically have cutaneous abnormalities. Loeys-Dietz syndrome type II constitutes the remaining patients and does not typically have craniofacial findings, with the exception of isolated bifid uvula. Considerable overlap is found between the subtypes, and they are considered part of the same clinical continuum.

The most important complication in Loeys-Dietz syndrome is aortic root dilation and dissection. The mean age of death in the original case series was 26 years.[23] Nearly all patients had aortic root aneurysms that lead to dissection. As noted previously, dissection can occur at aortic dimensions that are not considered high risk in MFS (less than 5.0 cm), and dissections have been reported in infancy and early childhood. Around half of patients with Loeys-Dietz syndrome have dilation or tortuosity in the arterial tree away from the aortic root. Notably, these

**Box 39-4**

### CLINICAL FEATURES OF LOEYS-DIETZ SYNDROME

**Vascular**
- Aortic root dilation and dissection
- Distal arterial aneurysms and tortuosity

**Skeletal Manifestations**
- Pectus excavatum or carinatum
- Scoliosis
- Joint laxity
- Arachnodactyly
- Talipes equinovarus

**Craniofacial Features**
- Ocular hypertelorism
- Bifid uvula (or uvula with a wide base or prominent ridge)
- Cleft palate
- Craniosynostosis

**Cutaneous Features**
- Translucent skin
- Easy bruising
- Dystrophic scars

**Other**
- Females are at risk for uterine rupture during pregnancy

A,** Parasternal long-axis view during systole shows doming of the aortic valve leaflets, effacement of the sinotubular junction, and dilation of the aortic root. **B,** Parasternal long-axis view during diastole shows eccentric valve leaflet closure and dilation of the sinus of Valsalva. *Ao,* Aorta.

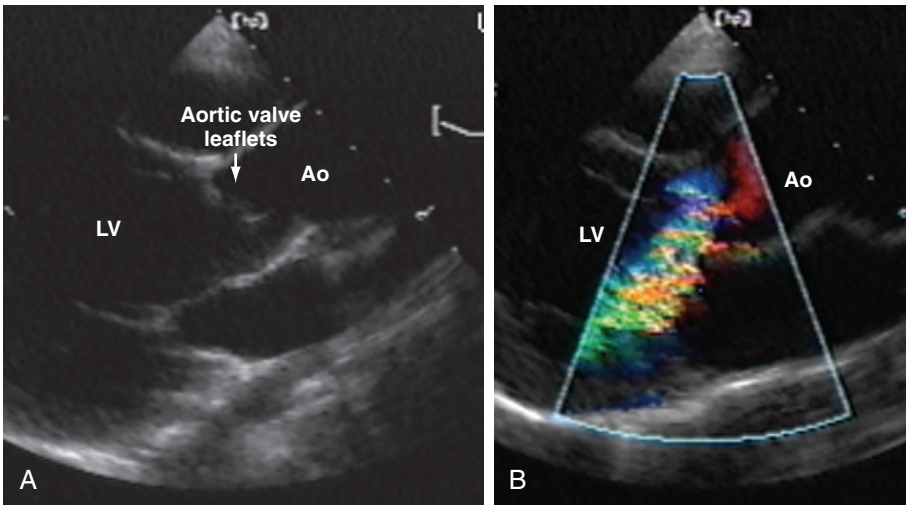

**Figure 39-2 A, A 10-year-old with Loeys-Dietz syndrome and severe aortic regurgitation from a bicuspid aortic valve and severe aortic root dilation.** Parasternal long-axis view of the thickened aortic valve leaflets, dilated LV, and aneurysm of the aortic root. **B,** Parasternal long-axis view of the severe jet of aortic regurgitation from the combined aortic valve and aortic root pathologic processes. *Ao,* Aorta.

distal lesions are not detected with echocardiogram. These vascular features differentiate the vascular disease in Loeys-Dietz syndrome from MFS. Additional cardiac malformations include patent ductus arteriosus, atrial septal defects, and bicuspid aortic valve.

## BICUSPID AORTIC VALVE

Bicuspid aortic valve is the most common form of congenital heart disease and affects between 0.5% and 2% of general population.[26] Clinical studies have identified a 9% prevalence rate of bicuspid aortic valve in first-degree relatives, which validates the inherited basis of this condition.[27,28] Interestingly, first-degree relatives have also been identified with aortic dilation in the absence of a bicuspid aortic valve.[29]

Patients with a bicuspid aortic valve are at increased risk of aortic aneurysm and dissection (Fig. 39-1). This appears to be a result of pathologic changes in the aortic wall that include decreased fibrillin-1, loss of elastic fibers, increased apoptosis, and altered smooth muscle cell alignment.[30] Patients with a bicuspid aortic valve have larger aortic annulus, sinus, and ascending aortic dimensions and an increased rate of aortic dilation over time (Fig. 39-2). Up to 15% of aortic dissections may occur in individuals with a bicuspid aortic valve.[31] Historically, the term poststenotic dilation was used as a hemodynamic explanation for the finding of aortic dilation in the presence of a bicuspid aortic valve. However, this relationship is now understood in fact to be the result of aortic pathology that is independent of the aortic valve disease itself.[32,33] The increased risk of aortic dissection in patients with a bicuspid valve is limited to a small group of the overall population of patients with a bicuspid valve.[34,35] Even after valve replacement, surgery for a bicuspid valve is a strong risk factor for subsequent aortic dissection. Thus it is likely that the concomitant finding of a bicuspid aortic valve and aortic aneurysm and dissection is a manifestation of what is the general class of systemic connective tissue disorders.[36]

Although multiple factors have been implicated in aortic dissection,[37] little is known of why or how a bicuspid aortic valve predisposes to aneurysm formation and dissection. In an

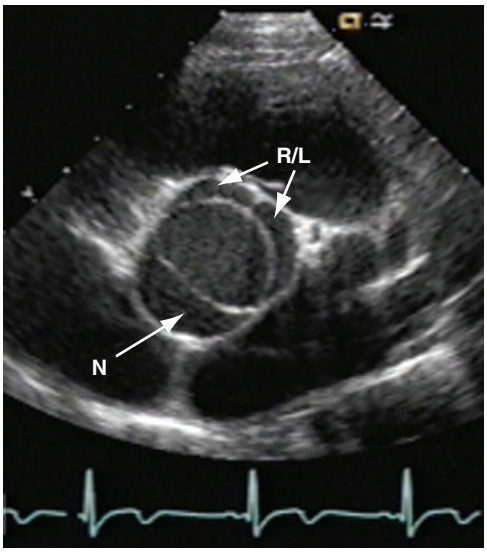

**Figure 39-3 Parasternal short-axis view of a patient with a dilated aortic root and associated bicuspid aortic valve.** The valve pathology is the result of fusion of the left (*L*) and right (*R*) coronary cusps. A raphe is noted between the left and right cusps. *N,* Noncoronary cusp.

attempt to address this question, Schaefer and associates[38] described differences in aortic dimensions and elasticity between different phenotypes. They found that subjects with type 1 bicuspid aortic valve (anterior-posterior leaflet orientation, with or without a raphe in the position demarcated by the left and right coronary cusps) had a larger dimension and increased wall stiffness at the sinuses of Valsalva (Fig. 39-3) than those with type 2 bicuspid aortic valve (right-left leaflet orientation, with or without a raphe in the position demarcated by the right and noncoronary cusps). The mechanism for these differences may be that the composition and elastic properties of the aortic wall are genetically related to aortic valve morphology. Hemodynamic differences may also contribute, with genetic upregulation altered by flow and force exerted on the aortic wall dependent on aortic valve morphology.

## TURNER SYNDROME

Patients with Turner syndrome are at high risk for the identification of left heart pathology, particularly a bicuspid aortic valve and coarctation of the aorta.[39] In addition, those with Turner syndrome have a higher incidence of systemic hypertension (even in the absence of anatomic cardiac pathology). Aortic dissection occurs in about 1.4% of patients with Turner syndrome,[40] and dissection often occurs at a young age (mean, 30 years).[41] Approximately 80% to 90% of those with aortic dissection have either systemic hypertension or a bicuspid aortic valve. Criteria with which to assign risk have been difficult to ascertain, particularly because most criteria are based on somatic growth (height, weight, body surface area). Because patients with Turner syndrome also have short stature, the general determinants of the relationship between somatic growth and expected aortic dimension remain problematic. For this reason, the definition of normal aortic size, especially in the presence or absence of potentially confounding factors (hypertension, bicuspid aortic valve, and coarctation of the aorta), is unclear. The general adult guidelines for the prediction of heightened risk for aortic dissection[42] in those with Turner syndrome and aortic dilation remain to be determined. In addition, the relative aortic dimensions when aggressive pharmacologic or surgical intervention should be instituted remain unclear. The presence of a generalized vasculopathy in those with Turner syndrome is well described and is characterized by aortic wall stiffness, arterial dilation, vessel wall thickening, and abnormal pulse wave propagation.[43] Because patients with Turner syndrome without aortic pathologic findings or systemic hypertension are found to have isolated aortic dilation, an intrinsic aortopathy is suggested to be a primary phenotypic feature of this condition.

A recent cross-sectional study of girls with Turner syndrome less than 18 years of age revealed a number of interesting echocardiographic findings.[44] When the group of subjects with Turner syndrome was compared with the control population, subjects with or without features that would be considered high risk (systemic hypertension, bicuspid aortic valve, coarctation or repaired coarctation of the aorta, or other organ system abnormalities, including renal or thyroid disease) had larger proximal aortas in almost all of the cases. The prevalence rates of individuals with Z-scores of 2 or more were 12% for the aortic annulus, 20% for the aortic root, 18% for the sinotubular junction, and 30% for the ascending aorta. These prevalence rates corresponded with increased relative risks of 4.8 to 12.0 times those of the control population. Even in the absence of a bicuspid aortic valve, patients with Turner syndrome had a larger aorta at the aortic root, sinotubular junction, and ascending aorta, suggesting that Turner syndrome alone predicts aortic dilation. The effect of a bicuspid aortic valve added incrementally to this independent effect of Turner syndrome on aortic dimension.

Although the data regarding aortic dilation in the presence of Turner syndrome raise obvious concerns regarding risk for dissection, additional work is needed to determine the gravity of this risk. Similarly, a better understanding as to the parameters relating dilation to dissection will allow us to develop treatment protocols appropriate to the specific features present in the individual patient with Turner syndrome. In the meantime, no global therapeutic guidelines are available. Most specialists caring for individuals with Turner syndrome therefore manage these patients in a manner similar to that of those with a bicuspid aortic valve.[45]

## FAMILIAL THORACIC AORTIC ANEURYSM AND DISSECTION

Up to 20% of patients without syndrome referred for repair of aortic aneurysm or dissection have a first-degree relative with a similar condition.[46,47] The diagnosis of familial thoracic aortic aneurysm and dissection is rendered based on the following criteria: progressive enlargement of the ascending aorta, positive family history of thoracic aortic aneurysm and dissection, and exclusion of syndrome causes of thoracic aortic aneurysm and dissection such as MFS, Loeys-Dietz syndrome, and Ehlers-Danlos syndrome. Recent work has indentified a genetic cause in some cases, with causative mutations thus far identified in genes for transforming growth factor–β receptors 1 and 2, smooth muscle cell–specific myosin heavy chain 11, and smooth muscle–specific alpha actin. Of note, patients with familial thoracic aortic aneurysm and dissection typically come to medical attention earlier than patients with spontaneous dissections or dilation but later than those with MFS or Loeys-Dietz syndrome.

## Histopathology

The fibrous structures of the heart are composed primarily of connective tissue proteins. These serve as a framework whereby the contractile myocardial tissue is structurally supported. Connective tissue also supports the underlying structure of the large blood vessels and valves. Collagen and elastin fibrils underlie the endocardial cells of the heart and blood vessels. Type I collagen fiber bundles make up the support structure for the atrioventricular valves and constitute the primary elements of the valvar fibrous rings. The major structural support of the large blood vessels is elastin and collagen types I and III; lesser amounts of types IV, V, and VI collagen also contribute to vessel wall integrity.

The aorta is comprised of three layers: the intima, media, and adventitia. The medial layer consists of concentric layers of smooth muscle cells, collagen, and elastin with extracellular matrix proteoglycans. In connective tissue disorders, dilation of the aortic root is caused by degenerative changes as a result of disruption and loss of elastin fibers, loss of smooth muscle cells, increase in collagen, and deposition of proteoglycans. This process has historically been termed cystic medial necrosis. However, because there is no true necrosis or cyst formation, the preferred terminology is medial degeneration. Molecular studies have identified some mechanisms that potentially underlie this process. Increased levels of matrix metalloproteinases, particularly matrix metalloproteinase-2 and matrix metalloproteinase-9, have been found in the medial layer of aortic aneurysms.[48-52] Matrix metalloproteinase-2 and matrix metalloproteinase-9 have elastolytic activity.

## Echocardiographic Findings

### AORTIC DILATION

The aortic root is comprised of the aortic valve annulus, the sinus of Valsalva, the sinotubular junction, and the ascending aorta. By convention, echocardiographic measurements of these regions are performed from the parasternal long-axis view at early systole (Fig. 39-4). The regions of the aortic arch are best viewed from the suprasternal notch (Fig. 39-5).

In addition, the aortic valve and ascending aorta may be imaged in children from the subcostal imaging plane (Fig. 39-6). In the presence of a connective tissue disorder, dilation may occur at any position along the aortic root and throughout the descending thoracic and abdominal aorta. However, the most typical sites of dilation encompass the sinus of Valsalva, sinotubular junction, and proximal ascending aorta. These sites develop the most significant pathology in that their position subjects them to the highest sheer stresses as a result of pulsatile expansion during systole.[53] Effacement of the sinotubular junction is a common finding, in which the sinotubular junction and proximal ascending aorta develop a flattened appearance and have essentially the same diameter as the sinus of Valsalva (see Fig. 39-6, *D*). The term *effacement* is qualitative and is not associated with defined measurements. In fact, effacement encompasses a spectrum of findings, initially manifest subtle changes in the natural tendency for the sinotubular junction to abruptly change direction and caliber at the onset of the proximal ascending aorta. As the severity of effacement progresses, there is a progressive transition to a morphologic pattern characterized by a constant caliber of vessel from the sinus of Valsalva through the proximal ascending aorta.

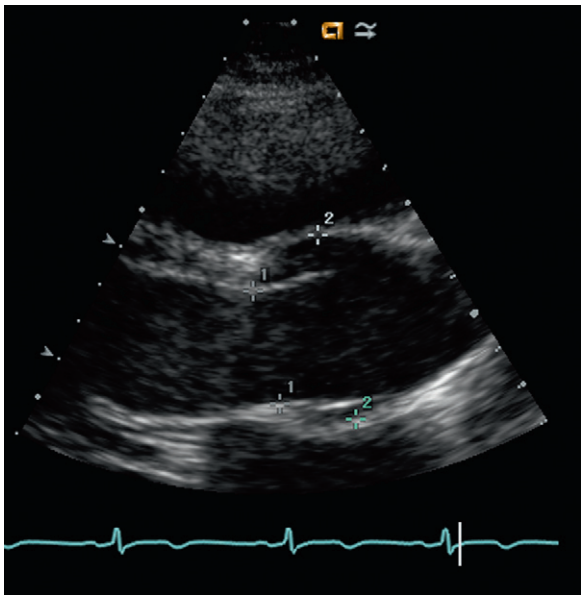

**Figure 39-4 Aortic sinus measurements.** Imaging of a 12-year-old with Marfan syndrome performed in the parasternal long-axis plane. The patient has severe dilation of the sinus of Valsalva (#2: 4.39 cm; 4.2 Z-scores) and normal aortic valve annulus (#1:2.7 cm; 1.6 Z-scores).

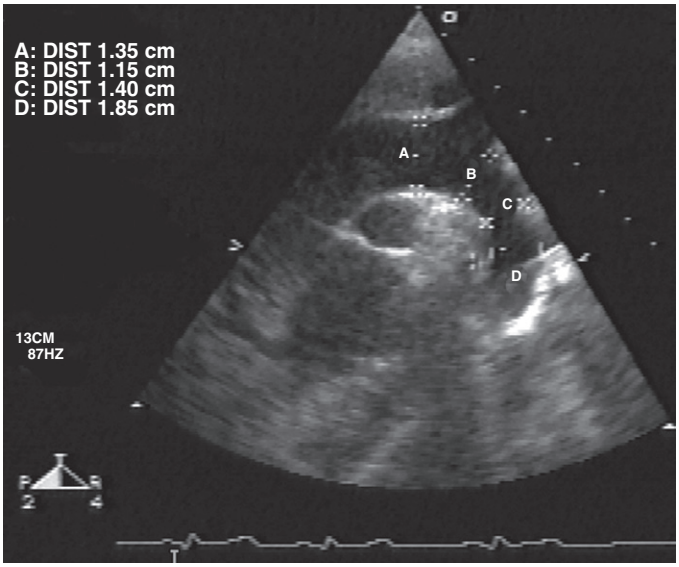

**Figure 39-5 Aortic arch imaging from the suprasternal long-axis imaging plane at end-systole.** Image shows the appropriate locations for measurement: the distal ascending aorta (*A*), just before the innominate artery; the transverse aorta (*B*), between the innominate artery and the left carotid artery; the aortic isthmus (*C*) just before the left subclavian artery; and the proximal descending aorta (*D*) just beyond the left subclavian artery.

In addition, as the severity of aortic root dilation worsens, aortic regurgitation can develop. This results from either asymmetric dilation of one or more cusps or generalized dilation at the aortic valve annulus. Either mechanism has the potential to alter the geometry of the aorta in such a manner that regurgitation develops (Figs. 39-7 and 39-8). In those situations in which the thoracic aorta cannot be imaged completely with TTE imaging, TEE should be used. Studies suggest that TEE is comparable with computed tomographic scan in defining thoracic aortic aneurysms.

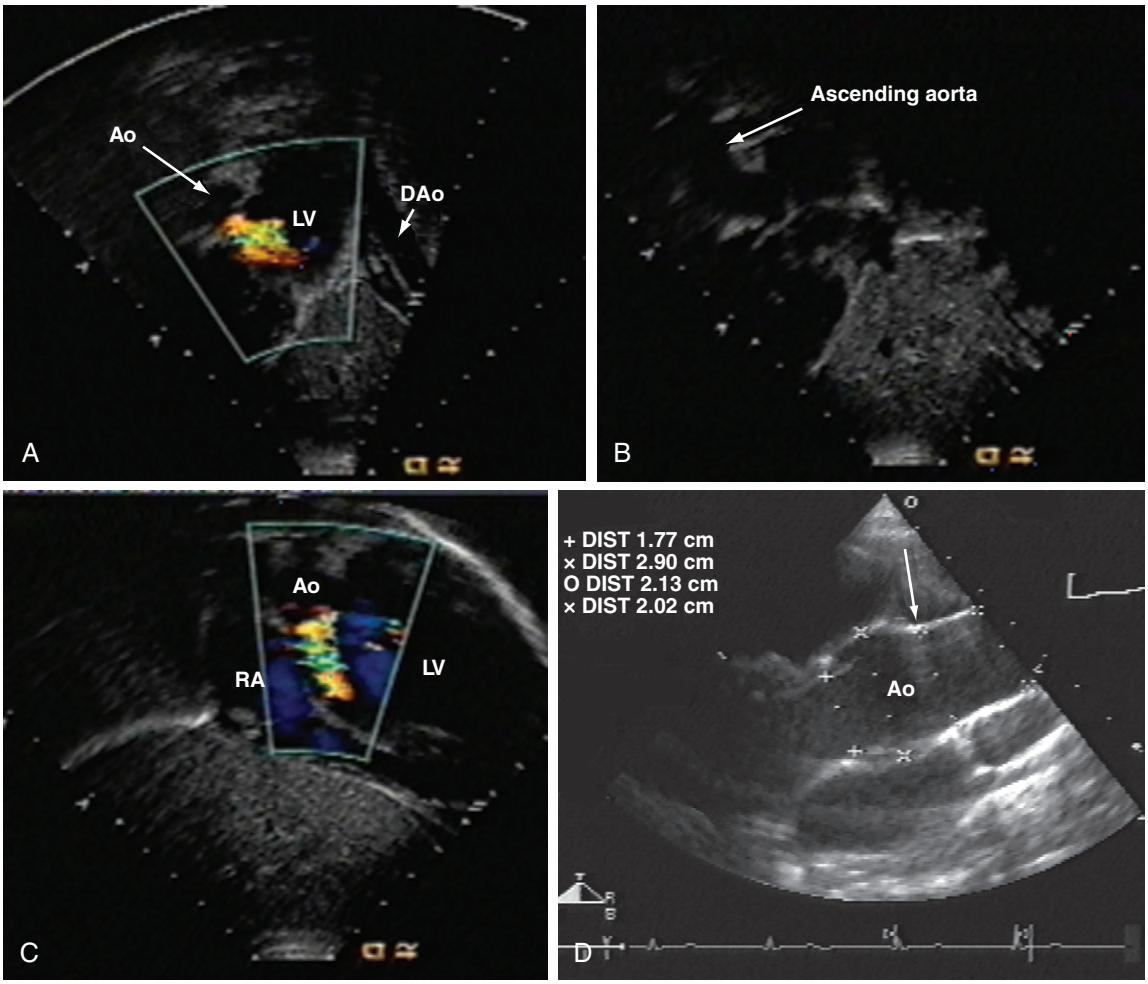

**Figure 39-6** **A 3-year-old with a transforming growth factor–β receptor mutation. A,** Subcostal short-axis imaging identifies moderate aortic regurgitation from dilation of the aortic root. **B,** Subcostal short-axis imaging allows visualization of the left ventricular outflow tract through the ascending aorta. **C,** Subcostal long-axis imaging of moderate aortic regurgitation. **D,** Image shows dilation of the aortic root resulting in effacement of the sinotubular junction *(arrow). DAo,* Descending aorta.

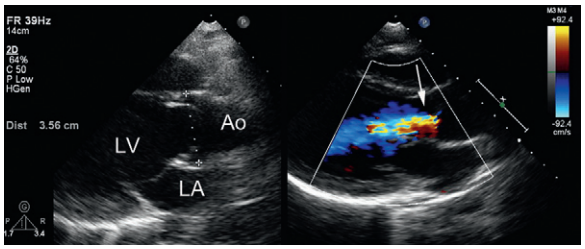

**Figure 39-7** **Aortic regurgitation due to aortic dilation.** *Left:* Parasternal long-axis imaging of a 16-year-old female with an mildly dilated aortic sinus of Valsalva, measuring 3.56 cm (2.8 Z-scores). *Right:* Color Doppler imaging demonstrating moderate aortic regurgitation (*arrow*) in the same patient. *Ao,* Aorta.

The normal adult abdominal aorta measures 2.0 cm at the level of the celiac trunk and 1.8 cm just below the renal arteries. Tapering occurs as the aorta approaches the level of the iliac arteries. Most abdominal aortic aneurysms form between the renal and iliac arteries. Clinically significant abdominal aortic aneurysms measure more than 4.0 cm in diameter. High degrees of sensitivity and specificity should be expected from abdominal ultrasound/echocardiography, but excessive body habitus can occasionally hamper complete visualization. In these cases, abdominal aortic angiography, computed tomographic scan, or aortic magnetic resonance imaging should provide data with which to achieve a definitive diagnosis.

Aortic aneurysms are classified as either true or false (pseudoaneurysm). A true aneurysm involves weakening and dilation of the entire vessel wall. A pseudoaneurysm occurs when a full thickness defect in the aortic wall allows blood to circulate out of the confines of the artery. The circulating blood is contained by the surrounding soft tissues. The most common etiologies for a true aneurysm include atherosclerosis, medial degeneration, and aortic dissection. Pseudoaneurysms are often the result of trauma or infection (e.g., endocarditis). Sinus of Valsalva aneurysm is associated with a number of secondary phenomena. The expansion of the aneurysm typically takes the path of least resistance into the right heart structures. Affected sites can include aortic valve leaflet distortion and aortic regurgitation, coronary artery occlusion, right ventricular outflow tract obstruction, tricuspid regurgitation, obstruction of the right pulmonary artery, and descending aortic obstruction.[54,55] With two-dimensional (2D) echocardiography, the dilated sinus can be elucidated.

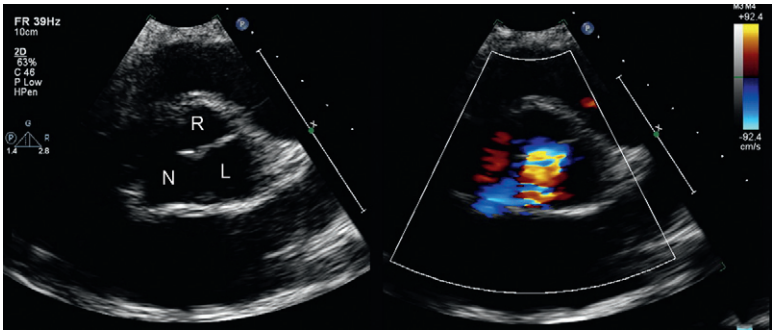

**Figure 39-8 Functional aortic regurgitation in short axis views.** *Left:* Parasternal short-axis imaging of the aortic valve in the patient from Figure 39-10 showing the right (*R*), left (*L*) and noncoronary (*N*) leaflets in diastole. *Right:* Color Doppler imaging showing the central aortic regurgitant jet.

## AORTIC DISSECTION

Patients with acute aortic dissection need emergent assessment and therapy. Prompt diagnosis is crucial to differentiate these patients from those with worrisome symptoms from more benign conditions. Mortality rate is estimated at about 1% per hour in the first 48 hours for those patients who survive to reach an acute care setting.[56] In addition to providing a diagnosis, the details of anatomy and physiology are vital to care. These include classification of the dissection, definition of the site of rupture, detection of extravasation, assessment of aortic regurgitation, and assessment of side-branch involvement.[57] TTE provides a rapid and readily accessible diagnostic tool and, in many cases, can answer all of the previous questions. TTE is frequently diagnostic in the detection of proximal aortic root dissection by revealing a progressively enlarging aortic root. In addition, the presence of a dissecting hematoma is oftentimes identified.[58] See Chapter 36 for a complete discussion of the echocardiographic features of aortic dissection.

## OTHER AORTIC ARCH MANIFESTATIONS

In addition to the natural history of aortic dilation and dissection that occurs in a subset of patients with connective tissue disorders, pathologic dilation can occur after aortic root surgery. In a study of patients with MFS, a retrospective analysis was performed based on presence or absence of prior elective aortic root surgery.[59] Multivariate analysis showed that a previous elective aortic root surgery was associated with a fourfold increased risk of subsequent dilation of the descending aorta. In addition, an increased descending aortic diameter was associated with a higher risk of aortic root dissection, independent of the diameter of the aortic root itself. These authors raised a cautionary flag in that only 37% of their patient population had complete measurements obtained at all aortic levels, suggesting the possibility that a large number of patients with a dangerous degree of aortic dilation are going undetected even when imaging studies are performed.

## MITRAL VALVE PROLAPSE

Mitral valve prolapse is defined as the displacement of abnormally thickened and redundant mitral valve leaflets into the left atrium during systole (Figs. 39-9 and 39-10). This geometric change in the integrity of the valve can result in poor coaptation and resultant mitral regurgitation. Mitral regurgitation eventually leads to left atrial and, subsequently, left ventricular dilation, which in-and-of itself worsens the degree of regurgitation.

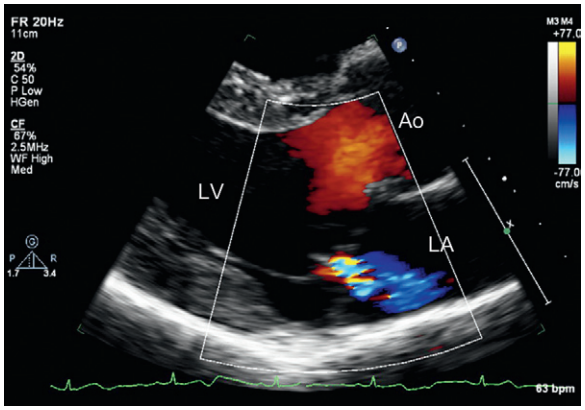

**Figure 39-9 Mitral valve prolapse.** Parasternal long-axis view of the mitral valve during systole shows redundant chordae, buckling of the anterior and posterior mitral valve leaflets, and resultant mitral valve prolapse and mitral regurgitation. The mitral valve leaflets are displaced in a posterosuperior direction into the LA. *Ao,* Aorta.

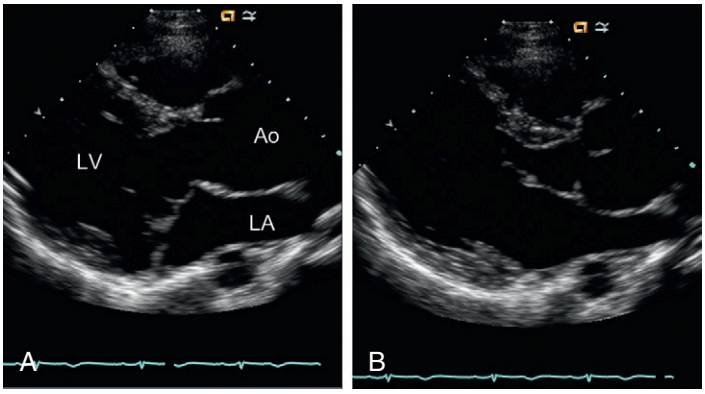

**Figure 39-10 Mitral valve prolapse. A,** Parasternal long-axis view of the mitral valve at end-systole shows buckling of the anterior and posterior mitral valve leaflets and resultant mitral valve prolapse. **B,** Parasternal long-axis view of the mitral valve at end-diastole shows thickening of the anterior and posterior mitral valve leaflet tips. *Ao,* Aorta.

Echocardiography is the current gold standard for the diagnosis and evaluation of mitral valve prolapse. Echocardiographic criteria have been established for the detailed assessment of the mitral valve; mitral valve prolapse is now defined as displacement of one or both leaflets by greater than 2 mm above the mitral annulus in the parasternal long-axis or apical long-axis view. Mitral valve prolapse is most accurately diagnosed from the parasternal views; apical imaging provides only confirmatory information and cannot be used for diagnosis without the presence of prolapse in the parasternal long-axis plane.

Mitral valve prolapse is further divided into classic and nonclassic forms: classic is defined as leaflet thickness of more than 5 mm; in the nonclassic form, the leaflets are less than 5 mm. Complications of endocarditis or the development of severe mitral regurgitation are more typically seen in the classic form of the disease.[60] The connective tissue disorders are more commonly associated with redundancy of the mitral valve leaflets, resulting in mitral valve prolapse. This is in distinction to mitral valve prolapse in the adult population caused by calcific disease in which the leaflets are less redundant but more thickened.

Evaluation of the valve has been greatly enhanced since the introduction of three-dimensional (3D) imaging. Although mitral valve prolapse is typically sporadic, it is also associated with disorders of connective tissues, including MFS, Ehlers-Danlos syndrome, osteogenesis imperfecta, and the MASS phenotype (defined previously). Because the association of MFS and mitral valve prolapse is common, the suspicion arose that isolated mitral valve prolapse might be the result of a mutation of fibrillin-1.[61] However, this association has never been established.

Mitral valve prolapse is the most prevalent valve abnormality in MFS, with a reported prevalence rate of greater than 35%.[62] It is important to recognize that surgical repair of mitral regurgitation can exacerbate aortic dilation after surgery as a result of the increased hemodynamic stresses on the aorta.

### *Left Ventricle*

Although aortic arch and mitral valve disease are most commonly seen in the presence of connective tissue disorders, abnormalities of left ventricular systolic and diastolic function are beginning to be elucidated.

#### Diastolic Function

With both cardiac magnetic resonance imaging and echocardiography, left ventricular diastolic function has been evaluated in a number of small studies. Impaired left ventricular diastolic function has been demonstrated with echocardiographic identification of an increase in deceleration time and an increase in isovolumic relaxation time; these findings were attributed to impaired elastic recoil.[63] An unusual pattern of transmitral flow was seen in which decreased ventricular compliance (decreased deceleration time) and reduced myocardial relaxation both occur.[64] With tissue-Doppler imaging, a prolongation of the early filling phase with reduced velocities at the mitral annulus (Ea) has been shown, which suggests that myocardial tissue relaxation is impaired.[65]

Echocardiographic data obtained in children as young as 3 years of age with MFS show early left ventricular diastolic function (relaxation) impairment.[63] More recently, in a study of 40 children and young adults with MFS compared with healthy age-matched controls, echocardiographic indices of left ventricular diastolic function (including prolonged deceleration time and isovolumic relaxation time and decreased mitral E/A ratio) also suggested impaired relaxation.[66] The presence early in life of increased myocardial stiffness, followed later in life by the development of aortic wall stiffness as the aorta distends,[67] may together contribute to the development of left ventricular systolic and diastolic dysfunction.

#### Systolic Function

Reduced systolic contractility in MFS has been thought to be solely a secondary phenomenon from associated aortic or mitral valve regurgitation. However, it has been suggested that, in the absence of valvular heart disease, subtle findings suggest that left ventricular systolic contractility is adversely affected. A small series from the Mayo Clinic showed no significant deterioration in ejection fraction and left ventricular end-systolic and end-diastolic dimensions; in addition, this study followed these parameters serially over a 10-year period without obvious changes developing longitudinally.[68] However, these findings differed from a more recent large-scale study of 234 adults with MFS. Although none of the patients met criteria for dilated cardiomyopathy, a small subset of the patients did show increased left ventricular end-systolic and end-diastolic dimensions, with an associated mild deterioration in ejection fraction.[69] In additional, meridional wall stress was similar between patients and controls; this suggests that, as opposed to an alteration in afterload causing left ventricular impairment, more likely the observed differences were from primary left ventricular contractile dysfunction.

The pathogenesis of left ventricular systolic and diastolic dysfunction in patients with MFS is incompletely understood but is likely the result of the primary structural and functional disorder in the fibrillin-1 protein. Microfibrils, which act as scaffolding for the formation of elastic fibers and contribute to their function, play an important role in mediating elastic recoil. These microfibrils contain the protein fibrillin-1 as one of their primary components. In that mutations in fibrillin-1 interfere with microfibril function, this in turn is predicted to lead to impairment of left ventricular diastolic elastic recoil.

### *Pulmonary Artery*

As opposed to the well-defined left heart pathology, abnormalities of the right heart are less well recognized. Dilation of the main pulmonary artery does occur, and serial echocardiographic measurements should be obtained. In the adult population, good correlation has been found between progressive dilation of the aortic root and main pulmonary artery.[70] However, dangerous pulmonary artery pathology from pulmonary artery aneurysm or dissection has not been reported, and the clinical significance of this finding requires further clarification. The population with associated pulmonary hypertension may be at risk given the expected abnormal increase in tensile stress thus placed on the pulmonary artery.

## Natural History

Of the connective tissue disorders described in this chapter, MFS is by far the best understood. Most patients with MFS present with ascending aortic dilation or dissection. Rarely does a patient present with a type B dissection of the descending thoracic aorta. However, there is evidence that identification of progressive descending aortic dilation predicts the eventual development of dissection in this region.[59] For this reason, even in the absence of significant ascending aortic dilation, recommendations have been made that serial assessment include careful monitoring of the entire aorta (from the level of the aortic valve to the abdominal aorta).

A distinct (and typically severe form) of MFS can be seen early in life; it is termed infantile MFS. Polyvalvar disease is common, most often resulting in mitral valve prolapse with associated marked mitral regurgitation and severe skeletal and pulmonary emphysematous changes. Congestive heart failure and respiratory compromise often lead to early death.[71]

The pregnant woman with MFS is at increased risk for aortic dissection, although the risk is low when the aorta is less than

**TABLE 39-1 Summary of Clinical and Echocardiographic Findings for the Most Common Forms of Connective Tissue Disorders**

| | *Affected Cardiac Structures* | *Characteristic Findings* | *Functional Sequelae* | *Prevalence* |
|---|---|---|---|---|
| Marfan syndrome | • Mitral valve<br>• Aortic root<br>• Ascending aorta | • Mitral valve prolapse<br>• Tricuspid valve prolapse<br>• Dilation of the aortic root | • Mitral regurgitation<br>• Aortic regurgitation<br>• Susceptibility to dissecting aortic aneurysm | 3:10,000 |
| Ehlers-Danlos, type IV | • Aortic root<br>• Large and small arteries | • Large and small arterial aneurysm<br>• Arteriovenous fistulae | • Aortic regurgitation<br>• Susceptibility to dissecting aortic aneurysm<br>• Dissection often spontaneous | ~1:250,000 |

4.0 cm.[72] Echocardiograms should be performed serially throughout the pregnancy, especially during the third trimester when growth acceleration can occur.

In general, annual TTE assessment is recommended in patients with mild to moderate aortic dilation, so long as these findings have been stable. The major exception is for patients with Loeys-Dietz syndrome in whom TTE should be performed every 6 months and magnetic resonance angiograms (from head to pelvis) yearly. In young children, and in those who have severe disease, serial echocardiograms on a 6-month basis are recommended. Conversely, in individuals without aortic dilation, but with other features suggestive of a connective tissue disorder or a strong family history, echocardiograms are generally performed every few years until adulthood. Patients who manifest rapidly progressive disease and are thus approaching criteria for surgical intervention are followed at a minimum of every 6 months. This is generally accepted as growth approaching 5 mm every 6 months. Table 39-1 summarizes the clinical cardiac and echocardiographic features found in the most common connective tissue disorders. In addition, the prevalence of these connective tissue conditions in the general population is reviewed.

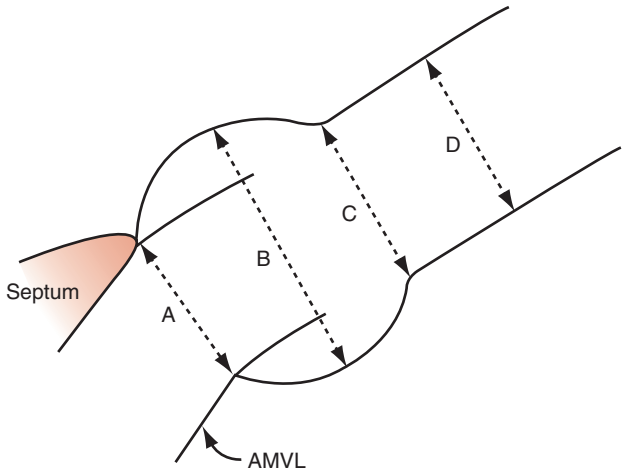

**Figure 39-11 Aortic root measurements on echocardiography.** Schematic shows the aortic valve annulus (*A*), sinus of Valsalva (*B*), sinotubular junction (*C*), and proximal ascending aorta (*D*), Measurements are obtained at early systole in children and at end-diastole in adults. *AMVL*, Anterior mitral valve leaflet.

## METHODS OF ASSESSMENT

Standard 2D imaging remains the screening tool for the assessment of valve morphology and for the measurement of aortic dimensions. The precision of this assessment is operator-dependent and is also mitigated by image quality (primarily because of issues of patient body habitus). Oblique measurements of the aorta can overestimate actual dimensions, as occurs for an aortic diameter that is not drawn perpendicular to the aortic flow center line. These measurements are typically acquired from the parasternal long-axis view, the long-axis view of the suprasternal notch, and the subcostal plane. Some laboratories measure the sinus of Valsalva with M-mode. Although this can provide reproducible and accurate measurement data, we recommend all measurements from 2D imaging with data acquired at early systole. The aortic valve annulus, sinus of Valsalva, and sinotubular junction (and the proximal aspect of the ascending aorta) are obtained from the parasternal long-axis view (Fig. 39-11), and the distal ascending aorta (just before the takeoff of the innominate artery), the transverse aortic arch, and the aortic isthmus are measured from the suprasternal notch (Fig. 39-12). In some individuals, the proximal descending aorta can be imaged from the parasternal window. In the pediatric population, it is common to obtain suitable images to visualize the distal thoracic aorta and abdominal aorta from the subcostal imaging plane (Figs. 39-13 and 39-14). Each of these areas should be imaged with aortic measurement in every patient who comes through the echocardiography laboratory.

Imaging of the valves can be enhanced with the acquisition of 3D data. With the availability of live 3D imaging, valve structure and function information can now be obtained in such a manner that immediate decisions can be made regarding the nature of the pathologic process. Although 3D imaging can also

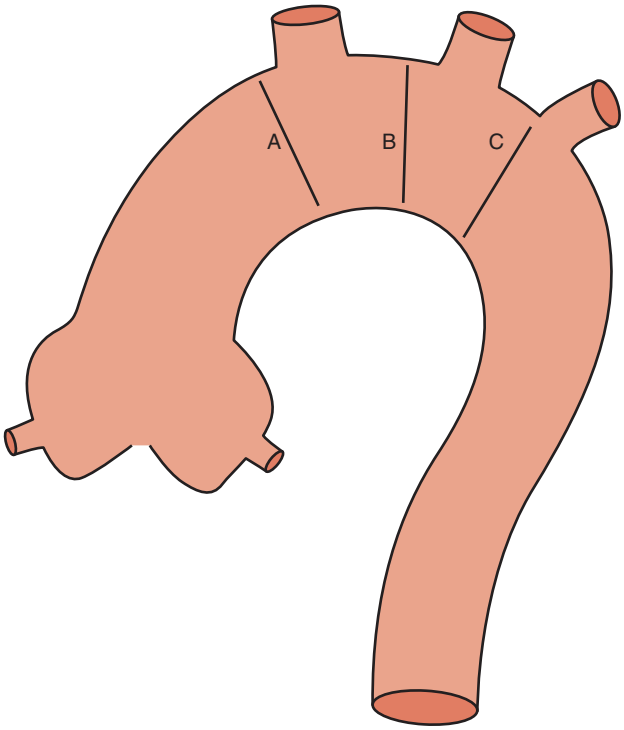

**Figure 39-12 Aortic arch measurements.** In the suprasternal long-axis–imaging plane measurements are obtained of the distal ascending aorta (*A*) just before the innominate artery, the transverse arch (*B*) between the innominate artery and the left carotid artery, and the aortic isthmus (*C*) just before the left subclavian artery.

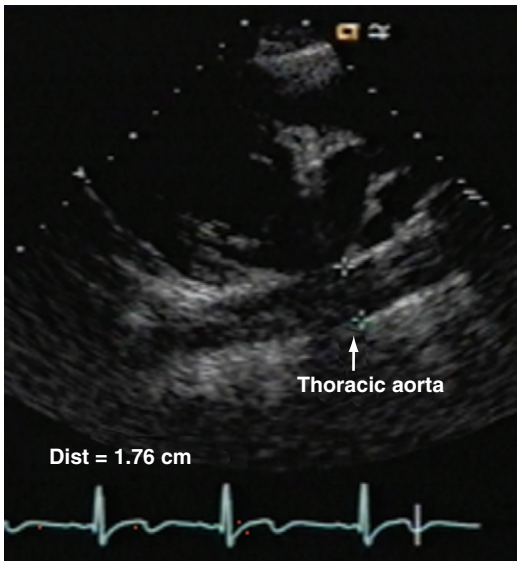

**Figure 39-13 Descending thoracic aorta.** Subcostal long-axis view shows the preferred location at which to measure the distal descending thoracic aorta.

be used for the acquisition of aortic arch images, this requires unique operator skills. Therefore, many laboratories obtain valve data with 3D imaging on a relatively frequent basis, but acquisition of 3D volume rendered images of the aortic arch are less common.

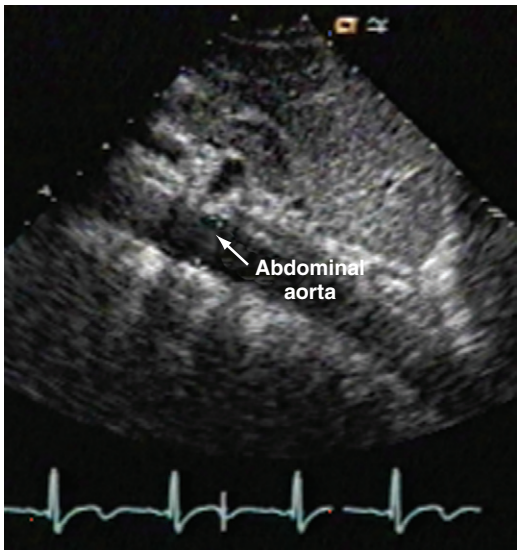

**Figure 39-14 Subcostal long-axis view.** Image shows the preferred location at which to measure the descending aorta inferior to the diaphragm.

Normalization of aortic measurements is an important aspect surrounding accurate data interpretation. Dependence on the accuracy of these normalized data is particularly acute in the pediatric population, where rapid changes occur during growth. Because of the prognostic significance of aortic measurements in patients with connective tissue disorders, aortic dimensions have been extensively studied with 2D echocardiography. Normal values have been reported for children and adults based on a range of indices, including age, body surface area, and height.[73-78]

In a study of 52 healthy infants and children (aged 1 month to 15 years) and 135 healthy adults (20 to 74 years), the aorta was measured at end-diastole in the parasternal long-axis view at four levels: aortic annulus, sinus of Valsalva, sinotubular junction, and proximal ascending aorta at its maximal dimension. Of note in this study, 2D measurements at the sinus of Valsalva were larger than those obtained with M-mode. When 2D values were normalized on M-mode nomograms, falsely diagnosed aortic dilation was found in 40% of healthy children and adults.[75]

Rigorous decisions are critical regarding which set of data is used as the standard in any individual echocardiography laboratory. Once a published dataset has been agreed on and implemented, all subsequent patient studies should be normalized with the same criteria. In the situation in which patients are plotted against differing normal datasets, wide variation in divergence from the norm can occur. As opposed to the use of published datasets, some groups have relied on either internally derived normal controls or unpublished data obtained from large institutional studies.[79]

The pediatric patient with marked aortic dilation oftentimes presents a difficult clinical dilemma. Although the aorta may be 50% to 75% larger than predicted when normalized for body surface area, little data are available to assign a definitive risk for the short-term development of aortic dissection. Each medical center approaches this problem in various ways, with no universally agreed-on algorithm. In an attempt to better

predict pediatric risk for aortic dissection, noninvasive assessment of aortic wall dysfunction has been undertaken. In 19 pediatric patients with MFS, transthoracic M-mode tracings were used to calculate aortic elastic properties.[80] Significant differences from control patients were seen, with patients with MFS showing decreased aortic distensibility, increased aortic wall stiffness indices, decreased systolic diameter increase, and decreased maximum systolic area increase. Although this study did not attempt to predict future risk, further work of this type may allow use to provide better prognostic data for the pediatric population with connective tissue disorders.

### LIMITATIONS OF ASSESSMENT

Although transthoracic 2D and M-mode assessment are the most common methods for assessment of the mitral valve and aorta in patients with connective tissue disorders, a number of limitations are associated with these methods. Data acquisition is equipment and operator dependent. Measurements of aortic dimensions are affected by patient body habitus, and significant overestimate can be introduced into these measurements if oblique measurements are obtained.

Transesophageal echocardiography is a value tool in assessment of the aorta in those patients with difficult transthoracic acoustic images. In addition to the routine use as a tool to obtain accurate measurements of the aortic root, TEE can also be used to evaluate properties of aortic distensibility. Measurement of aortic distensibility, stiffness index, and pulsed-wave velocity can be obtained with M-mode data from the TEE short-axis view. Tissue-Doppler imaging has been applied to the evaluation of thoracic aortic elasticity in patients with MFS. Acceleration time, maximal wall expansion velocity, and wall strain were calculated from tissue-Doppler imaging tracings in 31 patients with MFS. Data derived from TEE imaging found that tissue-Doppler imaging data were complementary to M-mode, together serving as a significant predictor of progressive aortic dilation and eventual dissection.[81]

## Therapeutic Strategies

### PHARMACOLOGIC

Pharmacologic strategies for the connective tissue diseases are based on studies for patients with MFS. For the past two decades, the standard of care in the treatment for MFS with associated aortic dilation has been β-adrenergic blockade. The validation for this approach is based on longitudinal follow-up data that assessed the progression of aortic dilation with and without β-blocker therapy showing a beneficial response in a subset of these patients.[82] Treated patients showed slower aortic root growth, less risk of the development of aortic dissection, less common need for aortic surgery, and less mortality. This therapeutic strategy has been shown in adults as well as children.[83] Although therapy does not necessarily result in avoidance of aortic surgery altogether, in general, surgical intervention is forestalled. In addition, the presence of significant aortic dilation has been shown to be less amenable to β-blocker therapy than is the case for the earlier treatment of the patient with milder aortic dilation.[82] Some studies have shown improved ascending aortic stiffness associated with β-blocker therapy in patients with MFS,[84,85] and others have shown no effect, or worsening of indices of aortic stiffness.[86] The initiation of β-blocker therapy is typically based on a confirmed clinical diagnosis of MFS (based on the revised Ghent criteria) and the attainment of quantitative aortic root dilation. This is generally defined as the presence of aortic sinus of Valsalva dimensions as measured with echocardiography or magnetic resonance imaging with more than 2.0 Z-scores from the mean for body surface area.

**TABLE 39-2 Three-Year Study of Angiotensin-Converting Enzyme Inhibitor versus β-Blocker Therapy for Marfan Syndrome**

| *Variable* | *Enalapril* | *β-Blocker* | *P Value* |
|---|---|---|---|
| Mean initial aortic diameter (mm) | 33 ± 8 | 31 ± 6 | .7 |
| Mean initial % predicted aortic size | 118 ± 18 | 118 ± 14 | .7 |
| Mean change in aortic diameter (mm) during the study | 0.1 ± 1.0 | 5.8 ± 5.2 | <.001 |
| Aortic stiffness index | 8.0 ± 2.9 | 18.4 ± 3.8 | <.05 |
| Aortic distensibility ($cm^2/dynes^{-1}$) | 3.0 ± 0.3 | 1.9 ± 0.4 | <.02 |
| Aortic root replacement | 2 | 7 | |

Adapted from Yetman AT, Bornemeier RA, McCrindle BW: Usefulness of enalapril versus propranolol or atenolol for prevention of aortic dilation in patients with the Marfan syndrome. *Am J Cardiol* 95:1125-1127, 2005.

In patients intolerant of β-blocker therapy, either because of associated reactive airways disease or other side effects (e.g., fatigue or dizziness from hypotension), other pharmacologic strategies have been used to delay progressive aortic dilation. These include calcium channel blockers[83] and angiotensin-converting enzyme inhibitors. In a 3-year longitudinal study of patients with MFS, comparing therapy with β-blockers versus angiotensin-converting enzyme inhibitors, patients treated with the latter were shown to have less aortic dilation (Table 39-2).[87] In addition, with echocardiographic measurements, both aortic stiffness index and aortic distensibility improved with angiotensin-converting enzyme inhibitor therapy.

Recent data have suggested a role for the angiotensin-1 receptor blocker (ARB) losartan. Studies have shown that myxomatous mitral valve disease, aortic dilation, and impaired pulmonary alveolar septation, all features of the murine model of MFS, are mediated by excessive transforming growth factor–β signaling. Losartan has been hypothesized to delay aortic dilation due to its effect in inhibiting transforming growth factor–β signaling in the aortic wall. Treatment with losartan in a mouse model of MFS, which carries a fibrillin-1 mutation, showed histologic improvement in aortic wall elastic matrix architecture. In addition, there was echocardiographic evidence of reduced aortic growth in the losartan-treated group.[88] A limited, nonrandomized clinical study suggested that losartan may slow the rate of aortic dilation in children, but the patient numbers are too small to judge at present.[89] A multicenter randomized blinded clinical trial comparing the β-blocker atenolol with losartan for the treatment of aortic dilation in MFS is currently being conducted by the Pediatric Heart Network and National Institutes of Health.[90] Hopes are that this study will provide important therapeutic guidance for the medical management of patients with MFS. Losartan therapy suggests an exciting new line of investigation in that it uses a strategy that is directed at disease pathogenesis and may be the first step towards actual disease prevention.

As noted previously, treatment guidelines for other connective tissue disorders with aortic aneurysm typically follow MFS

guidelines. However, the effectiveness of this strategy has not been evaluated (i.e., no clinical trials have been performed). The main exception is that patients with Loeys-Dietz syndrome are often treated with ARBs, including losartan as a first-line therapy rather than β-blockers.

### SURGICAL

In adults with MFS, the threshold for consideration of aortic root replacement occurs when the diameter reaches 5.0 cm (Fig. 39-15).[42,91] A clearly established risk exists when the aortic dimension exceeds 6.0 cm, with a fourfold increase in the cumulative risk of aortic dissection or rupture.[42] Factors that are used to modify these parameters downward include rapid aortic growth (more than 0.5 cm per year), a family history of early aortic dissection (particularly at less than 5 cm), females considering pregnancy (prophylactic aortic root replacement if the diameter is more than 4.0 cm), and the associated finding of moderate or severe aortic regurgitation. However, some patients (even in the absence of factors that would place them at higher risk) have aortic dissection develop at a diameter of less than 5 cm.[91] For this reason, patient education regarding the symptoms of aortic dissection is crucial. It should be noted that thresholds for surgical intervention are typically based on the external aortic diameters such as reported from magnetic resonance imaging or computed tomographic scan, rather than the internal diameter typically reported with echocardiograms. The external diameter is typically 0.2 to 0.4 cm larger than the internal diameter.

In the younger pediatric population with MFS (before adolescence), identification of aortic pathology of such severity that surgical intervention must be considered is relatively uncommon. However, when this situation does exist, decisions surrounding timing of aortic surgery are complicated by the lack of adequate data to predict when the risk of aortic dissection has reached unacceptable levels. We suggest that the preadolescent child with a connective tissue disorder is a candidate for surgery with the following conditions:

1. Maximal normalized aortic dimension of more than 8 to 10 standard deviations above the mean for body surface area
2. Accelerating aortic growth (more than 5 mm per 6 months)
3. Family history of early aortic dissection
4. Additional pathologic lesion requiring intervention (i.e., aortic regurgitation, mitral regurgitation from mitral valve prolapse)

The actual decision to proceed with aortic surgery in the pediatric population is frequently based on less well-defined theoretic concerns. Oftentimes, a maximal aortic dimension of more than 8 to 10 standard deviations from than the mean (as listed previously) is accepted.

Surgical indications for non-MFS connective tissue disorders are considerably less well understood and mostly based on small case series. In general, we recommend, based on the currently available literature, that surgery for patients with aortic diameters 5.0 cm or greater, rapid aneurysm progression (more than 0.5 cm per year), or aortic diameters of 4.5 cm if surgery is being performed on the aortic valve. There are a few exceptions to this practice, which are discussed subsequently. Patients with Loeys-Dietz syndrome and transforming growth factor–β receptor 1 or 2 mutations are at risk for aortic dissection at aortic diameters less than 5.0 cm. Therefore, current guidelines recommend aortic repair at a measurement between 4.0 and 4.2 cm internal diameter in adults.[19] For children with severe systemic manifestations of Loeys-Dietz syndrome, surgery should be considered once the aortic diameter exceeds the 99th percentile for age and the aortic valve annulus reaches 1.8 to 2.0 cm, which allows for the placement of a graft that can accommodate future somatic growth.[19,25] A small number of aortic dissections have also been reported in patients with alpha actin 2 or myosin heavy chain 11 mutations at diameters less than 5.0 cm. Therefore, surgical consideration in these patients may be reasonable at aortic diameters between 4.5 and 5.0 cm. Finally, given the high complication rate and tissue friability, whether early prophylactic repair of aortic aneurysms in Ehlers-Danlos syndrome type IV (vascular form) is indicated is unclear.

Surgical intervention for aortic dilation typically takes the form of either a composite graft and associated valve replacement (Bentall technique)[92] or procedures performed when the aortic valve remains competent and therefore the valve is spared.[93,94] The results of aortic replacement in adults are encouraging. In a report on 675 patients with MFS who underwent aortic replacement, a 1.5% operative mortality rate was seen in elective cases, as compared with 11.7% for emergency surgeries. Five-year and 10-year survival rates were 84% and 75%, respectively (Fig. 39-16).[91]

Although the success of aortic surgery has improved dramatically, postoperative complications remain. Pseudoaneurysm at the graft site or graft dehiscence is frequently difficult to detect with transthoracic imaging. In these situations, TEE has been clearly shown to provide additional diagnostic data.[6,95,96]

## Alternate Diagnostic Approaches

Magnetic resonance imaging and cardiac computed tomographic scan can be used in patients who have limited acoustic images or need detailed assessment in the situation where ambiguous data are present. This situation might include the patient with unusual tortuosity of the aortic arch, the question of dilation extending into the carotid arteries or circle of Willis, or an aortic dissection that cannot be entirely excluded. However, just as is the case with echocardiographic assessment, the accuracy of computed tomographic scan and magnetic

No. at risk

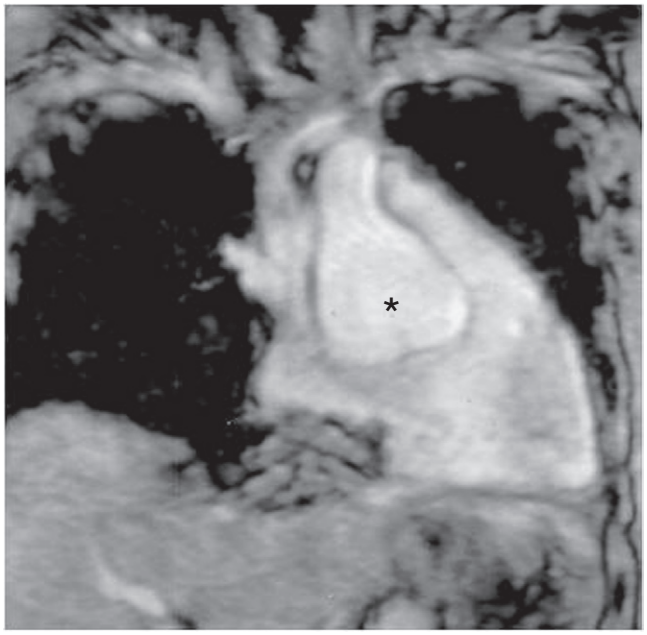

**Figure 39-17 Magnetic resonance imagining in a coronal plane.** Image shows a dilated aortic root in a patient with Marfan syndrome. *Location of the aortic root.

resonance imaging evaluation is reliant on availability of appropriate equipment and is operator dependent (Fig. 39-17).

Advances in magnetic resonance imaging have allowed for the evaluation of aortic elasticity in patients with MFS. The elasticity of the aorta has been found to be reduced in these patients. Magnetic resonance imaging velocity mapping of the aorta shows reduced aortic distensibility during systole and increased pulse wave propagation.[97] Use of magnetic resonance imaging velocity encoding shows a positive response to β-blocker therapy with a reduction in pulse wave propagation after β-blocker treatment. These techniques not only yield important information regarding the biophysical properties of the aorta in patients with connective tissue disorders but may also provide data to predict individual patient risk.[97]

## KEY POINTS

- A variety of disorders can lead to the connective tissue abnormalities, with many of these conditions manifesting similar cardiac features of aortic dilation and dissection and mitral valve prolapse.
- Although Marfan syndrome remains a clinical diagnosis primarily based on defined cardiac, skeletal, and ocular findings, refinement in genetic testing has improved diagnostic rates to close to 90%.
- In addition to the well-described fibrillin mutations associated with connective tissue disease, the role of transforming growth factor-β as a cause of these conditions is increasingly evident.
- In connective tissue disorders, dilation of the aortic root is caused by degenerative changes of smooth muscle cells, elastic fibers, and collagen, resulting in medial degeneration.
- Changes in mitral and aortic valve fibrous ring integrity, combined with dilation of the surrounding tissues causing alteration in valve geometry, result in the hemodynamic disturbances seen in the connective tissue disorders (predominantly regurgitation).
- In virtually all children and most adults, TTE is highly predictive of the pathologic changes in the mitral valve, aortic valve, and aorta associated with the connective tissue disorders.
- Transesophageal echocardiography and other imaging modalities (3D echocardiography, magnetic resonance imaging, and computed tomography) serve as adjunct modalities to diagnosis.
- In addition to valve and large vessel disease, the connective tissue disorders may also affect systolic and diastolic left ventricular function.
- When surgical intervention is contemplated for a bicuspid aortic valve in children and young adults and there is concomitant aortic dilation, careful consideration should be given to possible connective tissue conditions that might complicate the procedure and recuperation.
- In the growing child and teen, quantitative assessment of the aortic arch must incorporate the use of a well-validated nomogram to ensure clear understanding of the severity of dilation and rate of growth.

# 40 Aging Changes Seen on Echocardiography

MICHAEL A. CHEN, MD, PhD

**Background and Importance**
**Basic Principles and Echocardiographic Approach**
Normal Changes in Cardiac Structure
Normal Changes in Cardiac Function
**Clinical Outcome Data**
Valvular Heart Disease
Left Ventricular Hypertrophy
Left Atrial Size and Outcomes
Heart Failure
Coronary Artery Disease and Stress Testing
Cardiogenic Thromboembolism
Cardiac Amyloidosis
**Clinical Recommendations**

## Background and Importance

In the United States, by 2030, an estimated 72.1 million people will be age 65 or older (39.6 million in 2009), with 8.7 million of them over the age of 85 (5.6 million in 2009).[1] Cardiovascular disease is the leading cause of death and disability, and advanced age is a major risk factor for its development. Normal aging results in pervasive changes in cardiovascular structure and function, as well as alterations in other organ systems. Many normal age-related changes in cardiovascular structure and function are readily identifiable on echocardiography. This is also true of conditions that are pathologic, but common in the elderly.

## Basic Principles and Echocardiographic Approach

The echocardiographic techniques used to acquire images and other data are the same for the elderly as for younger persons.

### NORMAL CHANGES IN CARDIAC STRUCTURE

#### *Left Ventricular Wall Thickness and Chamber Dimensions*

Multiple studies have demonstrated increases in left ventricular (LV) wall thickness with age in patients without a history of hypertension or valvular or other cardiovascular disease[2-5] (Fig. 40-1). These cross-sectional studies involved from 53 to 136 normal healthy subjects and documented mild increases in LV wall thickness. For example, in a study by Gardin and colleagues,[2] 136 adults (78 men and 58 women aged 20 to 97 years) without evidence of cardiovascular disease were studied. The patients were stratified into six age groups, and significant increases in wall thickness with age were found. Comparing the youngest group (21 to 30 years) with the oldest group (more than 70 years), the mean septal wall thickness increased from 9.8 mm to 11.8 mm, and the mean posterior wall thickness increased from 10.1 mm to 11.8 mm. This represented increases of 20% and 18%, respectively.

#### *Left Ventricular Mass*

Based on data documenting increased wall thickness with increasing age, a number of prior echocardiographic studies, including a study of 700 healthy Japanese subjects aged 20 to 79 years, have suggested that there is an age related increase in LV mass (sometimes indexed for weight/height).[6-8]

The formula for LV (see Chapter 9) mass that is commonly used was derived by Devereux and co-workers[9]:

$$\text{LV mass} = 0.8 \times [1.04(\text{ST}_d + \text{LVID}_d + \text{PWT}_d)^3 - \text{LVID}_d{}^3] = 0.6\ \text{g}$$

where $ST_d$ is septal thickness at end-diastole, $LVID_d$ is LV internal dimension at end-diastole, and $PWT_d$ is LV posterior wall thickness at end-diastole.

In contrast to these findings, more recent studies of normal subjects using magnetic resonance imaging (MRI), including a study that was part of the Baltimore Longitudinal Study of Aging, have confirmed that MRI-derived wall thickness increases with age (particularly at the midventricle), with no change in the short-axis diastolic dimension (similar to prior echocardiographic data). On the other hand, LV length *declines* in both sexes over time. The resulting estimate of LV mass reveals no age relationship in women, although there is an age-related decline in men (due to a smaller increase in wall thickness). This suggests that with time, the LV becomes thicker and more spherical.[10,11]

The reason for the discrepancy in the findings between M-mode and two-dimensional (2D) echocardiographic data and MRI data lies in the algorithms used to calculate mass in the former techniques. These algorithms, such as the formula derived by Devereux and co-workers, assume an ellipsoid cavity and do not take into account changes in cavity shape. Thus, the calculations will be less accurate with cavities that are, for example, more spherical. Three-dimensional (3D) echocardiography has been shown to be a more accurate technique than 2D echocardiography in estimating LV mass in studies comparing the two techniques against weighing of the LV in both

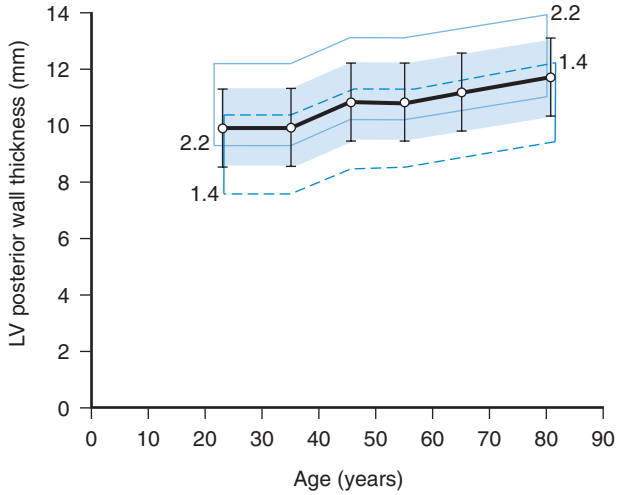

**Figure 40-1 Plot of LV posterior wall thickness in late diastole (mm) versus age in years.** For each age group the mean (*circle*) and 95% confidence interval (*blue shaded*) for normal values are depicted for a body surface area (BSA) of 1.8 $m^2$. The 95% confidence intervals are also shown for subjects with BSA values of 1.4 $m^2$ (*dashed lines*) and 2.2 $m^2$ (*solid lines*). *(From Gardin JM, Henry WL, Savage DD, et al: Echocardiographic measurements in normal subjects: evaluation of an adult population without clinically apparent heart disease.* J Clin Ultrasound *7:439-447, 1979. Copyright © 1979, John Wiley & Sons. Reprinted by permission John Wiley & Sons, Inc.)*

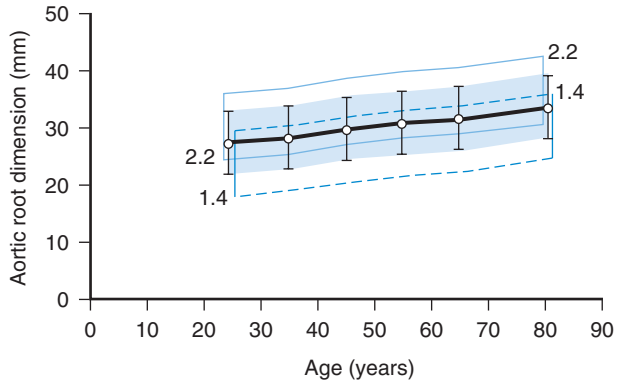

**Figure 40-2 Plot of aortic root dimension in late diastole (mm) versus age in years.** Mean value for each age group is depicted by a *circle* plotted at the mean age in the age group. The *bracket* and *shaded area* on either side of the circle represents the interval for normal values for a subject with a body surface area (BSA) of 1.8 $m^2$. The 95% prediction intervals are also shown for subjects with BSA values of 1.4 $m^2$ (*dotted lines*) and 2.2 $m^2$ (*solid lines*). *(From Gardin JM, Henry WL, Savage DD, et al: Echocardiographic measurements in normal subjects: evaluation of an adult population without clinically apparent heart disease.* J Clin Ultrasound *7:439-447, 1979. Copyright © 1979, John Wiley & Sons. Reprinted by permission John Wiley & Sons, Inc.)*

human and animal studies.[12-15] 3D echocardiography–derived LV mass estimates have also been shown to correlate well with MRI-derived estimates.[16-18]

### *Aortic Root Diameter*

A mild increase in the aortic root diameter is seen with age (Fig. 40-2). There is an approximately 6% increase in a normal population between the fourth and eighth decades.[3] A study of serial chest radiographs taken over 17 years noted an increase from 3.4 to 3.8 cm.[19] This enlargement may present an extra stimulus to the LV to hypertrophy, as it represents a larger blood volume that must be pushed forward.

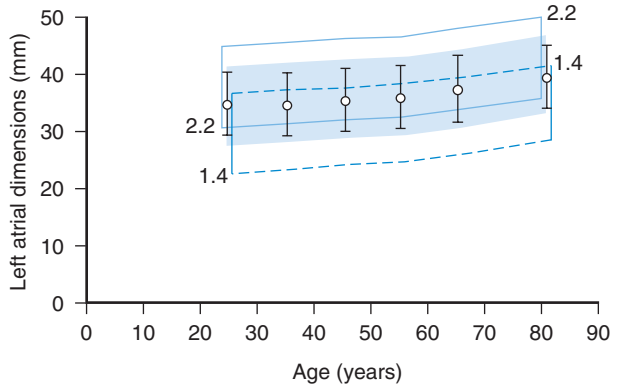

**Figure 40-3 Plot of LA dimension in late diastole (mm) versus age in years.** For each age group the mean and 95% prediction intervals for normal values are depicted for three different BSAs, as detailed in Figure 40-1. *(From Gardin JM, Henry WL, Savage DD, et al: Echocardiographic measurements in normal subjects: evaluation of an adult population without clinically apparent heart disease.* J Clin Ultrasound *7:439-447, 1979. Copyright © 1979, John Wiley & Sons. Reprinted by permission John Wiley & Sons, Inc.)*

### *Left Atrial Size*

There is a significant increase in size of the left atrium (LA) with age (Fig. 40-3). Because the LA is a 3D structure, many have argued that volume is a better way to evaluate LA enlargement rather than the 2D anterior-posterior diameter.[20,21] Some data suggest that the area-length method of calculating LA volume underestimates volume when compared with MRI,[22] whereas other data suggest that 3D echocardiography shows a good correlation with MRI.[23]

Recently, Aurigemma and colleagues,[24] using echocardiographic data from 230 subjects in the Cardiovascular Health Study who were free of cardiovascular disease and had a mean age of 75 ± 5 years, established reference ranges by gender for LA dimensions and volumes in this population. Table 40-1 shows the measurement ranges for LA parameters and clinical data regarding the patients in the study, and Table 40-2 shows the equations derived in the study that allow for estimation whether LA size is increased (i.e., above the 95th percentile for age/height/weight).

### *LV Dimensions*

In the studies that have documented increases in LV wall thickness, measurements of LV end-diastolic and end-systolic dimensions showed either a slight decrease to no change with age[2,3,6] (Table 40-3). Because LV stroke volume is the difference of LV end-diastolic and end-systolic volumes, supine resting LV stroke volume is also assumed to be unrelated to age.[25] MRI studies confirm the decreases in end-diastolic and end-systolic volumes, and these measurements correlate well with 3D echocardiography, although this method may underestimate volumes if trabeculations are not excluded from the analysis.[23,26]

### *Cardiac Chamber Dimensions*

Normal echocardiographic values are listed in Table 40-3. These normal changes should be taken into account when reporting abnormalities.

### *Cardiac Valves*

The four cardiac valves have been documented to change in morphology with age. These changes are most notable in the left-sided valves, and this is likely related to the higher pressures found in the associated chambers.

### Valve Circumference

Valve circumference has been found to increase with age.[27] In one study of 765 patients, the mean valve circumference, when indexed for body surface area, progressively rose through adult life, a trend that was greater for the semilunar than for the atrioventricular valves. Krovetz[28] reanalyzed data regarding aortic valve size and found that after approximately 18 to 21 years of age, the size of the aortic annulus increases in a near-linear fashion (Fig. 40-4).

**TABLE 40-1 Reference Ranges for LA Dimension and Volume and Selected Clinical Variables for the Subjects in the Cardiovascular Health Study**

| *Linear Dimensions* | *Sex* | *Mean* | *Range* | *Percentile 0.05* | *0.50* | *0.95* |
|---|---|---|---|---|---|---|
| Diameter, cm | Female | 3.0 ± 0.5 | 1.5-4.2 | 2.2 | 3.0 | 3.9 |

### Valve Thickness

One autopsy study of 200 disease-free hearts demonstrated significant increases in mean thickness of the aortic and mitral valves with increasing age. This study showed that compared with subjects who were less than 20 years of age, those who were older than 60 years had valves that were twice as thick[29] (Table 40-4).

### Valvular Calcification

Aging is associated with thickening and calcification of the aortic valve cusps, also called aortic valve sclerosis, as well as the mitral and aortic valve annuli (termed *mitral annular calcification* and *aortic annular calcification*, respectively) (Figs. 40-5 and 40-6). Calcium is found at the bases of the aortic cusps and

at the annulus, as well as at the margins of closure of the mitral leaflets on the atrial side and in the mitral valve annulus. The term *senile calcification syndrome* was coined to describe patients with aortic valve sclerosis, mitral annular calcification, and calcification of the epicardial coronary arteries.[19]

Various studies in elderly subjects have identified prevalence as high as approximately 50% for each of these lesions.[30-34] Although aortic valve sclerosis is equally common in men and women, mitral annular calcification is more frequently seen in women. The prevalence by age of mitral annular calcification in one study is listed in Table 40-5.

## NORMAL CHANGES IN CARDIAC FUNCTION

### *LV Systolic Function*

Resting ejection fraction, percent fractional shortening, and cardiac output by echocardiography as well as by radionuclide ventriculography are unaffected by age in healthy normotensive people.[25,35,36] In order to maintain a normal ejection time in the setting of late systolic augmentation of aortic impedance, there is a prolonged contractile activation of the LV wall in the elderly.[36] This prolonged contractile activation means that when the mitral valve opens, myocardial relaxation is incomplete (relative to younger persons), and thus the early diastolic filling rate is lower in the elderly. Studies of rat and dog cardiac muscle have shown no change in contractile function (resting tension, peak isometric tension, maximal rate of tension development) with age.[36,37]

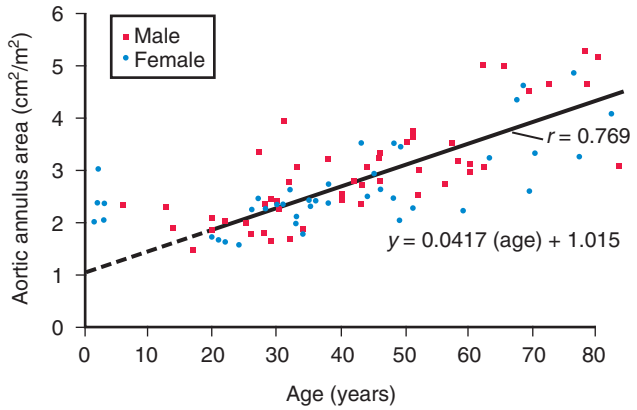

**Figure 40-4 Changes with age in the cross-sectional area of the aorta at the valve level.** Regression line shown is for patients over 20 years of age. Patients under 20 years of age, in general, have higher aortic annulus areas per square meter than predicted by the regression equation. *(From Krovetz LJ. ### *LV Diastolic Function*

Although LV systolic performance in the aged is preserved, LV diastolic function changes markedly with age. Seminal work in this area showed a reduction in mitral valve E-F closure slope on M-mode echocardiography.[2,3] Later work utilizing pulsed Doppler examination confirmed that there was a reduction in early diastolic peak filling rate (peak E-wave velocity) of approximately 50% between 20 and 80 years of age. There is a concomitant increase with age in peak A-wave velocity, representing late LV filling resulting from atrial contraction. This atrial "kick" is powered by a modest age-related increase in LA size. It is reasonable to consider the augmented atrial contribution to LV filling to be a successful compensatory mechanism to the reduced early diastolic filling rate into the thicker, presumably less compliant ventricle.

A number of mechanisms have been proposed to explain the changes in diastolic function that occur with aging, and all likely play some role. These mechanisms include a lower rate of calcium accumulation by the sarcoplasmic reticulum.[38] Studies of whole animal hearts and isolated cardiac muscle have documented prolonged isovolumic relaxation and increased myocardial diastolic stiffness.[39] Sclerosis of the mitral leaflets with resultant prolonged diastolic filling time (late closure) has also been proposed as a possible mechanism, as has an increase in afterload.

Data from the Framingham Heart Study were used to establish reference values for various Doppler parameters for elderly patients, as depicted in Table 40-6.[40] These data were obtained by studying 114 men and women aged 70 to 87 years of age who were screened and found to be free of cardiovascular disease. Notably, the vast majority (87%) of these subjects had peak E/A velocity ratios less than 1.0; 75% had values less than 0.86; and 25% had values less than 0.62. Because normal young subjects have E/A velocities greater than 1.0, it may be inappropriate to use this as the normal standard against which to compare the diastolic function of an elderly person (Fig. 40-7; also see Chapter 11).

### *Cardiac Response to Pressor Stress*

The usual response of increases in blood pressure and heart rate in response to sustained, isometric handgrip is altered in healthy elderly as opposed to young persons. Heart rate does not increase as much in the older group, but blood pressure is increased more than in the young. Accompanying these changes are mild increases in echocardiographically measured LV diastolic and systolic dimensions that occur in the aged.[41,42] Similar changes in LV cavity size and blunted heart rate increase have been seen in response to phenylephrine infusion in healthy older versus younger volunteers.[43] It therefore appears that because of reduced contractile reserve in the aged heart in response to increased afterload, overall systolic performance is maintained by cavity enlargement (i.e., the Frank-Starling mechanism).

### *Cardiac Response to Exercise Stress*

Multiple studies have shown that maximum oxygen consumption declines with age. This finding is likely multifactorial and involves changes in cardiac output, pulmonary function, and muscle function, among other factors. There has also been a documented age-associated decline in maximum exercise cardiac output that is a result of the aforementioned blunted heart rate response to exercise. With exercise, stroke volume is maintained with aging. The mechanism by which this occurs is that larger LV end-diastolic volumes are achieved with exercise, which offsets the blunted capacity of the aging heart to reduce end-systolic volume. The larger LV end-diastolic volume is achieved to some degree as a result of the slower heart rate (longer diastolic filling time), as well as the larger end-systolic volume.[44]

Ejection fraction, however, does not increase as much in older healthy individuals as in younger ones, and they do not reach the same peak as in younger persons.[44] This results from a decreased ability to reduce their end-systolic volumes. These findings likely result from multiple mechanisms. These include reduced myocardial contractility, increased vascular afterload, diminished autonomic modulation of LV contractility and arterial afterload, and arterial-ventricular load mismatching.[45]

## Clinical Outcome Data

### VALVULAR HEART DISEASE

### *Aortic Valve Sclerosis*

Aortic valve sclerosis is one end of the spectrum of calcific aortic valvular disease. Early aortic sclerosis is characterized by mild focal (not diffuse) areas of leaflet thickening without restriction of outflow, At the other end of the spectrum is aortic stenosis, which may progress to severe calcification with restricted leaflet motion and obstruction to LV outflow. The lesions of early aortic sclerosis are complex focal subendothelial

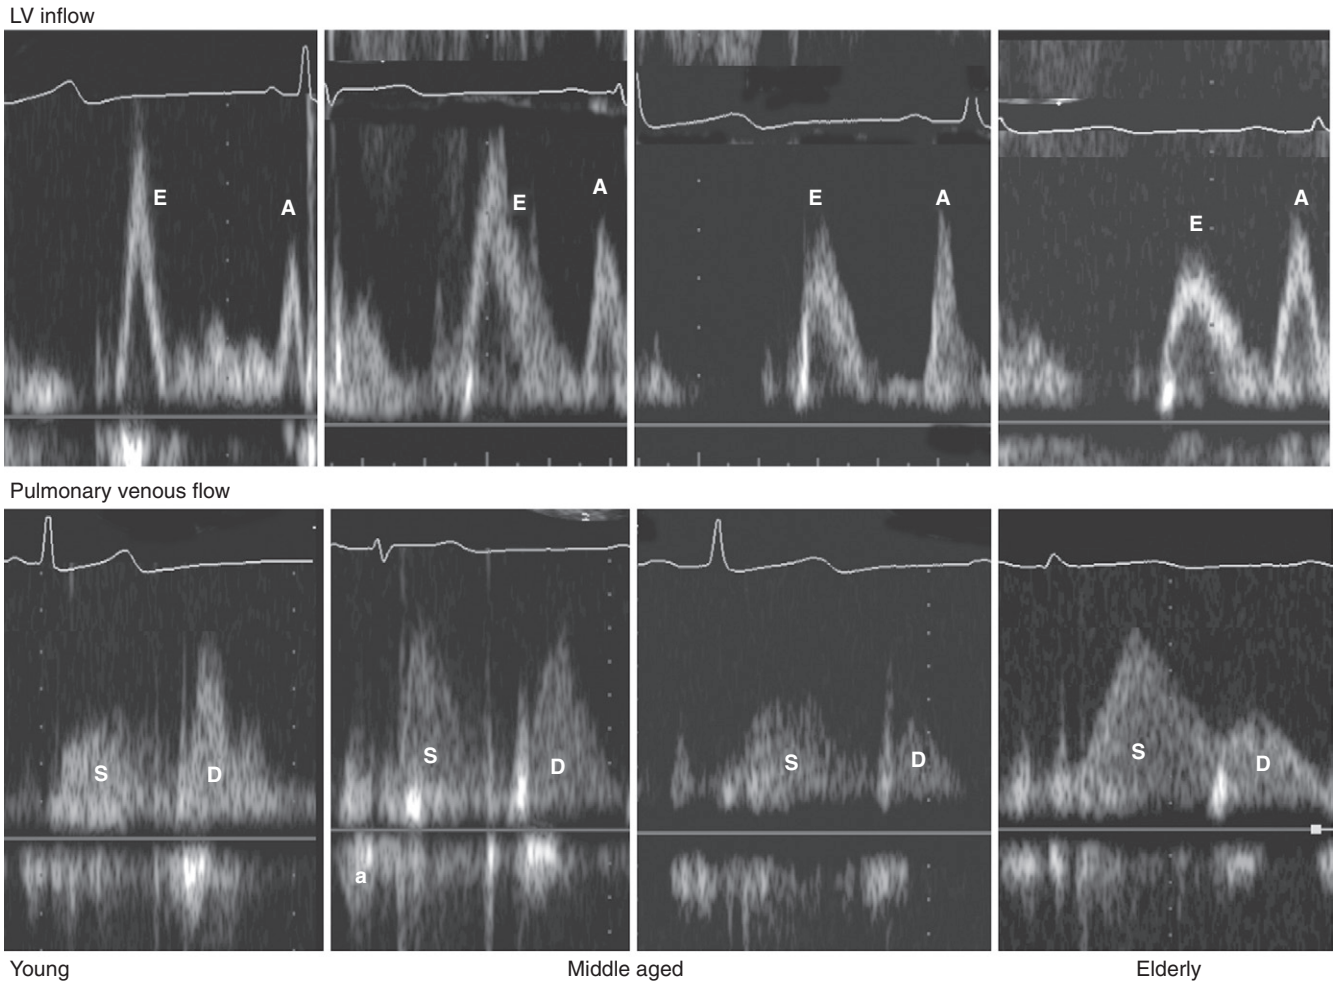

**Figure 40-7 Changes in LV and LA filling patterns with age.** Mitral inflow (*upper panels*) and pulmonary vein (*lower panels*) Doppler tracings from normal young, middle-aged, and elderly individuals. Normal progression of changes in LV filling is shown.

plaque-like lesions located on the aortic side of the valve leaflet that extend to the fibrosa layer. These lesions are probably reactions to increased mechanical or decreased shear stresses. Mechanical stresses are greatest on the aortic side near the attachments of the leaflets to the aortic root. Shear stress across the noncoronary cusp is lowest because of a lack of diastolic coronary blood flow, which probably explains why the noncoronary cusp is usually the first affected.[46] Patients with aortic stenosis who have bicuspid valves tend to present 20 years younger than patients with trileaflet valves, which supports the concept that mechanical stress (bileaflet valves are subject to a greater amount of such stress) is important in the pathogenesis of the disease.[46] The lesions of aortic valve sclerosis are active, with evidence of an accumulation of an inflammatory cell infiltrate, microscopic calcification, an accumulation of low-density lipoproteins and lipoprotein(a), and evidence of LDL oxidation.[47-50] As the process continues, calcification increases and there is active bone formation.[51] Ultimately, leaflet calcification can become so severe that opening of the valve is impaired, and hemodynamically significant aortic stenosis results. In longitudinal studies documenting progression from aortic valve sclerosis to aortic stenosis, moderate stenosis (jet velocity 3 to 4 m/s) was found in 3% of patients in one study and 5% in a second, and severe stenosis (jet velocity greater than 4 m/s) in 2.5% of patients in both studies.[52,53] Although the vast majority of patients will not progress to significant aortic stenosis, given the high prevalence of aortic valve sclerosis in the aging population, the sheer number of patients who could be affected is high, and thus its identification is important (see also Chapter 23).

### *Mitral Annular Calcification*

As noted, mitral annular calcification is characterized by calcification at the leaflet margins and in the annulus. It has been classified by its anatomic position. Anterior mitral annular calcification is defined by bright echodensities located at the level of the anterior mitral valve leaflet in systole and diastole and may extend from the annulus throughout the base of the heart into the mitral and aortic valves. Posterior mitral annular calcification is defined by similar echo signals anterior to the left posterior wall and merging with it.[54] Although many echocardiographers use personal subjective criteria to grade the severity of mitral annular calcification, a more systematic approach has also been used.[55] Mild mitral annular calcification can be defined as involving less than one third of the annular circumference (less than 3 mm in width) and are usually restricted to the angle between the posterior leaflet of the mitral valve and the LV posterior wall. In moderate mitral annular calcification, less than two thirds of the annular circumference is involved

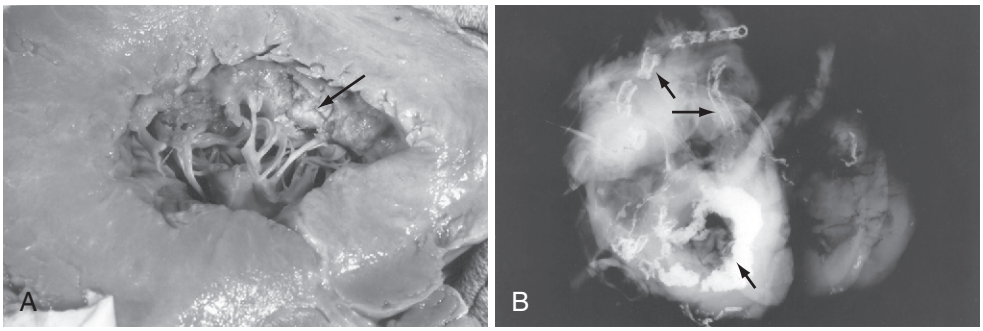

**Figure 40-8 Gross pathologic specimen depicting mitral annular calcification. A,** Ventricular aspect of mitral valve shows nodules of calcium deposited at annulus adherent to valve leaflet and chordae (*arrow*). **B,** Postmortem radiograph shows nearly "O"-shaped mitral annular calcification (*large arrow*) and calcified coronary arteries (*small arrows*).

(3 to 5 mm in width). In severe mitral annular calcification, more than two thirds of the circumference is affected (greater than 5 mm in width). It usually extends beneath the entire posterior mitral leaflet and may make a complete circle.

A rare variant of mitral annular calcification, called caseous calcification of the mitral ring, has been described. Echocardiographically, this entity is a large echodense structure with an echolucent center and smooth borders. Pathologically, it is composed of a mixture of calcium, cholesterol, and fatty acids.[56,57] It likely represents an active process, as in one longitudinal study, it was noted that some patients who had classic mitral annular calcification at baseline developed the appearance of caseous calcification, and some patients who had caseous calcification "reverted" back to the classic appearance.[58] Pathologically, in cases that have gone to surgery or autopsy, findings have included a calcified envelope surrounding caseous necrosis with cholesterol and fatty acids.[59] Others have found an amorphous eosinophilic acellular material surrounded by macrophages and lymphocytes.[57,60,61] Although the pathology is generally considered benign, it can be a nidus for infection[62] or thrombus and thus is a possible source of embolism.

### Mitral Annular Calcification and Valvular Dysfunction

There is a wide spectrum of calcification in mitral annular calcification and is probably progressive (Fig. 40-8). It usually begins with a small amount of calcium deposition at the basal insertion of the posterior mitral leaflet. Calcification of the annular connective tissue ensues and may form a ridge or ring that encircles the leaflets. As it progresses further, it may bulge into the LV cavity below the posterior leaflet and lift the leaflets toward the LA.[63,64] A larger extent of involvement may render the base of the posterior leaflet immobile and result in varying amounts of valvular regurgitation.[65] Actual leaflet calcification, however, is uncommon. The severity of mitral annular calcification seems to be correlated with the severity of associated mitral regurgitation when it is present.[65-67]

Mitral stenosis as a result of mitral annular calcification has also been described. In contrast to rheumatic mitral stenosis, where there is commissural fusion, in mitral annular calcification–associated mitral stenosis, the leaflets are not fused, but the increased flow velocities are a result of the decreased mitral annular excursion resulting from calcification.[68] Recent studies have suggested that mitral annular calcification, as the etiology of mitral stenosis, tends to be more mild in severity. However, it may be more common than previously thought and also is associated with risk factors for coronary artery disease.[69,70]

### Mitral Annular Calcification and Other Pathology

Mitral annular calcification is associated with LA well as LV enlargement.[55,71-73] In a prospective study of 976 elderly patients with and without mitral annular calcification, LA enlargement was 2.4 times more prevalent in patients with mitral annular calcification than in those without mitral annular calcification.[71]

### Mitral Annular Calcification and Conduction Abnormalities

Likely secondary to concomitant calcification within the conduction system (which may be contiguous as calcium extends from the annulus into the interventricular septum), mitral annular calcification is associated with conduction abnormalities such as atrioventricular block, sinoatrial node disease, bundle branch block, left anterior fascicular block, and nonspecific intraventricular conduction delay.[55,58,63,74]

### Mitral Annular Calcification and Atrial Fibrillation

Likely owing to the associated LA enlargement, atrial fibrillation is more common in patients with mitral annular calcification than in those without it. In various studies, the relative risk was increased from 1.4 to 12 times.[55,72,75,76]

### Mitral Annular Calcification and Thromboembolism

Mitral annular calcification is associated with a number of conditions that predispose to thromboembolic stroke, such as atrial fibrillation, mitral regurgitation and stenosis, LA enlargement, and heart failure. In addition, mitral annular calcification has been associated with aortic atheromata,[33,77] complex aortic debris,[78] and calcification of the thoracic aorta,[79] all of which could be sources of thromboembolic material. On the other hand, there is reason to suspect that mitral annular calcification itself may be involved in providing a source for thromboemboli. Although the calcification in mitral annular calcification is usually covered by a layer of endothelium, ulceration of the lining may expose the calcium and serve as a starting point for fibrin-platelet clot, which may embolize.[63,71] A number of studies designed to control for other factors have revealed an association of mitral annular calcification with cerebral embolization, with relative risks of 1.5 to 5.0.[55,71,75,80-84]

Studies have found mitral annular calcification to be an independent risk factor for stroke in patients who were in atrial fibrillation as well as those who were in sinus rhythm.[75] In the Strong Heart Study, mitral annular calcification, but not aortic valve sclerosis, was found to be a strong risk factor for incident stroke.[85] This has led to some advocating prophylactic

anticoagulation in patients with mitral annular calcification, regardless of rhythm.[86] Not all studies have found an association between mitral annular calcification and stroke, however.[87,88]

### Mitral Annular Calcification and Endocarditis

Abnormal valve morphology, hemodynamics, and endothelium have been implicated as predisposing the valve to infection (endocarditis).[71,63] In particular, patients with mitral annular calcification and chronic renal failure, seem to be at especially high risk.[89] Treatment of patients with antibiotics may also be less effective, as the avascular nature of the mitral annulus predisposes to periannular abscesses, and therefore some advocate antibiotic prophylaxis for patients with mitral annular calcification undergoing invasive procedures. However, the American Heart Association's most recent guidelines do not recommend prophylaxis for acquired aortic or mitral valve disease.[90,91]

### Mitral Annular Calcification and Renal Dysfunction

There has been increasing interest in studying the links between calcific valvular heart disease and renal dysfunction.[92] Data from the Cardiovascular Health Study[93] and the Framingham Offspring Study[94] have shown a relationship between chronic kidney disease and mitral annular calcification, but *not* with aortic valve sclerosis. On the other hand, data from the Multi-Ethnic Study of Atherosclerosis showed an association between impaired renal function and mitral annular calcification only among diabetics and did show a modest association between impaired renal function and aortic valve calcification.[95] The reasons for these differences have not yet been elucidated.

### *Aortic Valve Sclerosis and Mitral Annular Calcification: Cardiovascular Outcomes*

Several studies have found a strong association between mitral annular calcification and aortic valve sclerosis with adverse cardiovascular outcomes and mortality.[32,34,84,96-99] Otto and colleagues[34] found that in 5621 men and women 65 years of age or older who were participants in the Cardiovascular Health Study, aortic sclerosis (without hemodynamically significant outflow obstruction) was associated with an approximately 50% increase risk of death from cardiovascular causes and a 40% increase in the risk of myocardial infarction. In another study of 2358 elderly patients, those with aortic valve sclerosis had a risk of developing a new coronary event that was 1.8 times higher than those without it.[32] Lending support to the concept that calcific aortic valve disease and atherosclerotic vascular disease have a shared pathogenesis are data from Otto's study that older age, male gender, smoking, hypertension, and hyperlipidemia were associated with aortic sclerosis. Data from the Multi-Ethnic Study of Atherosclerosis have also linked mitral annular calcification with atherosclerotic vascular risk factors.[70] In the Northern Manhattan Study, 1655 subjects aged at least 40 years (average 68) without a history of myocardial infarction or stroke were followed for an average of approximately 7 years. The prevalence of mitral annular calcification was 27%, and after adjustment for traditional cardiovascular risk factors, mitral annular calcification was found to be a strong and independent predictor of myocardial infarction and vascular death (but not ischemic stroke). The risk increase was directly related to the severity of the calcification.[100]

Using data from the Cardiovascular Health Study, Barasch and co-workers[101] evaluated the prevalence and clinical outcomes of mitral annular calcification, aortic valve sclerosis, and aortic annular calcification. The 3929 subjects had a mean age of 76 years; 60% were women. In this study, mitral annular calcification was seen in 42% of subjects, aortic annular calcification in 44%, and aortic valve sclerosis in 54%. The rate of all three conditions being found in a single subject was 17%. Subjects with these conditions tended to be older, and those with mitral annular calcification had worse risk profiles (e.g., LV hypertrophy/mass, LA size, abnormal ejection fraction, carotid intimal media thickness, dyslipidemia, C-reactive protein) than those with aortic valve sclerosis and aortic annular calcification. In addition, this study showed that the severity of mitral annular calcification (estimated from 2D echocardiography, semiquantitatively) was associated with a higher prevalence of atherosclerotic vascular disease, independent of other risk factors. These conditions were associated with a significantly elevated risk of cardiovascular disease endpoints, and the strongest association was with the combined group (mitral annular calcification, aortic annular calcification, and aortic valve sclerosis) with heart failure (odds ratio 2.04, 95% confidence interval 1.34 to 3.09) (Figs. 40-9 and 40-10; Table 40-7).

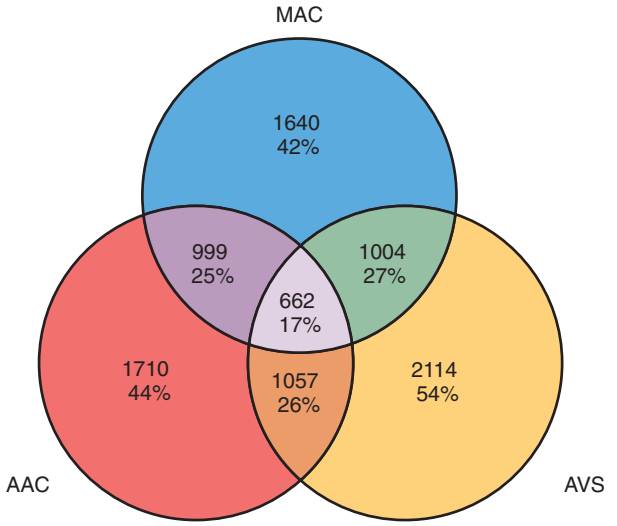

**Figure 40-9 Relationship between mitral annular calcification (*MAC*), aortic annular calcification (*AAC*), and aortic valve sclerosis (*AVS*) in 3929 participants in the Cardiovascular Health Study.** Numbers are total numbers of patients, and percentages refer to the percent of the total population of 3929 study participants. *(From Barasch E, Gottdiener JS, Larsen EKM, et al: Clinical significance of calcification of the fibrous skeleton of the heart and aortosclerosis in community dwelling elderly. The Cardiovascular Health Study (CHS).* Am Heart J *151:39-47, 2006. Reprinted with permission.)*

Although not definitively proven, a good deal of research has strongly suggested a relationship between calcification of the fibrous skeleton of the heart and aortic valve cusps and advanced atherosclerosis.[54,102-104] Inflammation and abnormalities of lipid metabolism have both been implicated in the development of both atherosclerosis and aortic valve calcification.[51,105-107] Other data have failed to support the association of inflammatory markers with calcific aortic valvular disease, however.[108]

## LEFT VENTRICULAR HYPERTROPHY

Data from both the Framingham Study and the Cardiovascular Health Study confirm that LV hypertrophy is a potent predictor of morbidity and mortality from coronary heart disease, heart failure, and stroke.[88,109,110]

The relationship between age and LV hypertrophy is complex. Evaluation of data from the Framingham Heart Study revealed

that age, height, systolic blood pressure, and body mass index were significant and independent predictors of LV mass in 4972 people aged 17 to 90 years. However, age was no longer a significant correlate of LV mass when people were screened out of the analysis who met one of the following conditions: evidence of cardiovascular disease on history, physical exam, electrocardiogram, chest radiography, or echocardiography; blood pressure greater than or equal to 140/90; on medications for cardiopulmonary disease; or at least 20% above or below recommended weight for height.[111] Thus, it seems that the increases in LV mass that are seen with age are often confounded by coexisting cardiopulmonary disease.

In the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation and Treatment of High Blood Pressure (JNC 7), the identification of LV hypertrophy in a patient with hypertension is considered evidence of target organ damage and thus is considered an indication for aggressive blood pressure management.[112]

## LEFT ATRIAL SIZE AND OUTCOMES

Elevated LA size has been shown to be a marker of cardiovascular risk. Largely from studies carried out in elderly populations, an enlarged LA is associated with an increased risk of atrial fibrillation, stroke, and death (including after myocardial infarction, in patients with mitral regurgitation, hypertension, and dilated cardiomyopathies).[113-119] Using data from the Strong Heart Study, Kizer and co-workers[120] showed that LA diameter (normal defined as less than 3.8 cm for women, less than 4.2 cm for men) was an independent predictor of incident cardiovascular events after adjustment for other factors (clinical, echocardiographic, inflammatory) (Table 40-8; Fig. 40-11). As noted, LA volume is emerging as a more robust measure of cardiovascular risk. In patients with mitral stenosis who are in sinus rhythm but have no history of embolism or thrombus, guidelines from the European Society of Cardiology as well as from the American College of Cardiology/American Heart Association suggest that anticoagulation can be considered if there is an enlarged LA or dense spontaneous echo contrast seen on echocardiography, albeit with lower level of evidence ratings.[91,121] Given this, Keenan and colleagues[122] compared measures of volume versus diameter in patients with mitral stenosis and showed that LA volume more strongly correlated with echocardiographic measures of thromboembolic risk (peak LA appendage emptying velocity, spontaneous LA contrast density during TEE) than LA diameter in patients with mitral stenosis (Fig. 40-12). These data would support using volumetric measurements over linear ones.

## HEART FAILURE

The reversal of early and late diastolic filling with age results in preserved end-diastolic and stroke volume (and therefore cardiac output), but a reduction in LV compliance may cause an elevated LV end-diastolic pressure in the elderly, especially with tachycardia (see Chapter 26). This would be expected to cause dyspnea to be more easily provoked and presumably forms the basis of heart failure in some patients.

## EXAMPLES OF THE ETIOLOGY OF HEART FAILURE WITH PRESERVED EJECTION FRACTION

- Diastolic heart failure
  - Hypertension
  - Restrictive cardiomyopathy
  - Infiltrative cardiomyopathy
  - Hypertrophic cardiomyopathy
  - Noncompaction cardiomyopathy
- Right heart failure
  - Severe pulmonary hypertension
  - RV infarction
  - Arrhythmogenic RV dysplasia
  - Atrial septal defect
- Valvular heart diseases
  - Severe valvular stenosis
  - Severe valvular regurgitation
- Pericardial disease
  - Cardiac tamponade
  - Constrictive pericarditis
- Intracardiac mass
  - Atrial myxoma
  - Apical eosinophilic thrombus
- Pulmonary vein stenosis
- Congenital heart diseases

Adapted from Oh JK, Hatle L, Tajik AJ et al: Diastolic heart failure can be diagnosed by comprehensive two-dimensional and Doppler echocardiography. *J Am Coll Cardiol* 47:500-506, 2006. Reprinted with permission.

The syndrome of heart failure is common in the elderly and is increasingly prevalent with increasing age. In the Framingham Heart Study, the incidence of heart failure increased fivefold from age 40 to 70 years.[123] The Cardiovascular Health Study, which studied older men and women, found an increased prevalence of heart failure in women, from 4.1% at age 70 to 14.3% at age 85 (Fig. 40-13). The figures for men were 7.8% increasing to 18.4%.[124] Heart failure with normal or near-normal systolic function is also particularly prevalent in the elderly. Multiple population-based studies have suggested that 50% or more of elderly patients with heart failure have normal or near-normal systolic function. These studies have also documented that heart failure with preserved ejection fraction (HFpEF) is more common in women than in men.[21,125-128] Because women outnumber men in the older age group, the problem is even more prevalent with advancing age.

There are multiple etiologies of HFpEF, and several are listed in Box 40-1.[129] Evaluation of patients with heart failure by

Copyright © 2007, Oxford University Press. Reprinted by permission of Oxford University Press.)*

echocardiography can lead to a diagnosis of the etiology of heart failure and as such can lead to more appropriate evaluation and treatment of the condition. It is important to recognize how prevalent heart failure is in the elderly, as well as the fact that patients with HFpEF also have impaired survival (although in some studies not to the same degree).[21,130,131] Furthermore, it has been shown that patients who do not have the syndrome of heart failure, but who have been found to have diastolic dysfunction, also have higher mortality than those with normal diastolic function.[132]

The current European Society of Cardiology consensus statement[133] on the diagnosis of heart failure with a normal ejection fraction include echocardiographic measures of abnormal diastolic function (Fig. 40-14).

## CORONARY ARTERY DISEASE AND STRESS TESTING

The identification of findings supportive of a diagnosis of coronary artery disease is very common in the elderly, as age is a major risk factor for coronary disease. Wall motion abnormalities, wall thinning, and aneurysm formation from prior myocardial infarction may be seen.

Stress echocardiography (exercise or pharmacologic) is a modality commonly used to evaluate for coronary artery disease and sometimes to evaluate myocardial viability (see also Chapters 15 and 16). The techniques used are the same for the elderly as for the younger patient. Age-adjusted normative values for target heart rate and exercise time are widely available. In addition, treadmill protocols that have a more

| | *Overall* | *1-VD* | *2-VD* | *3-VD* | *Specificity* | *Accuracy* |
| Dobutamine | 86.5% (77/89) | 74% (14/19) | 88% (22/25) | 91% (41/45) | 84% (26/31) | 86% (103/120) |
| Adenosine | 66.3% (59/89) | 42% (8/19) | 76% (19/25) | 71% (32/45) | 90% (28/31) | 72.5% (87/120) |
| *P* value | <0.001 | o.227 | 0.124 | <0.01 | <0.001 | <0.001 |

Data in parentheses indicate number of patients.
This study enrolled 120 patients ≥70 years old with chest pain and known or suspected coronary artery disease who underwent both dobutamine and adenosine stress echocardiography, as well as coronary angiography.
From Anthopoulos LP, Bonou MS, Kardaras FG, et al: Stress echocardiography in elderly patients with coronary artery disease: applicability, safety and prognostic value of dobutamine and adenosine echocardiography in elderly patients. *J Am Coll Cardiol* 28(1):52-59, 1996. Reprinted with permission.
*1-VD*, One-vessel coronary artery disease; *2-VD*, two-vessel coronary artery disease; *3-VD*, three-vessel coronary artery disease.

gentle increase in speed or incline are common (e.g., the Modified Bruce, Naughton, and Balke protocols). Because many elderly have comorbid conditions that make exercise stress testing unattractive or impossible (e.g., chronic obstructive pulmonary disease, orthopedic/arthritic conditions, neuromuscular disorders, or peripheral vascular disease), the use of pharmacologic stress increases the number of patients eligible for stress testing in this age group. Vasodilators such as adenosine or dipyridamole and catecholamines (dobutamine) as pharmacologic stress agents are used in this population.

Studies in elderly patients referred for stress testing on clinical grounds, as well as in the post–myocardial infarction population, have demonstrated the value of exercise, adenosine, dipyridamole, and dobutamine echocardiography in predicting clinical outcomes.[134-138]

Some data suggest that dobutamine stress echocardiography (DSE) is more sensitive and accurate than, but as specific as, adenosine stress echocardiography (Table 40-9).

### *Safety*

The safety profile of these various types of stress testing in the elderly is good. Exercise echocardiography is similar to standard exercise testing with regard to safety, although some caution is needed as patients are guided back to the scanning bed from the treadmill. In one study of 454 patients, half at least 70 years old and half less than 70 years old, DSE was associated with higher rates in the elderly versus younger patients of asymptomatic hypotension (defined as a drop in systolic blood pressure of >20 mm Hg) of 37% versus 12%. There were also significantly higher rates of supraventricular tachycardia (7% versus 1%) and of premature ventricular contractions (74% versus 32%). There was a nonsignificant trend toward more frequent ventricular tachycardia (5% versus 2%) and of atrial fibrillation (3% versus 0.4%). The authors report that all arrhythmias resolved either with dobutamine infusion cessation or with administration of metoprolol.[139] Similar results were reported by Hiro and colleagues.[140] Newer protocols that call for early administration of atropine (when dobutamine infusion is at 20 mcg/kg/min if the heart rate is less than 100) during DSE have suggested a reduction in minor adverse effects, with similar diagnostic accuracy, including in an elderly population[141,142] (Fig. 40-15 and Table 40-10).

Dipyridamole and adenosine can cause bronchospasm, hypotension, and arrhythmias, and for the most part these effects do not seem to be age related.[143,144] However, elderly patients undergoing adenosine stress tests may be more likely to experience transient atrioventricular block. In one study of 120 patients 70 or more years old, this occurred in 6% of tests.[136]

In another study it occurred in 18% of patients at least 75 years old versus 8% in those less than 75 years of age.[145]

Regadenoson is a new adenosine A(2A) specific receptor agonist that, because of its selective nature, is not associated with bronchospasm or atrioventricular node block as the nonspecific agents (adenosine and dipyridamole) are.[146] It is approved for use in stress myocardial perfusion (single photon emission computed tomography) imaging with a good tolerability and safety profile, including in the elderly,[147,148] and is being evaluated for use with atropine in stress echocardiography.[149] It may be an alternative stress echocardiography agent for patients with reactive airway disease and contraindications to dobutamine.

## CARDIOGENIC THROMBOEMBOLISM

Cardiac sources of embolism are thought to be responsible for ischemic strokes in as many as 30% of cases (see also Chapter 41).[150-152] Embolization of the components of mitral annular calcification as well as of atherosclerotic intraaortic debris is more common in elderly patients (see Figs. 40-6, 40-8, and 40-16). Aortic sclerosis has also been associated with the risk of stroke, but an independent association between aortic valve calcification and cerebral infarcts has been demonstrated only in the presence of aortic stenosis.[34,87,153] As noted previously, the association between mitral annular calcification and stroke is stronger.[85] As with younger patients, LV thrombus (usually associated with LV dysfunction), LA thrombus (usually associated with atrial fibrillation and/or flutter), vegetations, paradoxic emboli (across a patent foramen ovale), and myxoma are potential sources of embolism. Atrial fibrillation and flutter are more common in the elderly, although the prevalence of patent foramen ovale decreases with age. Many studies have demonstrated the higher sensitivity of transesophageal echocardiography (TEE) to detect potential sources of embolism, including in the elderly population.[154]

## CARDIAC AMYLOIDOSIS

Amyloid infiltration of the heart in the elderly has been described for decades and has been variously termed *senile amyloidosis of the heart* or *amyloidosis localized to the heart* (see also Chapter 28).[155,156] However, a more appropriate term is probably *systemic senile amyloidosis*, as evidence of small amyloid deposits has been found in the aorta, lung, gastrointestinal tract, liver, and kidney.[157,158] In addition to systemic senile amyloidosis, amyloid infiltration of the heart occurs in primary amyloidosis and amyloidosis associated with multiple myeloma, as well as secondary amyloidosis that is associated with chronic inflammation. The protein of senile amyloidosis is different from that of primary amyloidosis, and it portends a much better prognosis.[159] In one autopsy study of 244 patients who were greater than 60 years of age, amyloid was found in the heart in 50% of patients.[160] Although it infrequently causes clinical symptoms or signs,[161,162] it has been associated with atrial fibrillation, ventricular arrhythmias, and heart failure (usually when there is a large burden of involvement).[163,164] Studies have shown a male predominance in the primary systemic type, but an even greater predominance in the senile type.[159,164,165] In a study by Smith and colleagues[164] that compared patients with senile and primary amyloidosis, the male-to-female ratio was 5.5:1 for the senile group, and 1.6:1 for the primary group. The patients with senile amyloidosis were older with a mean age of 83 years, whereas only 4 of the 21 patients with primary amyloidosis were over 70 years old. Amyloid deposits can be found in the ventricular myocardium, as well as in the atrial mural endocardium. Less common sites of deposition in the senile type include the valves, Epicardium, and intramyocardial blood vessels.[166] Echocardiographic evidence of cardiac amyloidosis includes increased myocardial echogenicity with a "speckle" pattern, increased interatrial septal thickness, and valve thickening. The latter two characteristics are common in other conditions. Finding LV hypertrophy on echocardiography along with a low-voltage pattern on an electrocardiogram is suggestive of an infiltrative cardiomyopathy.

## Clinical Recommendations

1. Norms for chamber dimensions should be adjusted based on age.

2. Although valvular calcification is common (aortic valve sclerosis, aortic annular calcification, and mitral annular calcification), because its presence is associated with adverse outcomes, it should not be considered normal. Instead, cardiac calcification should be viewed as an important risk marker.
3. Diastolic filling parameters commonly change with age in a generally predictable manner, but do predispose patients to having adverse events/outcomes (e.g., atrial fibrillation, heart failure). Thus, they should not be considered normal, but rather the specific physiologic abnormalities should be described (e.g., impaired relaxation).
4. Although stress testing is generally safe to perform in the elderly population, practitioners should be aware that these patients are more likely than younger patients to experience supraventricular tachycardia, premature ventricular contractions, and asymptomatic hypotension with dobutamine, as well as transient atrioventricular block with adenosine.

## KEY POINTS

- Age is a major risk factor for cardiovascular disease, and many normal and pathologic changes that are common with age are readily detected on echocardiography.
- These changes in cardiac structure primarily affect the LV, LA, and valves.
- There are predictable changes in LV performance with age, particularly changes in diastolic function.
- Valvular calcification (including aortic valve sclerosis, aortic annular calcification, and mitral annular calcification) is common and is associated with adverse cardiovascular outcomes in the elderly.
- LV hypertrophy, elevated cardiac mass, and increased LA size also are associated with adverse cardiovascular outcomes.
- Heart failure and in particular diastolic heart failure are very common in the elderly.
- Pharmacologic stress testing is frequently requested in the elderly, and a heightened awareness of possible complications is advisable.

# Echocardiographic Evaluation of the Patient with a Systemic Embolic Event

MARCO R. DI TULLIO, MD

**Background**
Cardiac Embolism
Cardioembolic and Cryptogenic Stroke
**Basic Principles and Echocardiographic Approach**
**Technical Aspects**
Transesophageal Echocardiography versus Transthoracic Echocardiography in Cryptogenic Cerebral Ischemia
Safety of Transesophageal Echocardiography
**Clinical Utility and Outcome Data**
Myocardial Infarction, Left Ventricle Dysfunction, and Thrombus
Valvular Vegetations and Strands
Intracardiac Tumors
Left Atrial Thrombus and Spontaneous Echo-Contrast
Atrial Septum Abnormalities: Patent Foramen Ovale and Atrial Septal Aneurysm
Atherosclerotic Plaques in the Proximal Aorta
Echocardiography in the Catheterization Laboratory
**Research Applications**
**Potential Limitations and Future Approaches**
**Alternate Approaches**

## Background

### CARDIAC EMBOLISM

The heart and the aorta are potential sources of embolism to the systemic circulation. When the heart or the proximal segment of the aorta is the source for the embolism, the brain is the most frequent target. This circumstance, along with the fact that cerebral embolism often results in life-threatening or severely disabling consequences, makes the investigation for cardiac embolic sources especially aggressive after a cerebral embolic event, in an attempt to identify lesions that can be treated to prevent recurrences. Also, the largest amount of outcome data and information on means for reducing the incidence of recurrent embolic events in patients with cardioaortic embolic sources comes from the literature on embolic stroke. Therefore, this chapter mainly reviews the current knowledge on the diagnostic workup in patients with cerebral embolic events from a cardiac or aortic source. However, the same embolic sources (with the addition of those that originate from more distal segments of the aorta) and principles for investigating them also apply to embolic events that occur in any vascular territory of the systemic circulation.

### CARDIOEMBOLIC AND CRYPTOGENIC STROKE

Stroke is the third leading cause of death in the United States, after cardiac disease and cancer. Approximately 6,400,000 Americans 20 years of age or more have had a stroke.[1] Each year, approximately 795,000 people experience a stroke, as a first event in 80% of cases.[1] In addition, the number of transient ischemic attacks (TIAs), temporary episodes of neurologic dysfunction that have similar risk factors as stroke and often are prelude to it, is estimated at 200,000 to 500,000 per year.[1] The vast majority of strokes (87%) have an ischemic origin,[1] meaning that the etiology of the stroke consists of a blockage of the blood supply to the affected territory. The remainder is accounted for by intracerebral (10%) or subarachnoid (3%) hemorrhage.

Ischemic stroke has a cardioembolic source in approximately 20% of cases.[2] In addition, cases that have no apparent cause (also called cryptogenic strokes) often have clinical presentation and neuroimaging findings that are suggestive of an embolic event, but the embolic source is missing. In the Stroke Data Bank, a large observational study of more than 1800 patients with stroke, the classification of ischemic strokes into the three traditional diagnostic subtypes (large vessel atherosclerotic, cardioembolic, and small vessel disease) left approximately 40% of patients with no clear stroke etiology.[3] When forcibly reclassified into those three etiologic subtypes on the basis of the patient's clinical presentation and diagnostic workup, almost two thirds of cryptogenic strokes were considered of most likely cardioembolic origin.[3] The need for a better understanding of established cardioembolic sources and the identification of newer ones has indeed characterized the involvement of cardiologists, and especially echocardiographers, in the field of stroke diagnosis and prevention in the past 20 years. This effort has led to the reduction of the proportion of strokes labeled as cryptogenic,[4] often the alteration of the management of stroke, and the use of more rational and effective preventive strategies for decreasing the incidence of recurrent events.

## Basic Principles and Echocardiographic Approach

Transthoracic echocardiography (TTE) and, especially, transesophageal echocardiography (TEE) have been widely used for searching cardiac embolic sources and still represent the

mainstay for investigation in patients with stroke or TIA. TTE is performed in cases in which the cardiac chamber of interest can be optimally visualized, as in the case of the left ventricle (LV) in a search for an apical thrombus, or for the assessment of segmental wall motion abnormalities. Other examples of TTE use may include the assessment of left atrial (LA) size or of the presence of mitral annular calcification. TTE can also be indicated as a screening test for determination of whether to proceed to the more invasive TEE. In this latter category is the evaluation for presence of a patent foramen ovale (PFO) with TTE with contrast injection or the assessment for intracardiac masses or valvular vegetations in patients with low probability for these conditions. TEE, on the other hand, is preferred when TTE cannot clearly visualize the cardiac or aortic structures of interest and in all instances in which high-resolution imaging of such structures is needed. TEE is superior to TTE for the visualization of the atrial septum and the cardiac valves and allows, for example, a much more accurate diagnosis of PFO or infective endocarditis (IE). TEE also provides an accurate visualization of structures, such as the LA appendage or the proximal thoracic aorta, that are important targets of the investigation for embolic sources. The following section reviews the diagnostic accuracy of TTE and TEE for the detection of cardiac embolic sources and some technical aspects of their performance.

## Technical Aspects

### TRANSESOPHAGEAL ECHOCARDIOGRAPHY VERSUS TRANSTHORACIC ECHOCARDIOGRAPHY IN CRYPTOGENIC CEREBRAL ISCHEMIA

Several studies have compared the diagnostic yield of TEE and TTE in the investigation for potential cardiac embolic sources in patients with cryptogenic cerebral ischemia (stroke or TIA). TEE has been repeatedly shown to have greater sensitivity than TTE for this purpose. Initial studies in the 1990s reported on a greater than two-fold increase in detection rate of embolic sources with TEE compared with TTE.[5] This observation has been confirmed in recent years, when technologic advancements in the echocardiographic equipment may have narrowed the diagnostic gap between the two techniques. In 231 patients with cryptogenic stroke or TIA, a potential source of embolism was observed in 55% with TEE but in only 16% with TTE.[6] A major embolic source, with an absolute indication to anticoagulation therapy, was found in 20% of patients with TEE and in only 4% with TTE.[6] The great diagnostic yield of TEE was confirmed in a more recent study on 702 consecutive patients with ischemic stroke or TIA.[7] TEE revealed relevant findings in 52.6% of patients, with PFO (21.7%) or previously undiagnosed valvular disease (15.8%) the most common findings.[7] In another series of 503 patients with acute brain ischemia, TEE findings led to the initiation of systemic anticoagulation therapy in 65 of 212 patients (30.6%) with cryptogenic stroke.[8] Therefore, TEE has emerged as the most sensitive and clinically useful diagnostic technique for the search for cardiac and aortic embolic sources, and TTE is used as a screening technique and for specific indications that are highlighted later in the chapter. Table 41-1 shows a clinically useful classification of embolic sources and the appropriate diagnostic techniques for each of them.

**TABLE 41-1 Echocardiographic Evaluation of Cardioaortic Embolic Sources**

| | *Possibly Associated Conditions* | *Age Group* | *Best Diagnostic Test* |
|---|---|---|---|
| LV thrombus | Prior myocardial infarction, dilated cardiomyopathy | Any | TTE |
| LA thrombus or spontaneous echo-contrast | Atrial fibrillation, mitral valve disease | Any | TEE |
| Valvular vegetations | Infective endocarditis (fever, murmur, systemic symptoms), lupus erythematosus | Any | TEE or TTE (less sensitive) |
| Valvular disease | Variable | Any | TTE for initial evaluation; TEE for further assessment (especially for prosthetic valves) |
| Cardiac tumors (myxoma, fibroelastoma, secondary malignancies) | None, or nonspecific systemic symptoms | Any | TTE for screening; TEE if suspicion high despite nondiagnostic TTE |
| Patent foramen ovale | None | Any; more frequent in patients <55 years | TTE with contrast for screening; TEE if more detail is needed |
| Atrial septal aneurysm | None | Any; more frequent in patients <55 years | TTE for screening; TEE for better imaging |
| Valve strands | None | Any | TEE |
| Aortic plaques | Diffuse atherosclerosis | >60 years | TEE |

### SAFETY OF TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography is a safe, although semiinvasive, diagnostic test. Major complications are uncommon and frequently occur in the setting of unsuspected esophageal disease. In a European series of more than 10,000 patients,[9] one death was observed. In an additional 2.7% of patients, the test could not be performed because of unsuccessful intubation (1.9%) or patient intolerance (0.8%). Similar results were obtained in a study from the Mayo Clinic on 15,381 consecutive patients, with two deaths (0.01%) and an overall incidence rate of complications of 1.7%.[10] More information on TEE performance and safety is provided in Chapter 1.

## Clinical Utility and Outcome Data

This section reviews the use of echocardiography for the investigation of specific embolic sources, the available data on the importance of each condition, and information on treatment to prevent recurrent events.

### MYOCARDIAL INFARCTION, LEFT VENTRICLE DYSFUNCTION, AND THROMBUS

Myocardial infarction (MI) and dilated cardiomyopathy are the conditions most frequently associated with LV thrombus formation, which may lead to cerebral embolism. In the first month after an acute MI, the incidence rate of stroke is between 2% and 3%; 50% of the events occur in the first 5 days (see Chapter 14).[11] In a study of 2160 patients with incident MI, the

incidence rate of stroke during the first month was 22.6 per 100 person-months, a 44-fold increase compared with controls.[12] The risk of stroke or TIA is elevated in the first 3 to 6 months; it declines thereafter but is still two-fold to three-fold higher than in controls during the first 3 years from the MI.[12]

The risk of stroke or TIA is mainly related to the formation of thrombus in the infarcted area. In a meta-analysis, the presence of echocardiographically confirmed mural thrombus carried a more than five-fold increase in stroke risk.[13] The frequency of thrombus formation is considered higher after anterior MI than after inferior MI. In a recent study of 642 patients with anterior MI, LV thrombus formed in 6.2%, without significant differences according to initial treatment modality (percutaneous coronary intervention, thrombolysis, or conservative management).[14]

Transthoracic echocardiography is commonly used for the detection of LV thrombus. In the presence of technically adequate images, TTE is at least as sensitive as TEE because most ventricular thrombi tend to form in the apical region of the ventricle (Fig. 41-1), which may or may not be optimally visualized with TEE. Therefore, the use of TEE to search for an LV thrombus should be reserved to patients with suboptimal TTE views. The use of a contrast agent for opacification of the LV chamber (Fig. 41-2) adds to the sensitivity of TTE and decreases the proportion of uncertain findings, further reducing the number of cases in which TEE may be needed. In a study on 123 patients with inconclusive TTE results, contrast injection revealed a thrombus in 14 and allowed its presence to be excluded in all others.[15] In 33 patients with suspected thrombus, contrast allowed its presence to be excluded in 13 (39%). Overall, the use of contrast led to a therapeutic change in a large number of patients, either as a treatment upgrade from antiplatelet agents to warfarin in cases with confirmed thrombus or as the avoidance of unnecessary anticoagulation therapy in others.[15]

Because most LV thrombi form in the apical region, apical views are usually the most useful TTE views for this diagnosis (see Fig. 41-1). Morphologic features of the thrombus, such as size, protrusion, and mobility, can be assessed and are important in evaluation of the thromboembolic potential. Whenever possible, the use of higher frequency transducers (3.5-MHz or 5-MHz) may further enhance the thrombus detection rate.

For patients with echocardiographically documented LV thrombus, prophylaxis with warfarin with a target international normalized ratio (INR) of 2.0 to 3.0 is recommended,[16] in addition to aspirin (75 to 162 mg), which is needed for secondary prevention of MI. Anticoagulation therapy should be lifelong in patients with atrial fibrillation; in patients in sinus rhythm with documented LV thrombus, at least 3 months of anticoagulation therapy is recommended,[17] with continuation

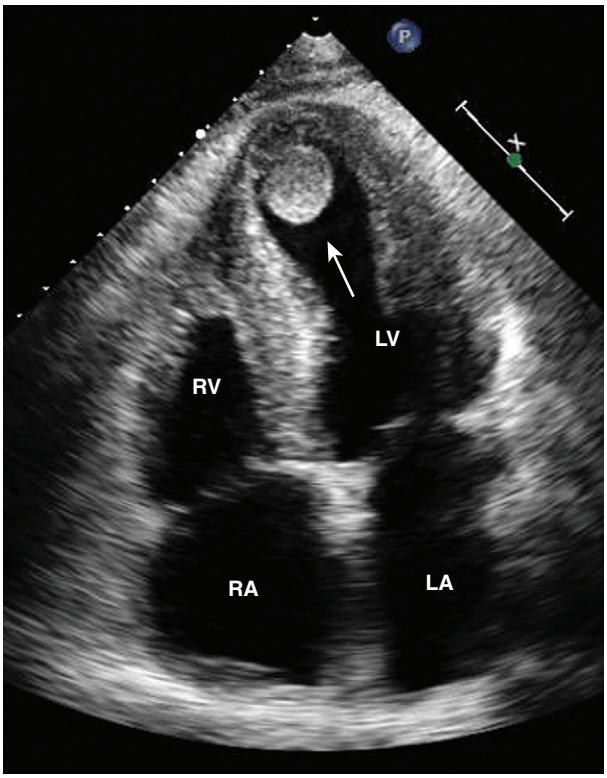

**Figure 41-1** **Example of large apical thrombus (*arrow*) with TTE.**

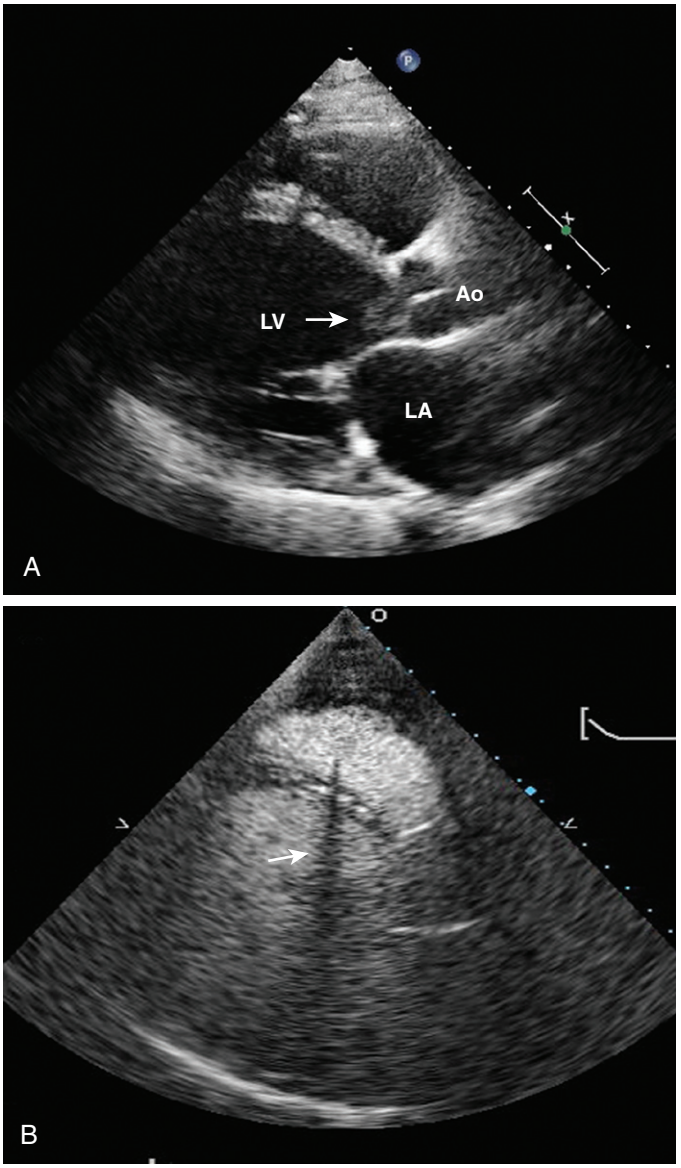

**Figure 41-2** **LV contrast utilization for the detection of intraventricular thrombus. A,** A faint echogenicity of uncertain significance (*arrow*) is visualized with TTE in the LV outflow tract. **B,** LV contrast injection shows the absence of any intracardiac mass in the LV outflow tract. A shadowing artifact from catheter in the RV is noted (*arrow*). *Ao*, Aorta.

of treatment based on follow-up echocardiographic findings (resolution or persistence of LV thrombus, severity of LV dysfunction). In 3404 patients who were randomized to systemic anticoagulation therapy or placebo after MI, anticoagulation therapy was associated with a 40% reduction in stroke risk over 3 years, and with an increase in the frequency of major hemorrhagic complications.[18] Long-term anticoagulation therapy is especially beneficial in patients with decreased LV function, whose risk of cerebrovascular events is particularly high.[19] However, the usefulness of systemic anticoagulation therapy in all patients with anterior MI, regardless of thrombus presence, appears questionable. In 2482 patients after anterior MI, 20% of whom were discharged on anticoagulation therapy, the use of such therapy for up to 90 days after the MI was not associated with a significant reduction in stroke risk in the following 4 years (hazard ratio [HR], 0.68; 95% confidence interval [CI], 0.37 to 1.26). Treatment with angiotensin-converting enzyme inhibitors (HR, 0.65; 95% CI, 0.44 to 0.95) and beta-blockers (HR, 0.60; 95% CI, 0.41 to 0.87), however, was.[20]

Only sparse information is available on the frequency of thrombus formation and the incidence of cerebral embolization in patients with dilated cardiomyopathy (see Chapter 26). The frequency of embolic events is thought to parallel the deterioration in LV function, but in the Study of Left Ventricular Dysfunction (SOLVD),[21] this relationship was observed only in women. Also, evidence shows that even mildly decreased LV systolic function may increase the stroke risk through unclear mechanisms.[22] Severe LV dysfunction may increase the risk of thromboembolic events, including stroke, as a result of the increased frequency of blood stagnation and therefore thrombus formation. An increased stroke incidence rate (up to 4% per year[23]) has been reported in patients with chronic heart failure, although this may be partly because of the frequent coexistence of atrial fibrillation. In patients with heart failure, the occurrence of a stroke is associated with a more than twofold increase in mortality rate.[12] Because heart failure is often accompanied by hypercoagulability,[24] antithrombotic treatment has been attempted to decrease the risk of embolic events. Although anticoagulation therapy is definitely indicated in patients with concomitant atrial fibrillation, its role in patients in sinus rhythm is controversial. In the largest treatment trial published to date, the Warfarin and Antiplatelet Therapy in Chronic Heart Failure (WATCH) trial, 1587 patient with symptomatic heart failure and LV ejection fraction were randomized to open label treatment with warfarin (target INR, 2.5 to 3.0), or to double-blind treatment with clopidogrel (75 mg daily) or aspirin (162 mg daily). During a mean follow-up period of 21 months, no significant differences were found between treatments in time to death, nonfatal MI, and nonfatal stroke.[25] Warfarin was associated with a reduction in nonfatal strokes ($P$ <.01 versus other treatments), but the number of events was small and the difference was offset by an increase in intracerebral bleeding.[25] The ongoing National Institute of Neurological Disorders and Stroke–sponsored Warfarin Aspirin in Reduced Cardiac Ejection Fraction (WARCEF) trial should soon provide new evidence on the efficacy of antithrombotic treatment in patient with reduced LV function.

## VALVULAR VEGETATIONS AND STRANDS

Vegetations on the mitral or aortic valve often embolize to the systemic circulation. The brain is frequently the target for the embolism, although the frequency of peripheral embolic events may be underestimated because these events are more easily misidentified. Neurologic complications occur in 20% to 40% of patients with IE (see Chapter 22).[26] In addition, silent brain infarcts on magnetic resonance imaging are found in approximately 50% of patients with IE.[27] In recent years, IE has become more often an acute rather than a subacute occurrence, and *Staphylococcus aureus* has become the most common etiologic organism.[28] Systemic embolism most commonly involves the spleen, the liver, the kidney, and the iliac or mesenteric arteries.[26] In a recent study of 2781 patients, stroke (16.9%), peripheral embolism (22.6%), and heart failure (32.3%) were the most frequently observed complications of IE. The frequency of embolic events in IE decreases rapidly after the initiation of effective antimicrobial treatment.[26] In a recent study of 1437 patients with left-sided IE, the incidence rate of stroke fell from 4.82 to 1.71 per 1000 patient-days between the first and second week of treatment and continued to decrease thereafter, regardless of valve or organism involved.[29] Overall, only 3.1% of patients had a stroke after the first week of therapy.[29] Early surgery may confer survival benefits, especially in patents at high risk of complications. In a recent study of 1552 patients with native valve IE (720 treated with surgery, and 832 with medical treatment), surgery was associated with a significant reduction in mortality rate (12.2% versus 20.1%; $P$ <.001).[30] Patients with stroke ($P$ = .02) or peripheral embolization ($P$ = .002) were among those who benefited the most from surgical treatment.[30] Therefore, the early identification of IE is of particular importance in patients with embolic events because of the potential repercussion on the choice of treatment.

Transesophageal echocardiography is the test of choice for the identification of valvular vegetations in IE (Fig. 41-3). TTE sensitivity for the diagnosis of IE is only about 58% to 63%,[31,32] although its specificity is high (98% to 100%).[31,32] More recent advancements in echocardiographic techniques, such as harmonic imaging, do not appear to have significantly improved the sensitivity of TTE for valvular vegetations.[33] The sensitivity of TEE is high (90% to 100%), as is its specificity (98% to 100%).[31,32] Echocardiographic characteristics of the vegetation that affect its embolic potential are size (more than 10 mm in diameter increases the risk), extension (more than one leaflet/valve), and mobility.[34,35] Table 41-2 shows the guidelines of the European Society of Cardiology[36] and the American Heart Association[37] for the use of echocardiography in IE. In cases that necessitate surgery, both the American Heart Association and the European Society of Cardiology endorse the use of intraoperative TEE. A negative TEE has a high negative predictive value for IE, with a range from 86% to 97%.[38] However, a TEE performed early in the course of the disease may be negative because the vegetation is still forming or is too small to be detected, hence the recommendation to repeat the test in cases in which the clinical suspicion of IE remains high.[36-38]

Vegetations on prosthetic valves are even more difficult to detect with TTE because the prosthesis itself may be interposed between the ultrasound beam and the vegetation, especially in case of mitral prostheses (see Chapter 25). The sensitivity of TTE for prosthetic IE is therefore low, whereas TEE has been reported to have 86% to 94% sensitivity and 88% to 100% specificity.[39] Therefore, TEE is recommended as the initial diagnostic test in all patients with suspected prosthetic valve endocarditis (Fig. 41-4).[40]

Valvular vegetations, or lesions that resemble them in echocardiographic appearance, may be found in patients without IE.

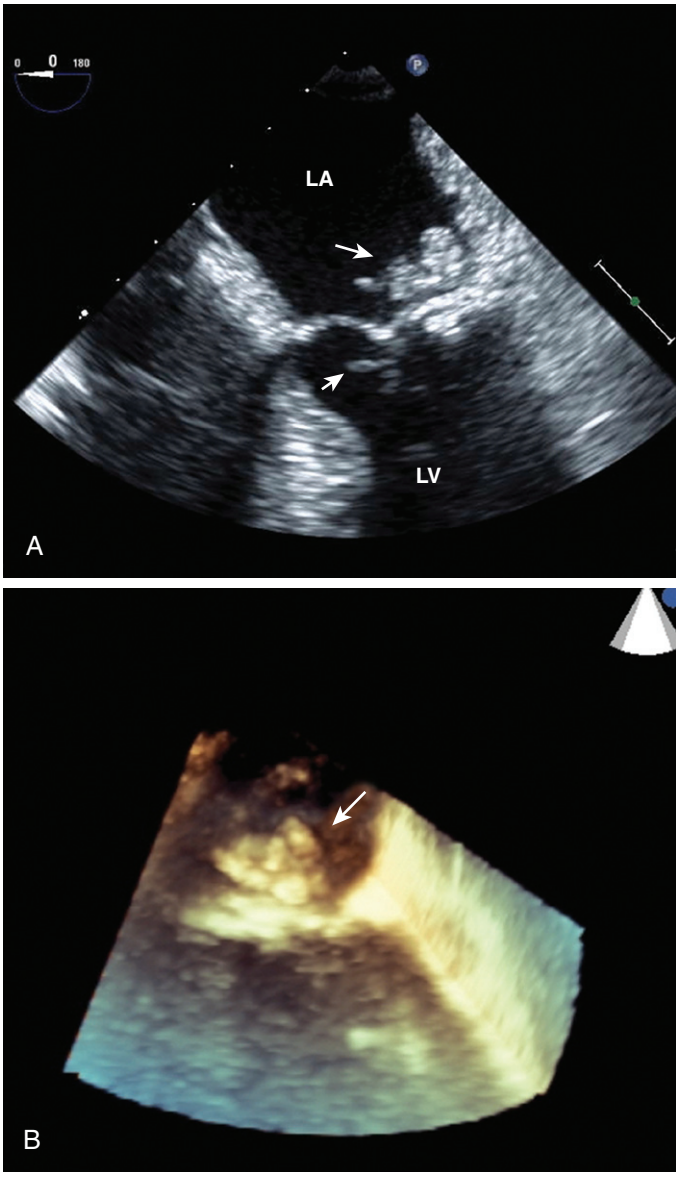

**Figure 41-3 TEE visualization of vegetation on the mitral valve. A,** A large vegetation (*arrow* in LA) is visualized on the atrial aspect of the posterior mitral leaflet. A small vegetation (*arrow* in LV) may be present on the chordal apparatus. **B,** 3D visualization of the same valvular vegetation (*arrow*) from an atrial point of view.

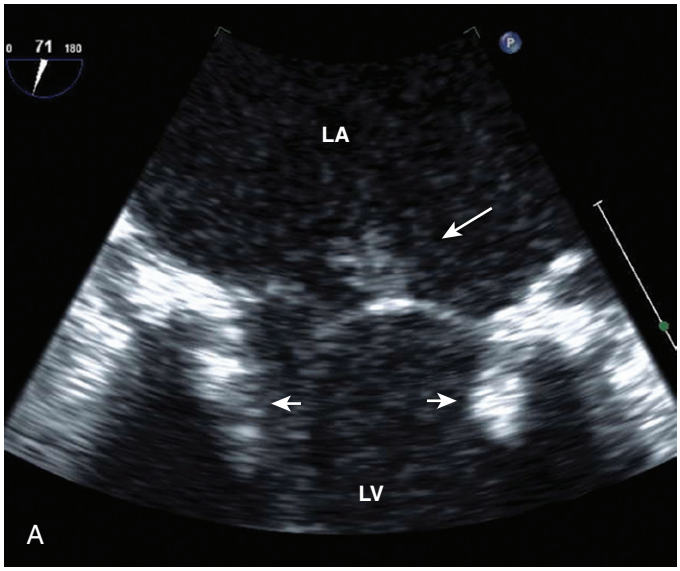
**TABLE 41-2 Guidelines for the Utilization of Echocardiography in Infective Endocarditis**

| | *American Heart Association 2005 (Endorsed by Infectious Diseases Society of America)* | *European Society of Cardiology 2009* |
|---|---|---|
| First diagnosis | TEE preferred; obtain TTE views for future comparison (TTE if TEE not immediately available, or in small children) | TTE, followed by TEE if TTE is negative but clinical suspicion of infective endocarditis is high |
| Repeat test | TEE after positive TEE as soon as possible in patients at high risk of complications (i.e., perivalvular extension)<br>TEE 7 to 10 days after initial TEE if:<br>1. No diagnosis of infective endocarditis but high clinical suspicion<br>2. Worrisome clinical course during treatment* | TTE or TEE in 7 to 10 days when first test is negative but clinical suspicion remains high<br>TEE in most patients with TTE-diagnosed vegetation (to measure size and evaluate for abscess)<br>TTE or TEE in case of new complications† |
| Completion of therapy | TTE to establish new baseline for valve morphology and function (TEE in case of complex anatomy) | TTE to establish new baseline for valve morphology and function |



*Unexplained heart failure progression, change in murmur, or new atrioventricular block or arrhythmia.
†New murmur, embolism, persisting fever, heart failure, abscess, or atrioventricular block.

Degenerative or myxomatous valve disease, systemic lupus erythematosus (Libman-Sacks lesions, seen in as many as one in 10 patients with lupus[41]), rheumatoid disease, antiphospholipid syndrome, malignant disease (marantic endocarditis), chordal rupture, and small intracardiac tumors may all produce valvular lesions that may be indistinguishable from those of IE.[38] The clinical scenario and the results of other diagnostic tests are therefore crucial for the correct diagnosis (see Chapter 37).

Filamentous strands, also known as Lambl excrescences, are frequently observed with TEE on the mitral and aortic valve (Fig. 41-5), especially in the elderly. Often representing fibrinous material growing on the valve's edge, valve strands have been linked to an increased risk of stroke or TIA in case-control studies.[42-44] However, patients with valve strands incidentally found on TEE showed a subsequent incidence of only 1% to 2% in an average follow-up period of 4 years.[45] In elderly patients with a recent stroke, mitral valve strands were not associated with an increased risk of recurrence.[44] Therefore, the risk of cerebral embolic events associated with valve strands is unclear, as is the need for preventive treatment. In 619 patients with acute ischemic stroke who underwent TEE and were randomized to warfarin or aspirin treatment as part of the Patent Foramen Ovale in Cryptogenic Stroke Study (PICSS), strands were found on the aortic valve in 36 (5.8%) and on the mitral valve in 172 (27.8%). No increased risk of recurrent stroke was observed in patients with valve strands during a 2-year follow-up period (HR, 1.05; 95% CI, 0.70 to 1.57; $P = .82$).[46] Valve strands are often found on valve prostheses, especially in the mitral position. In 300 patients with 421 left-sided prosthetic heart valves, strands were observed in 49% of patients (38% of prostheses).[47] A lower level of anticoagulation therapy (INR less than 2.5) was significantly associated with strands frequency, suggesting that more aggressive anticoagulation therapy may be necessary in these patients.[47]

## INTRACARDIAC TUMORS

Primary intracardiac tumors are rare; they been found in less than 0.2% of unselected autopsy series.[48] When present, however, they are associated with a high frequency of embolic events (see Chapter 46). This appears especially true for the two most common varieties of tumor, myxomas and papillary fibroelastomas. Approximately 75% of all cardiac tumors are benign, and 50% are myxomas.[49] Three of four myxomas originate from the LA, especially the fossa ovalis area of the interatrial septum.[50] Estimates are that 30% to 40% of all myxomas eventually embolize,[50] to the cerebral circulation in more than 50% of cases. Tumor fragmentation, or embolization of superimposed thrombus, is considered a potential embolic mechanism. The morphologic features of the myxoma are an important determinant of its embolic risk. Large mobile myxomas or those with villous excrescences are more likely to embolize than those with

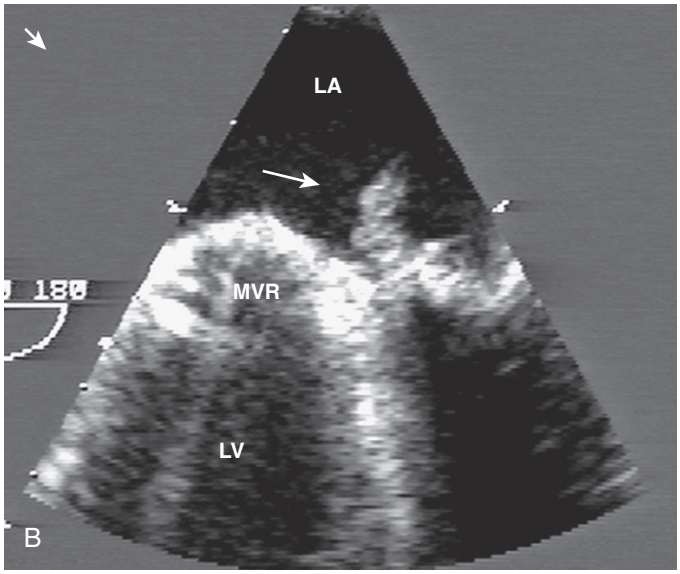


**Figure 41-4** **TEE visualization of vegetations on mitral prostheses. A,** A vegetation (*large arrow*) is visualized on the atrial aspect of a biological prosthesis. Note the native valve-like appearance of the leaflets and also the valvular supporting struts (*small arrows*). **B,** Large vegetation (*arrow*) on the lateral aspect of the annular ring of a mechanical prosthesis (*MVR*).

more solid polypoid aspects.[50] TTE can identify even relatively small myxomas (Fig. 41-6, *A*). TEE, however, can identify smaller tumors and help clarify morphologic aspects of importance for planning of the surgical resection, such as point of insertion into the cardiac wall and relation to adjacent structures (Fig. 41-6, *B*). Three-dimensional (3D) imaging (Fig. 41-6, *C*) may also help with the planning of the surgical approach because it more closely resembles the surgical view of the tumor. Surgical resection is recommended in all cases, especially when high-risk morphologic characteristics are present.

Papillary fibroelastomas are also frequently associated with cerebral embolism. Embolic events are often their first clinical manifestation because of their preferential location on highly mobile valve leaflets. Most fibroelastomas are diagnosed in the fourth or fifth decade of life, often after an episode of cerebral or cardiac ischemia.[51] In a review of 725 cases, the aortic valve was the most frequent location, followed by the mitral valve, whereas the LV was the most common extravalvular location.[52]

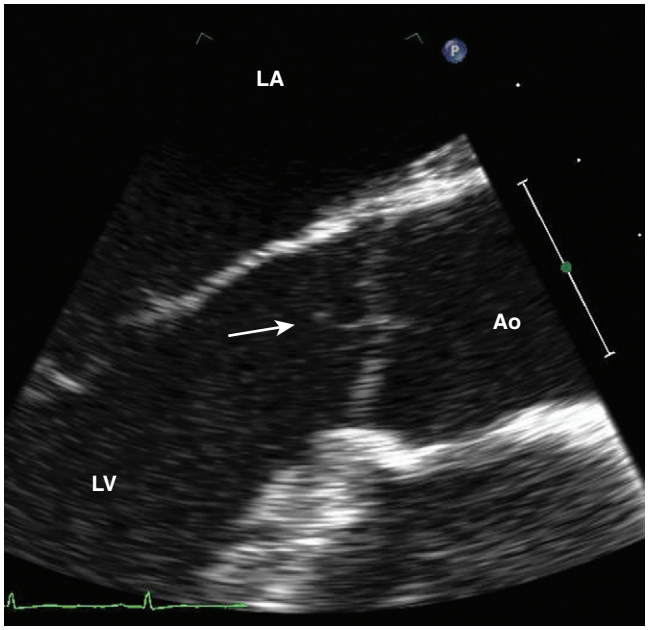

**Figure 41-5** **TEE visualization of filamentous strand (*arrow*) on the ventricular side of the aortic valve.**

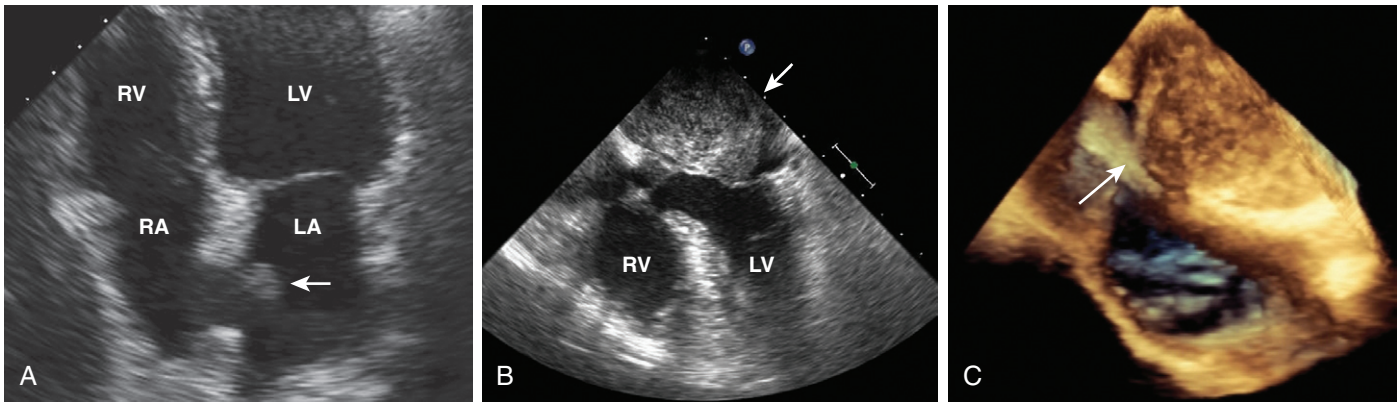

**Figure 41-6** **Left atrial myxoma. A,** TTE visualization of small myxoma (*arrow*) at the fossa ovalis area of the atrial septum. **B,** TEE visualization of large myxoma (*arrow*) almost filling the LA cavity and protruding towards the mitral valve. **C,** 3D imaging of the same tumor as in **B,** with clear visualization of the tumor insertion point in the fossa ovalis.

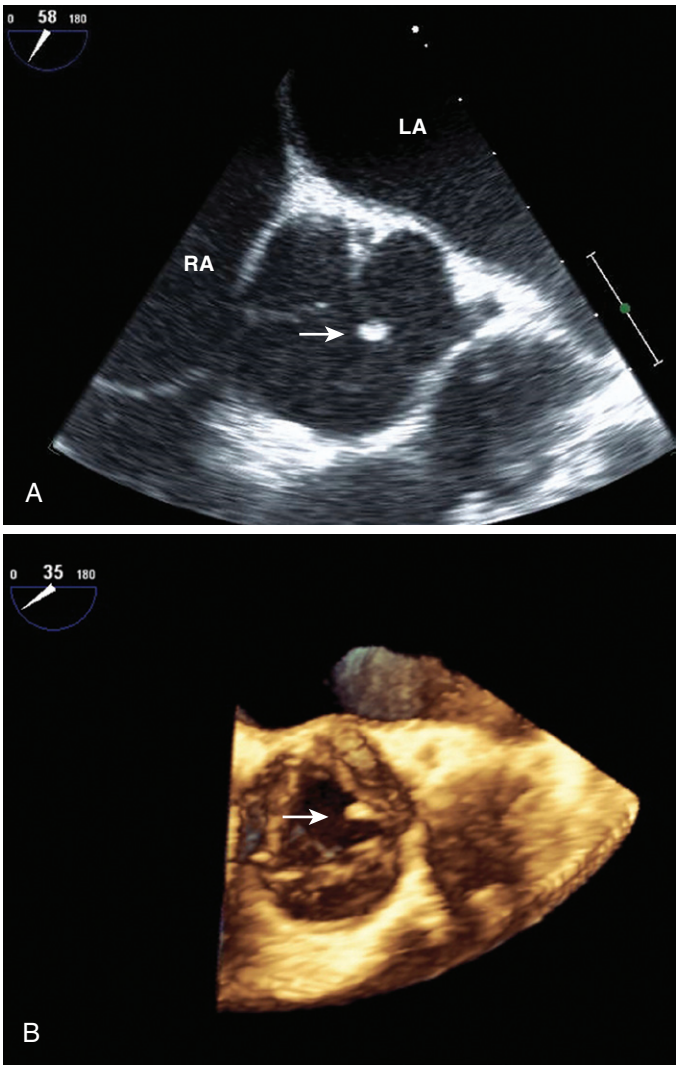

**Figure 41-7 TEE visualization of small papillary fibroelastoma on the aortic valve. A,** A small, brightly echolucent mass (*arrow*) suggestive of fibroelastoma is seen on the aortic aspect of the left coronary cusp (note the takeoff of the left main coronary artery on the right side of the screen). **B,** 3D imaging shows the small tumor (*arrow*) during the valve systolic opening.

Among morphologic characteristics, only mobility was an independent predictor of death or nonfatal embolization.[52] On the aortic valve, fibroelastomas are often located on the aortic side of the valve, unlike valvular vegetations, which tend to grow on the ventricular side. A clinically significant papillary fibroelastoma may be only a few millimeters large, which makes TEE a vastly better option than TTE for its visualization (Fig. 41-7). Although no controlled treatment studies are available, surgical resection appears indicated for all symptomatic fibroelastomas; in asymptomatic patients, oral anticoagulation therapy is usually used for nonmobile tumors; surgical resection should be strongly considered for mobile ones.[52]

Malignant primary tumors of the heart are rare, with an autopsy prevalence rate of 0.001% to 0.03%.[49] Sarcomas are the most common primary cardiac malignancies.[53] Cardiac obstruction, systemic or cerebral embolization, or systemic and constitutional symptoms are their modalities of presentation. Metastatic cardiac tumors are 20 to 40 times more frequent than primary tumors,[48] and the lungs constitute the most common primary location.[54] For the assessment of the associated embolic risk, the same considerations made for benign tumors on the usefulness of TEE and TTE apply. TEE is also invaluable in the assessment of tumor extension to adjacent structures and blood vessels, which may be critical for the decision about surgical treatment.

## LEFT ATRIAL THROMBUS AND SPONTANEOUS ECHO-CONTRAST

The presence of a thrombus in the LA is associated with significant risk of systemic embolization. LA thrombus, especially in the atrial appendage, is a frequent occurrence in the course of atrial fibrillation, although it is occasionally seen in patients in sinus rhythm with a recent cerebral ischemic event, especially when LV dysfunction coexists (see Chapter 42).[55]

Because of the proximity of the esophagus to the LA and the consequent possibility of use of high-frequency transducers, TEE is the test of choice to image the LA, and especially its appendage, which is difficult to image with TTE. With the use of modern omniplane transducers, the appendage can be imaged from a variety of angles, which allows a thorough investigation for the presence of thrombus. The presence of normal appendage trabeculations, the pectinate muscles, can be evaluated (Fig. 41-8, *A*). The sensitivity of TEE for thrombus detection is 90% to 95%, and its specificity is 95% to 100%.[56,57] An example of LA appendage thrombus is shown in Fig. 41-8, *B*. Three-dimensional imaging may also contribute to better thrombus visualization by providing alternate views (Fig. 41-8, *C*). The frequency of LA thrombus in atrial fibrillation is estimated at more than 20%.[58] In patients with a recent embolic event, the frequency is reported at 22% to 43%.[56,58] Although more frequent in chronic atrial fibrillation (27%), LA thrombus is also often observed in atrial fibrillation of less than 3 days duration (14%),[58] especially when accompanied by an embolic event (21% to 43%).[56,58]

Various conditions predispose to LA thrombus formation. A decreased LV systolic function has been shown to increase its likelihood, even in patients in sinus rhythm. In a study on 48 patients with stroke in sinus rhythm with LV ejection fraction of less than 45%, an atrial thrombus was found with TEE in 10 (21%).[59] LV ejection fraction of less than 35% was one of the two independent predictors of thrombus presence; the other predictor was LA appendage flow velocity of 55 cm/s or less.[59] The measurement of flow velocity in the appendage is indeed a useful clinical indicator of risk of thrombus formation. The appendage flow velocity can be obtained with pulsed Doppler interrogation of the inlet of the appendage in essentially all patients with TEE (Fig. 41-9, *A*) and occasionally with TTE. In patients with normal appendage function, velocities of 55 to 80 cm/s or higher are observed. The risk of thrombus formation appears to start rising with velocity of less than 55 cm/s[60] and increases as the velocity decreases. In the TEE substudy of the Stroke Prevention in Atrial Fibrillation III (SPAF III), a velocity of 20 cm/s or less was associated with increased frequency of thrombus (17%, versus 5% in patients with higher velocity; $P < .001$).[61] A decreased LA flow velocity is also a determinant of another important TEE finding that is associated with thrombus formation and thromboembolic risk: the presence of spontaneous echo-contrast (SEC). SEC is defined as dynamic, slow-swirling echoes that resemble a smoky haze within the body of the atrium or its appendage (Fig. 41-9, *B*). SEC represents increased echogenicity as a result of blood cell aggregation

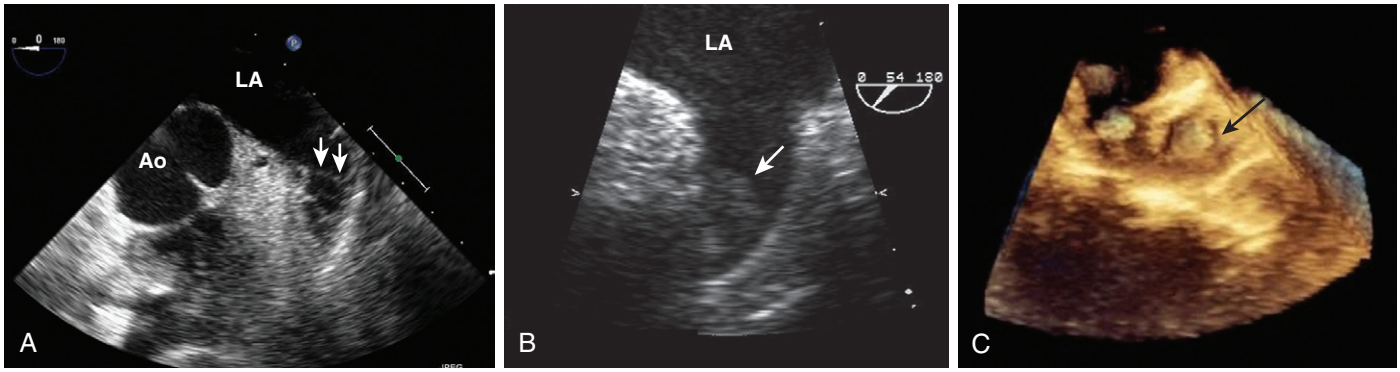

**Figure 41-8 Visualization of the LA appendage with TEE. A,** Prominent pectinate muscles (*arrows*) are visualized in the LA appendage. **B,** A thrombus (*arrow*) in the medial wall of the appendage near the apex. **C,** 3D imaging from an atrial viewpoint shows protrusion of the thrombus (*arrow*) towards the atrial chamber. *Ao,* Aorta.

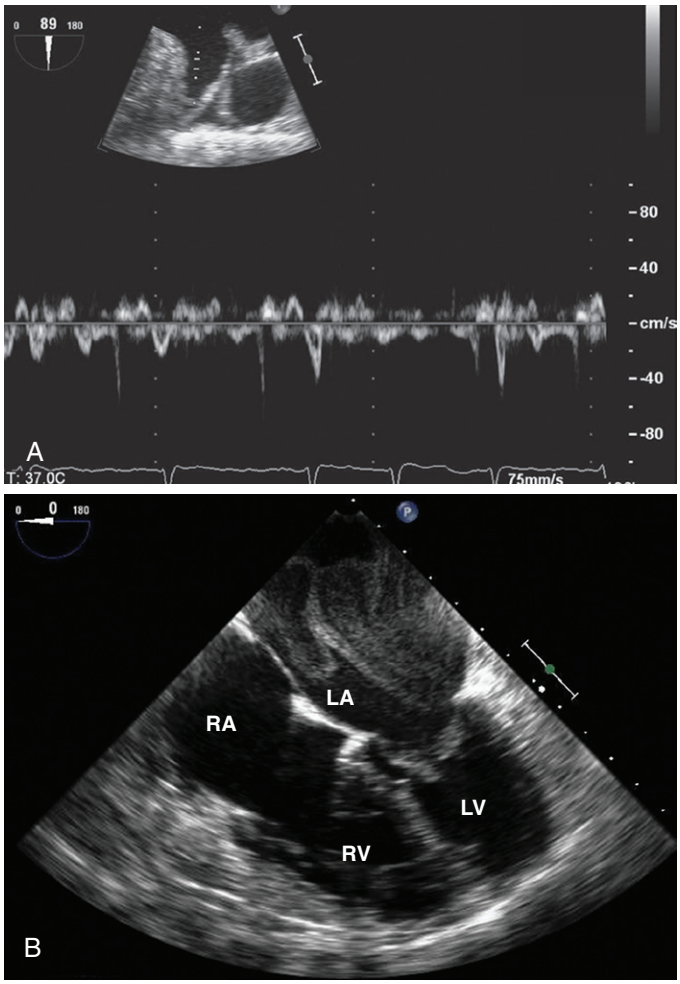

**Figure 41-9 Assessment of the LA appendage for embolic potential. A,** Pulsed Doppler interrogation of the appendage. Low emptying velocity (approximately 20 cm/s; see scale *on the right of the screen*) is shown. **B,** Example of dense spontaneous echo-contrast in the body of the LA.

at low shear rates and is therefore an indicator of stagnant blood or low flow states. SEC has been associated with severely decreased (lower than 25 cm/s)[62] but also mildly or moderately decreased (lower than 55 cm/s) appendage flow velocities.[60] SEC can be occasionally seen with TTE in low flow states (e.g., in the LV or aorta of patients with severely reduced LV function) but is better visualized with TEE because of the higher transducer frequency and, for the LA, the proximity to the chamber of interest. Accurate gain and compression settings are necessary to optimize the view and increase detection; relatively high gain settings may be necessary to maximize the detection rate, and white noise artifacts created by these settings may usually be identified because of their fixed, nonswirling appearance. The atrium and appendage should be imaged from different angles, and enough time should be spent in the imaging to ensure the capture of an often transient phenomenon such as SEC. LA SEC is present in more than 50% of patients with atrial fibrillation who undergo TEE. In a series of 272 patients, SEC was found in 161 (59%). During a mean follow-up period of 17.5 months, the rate of stroke or other embolic events was increased by four-fold in patients with SEC (12% per year versus 3% per year; $P = .002$).[63] SEC was also associated with increased mortality (25 versus 11 deaths; $P = .025$).[63] In the SPAF III study, the presence of SEC almost tripled the risk of stroke.[61] In a recent series of 295 patients with nonvalvular atrial fibrillation, the presence of atrial SEC or thrombus increased mortality by three-fold over a 5-year follow-up period,[64] although it was not an independent predictor of stroke or death in patients on anticoagulation therapy (odds ratio [OR], 1.55; 95% CI, 0.50 to 4.83).

The TEE-derived variables described previously (LA appendage thrombus and reduced flow velocity; SEC) may also aid in the choice of treatment for the prevention of thromboembolic events in patients with atrial fibrillation. Although prognostic scores such as CHADS(2) (Cardiac Failure, Hypertension, Age, Diabetes, Stroke or TIA [doubled]; Table 41-3) have been devised based on the probability of incident events,[65] some gray areas still exist. In general, oral anticoagulation therapy is recommended when the expected stroke risk is 5% per year or more; at the other end, aspirin may be chosen for patients when the expected stroke risk is lower than 2% per year. The intermediate risk group (3% to 4% risk per year) is more controversial.[66] The 2006 American College of Cardiology/American Heart Association/European Society of Cardiology guidelines for the management of patients with atrial fibrillation recommend the use aspirin 81 to 325 mg daily for patients with no risk factors and anticoagulation therapy with warfarin to an INR of 2 to 3 (target, 2.5) in patients with one high-risk factor (previous stroke, TIA, or embolism; mitral stenosis; prosthetic heart valve [if mechanical, INR of more than 2.5]) and in those

**TABLE 41-3 Use of TEE Before Cardioversion in Atrial Fibrillation: The ACUTE Study[69]**

| | *Conventional Treatment* (N = 603)* | *TEE-Guided Strategy (N = 609)* | P *Value* |
|---|---|---|---|
| Time to cardioversion (days) | 30.6 | 3.0 | <.001 |
| Successful cardioversion (%) | 65.2 | 71.1 | .03 |
| Hemorrhagic events (%) | 5.5 | 2.9 | .03 |
| Embolic events within 8 weeks (%) | 0.5 | 0.8 | .5 |

*Three weeks of oral anticoagulation therapy before cardioversion.

with two or more moderate-risk factors (age 75 years or more; hypertension; heart failure; LV ejection fraction 35% or less; diabetes mellitus).[66] In patients with one moderate-risk factor, the choice between aspirin and warfarin was left to the physician's discretion. The use of TEE, and the detection of one of the high-risk echocardiographic indicators described previously, may tilt the therapeutic choice toward the use of anticoagulation therapy. In fact, even in the presence of a CHADS (2) score of 0 or 1, the annual stroke risk is not entirely negligible (1.9% to 2.8%); also, in a recent study on 295 patients with score 0 or 1, the prevalence of LA thrombus with TEE was 3% and that of dense SEC was 8%.[64] Therefore, 11% of patients with a low score had an indication for anticoagulation therapy when TEE was performed, which emphasizes the usefulness of TEE in the management of this patient group. Among newer therapeutic options, the oral thrombin inhibitor dabigatran has been shown to be at least as effective as warfarin in preventing strokes in atrial fibrillation and may therefore be a valid alternative to warfarin, without the need of frequent laboratory tests for monitoring of the anticoagulation intensity.[67] Other options, such as treatment with aspirin plus clopidogrel, have been proven inferior to warfarin in preventing stroke, although better than aspirin alone.[68]

The utility of TEE in atrial fibrillation goes beyond the assessment of thrombus or SEC. In the SPAF III TEE substudy, among multiple possible predictors of events, only SEC and complex aortic arch plaques (see subsequent discussion in the chapter for the definition) were found to be independently associated with recurrent vascular events.[61] Adjusted-dose warfarin treatment decreased the event rates by 75% in patients with atrial fibrillation and complex arch plaques (4.0% versus 15.8%; $P = .02$), and in patients in whom TEE failed to identify such plaques, the event rate was low (1.1% to 1.2% per year) regardless of treatment type.[61]

Transesophageal echocardiography may also used to exclude LA thrombus before cardioversion of atrial fibrillation, eliminating the need for several weeks of preprocedural anticoagulation therapy. In the Assessment of Cardioversion Using Transesophageal Echocardiography (ACUTE) study, the safety and efficacy of a TEE-based strategy to shorten anticoagulation therapy before electrical cardioversion was shown (see Table 41-3).[69]

Despite TEE's general superiority, TTE may be still a useful test in patients with atrial fibrillation because it allows the evaluation of the mitral valve and of the size of the LA, whose dilation is associated with increased risk of thrombus formation. TTE may also allow the detection of thrombus in the body of the LA. Finally, TTE may provide useful information in patients in whom TEE is not feasible or contraindicated. The combined use of two-dimensional (2D) and 3D TTE imaging identified all seven LA thrombi in a group of 91 patients with atrial fibrillation.[70]

## ATRIAL SEPTUM ABNORMALITIES: PATENT FORAMEN OVALE AND ATRIAL SEPTAL ANEURYSM

In the last two decades, the presence of a PFO has been associated with increased risk of ischemic stroke, especially when cryptogenic. The foramen ovale, a normal component of the fetal circulation, closes after birth but may remain partially open in 15% to 35% of healthy subjects.[71-74] An atrial septal aneurysm (ASA), a localized protrusion of the septum into either atrial chamber, has also been associated with an increased embolic risk. ASA is infrequently observed in the general population (approximately 1% to 4% of subjects)[75-78] but, when present, is associated with a PFO in more than 60% of cases.[79-87]

### *Detection of Patent Foramen Ovale*

An atrial septal defect is a fixed opening that allows the bidirectional shunting of blood, but a PFO is a functional opening that becomes patent when the pressure in the right atrium exceeds the pressure in the LA, as it happens at end-systole. Therefore, the diagnostic techniques for detection of a PFO are based on the demonstration of a right-to-left shunt, at rest or during maneuvers, such as coughing or Valsalva maneuver, which increase the right atrial pressure. TTE or TEE with contrast injection (agitated saline solution or polygelatin agents) is generally used. Five injections under different conditions (rest, Valsalva maneuver, cough) have been recommended.[88]

Transesophageal echocardiography has nearly 100% sensitivity and specificity for PFO detection when both color Doppler scan and contrast evaluation are performed.[89] The prevalence of PFO in a TEE study on a sample of the general population was found to be 24.3%,[76] similar to that observed in autopsy studies. With use of a longitudinal bicaval view, TEE often allows the direct visualization and measurement of the PFO opening (Fig. 41-10, *A*), the semiquantitative assessment of the shunt (with count of the shunting microbubbles; Fig. 41-10, *B*), and the differentiation from a shunt caused by transpulmonary recirculation, which can be excluded through the direct visualization of the pulmonary veins. TEE is very accurate in detection of the presence of an ASA (Fig. 41-11, *A*), generally diagnosed by the protrusion of the septum of at least 10 mm,[79,90] measured by adding the maximum excursions of the septum from the midline into either atrium.

Because TEE is a semiinvasive test that requires conscious sedation, its use is appropriate in cases that are diagnostically equivocal or when the morphologic characterization of the PFO is necessary (e.g., when PFO closure is entertained). For screening purposes, TTE with contrast is used. Contrast TTE (Fig. 41-10, *C*) has been reported to have lower sensitivity than TEE for PFO detection (50% to 60%),[91-98] but recent advances in imaging technique have improved its sensitivity (80% to 90%).[99,100] In a sample of the general population, the prevalence of PFO with contrast TTE was reported to be 14.9%,[77] lower than in the TEE-based study. The direct visualization of the PFO opening is not obtained with TTE; therefore, the distinction with intrapulmonary shunt is based on the timing of microbubbles appearance in the left-sided chambers (within three cardiac cycles from complete opacification of the right

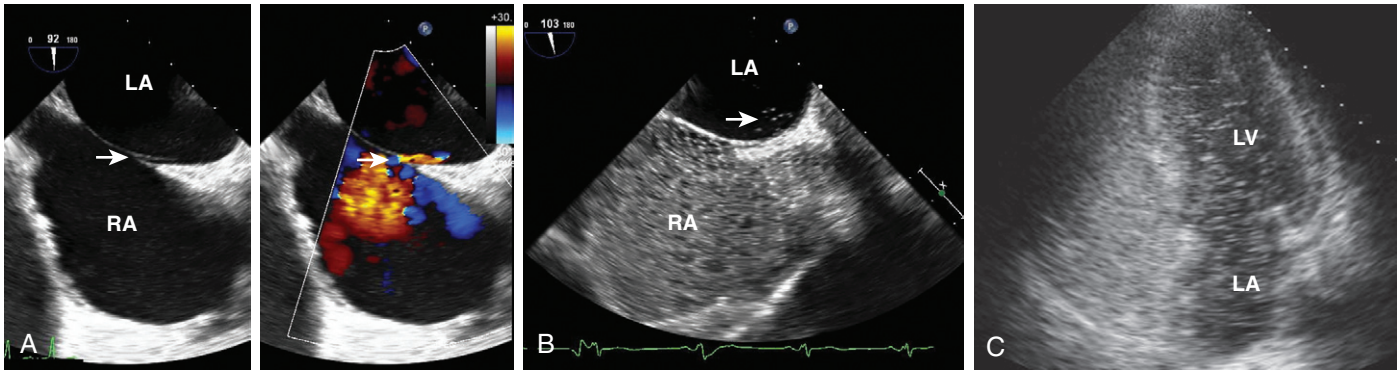

**Figure 41-10 Echocardiographic visualization of patent foramen ovale. A,** Visualization of patent foramen ovale with TEE. atrium for PFO; delayed appearance in case of intrapulmonary shunt). Saline contrast with transmitral pulsed wave Doppler imaging has been used to quantify the PFO functional size.[101] An ASA can also be visualized with TTE (Fig. 41-11, *B*), although its sensitivity is lower than that of TEE.[79]

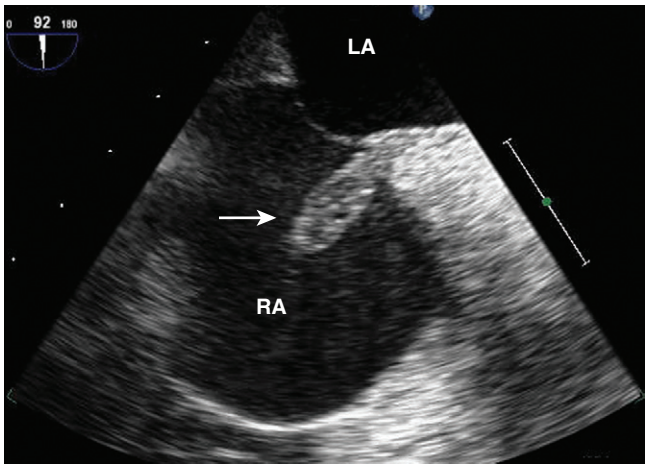

**Figure 41-12 TEE visualization of large thrombus (*arrow*) lodged in a patent foramen ovale.**

Transcranial Doppler imaging with contrast injection can also detect the presence of a PFO. Its sensitivity has been shown to be intermediate between that of TEE and TTE in some studies[92,94,95] but essentially equivalent to TEE in others.[96,98] Potentially important disadvantages of transcranial Doppler imaging are the impossibility to distinguish between PFO and intrapulmonary shunt and to assess for coexistence of an ASA.

### *Patent Foramen Ovale, Atrial Septal Aneurysm, and Stroke Risk*

Paradoxical embolization (i.e., embolization to the systemic circulation of a thrombus originating in the venous circulation) is the purported embolic mechanism associated with a PFO, a mechanism confirmed by the occasional detection of thrombus lodged in the PFO (Fig. 41-12). The relationship between PFO and cryptogenic stroke was first described in patients younger than 55[102] or 40[103] years of age and then extended to older patients, in whom such relationship has been more controversial, having been either supported[104] or negated.[105,106] Over the years, several studies with contrast TTE or TEE have confirmed the association between PFO and cryptogenic stroke in younger patients.[104,105,107-109] A recent large TEE study confirmed the existence of an association between PFO and stroke in the older age group.[109] After adjustment for age, aortic plaque thickness,

†Controls were patients with stroke of known cause.

hypertension, and coronary artery disease, PFO was strongly associated with cryptogenic stroke in both younger (OR, 3.70; 95% CI, 1.42 to 9.65; $P = .008$) and older patients (OR, 3.00; 95% CI, 1.73 to 5.23; $P < .001$).[109] Overall, the available evidence suggests an approximately four-fold increase in stroke risk from PFO in younger patients (Table 41-4, *A*) and a two-fold increase in older patients (Table 41-4, *B*).

### *Possible Associated Factors*

Because a PFO is present in approximately 25% of the general population but only a small fraction of individuals with a PFO will have a stroke, it is reasonable to believe that conditions may exist that increase the stroke risk. A recent meta-analysis of published studies suggested that the presence of a PFO may be an incidental rather than causative finding in one third of patients with cryptogenic stroke with a PFO,[110] again underscoring the possibility that associated factors may be important in increasing the embolic risk.

Anatomic characteristics of the atrial septum and of the right atrium have been suggested among potential cofactors. The width of the septal separation seen with TEE has been associated with increased stroke risk. Patients with presumed paradoxical embolization tend to have larger PFOs compared with controls, as assessed with contrast TTE,[103] TEE,[111-114] transcranial Doppler imaging,[93,115] and cardiac catheterization.[116] A PFO size of 2 mm or more[117] was more frequently seen in patients with stroke considered of embolic origin on the basis of brain imaging criteria,[117] and PFO size of more than 4 mm may be an independent risk factor for recurrent cerebrovascular events.[118] The degree of shunt, intended as the number of shunting microbubbles counted in the LA in a still frame, appears too subject to observer variability issues to be reliably used for risk stratification.

The presence of an ASA (see Fig. 41-11) has also been associated with an increased risk of stroke. Because ASA is frequently associated with a PFO and PFO size tends to be larger in patients with ASA,[87,119] the stroke risk is often considered to be the result of the coexistent PFO. However, the stroke risk in a meta-analysis was higher in subjects with PFO plus ASA than in those with either condition alone.[120] In stroke patients less than age 55 years who were treated with aspirin, the 4-year recurrent stroke rate with isolated PFO (2.3%) was similar to that with no PFO (4.2%) but was markedly higher (15.2%) with combined PFO and ASA.[121] A study with brain magnetic resonance imaging in 48 patients with cryptogenic stroke showed that patients with PFO and ASA had more multiple acute brain lesions than patients with PFO alone (53% versus 17%; $P = .01$), even after adjustment for PFO size, degree of shunt, and vascular risk factors.[122] Therefore, there may be more to the stroke risk associated with an ASA than the coexistence of a PFO. Other potential stroke mechanisms include in situ thrombosis formation, which appears infrequently,[79] and possibly a predisposition to the development of atrial arrhythmias,[123] which has also been questioned.[124]

A prominent Eustachian valve (the remnant of the right valve of the fetal sinus venosus that directs the blood from the inferior vena cava to the foramen ovale) has been found more frequently in patients with suspected paradoxical embolism,[125] but this has not been confirmed.[114] A Chiari network (threads and fibers that variably connect the Eustachian valve to other atrial structures) is present in approximately 2% of the general population[126] but is more frequently seen in patients with a PFO, ASA,[87] or unexplained arterial embolism.[126]

An increase in pressure in the right-sided cardiac chambers increases the likelihood of paradoxical embolization through a PFO. Pulmonary embolism,[127,128] right ventricular infarction,[129] and severe tricuspid regurgitation[130] have been associated with increased degree of shunting. Patients on mechanical LV assist device support also present an increased right-to-left shunting through the PFO, as a result of the decompression of the left-sided chambers.[131]

An increased prevalence of deep venous thrombosis has been reported[132] but not confirmed[133,134] in patients with cryptogenic stroke with a PFO. Pelvic vein thrombi were found more frequently in young patients with cryptogenic stroke than in those with defined causes of stroke.[135]

Prothrombotic states may increase the likelihood of thrombus formation and, therefore, paradoxical embolization. An increased prevalence of G20210A and factor V Leiden mutations has been reported in patients with cryptogenic stroke and PFO,[136-139] with the former mutation more frequent than the latter (8.2% versus 2.1%).[140] The association of either genotype with PFO increased the stroke risk by 4.7-fold.[140] An association between PFO size and presence of antiphospholipid antibodies has been suggested.[141] Recent surgery, trauma, or use of oral contraceptives may increase the likelihood of paradoxical embolization through a PFO.[142]

### *Prevention of Recurrent Embolism*

Because paradoxical embolization is the purported stroke mechanism from a PFO, antithrombotic treatment (systemic anticoagulation therapy with warfarin or use of antiplatelet agents such as aspirin) has been tested for preventive purpose. More recently, transcatheter closure of the PFO has also been used. The assessment of the relative efficacy of these approaches is hampered by the paucity of randomized clinical trials in the field. In the sole randomized double-blind trial of medical treatment, the previously mentioned PICSS, 630 patients with noncardioembolic stroke were randomized to aspirin 325 mg or warfarin (target INR, 1.4 to 2.8)[143] as part of the Warfarin Aspirin Recurrent Stroke Study.[144] After a 2-year follow-up period, no significant differences were observed in the rates of recurrent stroke or death among patients with or without PFO, both in the entire study group (14.8% versus 15.4%; HR, 0.96; 95% CI, 0.62 to 1.48; $P = .84$) and in the subgroup of patients with cryptogenic stroke (14.3% versus 12.7%; HR, 1.17; 95% CI, 0.60 to 2.37; $P = .65$). Although the comparison between treatment types was not the objective of the study, no significant differences in recurrent stroke or death rates were observed in patients treated with warfarin (9.5%) or aspirin (17.9%; HR, 0.52; 95% CI, 0.16 to 1.67; $P = .28$). PFO size and coexistence of an ASA also did not significantly affect the stroke risk.[143] Similar results were obtained in a more recent multicenter TEE study from Spain in 200 patients with stroke with a PFO treated with warfarin or antiplatelet agents, in which degree of right-to-left shunt or coexistence of an ASA were also not associated with an increased risk of recurrent stroke.[145]

Given the efficacy of antithrombotic treatment in prevention of recurrent events, the transcatheter closure of the PFO, which has all but replaced the formerly used surgical closure, would appear indicated only if its efficacy were to be found superior in randomized clinical trials or in patients with failure or contraindications to medical treatment. In the absence of results from such trials, transcatheter closure has had supporters[146] and critics.[147] The 2006 American Heart Association/American Stroke Association guidelines for the prevention of stroke in patients with ischemic stroke or TIA considered the data available at the time insufficient to make a recommendation for PFO closure in patients with a first stroke and a PFO.[148] PFO closure was recommended for consideration in patients with recurrent cryptogenic stroke despite medical therapy.[148] Otherwise, aspirin treatment was considered adequate in most patients, replaced by warfarin treatment in case of coexisting deep venous thrombosis or prothrombotic state. Five randomized trials that compare PFO closure and antithrombotic treatment are currently in different stages. In the first study to report its results, the CLOSURE I trial, no significant differences in recurrent stroke and death rates over a 2-year follow-up period were observed among 447 patients with stroke who had undergone PFO closure and 462 patients who were treated medically. For stroke, the incidence rate was 3.1% and 3.4%, respectively ($P = .77$).[149] Degree of shunt and presence of ASA did not significantly affect the results.

## ATHEROSCLEROTIC PLAQUES IN THE PROXIMAL AORTA

The presence of atherosclerotic plaques in the aorta is a risk factor for ischemic stroke and systemic embolization in the elderly. The association between proximal aortic plaques and ischemic stroke was first reported in a pathology study in which elderly patients who had died of a stroke had a much greater frequency of ulcerated aortic plaques than patients who had died of other neurologic diseases (26% versus 5%; age-adjusted OR, 4.0; 95% CI, 2.1 to 7.8).[150] The difference was especially significant for patients who had died of a cryptogenic stroke (61% versus 28%; adjusted OR, 5.7; 95% CI, 2.4 to 13.6) and persisted after adjustment for atrial fibrillation and carotid artery disease.[150] Only 3% of patients with ulcerated plaques were younger than 60 years, which suggests that this new stroke risk factor was only relevant to the elderly. TEE then provided an excellent opportunity to investigate the role of atherosclerotic plaques in vivo. TEE is the most sensitive and widely used technique for examination of the proximal portion of the aorta. The proximity of the esophagus to the aorta and the absence of interposed structures allow the use of high-frequency ultrasound transducers, which results in high-resolution images of the vessel. If ischemic stroke is the presenting clinical event, the portion of aorta proximal to the takeoff of the left subclavian artery is the focus of the examination, although the existence of retrograde diastolic flow has been shown in the aorta and the possibility of embolization to the brain from the initial segment of the descending aorta has been suggested.[151,152] The aorta can be accurately visualized with TEE from the aortic valve level to the initial curvature of the arch. The mid and distal segments of the aortic arch are also visible in all patients, whereas a small portion of the proximal arch cannot be visualized because of the interposition of the trachea. With TEE, an accurate assessment is possible of the presence and thickness of plaques (Fig. 41-13, *A*) and of the presence of ulcerations (Fig. 41-13, *B*) or superimposed thrombus (Figs. 41-13, *C*). TEE has been shown to be highly sensitive and specific for detection of aortic plaques[153,154] and superimposed thrombus (sensitivity, 91%; specificity, 90%).[154] TEE sensitivity for the detection of small plaque ulcerations, which may carry an additional embolic risk,[155-157] has been described as less than optimal (approximately 75%). The reproducibility of TEE measurements of aortic plaque thickness is very good, with agreement of 84% to 88% for the diagnosis of large (4 mm or more) plaques,[158] which are thought to carry higher stroke risk.[159]

With use of TEE, numerous case-control[155,157,159-162] and prospective studies[163-167] have confirmed the role of proximal arch plaques as risk factors for stroke and other embolic events (Table 41-5). Although the definition of large plaques has varied across the studies, the general consensus has been that a plaque thickness of 4 mm or more or 5 mm or more (measured perpendicular to the major vessel diameter; see Fig. 41-13, *A*) is associated with higher embolic risk. Unclear, however, is whether plaque thickness is directly related to the stroke mechanism or is rather a marker of diffuse atherosclerosis that portends the higher stroke risk. Smaller plaques (3 mm or more) have been

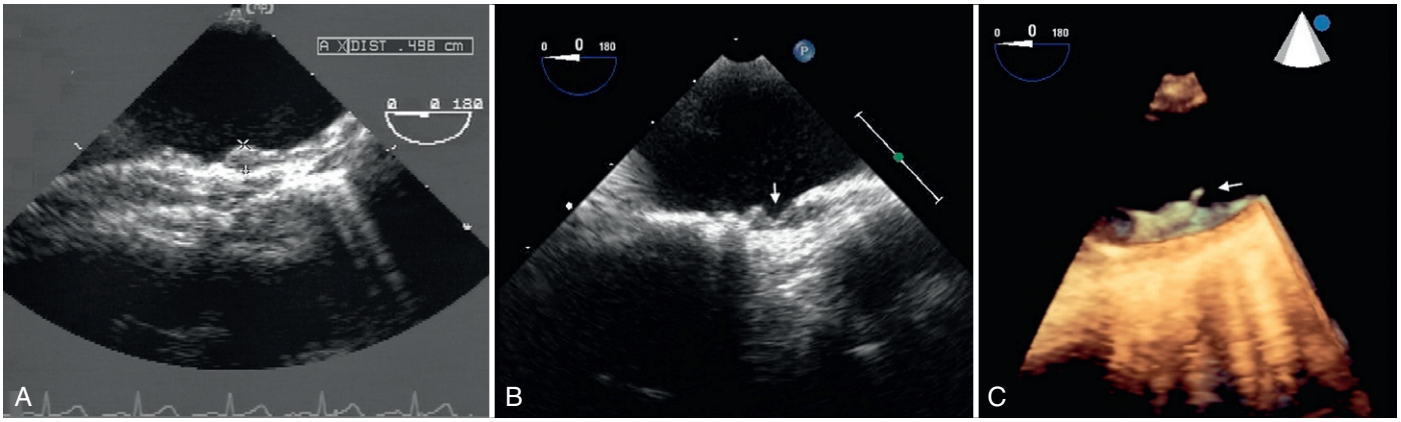

**Figure 41-13 TEE assessment of proximal aortic arch plaques. A,** A large plaque is present at mid arch, measuring approximately 5 mm in thickness. **B,** A large plaque is visualized at mid arch, with a large ulceration (*arrow*) in its intimal surface. **C,** 3D imaging of a large arch plaque. A small protruding component (*arrow*) is visualized, which was highly mobile in real-time imaging.

‡Recurrent stroke and other embolic events combined.

shown to be associated with stroke in women,[168] which suggests that plaque thickness could be a marker of other conditions related to the stroke mechanism that may differ between men and women. On the other hand, plaque progression, defined as increase in thickness over time, has indeed been shown to be associated with increased incidence of vascular events. In 117 patients with stroke or TIA, plaque progression at 1 year was significantly associated with the incidence of vascular events (stroke, TIA, myocardial infarction, or death) over a median follow-up period of 1.7 years (51% versus 11%; $P < .0001$).[169]

The complex morphology of a plaque may be more directly related to the stroke mechanism in individual patients. Morphologic features such as ulceration or mobility have been linked with an increased stroke risk,[153-156,161,170,171] especially in the case of cryptogenic stroke. On the other hand, the presence of calcification within the plaque has been shown to decrease the risk of subsequent events, possibly because it may indicate a more stable lesion.[172] TEE is a very sensitive test for detection of such morphologic variants, and especially the presence of superimposed mobile components, which have been shown to represent thrombus.[171,173,174] Mobile components superimposed to an aortic plaque are infrequently seen in elderly patients with stroke, with a range from 1.6% to 8.7% in different studies.[153,156,157,159,161,162,175,176] However, when present, they represent a strong risk factor for brain embolization.[161] Occasionally, mobile thrombi without severe atherosclerotic changes can be seen in patients younger than 60 years who present with an embolic event (23 cases of 27,855 TEE examinations in a multicenter cardiology study).[177] These thrombi usually have an insertion site on small atherosclerotic plaques and appear to represent a rare variant of atherosclerotic disease associated with embolic events in younger patients.[177]

When the embolic event affects the systemic circulation, the entire aorta, rather than its proximal segment, should be the focus of the investigation. The frequency of atherosclerosis is, in fact, higher in the descending than in the proximal aorta.[170,178]

Besides being the site of origin of thromboembolism to the brain and the peripheral circulation, the atherosclerotic aorta can also give origin to atheroembolic phenomena, in which cholesterol crystal emboli are sent to various segments of the arterial circulation. Atheroembolism is generally characterized by small embolic particles that lodge in small arterioles[179] and may occur spontaneously or after vascular surgery, arteriography, or anticoagulation therapy.[180,181] Atheroembolism has a wide spectrum of clinical presentations, from clinically silent episodes only recognized during diagnostic procedures[182-184] to complex clinical pictures characterized by multiple organ involvement (brain, retina, kidneys, gastrointestinal tract, lower limbs).[185,186] The simultaneous or consecutive involvement of different body segments may, in fact, greatly facilitate a correct diagnosis in case of subtle or subacute clinical presentation. Occasionally, intraaortic tumors may be responsible for peripheral embolization.

### *Therapy and Prevention of Recurrent Events*

The detection of complex aortic plaques has therapeutic and preventive implications. Because most embolic events associated with large or complex proximal aortic plaques are thought to be thromboembolic in origin and because activation of the coagulation system has been shown in patients with acute stroke and large aortic arch plaques,[162] systemic anticoagulation therapy has been suggested to reduce the frequency of recurrent events. Anticoagulation therapy with warfarin appears indicated in patients with thrombus superimposed to the plaque,[187] who represent a small fraction of the total. In patients with large but nonmobile plaque, the best preventive option is debated. In 516 patients with acute ischemic stroke treated with aspirin or warfarin as part of the PICSS, antithrombotic treatment did not affect the incidence rate of recurrent stroke and death over a follow-up period of 2 years, as large plaques (4 mm or more) remained associated with an increased risk of events (adjusted HR, 2.12; 95% CI, 1.04 to 4.32), especially those with complex morphology (HR, 2.55; 95% CI, 1.10 to 5.89). The risk was highest among patients with cryptogenic stroke, both for large plaques (HR, 6.42; 95% CI, 1.62 to 25.46) and large-complex plaques (HR, 9.50; 95% CI, 1.92 to 47.10).[188] Further studies with larger patient populations are needed to evaluate the possibility of differences in efficacy between warfarin and aspirin or other antiplatelet agents in specific patient subgroups, such as patients with cryptogenic stroke. The combination of aspirin and clopidogrel is being tested against warfarin in patients with large plaques.[189] Statins have been shown to reduce the risk of recurrent events in patients with stroke in the Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) study,[190] but no separate data were available for patients with severe aortic plaques. Surgical endarterectomy for high-risk plaques has been shown to carry a significant risk of intraoperative stroke[191] and should be reserved for carefully selected cases.

Embolism from an atherosclerotic aorta can have devastating consequences during cardiac surgery. In 921 consecutive patients undergoing cardiac surgery,[192] the incidence rate of postoperative stroke was 8.7% in patients with atherosclerotic disease of the ascending aorta and 1.8% in patients without it ($P < .0001$), and aortic atherosclerosis was the strongest predictor. When the presence of severe atherosclerosis is known, modification of the cannulation of the aorta or use of off-pump procedures can drastically decrease the incidence of perioperative stroke.[193] TTE from a suprasternal window can be considered as a screening test. TEE or epiaortic ultrasound imaging of the aorta[194] at the time of surgery may also be performed for this purpose.

## ECHOCARDIOGRAPHY IN THE CATHETERIZATION LABORATORY

In recent years, the proliferation of transcatheter-based therapeutic procedures has resulted in a more frequent presence of echocardiographers in the catheterization laboratory, often to guide the performance and evaluate the results of the interventional procedures (see Chapter 5). From the standpoint of embolic risk, procedures that involve the left-sided cardiac chambers carry the highest risk. Percutaneous transvenous balloon valvuloplasty, alcohol septal ablation for hypertrophic cardiomyopathy, and cardiac electrophysiology procedures such as pulmonary veins isolation for atrial fibrillation are examples of procedures with potential embolic risk. More recently, closure of atrial septal defect or PFO, percutaneous mitral valve repair, percutaneous aortic valve replacement for aortic stenosis, and placement of LA appendage occlusion devices for stroke prevention in atrial fibrillation are becoming increasingly common, although some of these procedures are currently performed only as part of registries or clinical trials. All of these procedures carry a risk of periprocedural complications. For PFO closure, major complications from the device implantation (death, major hemorrhage, cardiac tamponade, and fatal pulmonary emboli) occurred in approximately 1.5% of the patients in a meta-analysis of 1355 patients, and less severe complications (atrial arrhythmias, device arm fractures, device embolization, device thrombosis, electrocardiographic changes, and arteriovenous fistula) were reported in 7.9%.[195] Lower complication rates have been reported in more recent studies, reflecting improved device construction and greater operator experience. In a multicenter European study on 430 patients (mean age, approximately 51 years), periprocedural complications occurred in 11.5% of patients, 0.2% of which were defined as major.[196] Transcatheter PFO closure may also be associated with a risk of intraprocedural or periprocedural embolization to the brain. Microembolic signals were detected with transcranial Doppler imaging during the procedure in 28 of 29 subjects.[197] Brain magnetic resonance imaging in 35 subjects documented the appearance of new microembolic lesions after the PFO closure in three of them (8.6%).[198]

Transesophageal echocardiography is commonly used to guide the deployment of the PFO closure device. However, intracardiac echocardiography is currently considered at least as effective as TEE for this purpose, with the added advantage of not requiring conscious sedation or additional echocardiography physician support (see Chapter 6). TTE can be used to evaluate the correct position of the closure device (Fig. 41-14, *A*) and the presence of some possible complications (e.g., septal erosion, pericardial effusion). Contrast study is used to evaluate any residual shunt, which is relatively common in the first months after the procedure and tends to close over time. TEE may be necessary for a better visualization of the device (Fig. 41-14, *B*) and the assessment of complications such as thrombus or vegetation (Fig. 41-14, *C*).

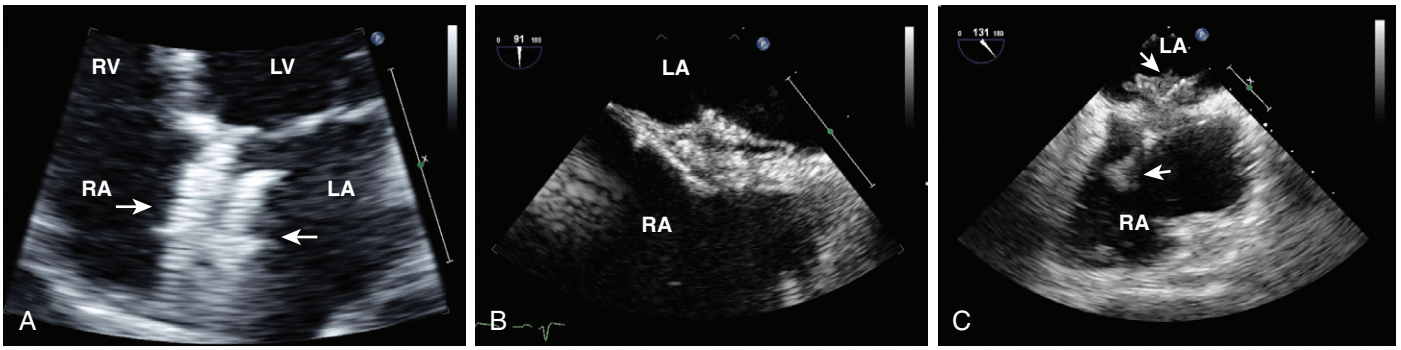

**Figure 41-14** **Echocardiographic visualization of patent foramen ovale closure device. A,** Visualization with TTE. The arms of the device (*arrows*) are clearly visualized on each atrial side. **B,** Visualization with TEE. The device arms are seen encasing the septum. **C,** TEE visualization of patent foramen ovale closure complication. Large echogenic masses (*arrows*) are seen on both sides of the device and were found to be infected thrombus at surgery.

## Research Applications

Most of the outcome data described in this chapter, and especially the data regarding new cardioembolic sources such as PFO or aortic plaques, has been obtained with the use of echocardiography, and TEE in particular. It is therefore conceivable that echocardiography will continue to play a primary role in future research in the field. The easy-to-perform and noninvasive TTE will likely remain the prime diagnostic technique for assessment of the relevance of a putative cardioembolic source in population studies. The possibility to perform and serially repeat high-resolution studies that TEE affords allows the monitoring of therapeutic interventions to reduce the risk of recurrent events, by using the changes in morphologic appearance of a lesion as a surrogate marker of embolic risk (e.g., the evaluation of the effects of statins or antithrombotic therapy on the size and morphologic appearance of an aortic plaque). Further research applications will probably be fostered by advancements in image quality and more extensive application of newer technologies, such as 3D imaging.

## Potential Limitations and Future Approaches

Despite the continuous improvement in image quality, the most important limitation of TTE for embolic source assessment remains the suboptimal visualization of the cardiac structures in some patients, an issue that has also limited the application of 3D echocardiography to the clinical practice. For TEE, the most important limitations are its semiinvasive nature, which requires the use of conscious sedation, and the still suboptimal ability to provide tissue characterization (e.g., thrombus versus vegetation versus tumor, or lipid versus thrombotic components in an aortic plaque). Some of these limitations may be overcome or lessened with future technical advancements. Also, a future direction of cardioembolic research may be the use of these imaging advancements to refine the assessment of embolic risk associated with some potential cardioembolic sources. The 3D assessment of the volume of an aortic plaque may provide a better estimate of its embolic potential than the mere measurement of its thickness; the 3D analysis of PFO morphology and adjacent atrial structures may allow a better prognostication of the likelihood of paradoxical embolization to occur. Better imaging transducers with smaller footprints may allow more accurate imaging of the aortic arch from a suprasternal approach, allowing the assessment of the atheroembolic risk before cardiac procedures and reducing the number the patients referred for TEE. This refinement of the evaluation of the risk associated with recently discovered cardioembolic sources, along with the possible discovery of newer ones, may represent one of the most important research applications of echocardiography to cardioembolic research in the years to come.

## Alternate Approaches

When TTE images are inadequate for diagnostic purposes, or when the suspected embolic source cannot be accurately investigated by it (e.g., LA appendage thrombus in atrial fibrillation), TEE provides the most logical and diagnostically sensitive alternative. In cases in which TEE cannot be performed, such as the presence of esophageal pathology or other contraindications, the choice of alternate imaging techniques depends on the a priori probability of a cardioembolic source. No real alternatives to echocardiography exist to assess for valvular vegetations in IE, which leaves the diagnosis to be made on clinical grounds. For intracardiac masses, computed tomography or magnetic resonance imaging may represent viable alternatives. Transcranial Doppler scan with contrast injection and more recently intracardiac echocardiography have been used to assess patients with suspected PFO. Magnetic resonance imaging has been shown to correlate well with TEE for aortic plaque determination[199] and to accurately define fibrotic and lipid plaque components in animal models.[200] Dual-helical computerized tomography showed sensitivity of 87%, specificity of 82%, and overall accuracy of 84% for the detection of aortic plaques in comparison with TEE.[201]

## KEY POINTS

- Approximately 20% of all ischemic strokes have a cardioembolic etiology. Cardioembolism may also be involved in a large proportion of so-called cryptogenic strokes, which still account for approximately 30% of all ischemic strokes.
- Transesophageal echocardiography (TEE) has far greater sensitivity than transthoracic echocardiography (TTE) for the detection of cardioembolic sources. TTE is a viable alternative for the assessment of LV thrombus and intracardiac masses and as a screening test for PFO (with contrast injection).
- TEE performance should be considered, especially in patients with a stroke with embolic features on neuroimaging but no obvious source of embolus on TTE.
- TEE should be performed in case of high suspicion of IE, even when TTE is negative. TEE is the test of choice for suspected prosthetic endocarditis.
- Intracardiac tumors, although rare, have high embolic potential. Their detection in the setting of an embolic event is an indication to surgical excision.
- In atrial fibrillation, TEE can be useful to evaluate the need for systemic anticoagulation therapy, particularly in patients with intermediate embolic risk.
- TTE with contrast injection is an adequate test for the detection of a PFO. TEE should be reserved for questionable or poorly visualized cases or when a more accurate morphologic assessment is needed (e.g., when PFO closure is entertained).
- Aortic arch plaques are a strong embolic risk factor in the elderly. TEE can identify morphologic features (ulceration, mobile components) that may suggest the need for more aggressive treatment (anticoagulation therapy).
- Unsuspected severe atherosclerosis of the proximal aorta is a strong risk factor for periprocedural stroke during cardiac catheterization or cardiac surgery. TTE from a suprasternal window may be an appropriate screening test to identify patients in need of TEE for further assessment.

Technologic advances in two-dimensional (2D) and Doppler ultrasonography have led to the emergence of echocardiography as an integral tool in the evaluation and management of patients with cardiac dysrhythmias. Transthoracic echocardiography (TTE) and transesophageal echocardiography (TEE) provide detailed information about cardiac anatomy and function. Patients with ventricular tachyarrhythmias are routinely referred for echocardiographic examination for identification of suspected structural heart disease. Echocardiography may also play a role in characterization of ventricular dyssynchrony and response to cardiac resynchronization therapy (see Chapter 26).

In addition to ventricular arrhythmias, both TTE and TEE provide useful information in the evaluation and management of patients with atrial arrhythmias, particularly atrial fibrillation (AF). In this chapter, we review the detailed structural and functional information derived from TTE and TEE and how these data assist in the evaluation and management of patients with AF and atrial flutter.

## Echocardiographic Assessment of Atrial Anatomy and Function

### LEFT ATRIAL ANATOMY

TTE is a reliable and reproducible method to assess the anatomy of the body of the left atrium (LA). 2D directed M-mode echocardiography[1-3] in the parasternal long or short axis allows for the measurement of LA dimension (Fig. 42-1, *A*). Overall, this unidimensional index correlates well with angiographically derived LA area and volume[2,3] but may be disproportionately erroneous in common disease states associated with asymmetric atrial dilation, such as mitral valve disease[4] or situations in which the LA is deformed by extrinsic structures.

2D TTE provides more accurate assessment of atrial anatomy. The LA is well seen from both the parasternal and the apical windows. In many laboratories, LA anatomy is characterized by the M-mode or 2D dimension from the parasternal long or short axis and the LA length from the apical four-chamber view (see Fig. 42-1, *B*). However, because the LA is not spherically shaped and asymmetric enlargement may occur, 2D-derived LA volume provides a more accurate measure of LA size[5] and is advocated by the American Society of Echocardiography.[6] It more favorably compares with volumetric methods such as cardiovascular magnetic resonance and cardiac computed tomography.[7,8] With the biplane method,[9] maximum LA area and length are measured in the apical four-chamber ($A_{4C}$, $L_{4C}$) (see Fig. 42-1, *B*) and two-chamber ($A_{2C}$, $L_{2C}$) orientations with volume derived as:

$$\text{LA volume} = 1.7(A_{4C})(A_{2C})/[(L_{4C} + L_{2C})/2]$$

Population-based studies suggest LA volumes of 41.9 ± 11.9 mL or when normalized for body surface area, 22 ± 5 mL/m$^2$.[10] Increasing LA volume predicts development of AF in the general population[11] as well as after cardiac surgery[12] and in hypertrophic cardiomyopathy.[13,14] Biplane and Simpson's methods compare closely.[9] In situations in which there is focal atrial asymmetry, such as distortion of the LA from an extrinsic structure (e.g., mediastinal tumor, hiatal hernia, or descending thoracic aortic aneurysm), accurate calculation of LA volume may be improved by using a Simpson approach.

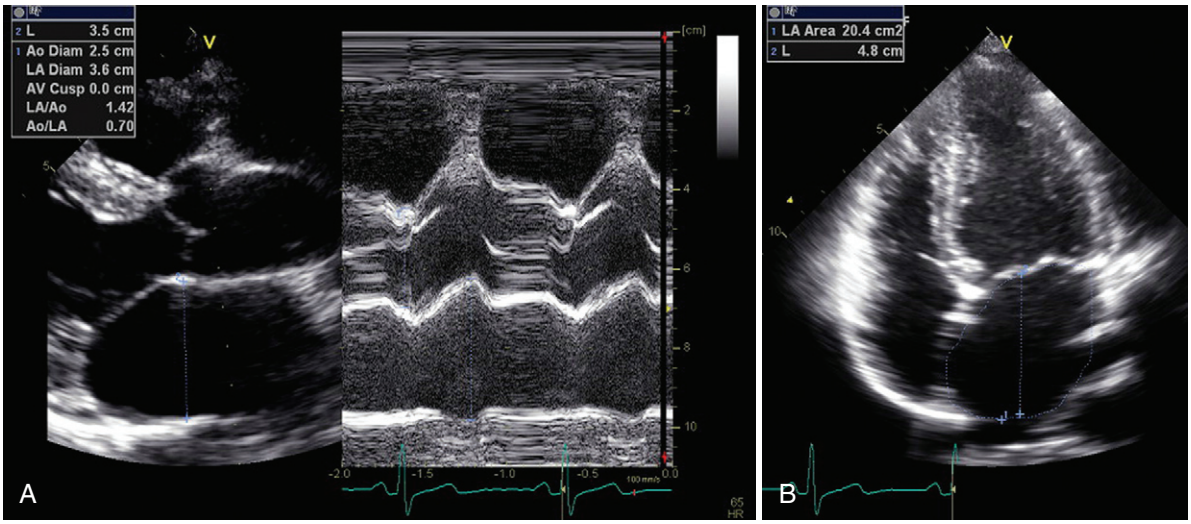

**Figure 42-1 Transthoracic echo (TTE). Parasternal long-axis view. A,** TTE image from parasternal long axis demonstrating measurement of the LA dimension from 2D and M-mode data. **B,** TTE from apical four-chamber view demonstrating measurement of LA length and LA area.

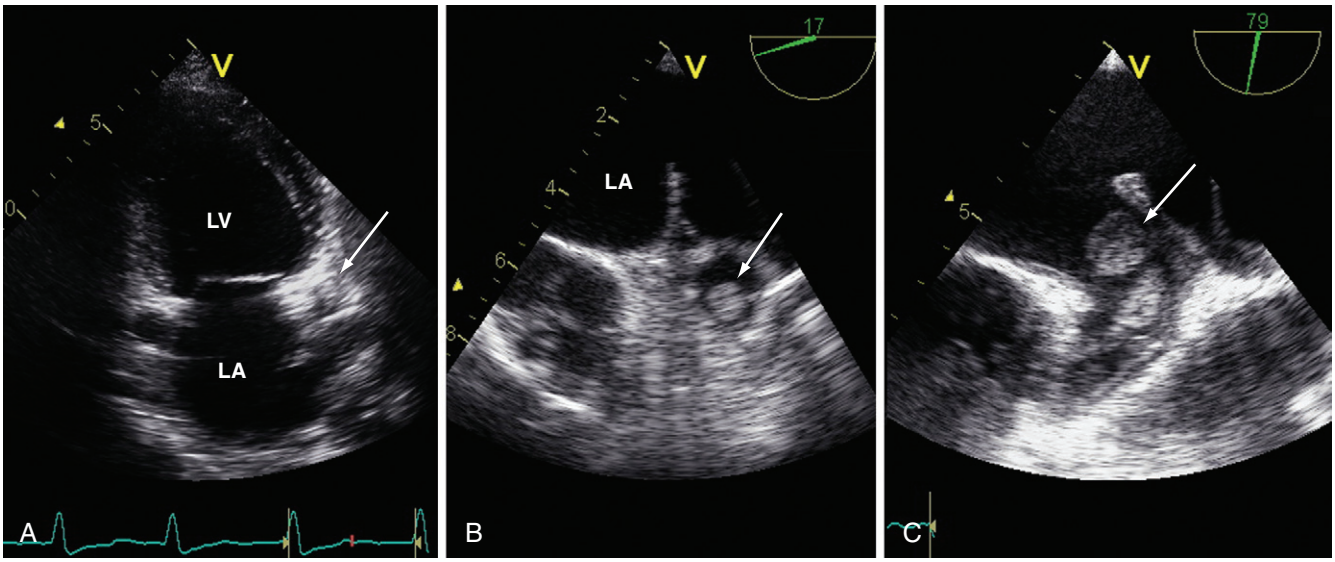

**Figure 42-2 Left atrial appendage thrombus. A,** TTE image taken from the apical two-chamber view demonstrating a thrombus (*arrow*) in the LA appendage. **B,** TEE in the same patient confirming the LA appendage thrombus. **C,** TEE in another patient demonstrating multiple thrombi in the LA appendage.

TEE is a well-tolerated but moderately invasive diagnostic imaging technique that allows for superior visualization of posterior structures such as the LA and LA appendage. Although TEE may be used to assess the body of the LA from orientations analogous to TTE imaging,[15] its greatest advantage over TTE is in evaluation of the anatomy and function of the left and right atrial appendages, structures poorly seen by TTE.

## IDENTIFICATION OF LEFT ATRIAL THROMBI

Anatomic imaging of the body of the LA may be readily obtained from 2D TTE, but identification or exclusion of LA and LA appendage thrombi is best performed by TEE. The sensitivity of TTE for detection of LA thrombi (Fig. 42-2, *A*) is only 39% to 63%,[16-18] with very limited success for identifying thrombi in the LA appendage. Even with modified views,[19] visualization of the LA appendage may be accomplished in less than 20% of patients.[20] Although identification of LA appendage thrombi using state-of-the-art TTE equipment has been described (see Fig. 42-2, *A*),[21] and echocardiographic contrast may be useful,[22] this has not been confirmed in a large series.

Imaging of the LA appendage is readily accomplished with multiplane TEE (Fig. 42-2, *B*). The normal length and neck width of the adult LA appendage in the horizontal and vertical imaging planes are 28 ± 5 mm and 16 ± 5 mm, respectively.[23] LA appendage anatomic indexes are dependent on imaging plane, with greater neck width and cross-sectional area when observed at a 135° imaging plane as compared with a 45° or 90° plane,[24] consistent with its shape idealized as a special ungula of a right circular cylinder.[25] The LA appendage commonly has multiple lobes and trabeculations (Fig. 42-3).

The accuracy of TEE for the identification of LA thrombi has been reported by several investigators and was initially based on older monoplane technology.[20,25-27] For nearly two decades, multiplane TEE technology has been the standard with superior visualization of the LA appendage. In our experience of nearly

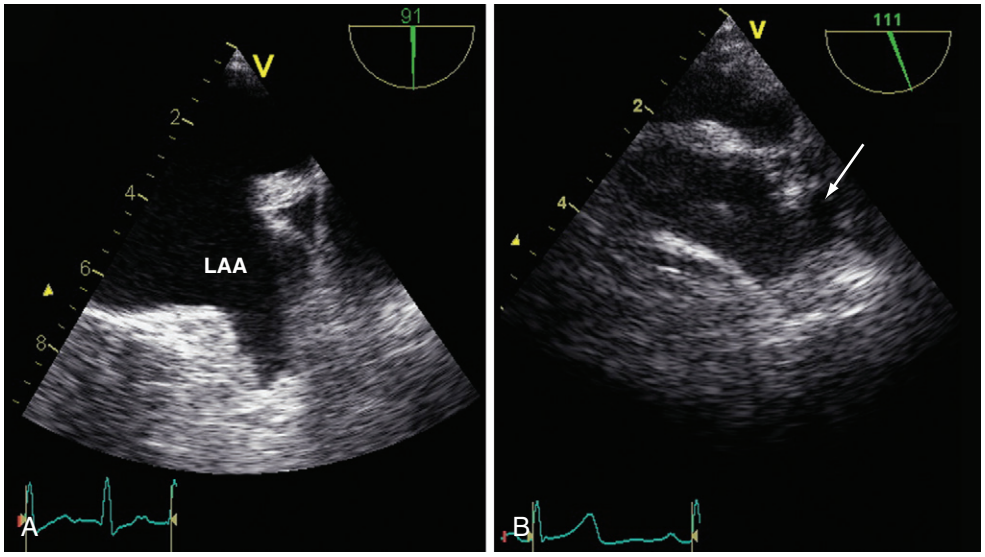

**Figure 42-3** **TEE of LA appendage. A,** Single-lobed LA appendage (*LAA*). **B,** LA appendage with an accessory lobe (*arrow*).

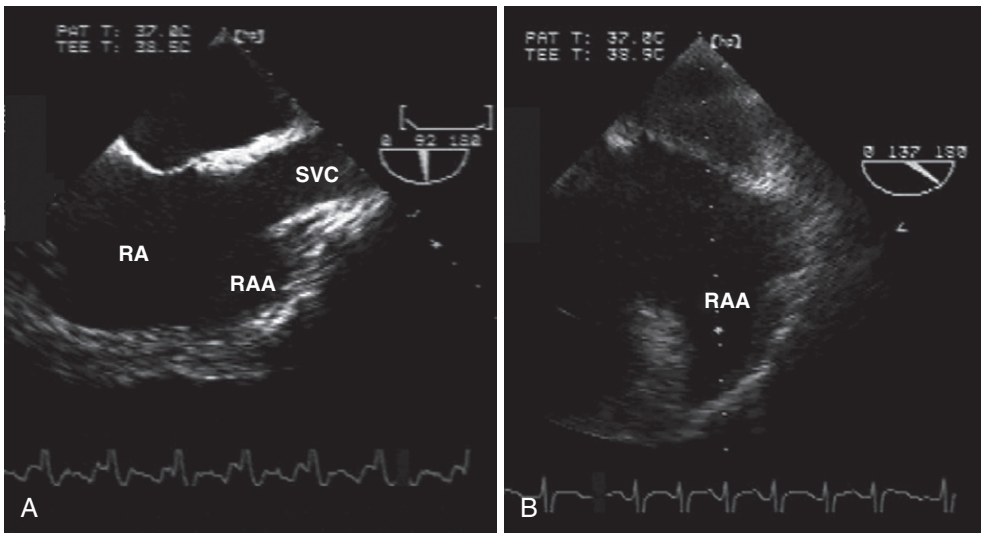

**Figure 42-4** **TEE of normal right atrial appendage (*RAA*). A,** 92° imaging plane. **B,** 137° imaging plane. *SVC*, Superior vena cava.

200 consecutive patients undergoing intraoperative TEE immediately before mitral valve surgery, TEE sensitivity and specificity for LA thrombi were 100% and 99%, respectively.[28] We have found the 90° imaging plane particularly advantageous for assessing the LA appendage for thrombus. Real-time three-dimensional (3D) TEE has been used to characterize LA appendage anatomy.[29] The accuracy of this technology for identification of LA appendage thrombus is currently unknown, though case reports and small series suggest a benefit (versus 2D multiplane TEE) when the appendage is heavily trabeculated.[30] For patients who are not candidates for conventional TEE, microprobe TEE or intracardiac echo[31,32] may be options, but these technologies have not been as well studied and few data are available on comparative accuracy.

## RIGHT ATRIAL ANATOMY

The right atrium has not been as well studied by either TTE or TEE. As is the case with the LA, 2D TTE provides a reasonably comprehensive assessment of right atrial (RA) volume. The primary transthoracic window is the apical four-chamber view, with RA area estimated using a length-diameter ellipsoid formula. Parasternal short-axis and subxiphoid windows provide complementary data. The RA appendage is rarely appreciated from TTE, but TEE at 90° (see Fig. 42-3) and 135° imaging orientations readily allow for visualization of this structure (Fig. 42-4).[33] RA appendage area and length are independent of transducer orientation with areas of 5.4 ± 2.4 $cm^2$ and lengths of 4.0 ± 0.9 cm reported for those in sinus rhythm.[33] Care must be taken to avoid mistaking normal structures (such as the Eustachian valve or Chiari network) for thrombi.[34]

TTE and TEE sensitivity and specificity data for identification of RA thrombi are relatively sparse. Schwartzbard and colleagues[35] reported on 20 patients with TEE evidence of RA thrombus, including 7 confirmed at surgery. TTE identified thrombus in only 6 patients (30%). All RA *appendage* thrombi were missed by TTE.

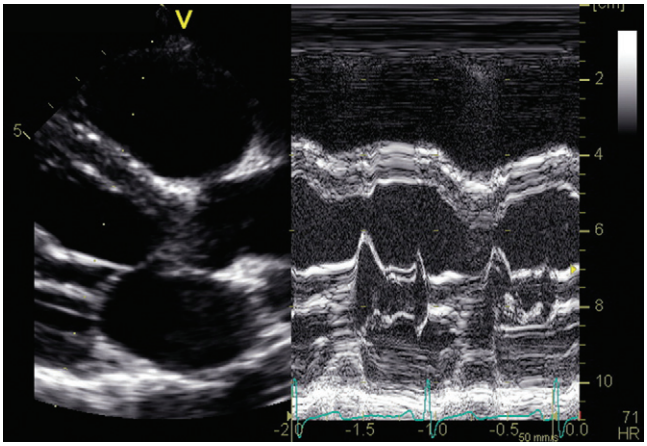

**Figure 42-5 TTE 2D guided M-mode demonstrating the normal motion of the mitral valve and atrial systole.** The height of the M-mode anterior leaflet A wave has been used as a measure of atrial mechanical function.

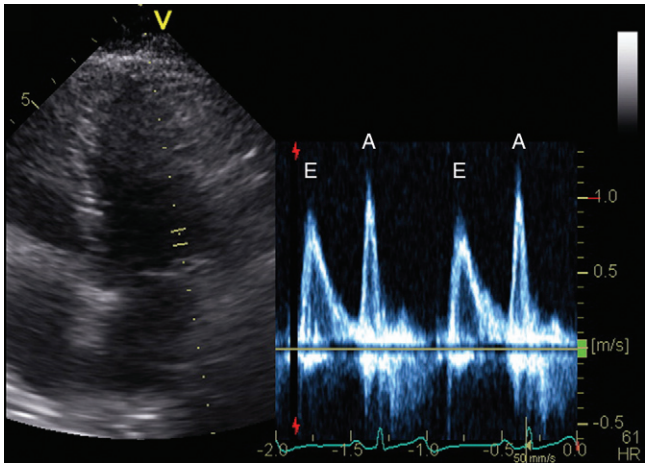

**Figure 42-6 TTE 2D guided spectral display of transmitral pulsed Doppler echocardiographic flow velocity.** *A,* Atrial filling wave; *E,* early filling wave.

## ATRIAL MECHANICAL FUNCTION

In addition to atrial anatomy, echocardiography is a powerful tool for evaluation of atrial systolic function. The atria are traditionally believed to have two primary functions: as passive conduits or reservoirs for oxygenated blood passing from the vena cava or pulmonary veins to the ventricles, and as booster pumps to augment passive diastolic ventricular filling.

Before the advent of echocardiography, assessment of atrial mechanical function had been limited to invasive catheter-based techniques,[36] an impractical approach for serial assessments. M-mode echocardiographic assessment of mitral valve motion (Fig. 42-5) can be used in patients with cardiac arrhythmias.[37] Normal anterior mitral leaflet excursion is 13 mm,[37,38] with depressed excursion seen with mitral stenosis, with low cardiac output, and with atrial mechanical dysfunction.

Transmitral Doppler has become recognized as an accurate technique for quantifying atrial mechanical function. In the absence of aortic regurgitation, left ventricular (LV) filling may be divided into passive and active phases. The initial (early, or E) wave in the transmitral Doppler flow profile represents passive ventricular filling, and the final (atrial, or A) wave represents active filling during atrial systole (Fig. 42-6). This transmitral Doppler flow profile can be influenced by a number of factors, including heart rate, loading conditions, and sample volume position. The most common indexes of interest include peak A-wave velocity, percent A-wave filling, and peak and percent E/A ratios. Peak E- and A-wave velocities vary considerably with sample position. In our laboratory, we assess the transmitral profile at its maximum (between the tips of the mitral leaflets).

In addition to the previously described quantitative measures of transmitral Doppler data, the transmitral Doppler profile may also be used to calculate atrial ejection force, defined as that force which the atrium exerts to propel blood into the left ventricle (LV).[39] The atrial ejection force is based on Newtonian mechanics and is proportional to the mitral orifice area and the square of the peak A-wave velocity. As with more traditional E-wave and A-wave indexes, atrial ejection force may be dependent on loading parameters. If calculation of atrial ejection force is desired, a pulsed Doppler sample position at the level of the mitral annulus would be geometrically more appropriate.

## LEFT ATRIAL APPENDAGE FUNCTION

Because the LA appendage is a blind pouch, volumetric ejection must equal inflow during each cardiac cycle. Pollick and Taylor[40] noted that patients with sinus rhythm who were free of atrial thrombus had a characteristic contractile LA appendage apex and a noncontractile base. 2D TEE-guided pulsed Doppler has allowed for further characterization of LA appendage systolic performance. The pulsed Doppler profile taken at the mouth of the LA appendage displayed characterizing ejection and filling phases (Fig. 42-7, *A*). In a healthy adult population, peak LA appendage ejection and filling velocities are 46 ± 18 cm/s and 46 ± 17 cm/s, respectively.[41] Investigators have subsequently characterized LA appendage flow patterns as having four distinct morphologic types (see Fig. 42-7): type I, sinus; type II, flutter (regularized sawtooth); type III, fibrillatory (irregular sawtooth) with ejection velocity greater than 0.2 m/s; and type IV, stagnant/absent flow with peak ejection velocity of greater than 0.2 m/s. In rare instances, there may be a discontinuity between the body of the atrium and appendage[42,43] with sinus pattern on transmitral flow but a fibrillatory pattern in the appendage or even a discrepancy among LA appendage lobes.[44] Although anatomic indexes appear to be dependent on imaging plane, Doppler indexes of LA appendage ejection and inflow are independent of imaging plane.[24] Spontaneous echocardiographic contrast, a marker for stasis, is typically seen with type III or IV appendage flow, whereas LA appendage thrombi are most commonly seen with type IV flow.[45,46] As with transmitral Doppler data, LA appendage flow velocities are dependent on Doppler sample position and loading conditions.[47]

RA appendage function has not been as well studied, but can also be readily assessed by TEE using pulsed Doppler in the 90° or 180° orientations. One report indicated normal RA appendage ejection velocity of 40 ± 16 cm/s, significantly lower than LA appendage ejection velocity.[33]

# Echocardiography and Atrial Fibrillation

## PREVALENCE OF ATRIAL FIBRILLATION

AF is a common arrhythmia, with an overall prevalence of 0.4% in the United States,[48] and is responsible for more than 180,000 hospital admissions annually.[48] Its prevalence increases sharply

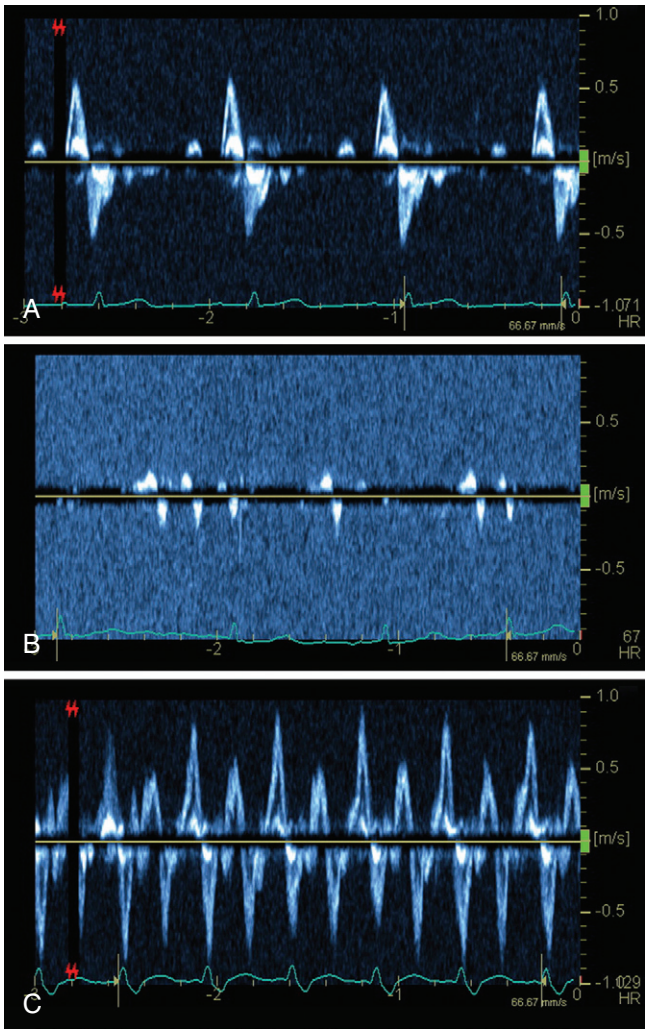

**Figure 42-7 TEE spectral display of pulsed Doppler echocardiographic flow velocity with the sample volume at the mouth of the LA appendage. A,** Patient in sinus rhythm. **B,** Patient with atrial fibrillation with minimal atrial appendage mechanical function. **C,** Patient with atrial flutter. Vertical calibration markings for each represent 0.1-m/s intervals.

with advancing age and is found in up to 4% of those over 60 years.[49] Data from the Framingham Heart Study suggest that an increased transmitral E/A was associated with an increased risk for the subsequent development of AF.[50] In an earlier Framingham Heart Study, the presence of permanent AF is associated with a near doubling of both overall and cardiovascular mortality.[51] Atrial flutter is a far less common sustained arrhythmia. Analogous detailed epidemiologic studies are not available.

## SYMPTOMS AND CLINICAL IMPACT

AF is characterized by a lack of organized atrial mechanical and electrical activity. This condition promotes stasis of blood within the atria and increases the risk of atrial thrombus formation. Thromboembolism associated with AF is believed to account for nearly half of all cardiac sources of emboli. In addition to the risk of thrombus formation, loss of organized atrial mechanical activity impairs the atrium's ability to act as a booster pump and thus impairs ventricular filling (and consequently cardiac output).[52] The mechanical function of the atria appears to be less severely impaired in atrial flutter, but thrombus formation remains a concern, particularly among patients with alternating AF and flutter or flutter in the setting of mitral stenosis or LV systolic dysfunction.

Important clinical issues related to AF include the following:

1. Thromboembolism, including cerebral and other systemic emboli and pulmonary emboli. These events are likely due to the migration of atrial thrombi during the period of AF or may relate to new thrombus formation during the peri-conversion period as a result of atrial stunning (see later). Among patients with nonvalvular AF, the vast majority (more than 90%) of atrial thrombi reside in the LA appendage (a structure best visualized by TEE). TEE evidence of spontaneous echocardiographic contrast and depressed atrial appendage ejection velocity (less than 0.2m/s) are markers for increased risk for both thrombus formation and for clinical thromboembolism.[46,53-55] Clinical markers for thromboembolism among patients with AF have been summarized by the CHADS2 scoring system (C = congestive heart failure, H = hypertension, A = age greater than 74 years, D = diabetes, S = stroke/neurologic event).[56] These same clinical risk factors have also been associated with increased risk of TEE evidence of LA thrombus.[57]
2. Hemodynamic decompensation, which may include depressed cardiac output, congestive heart failure, fatigue, and pulmonary edema. Decompensation is particularly common among patients with a noncompliant ventricle. Such a situation may occur with normal aging and with LV hypertrophy related to systemic hypertension or aortic stenosis. This hemodynamic deterioration is particularly common in the setting of a rapid ventricular rate, during which the diastolic filling period is preferentially shortened.
3. Palpitations, most commonly associated with AF and a rapid (greater than 100/min) ventricular response. Patients with controlled ventricular rates (less than 100/min) are often asymptomatic.
4. Tachycardia-induced cardiomyopathy, which may occur in patients with poorly controlled, rapid ventricular rates.

## ATRIAL SIZE AND ATRIAL FIBRILLATION

LA enlargement is common among patients with AF, particularly those with mitral valve disease and/or systemic hypertension. In addition, LA enlargement decreases the likelihood of long-term maintenance of sinus rhythm.[58,59] Aronow and co-workers[60] studied 588 patients and found LA enlargement in 57% of patients with permanent AF as compared with only 8% of those with sinus rhythm. Data from the Framingham Heart Study suggest that among those without a history of AF, LA enlargement is among the strongest predictors for the subsequent development of nonvalvular AF.[51] Several groups have reported that LA size increases with sustained AF.[61-63]

Although AF promotes further LA enlargement, data suggest that cardioversion of AF and long-term maintenance of sinus rhythm may reverse this process. Using M-mode techniques, DeMaria and associates[38] reported a decrease in LA dimension within 1 hour of cardioversion. We studied a group of 21 patients with AF of 5 months' duration.[64] Patients with persistent sinus rhythm had significantly smaller left atria 3 months after cardioversion as compared with precardioversion data. In contrast, the group of patients who reverted to AF had no change in LA size. Similarly, Gosselink[65] and Van Gelder,[66] with

their co-workers, reported on atrial size in 41 and 120 patients, respectively, with permanent AF undergoing precardioversion. At 6 months after cardioversion, both LA and RA volumes decreased among patients with persistent sinus rhythm, with no change in the group who reverted to AF. Similar results have also been seen 6 to 12 months after pulmonary vein isolation using 2D[67] and real-time 3D TEE LA volume methods.[68] These data strongly suggest that restoration of sinus rhythm may reverse the process of progressive LA and RA enlargement.

Because atrial enlargement may be deleterious and cardioversion to sinus rhythm may prevent or reverse such dilation, we think that avoidance of cardioversion should *not* be based solely on an absolute LA dimension or volume. Patients with permanent (more than 1 year) AF, rheumatic mitral valve disease, and prominent LA enlargement (dimension greater than 6.0 cm; volume greater than 44 mL/m$^2$), however, are far less likely to have long-term maintenance of sinus rhythm.[69]

## DETECTION OF ATRIAL THROMBI IN ATRIAL FIBRILLATION

AF is believed to be responsible for almost half of cardiogenic thromboembolism. Several large, multicenter, prospective randomized studies have confirmed the beneficial effect of chronic warfarin anticoagulation (international normalized ratio [INR] 2.0 to 3.0) or the oral thrombin inhibitor dabigatran (110 or 150 mg twice daily) in patients with nonvalvular AF[70-75] for clinical stroke prevention, with one retrospective study suggesting an INR of greater than 2.5 immediately before cardioversion to be particularly beneficial.[76] Because TTE is so limited for the assessment of atrial thrombi,[16-18] data on the prevalence of LA thrombi were not available until the introduction of TEE. Among patients presenting with AF of greater than 2 days' or unknown duration, we found atrial thrombi in 13%,[77,78] of which more than 92% were LA thrombi and nearly all involved the LA appendage. These data are similar to those reported by others,[79-85] but higher than the approximately 6% incidence of clinical thromboembolism following cardioversion without prolonged anticoagulation.[86-89] This apparent discrepancy may be because some thrombi may not migrate and some embolic events may be clinically silent.[90,91] Patients at particularly high risk for atrial thrombi (Table 42-1) include those with rheumatic mitral valve disease, depressed LV systolic function, recent thromboembolism,[92] and TEE evidence of severe LA spontaneous echocardiographic contrast and complex aortic debris.[55,91] Duration of AF and LA dimension are not predictive of LA thrombi.[71,72] The CHADS2 scoring system has also been associated with increased risk of TEE evidence of LA thrombus[57,93]: LA thrombi and spontaneous echocardiographic contrast are very rarely found in patients with a CHADS2 score of 0 with a progressive increase in atrial thrombi with increasing CHADS2 score (Fig. 42-8). Despite these provocative data, expedited cardioversion (without anticoagulation and screening TEE) or without a month of therapeutic warfarin is currently not recommended for the CHADS2 = 0 group. Similarly, preliminary data suggest that TEE evidence of LA appendage thrombi is not seen among those with a totally normal TTE.[94] In contrast to data suggesting that at least moderate mitral regurgitation is protective against clinical thromboembolism,[95,96] we have found that mitral regurgitation is not protective against LA thrombi (see Table 42-1) among those with new-onset AF.[77]

[†]TEE could not be completed in six patients. Data for these six are excluded.

Immediate cardioversion is generally advocated for patients with AF of less than 2 days' duration,[97] under the assumption that the prevalence of atrial thrombi in this group was very low. This common teaching was challenged when Stoddard and colleagues[98] reported a 14% prevalence of atrial thrombi among patients with AF of less than 3 days' duration and a prevalence of 27% in those with a duration of at least 3 days in a predominantly male population. In contrast, we found clinical thromboembolism following cardioversion (without antecedent TEE or prolonged warfarin anticoagulation) of less than 1% among patients with AF of less than 2 days' duration.[99] Thus, prolonged warfarin or screening TEE is likely not needed in this group (unless there is a history of thromboembolism, severe LV systolic dysfunction, or mitral stenosis). Although we perform cardioversion of AF of less than 48 hours' duration without prolonged warfarin or screening TEE, we do initiate therapeutic anticoagulation at presentation (intravenous unfractionated heparin or low molecular weight heparin) rather than delaying anticoagulation until the patient has been in AF for 48 hours. If TEE is performed in this short-duration AF group, evidence of LA appendage thrombi is found in 1.4% to 4% of the group,[100] with thrombus and spontaneous echocardiographic contrast associated with depressed LV systolic function and enlarged LA.

As might be expected, atrial thrombi are more common among AF patients who present with acute thromboembolism. In our experience, residual LA thrombi are found in nearly 50% of these patients.[101] Because this group represents a very high clinical risk for whom chronic warfarin (or dabigatran) is indicated, we do not perform TEE to search for thrombi unless cardioversion is desired.

RA thrombi are far less common among patients with AF and represent less than 5% of all atrial thrombi identified by TEE.[77,78,102] RA spontaneous echocardiographic contrast is also distinctly unusual, seen in only 10% of AF patients,[77] and is highly predictive for RA thrombi.

### *Atrial Fibrillation and Predictors of Thromboembolism*

Compared with patients who present with new-onset AF and undergo TEE before cardioversion, risk factors of thromboembolism differ in patients with nonvalvular AF. Prior thromboembolism and LV systolic dysfunction are among the strongest independent predictors of clinical thromboembolism in patients with nonvalvular AF.[103] The TEE substudies of the Stroke Prevention in Atrial Fibrillation Investigators Committee (SPAF) III study[55] have extended echocardiographic indexes known to be associated with thromboembolism to include dense spontaneous echocardiographic contrast, depressed (less than 20 cm/s) LA appendage ejection velocity, LA thrombus, and complex (more than 4 mm thick and/or with mobile components) aortic atheroma. Importantly, the SPAF-III data suggest that these TEE indexes may identify high- and low-risk subgroups from among clinically high-risk patients (age, female gender, systemic hypertension, LV dysfunction, prior thromboembolism).[55] A subsequent study by Bernhardt and co-workers[104] confirmed the predictive power of these TEE measures for stroke.

### *Guidance of Early Cardioversion*

Cardioversion of AF is performed in an effort to improve cardiac function, relieve symptoms, and potentially decrease thrombus formation. However, data from several large prospective studies demonstrate no mortality or thromboembolic advantage to aggressive cardioversion and maintenance of sinus rhythm (versus chronic anticoagulation and rate control).[105-107] (For symptomatic patients who are difficult to rate control, however, cardioversion is still advocated.) Unfortunately, successful cardioversion of nonvalvular AF is associated with an approximately 6% incidence of clinical thromboembolism among patients who are not systematically anticoagulated for several weeks before cardioversion.[86-89] Because atrial thrombi are poorly detected by TTE, conventional care of patients with AF of unknown or prolonged (more than 2 days) duration had demanded that these patients receive several weeks of anticoagulation before cardioversion, with one study suggesting that an INR greater than 2.5 immediately before cardioversion further reduces risk.[76] Cardioversion is then followed by several weeks of anticoagulation while atrial mechanical function recovers[108] and for prophylaxis should the patient revert to AF. Although no randomized and only two prospective studies[79,82,109] have been reported, a month of precardioversion warfarin therapy decreases the risk of a clinical embolic event following cardioversion to less than 1.6%.[76,79,82,88,89] The majority of these clinical embolic events occur within the first 10 days after cardioversion (Fig. 42-9).[109,110] Use of warfarin, however, carries a risk of major (2%) and minor (10% to 20%) hemorrhagic complications.[79,82,111] In addition, many patients have a subtherapeutic INR during the month before cardioversion. For these individuals, the warfarin dose is increased and the "1-month clock" restarted, an approach supported by TEE studies demonstrating LA appendage thrombi in patients with a transient subtherapeutic INR.[112,113] Finally, conventional therapy leads to a delay in cardioversion for the large majority of patients who do not have an atrial thrombus, and a second hospitalization is needed for cardioversion.

## Rationale and Advantages

A TEE-guided approach to early and safe cardioversion (Fig. 42-10) has several advantages over traditional strategies for hospitalized patients with AF (Box 42-1). Currently, up to 8 weeks

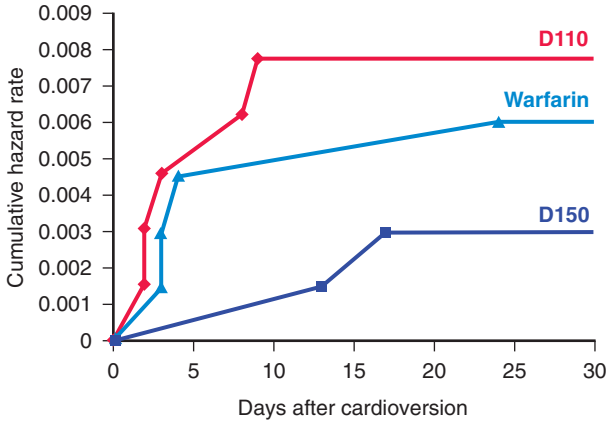

**Figure 42-9 Timing of thromboembolic events after cardioversion in patients receiving warfarin, dabigatran 110 mg twice daily (*D110*), and dabigatran 150 mg twice daily (*D150*).** Note that the vast majority of events are within the first 10 days after cardioversion. *(Reprinted from Nagarakanti R, Ezekowitz MD, Oldgren J, et al: Dabigatran versus warfarin in patients with atrial fibrillation: an analysis of patients undergoing cardioversion.* Circulation *123:131, 2011.)*

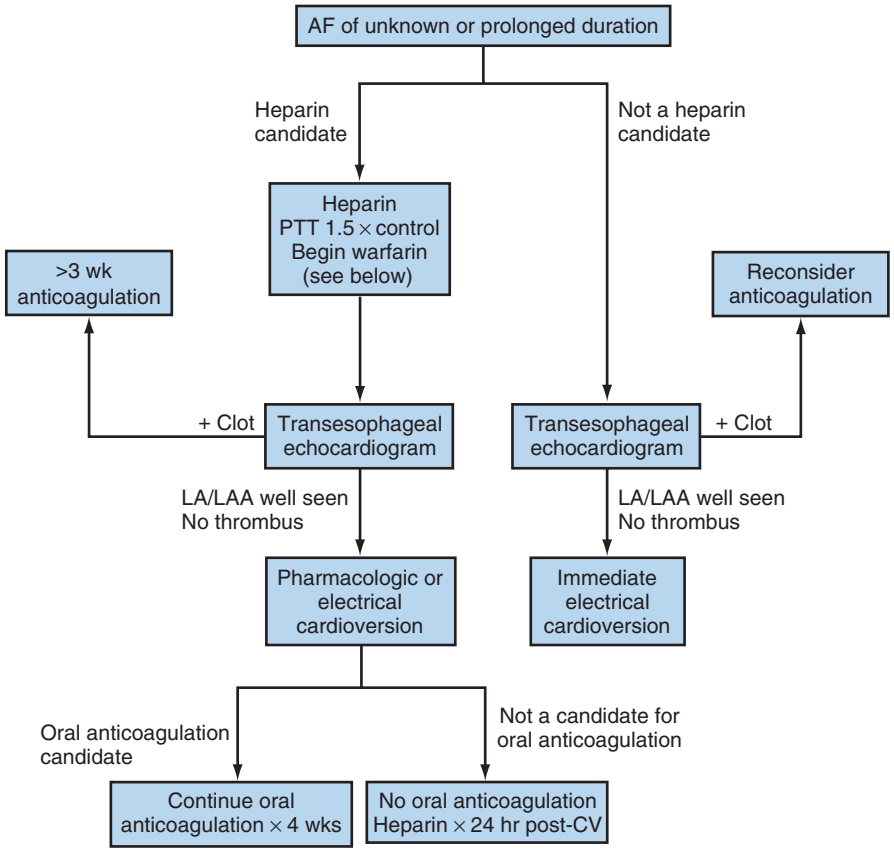

**Figure 42-10 Schematic of TEE-guided approach to early cardioversion.** Long term, either chronic warfarin or dabigatran can be used as guided by CHADS2 score. *AF*, Atrial fibrillation; *LAA*, left atrial appendage; *PTT*, partial thromboplastin time.

of oral anticoagulation is recommended with cardioversion,[97,114,115] including 1 month before and 1 month after cardioversion. This period of anticoagulation exposes patients to a significant risk of a hemorrhagic complication[79,82,111] by doubling the exposure to systemic anticoagulation (versus an expedited TEE approach). For uncertain reasons, the AF population appears to be at increased risk of hemorrhagic complications during the second month of anticoagulation.[79]

Early cardioversion offers physiologic advantages over traditional therapy. A shorter duration of precardioversion AF is among the strongest predictors for long-term maintenance of sinus rhythm.[59] Almost 60% of patients hospitalized for AF at our hospital[77,78] have been in AF for less than 1 month. For these individuals, traditional treatment of a month of precardioversion anticoagulation serves to more than double the total period of AF before cardioversion. The TEE-guided approach has been shown to be associated with fewer recurrences of AF[78] and to increased prevalence of sinus rhythm at 6 months postcardioversion.[116]

Early cardioversion may also lead to a more rapid return to normal atrial function. The recovery time for return of atrial mechanical function is directly related to the duration of precardioversion AF (Fig. 42-11).[108,117] Patients with AF for less than 2 weeks before cardioversion have complete return of atrial mechanical function within 24 hours of cardioversion, whereas those with AF of 2 to 6 weeks require a week. Those with

**Box 42-1**

## BENEFITS AND RISKS OF TEE-GUIDED CARDIOVERSION

**Benefits**

Shorter initial duration of atrial fibrillation (AF)
- Enhanced recovery of atrial mechanical function
- More rapid resolution of symptoms of congestive heart failure
- Increased likelihood that sinus rhythm will be maintained

No need to return for elective cardioversion after 1 month of warfarin or dabigatran anticoagulation

Shorter total duration of AF before cardioversion
- Fewer hemorrhagic complications
- Lower cost for warfarin medication and monitoring

Similar thromboembolic events than conventional therapy(?)

More cost-effective than conventional therapy (if TTE is not performed)

Identify high-risk population that requires lifelong warfarin or dabigatran regardless of clinical risk factors(?)

**Risks**

TEE may miss clinically relevant thrombi that subsequently migrate and cause stroke/thromboembolism

Morbidity associated with TEE

Cost of TEE

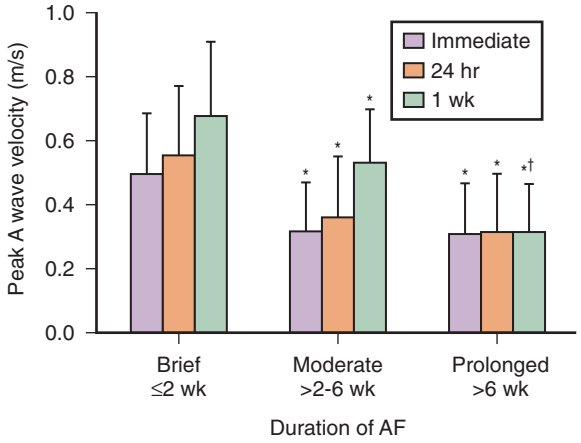

**Figure 42-11 Comparison of transmitral pulsed Doppler peak A-wave velocity among patients with brief (<2 weeks), moderate (2-6 weeks), and prolonged (>6 weeks) atrial fibrillation (AF) immediately after, at 24 hours, and at 1 week after cardioversion.** *$P$ <.05 vs. brief duration. †$P$ <.05 vs. moderate duration. *(From Manning WJ, Silverman DI, Katz SE, et al: Impaired left atrial mechanical function after cardioversion: Relationship to the duration of atrial fibrillation.* J Am Coll Cardiol *23:1537, 1994.)*

precardioversion AF for more than 6 weeks require up to 3 weeks for full atrial mechanical recovery.[108] With elimination of TTE, a TEE-guided procedure is cost effective.[118,119] The costs of the TEE approach include the cost of and morbidity of TEE and the risk that TEE will not be adequate to identify clinically relevant atrial thrombi.

## TEE-Guided Cardioversion Safety Data

We reported on our experience with a TEE-guided approach (see Fig. 42-6) to early cardioversion among 533 patients with AF of unknown or prolonged duration who underwent precardioversion TEE in the absence of prolonged chronic anticoagulation.[77,78,102] Seventy-six atrial thrombi were identified in 70 patients (13%). Of the 463 without TEE evidence of thrombi, 413 (89%) were successfully cardioverted, all without prolonged anticoagulation, and 1 (0.2%; 95% CI, 0 to 0.8%) experienced a clinical thromboembolic event. The only adverse event occurred in an elderly woman with mild rheumatic mitral stenosis who presented 1 week after cardioversion with a brachial artery embolus. She had been therapeutically anticoagulated between TEE and presentation with the adverse event.[78] None of the 70 patients with atrial thrombi were cardioverted, but 5 (7%) died during the index hospitalization. Repeat TEE to document resolution of atrial thrombi was recommended for all with atrial thrombi, with cardioversion only after documentation of thrombus resolution.

Other prospective studies using a similar anticoagulation regimen have shown similar results. Stoddard and co-workers[81] reported on 82 patients undergoing elective cardioversion of AF. Atrial thrombi were identified in 13% of patients. Of 71 patients without atrial thrombi, 66 underwent successful cardioversion, and no patient experienced a clinical embolic event. The pilot study data from the Assessment of Cardioversion Using Transesophageal Echocardiography (ACUTE) trial reported no thromboembolic complications among 47 patients treated with an anticoagulation strategy similar to ours.[79] The larger 1222-patient, multicenter, randomized ACUTE trial[82] directly compared conventional therapy of 4 weeks of precardioversion warfarin with a strategy of therapeutic anticoagulation followed by TEE and early cardioversion if no atrial thrombi are seen. At 8 weeks, equivalence was found for both approaches, though with 0.5% thromboembolic events in the conventional arm and 0.8% in the TEE arm. A subsequent prospective study by Strandberg and colleagues[83] using subcutaneous low molecular weight heparin and warfarin before TEE in 274 patients had a clinical stroke rate of 0.3%. Of note, nearly all of the adverse events in the ACUTE TEE arm occurred while the patient had either a subtherapeutic (less than 2.0) INR or was in AF. In contrast, the adverse events in the conventional therapy arm occurred in patients in sinus rhythm and with a therapeutic INR. These data highlight the importance of therapeutic post-cardioversion anticoagulation. Interestingly, the absence of an atrial thrombus on a prior TEE while in AF does not appear to preclude the need for a TEE if a patient returns with AF in the absence of chronic anticoagulation.[120] Six-month ACUTE data[121] showed that hemorrhagic complications were lower in the TEE arm (4.4% versus 7.5%, $P = 0.04$), but maintenance of sinus rhythm was similar (62.2% versus 58.1%).

Although these reports supporting an expedited TEE-guided approach using short-term precardioversion anticoagulation are encouraging, several adverse events have occurred among patients with a negative TEE for atrial thrombi who have undergone early cardioversion using monoplane TEE or in the absence of systemic anticoagulation.[122] Many underwent electrical cardioversion several days or weeks following TEE with no anticoagulation during the intervening period. For these patients, it is impossible to exclude the possibility that atrial thrombi may have formed between the TEE and cardioversion, or even after cardioversion. Impaired atrial mechanical function,[108,123] impaired atrial appendage function,[124,125] or new spontaneous contrast[81,125] have all been documented following cardioversion.

Although no data have been reported for conventional cardioversion approaches, a prospective study of 127 patients undergoing TEE-guided cardioversion reported no clinical embolic events, but cerebral magnetic resonance imaging (MRI) demonstrated that 4.7% of patients had new embolic lesions suggestive of a silent embolic event.[126]

As in our original report,[102] we strongly recommend that all patients undergoing a TEE-guided early cardioversion strategy be therapeutically anticoagulated with intravenous unfractionated heparin or warfarin at the time of TEE, continuing through cardioversion, and that warfarin (or dabigatran) anticoagulation be continued for at least 1 month after cardioversion. TEE should be performed (without preceding TTE to reduce costs[118]) immediately before cardioversion to adequately visualize the atria and appendages and to exclude the presence of atrial thrombi. Heightened vigilance for thrombi is necessary if there is prominent spontaneous echocardiographic contrast or poor (less than 0.2 m/s) atrial appendage ejection velocity or an increased CHADS2 risk score. Though of unproven efficacy,[127] if a thrombus is seen on TEE, we think that cardioversion should be deferred and the patient maintained on warfarin (or dabigatran 150 mg twice daily) for 4 weeks followed by repeat TEE to document thrombus resolution before cardioversion.[128] Patients with RA appendage thrombi should be treated in a similar manner. If the atrial appendage cannot be adequately cleared of thrombus, the patient should be treated conservatively with a month of therapeutic warfarin (or dabigatran) before cardioversion. The use of low-molecular-weight heparin or dabigatran precardioversion anticoagulation or as a bridge

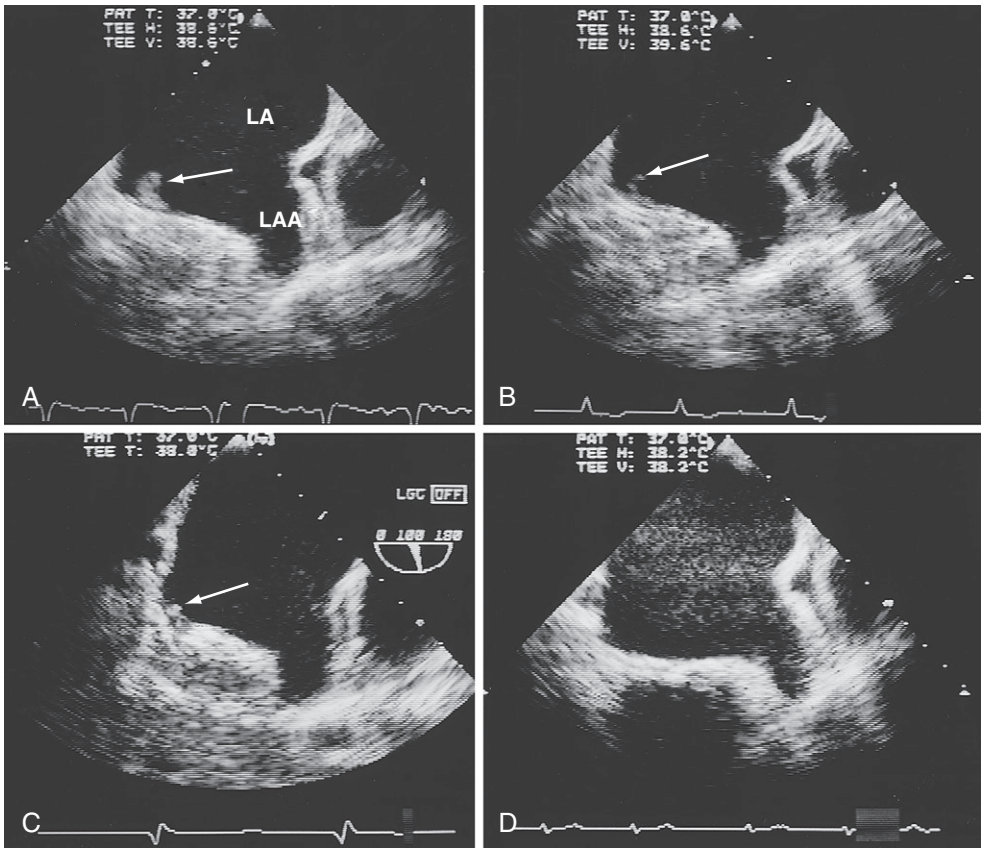

**Figure 42-12 Serial TEE studies showing the LA and LA appendage (*LAA*) viewed in the vertical plane with a 5-MHz biplane probe.** The thrombus (*arrow*) is in the body of the LA, closely associated with the mitral annulus in the posterior portion of the LA. **A,** Initial study demonstrating a mobile 12-mm thrombus. **B,** Thrombus persists but is smaller after 1 week of warfarin therapy. **C,** After 3 weeks of warfarin, the thrombus continues to be seen (*arrow*). **D,** Complete resolution of thrombus is seen after 5.5 weeks of warfarin. *(From Collins LJ, Silverman DI, Douglas PS, Manning WJ: Cardioversion of non-rheumatic atrial fibrillation: Reduced thromboembolic complications with 4 weeks of pre-cardioversion anticoagulation are related to atrial thrombus resolution.* Circulation *92:162, 1995, with permission.*Copyright 1995 American Heart Association.)

to therapeutic warfarin to expedite patient discharge has been less extensively studied, but appears to be a reasonable option with regards to safety and shortens hospitalization.[7,109,129,130] Further support for the use of pre-TEE anticoagulation comes from data demonstrating that clinical thromboembolism is less common among those with TEE evidence of a LA appendage thrombus if warfarin was initiated before the TEE.[131]

Although not directly supported by prospective clinical trials, it is our clinical practice to treat patients with AF who have TEE evidence of atrial thrombi with lifelong warfarin (INR 2 to 3) or dabigatran (150 mg twice daily), even if thrombus resolution has been documented and independent of CHADS2 score. We think that such an approach is prudent, given that the overall recurrence rate of AF is high, and these patients have already selected themselves as being at increased risk for atrial thrombus formation. [55] One prospective study with serial cranial MRI scans reported that more than half of patients with LA appendage thrombi on TEE suffered cerebral embolism and/or death during the succeeding 3 years.[132]

### *Resolution of Atrial Thrombi*

The use of several weeks of anticoagulation before cardioversion results in a reduction of cardioversion-related thromboembolism from 6% to <1%. The mechanism by which warfarin conveys this beneficial effect had been presumed to be thrombus organization and adherence to the atrial endocardium, thus reducing the likelihood of postcardioversion migration.[133] Consistent with this hypothesis, several investigators have reported that atrial thrombi in patients with rheumatic mitral valve disease may not resolve even after several months of warfarin.[134,135] In nonrheumatic, new-onset AF, a different mechanism appears responsible. We have found that after 4 weeks of warfarin, more than 80% of atrial thrombi have completely resolved[136] (Fig. 42-12). Similar data have been reported by others.[80,85,127,137,138] These data support the hypothesis that the mechanism of warfarin's benefit is related to thrombus resolution or silent migration and prevention of new thrombus formation (rather than thrombus organization and adherence). Although randomized data are not available and clinical reports in small groups are inconclusive,[127] we interpret these data as supportive of the need for follow-up TEE examination for documentation of thrombus resolution before cardioversion.[128]

## MECHANISM OF THROMBOEMBOLISM AFTER CARDIOVERSION

Although usually occurring within 72 hours, clinical thromboembolism has been reported up to 10 days following successful cardioversion in patients with maintained sinus rhythm.[109,110] Such adverse events have classically been attributed to migration of LA thrombi that were present at the time of cardioversion.[97,140] TEE has documented the new appearance of, or more pronounced, spontaneous echocardiographic contrast in the LA following electrical cardioversion.[81,125] In addition, more

depressed LA appendage ejection velocity is common after spontaneous or electrical cardioversion.[124,125] These findings have led to the hypothesis that atrial thrombi may form in the immediate postcardioversion period because of atrial injury or stunning. Indeed, LV stunning as a result of electrical cardioversion has been previously described,[141,142] and relatively impaired atrial mechanical function is seen after electrical (as compared with pharmacologic) cardioversion.[118,143] Finally, in rare instances, there may be a discontinuity between the body of the atrium and the appendage,[42,43] with a sinus pattern on the surface electrocardiogram and transmitral Doppler echocardiogram but a fibrillatory pattern in the appendage. Discordance among LA appendage lobes has also been reported.[44] Premature (less than 1 month postcardioversion) discontinuation of warfarin may thereby lead to new thrombus formation. These data all emphasize the importance of therapeutic (INR 2.0 to 3.0) warfarin (or dabigatran) anticoagulation during the pericardioversion and postcardioversion period. For patients who are not considered candidates for out-of-hospital warfarin or dabigatran, we recommend therapeutic anticoagulation with heparin for at least 24 hours after cardioversion.

## ASSESSMENT OF RETURN OF ATRIAL MECHANICAL FUNCTION AFTER CARDIOVERSION

The noninvasive nature of echocardiography makes it the ideal modality for the serial assessment of atrial function after cardioversion. DeMaria and colleagues[38] reported serial M-mode data of anterior mitral leaflet excursion before and after cardioversion among 35 patients with AF of 14 months' duration. One hour after cardioversion, prominent mitral "A" waves were found in 94% of subjects, although anterior leaflet excursion was less than that seen in normal subjects (7.5 mm versus 13 mm). These early data suggested that atrial mechanical contraction was reduced after cardioversion despite normal atrial depolarizations on electrocardiography. Two patients had no discernible atrial anterior mitral leaflet motion, and both of these patients reverted to AF within 1 week. They also found an increased LV end-diastolic dimension, with unchanged end-systolic dimension, consistent with an improvement in LV ejection fraction. Similarly, Orlando and co-workers[144] used M-mode echocardiography 5 hours after cardioversion and found that 4 of their 15 patients (27%) had no transmitral A wave. In their experience, neither the presence of an A wave nor its amplitude correlated with long-term maintenance of sinus rhythm.

Pulsed Doppler echocardiography permits serial noninvasive evaluation of flow across the mitral valve and accurately reflects the LA contribution to total LV filling. As reported by van Gelder and associates[145] and Viswanahan and colleagues,[146] these temporal changes in transmitral Doppler spectra parallel improvements in LV ejection fraction[148] and peak oxygen consumption.[145]

Shapiro and co-workers[123] reported transmitral Doppler data from a group of patients with AF of less than 2 days' duration. Peak A-wave velocities immediately after cardioversion were similar to those in a control (sinus) population. In contrast, patients with AF of more than 1 year before cardioversion had significantly smaller A-wave amplitude after cardioversion. We performed serial transmitral pulsed Doppler examination in 21 patients undergoing elective conventional cardioversion, with a duration of AF of 5 months.[60] Over 3 months of follow-up, there were significant increases in both peak A-wave velocity and percent atrial contribution to total LV filling. Neither index returned to normal until 3 weeks after cardioversion (see Fig. 42-11). Additional studies have confirmed that transmitral Doppler data are not predictive of the long-term maintenance of sinus rhythm.[144,147] Thus it appears that return of atrial mechanical function is not sufficient to allow for premature discontinuation of postcardioversion anticoagulation.

Atrial compartment surgery, or the maze procedure, has received considerable interest as an approach to prevent recurrent AF. Shyu and colleagues[148] studied 22 patients with chronic AF who underwent maze surgery. Over 70% of their group had no transmitral A wave 1 week after surgery, despite sinus rhythm on electrocardiography. Even after 2 months, 40% of their patients had not regained evidence of A waves. Of note, RA function appeared to recover more rapidly than LA function. Transient depression and then improvement in atrial mechanical function has also been demonstrated after pulmonary vein isolation.[149] Shortly after ablation for paroxysmal AF, LA minimal volumes increase, whereas maximal volumes are unchanged, resulting in a short-term decrease in LA ejection fraction. Subsequently, volumes and ejection fraction improve[150] with a 23% decline in LA area at 1 year.[151,152] Tissue Doppler myocardial (A′) velocities were similarly relatively depressed early after ablation.[150]

Studies of atrial mechanical function in patients with AF of an intermediate (3 days to 4 weeks) duration had been previously limited by the relative scarcity of such patients. This was due to the recommendation that patients with AF of more than 2 days' duration receive anticoagulation for a month before cardioversion. Our TEE cardioversion trial allowed us to evaluate atrial function among patients with this intermediate duration of AF. We found that both the immediate peak A velocity and the percentage A-wave filling were significantly lower in the groups with AF of moderate (more than 2 up to 6 weeks) and prolonged (more than 6 weeks) duration as compared with the patients only brief (2 weeks or less) duration of AF.[108] This depression in peak A velocity persisted until at least 1 week following cardioversion. In addition, 1 week after cardioversion, both peak A velocity and percentage A-wave filling were depressed in the group with prolonged duration as compared with the group with moderate-duration AF. As compared with 3-month postcardioversion data, full recovery of atrial mechanical function was achieved within 24 hours for patients with brief (less than 2 weeks) duration, within 1 week for moderate (2 to 6 weeks) duration, and within 1 month for prolonged (more than 6 weeks) duration AF. Twenty-seven patients (45%) reverted to AF during follow-up. Those reverting to AF had a longer AF duration before cardioversion (10.2 versus 5.3 weeks; $P = .04$). There were no differences between groups in LA dimension, patient age, mode of cardioversion, peak A-wave velocity, or percentage of A-wave filling.

Data suggest early atrial mechanical function post-electrical cardioversion may be modulated by angiotensin receptor blockers. Dagres and colleagues[153] studied 50 patients with AF of more than 4 weeks' duration undergoing elective electrical cardioversion, randomizing half to receive irbesartan. Immediately after cardioversion, LA appendage ejection velocities were less depressed in the irbesartan group and the prevalence of spontaneous echocardiographic contrast was lower (32% irbesartan versus 64% of controls). The clinical impact remains to be further explored.

### EVIDENCE OF ELECTRICAL INJURY TO THE ATRIA

LV myocardial injury as a result of electrical cardioversion has been previously described.[141,142] TEE data acquired with electrical cardioversion have shown new or more pronounced LA spontaneous echocardiographic contrast following electrical cardioversion[81,125] as well as depressed LA appendage ejection velocity.[124] We reported on transmitral Doppler data from 33 patients with AF of less than 5 weeks' duration following elective electrical or pharmacologic (primarily quinidine or procainamide) cardioversion.[143] Immediately following cardioversion, patients who underwent electrical cardioversion demonstrated lower transmitral peak A-wave velocity. This relative depression in atrial systolic function persisted at the 24-hour study but had resolved at 1 week. Similarly, Mattioli and colleagues[154] randomized 64 patients with AF (duration 1 day to 6 months) to either direct-current shock or pharmacologic cardioversion. Recovery of atrial mechanical function occurred sooner with pharmacologic cardioversion. Finally, Pollak and Falk[155] performed electrical cardioversion in 37 patients receiving sotalol or placebo. They found relatively depressed atrial function among the group receiving sotalol as compared with placebo.

### SPONTANEOUS ECHOCARDIOGRAPHIC CONTRAST

Spontaneous echocardiographic contrast, or *smoke*, refers to the presence of dynamic smokelike echoes in a cardiac cavity and is occasionally seen in the LA by TTE with mitral stenosis and AF. More commonly, TTE evidence of spontaneous echocardiographic contrast is seen in the LV apex with a high-frequency transducer in patients with an apical aneurysm. Spontaneous echocardiographic contrast likely represents stasis of blood within the cavity, but it may also reflect alterations in blood components such as platelets, red cells, and fibrinogen. Black and associates[156] found an association between spontaneous echocardiographic contrast and erythrocyte aggregation in low shear rate conditions. Aspirin and warfarin therapy do not appear to affect the presence of LA spontaneous echocardiographic contrast.[156] At least mild spontaneous echocardiographic contrast may be seen in over half of patients with AF[55,77,102] and in over 80% of patients with AF and LA appendage thrombi.[77] Among patients with nonvalvular AF, Chimowitz and co-workers[157] found that LA spontaneous echocardiographic contrast was associated with an increased risk of stroke, a finding also confirmed by Bernhardt for both clinical and silent strokes.[91] Black and associates[156] found that spontaneous echocardiographic contrast by TEE was an independent predictor of LA thrombus among patients with suspected cardioembolism. Although unproved, it seems likely that recovery of atrial mechanical function would decrease or abolish spontaneous echocardiographic contrast. The SPAF-III TEE substudy[55] suggests that warfarin anticoagulation decreases the risk of thromboembolism in patients with spontaneous echocardiographic contrast.

## Echocardiography and Atrial Flutter

Sustained atrial flutter is far less common than AF. As a result, there are fewer data regarding atrial function at baseline and following cardioversion. It has generally been accepted that the relatively preserved atrial mechanical function (see Fig. 42-7, *C*) with atrial flutter results in a lower risk of thromboembolism (as compared with AF). In a retrospective review, Arnold and colleagues[89] reported on 122 patients with atrial flutter at the time of cardioversion, including 74% who were not receiving anticoagulation. No patient experienced a clinical thromboembolic event. These data support the concept that patients with atrial flutter do not require anticoagulation before cardioversion. However, there have been reports of atrial thrombus identified during TEE study among patients with atrial flutter[85,158,159] and postcardioversion thromboembolism. A limitation of interpreting the literature on atrial flutter is the definition of the arrhythmia. For many studies, a patient is defined as having atrial flutter if it is the rhythm during the intervention or period of observation (e.g., at the time of TEE or cardioversion). Many patients may have alternating periods of AF and flutter, making clinical distinction of pure atrial flutter difficult. Irani and co-workers[160] performed TEE in 47 consecutive patients with atrial flutter (and without AF by history or Holter monitoring). They found that 11% of patients had LA thrombus, and 31% had LA spontaneous echocardiographic contrast, values similar to those found in patients with AF. Similar to our findings for AF, moderate or severe mitral regurgitation was not protective against thrombus formation for this group.

Jordaens and associates[161] studied 22 patients with atrial flutter with serial transmitral Doppler echocardiography after cardioversion. Analogous to data on AF, they found that 20% of patients had Doppler evidence of atrial standstill immediately after cardioversion. There was a progressive increase in peak A-wave velocity and percentage of A-wave filling over a 6-week period. Based on these data, our recommendation is to treat patients with atrial flutter in the same manner as those with isolated AF. We would generally treat conservatively patients who had atrial flutter in the setting of rheumatic mitral valve disease, a history of thromboembolism, or LV systolic dysfunction, with short-term anticoagulation and screening TEE or 1 month of anticoagulation before elective cardioversion.

## Echocardiography and Guidance of Therapeutic Interventions in Atrial Fibrillation

More than a decade ago, Haissaguerre and colleagues[162] demonstrated that the origin of AF was rapid electrical discharges originating in the pulmonary veins. Subsequently, pulmonary vein isolation has evolved as a moderately invasive percutaneous approach for primary antiarrhythmic therapy for AF by promoting long-term maintenance of sinus rhythm.[163] TEE is often used immediately before pulmonary vein isolation to exclude atrial thrombi as well as to guide transseptal puncture.[164,165] Intracardiac echocardiographic is a viable alternative for guiding transseptal puncture.[166] TEE studies demonstrate a 5% reduction in pulmonary vein diameter and an increase in peak velocity.[167] Decision analysis models suggest that it is cost effective with an absolute stroke risk reduction of 1.2%.[168] Other than LA appendage thrombus, TEE parameters do not appear to be predictive of stroke complications.[169] Postprocedure TTE is often performed to exclude pericardial effusion before resuming anticoagulant therapy.[170] Although TEE can also be used to monitor for pulmonary vein stenosis using both color and pulsed-wave Doppler,[171,172] this complication is

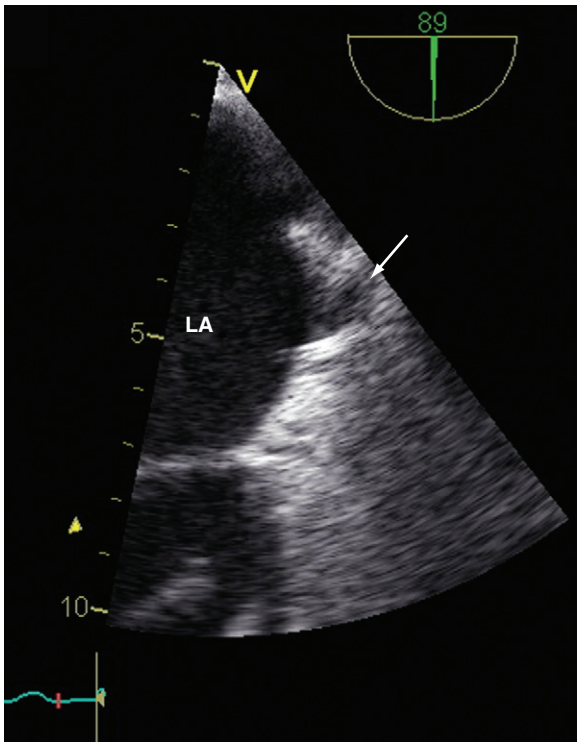

**Figure 42-13 TEE in a patient several months following surgical excision of the LA appendage.** Note the residual LA appendage with thrombus (*arrow*).

fortunately far less common today with use of ablation in the body of the atria (rather than within the pulmonary vein). In addition, use of TEE for identification of pulmonary vein stenosis has largely been supplanted by cardiac CT and/or magnetic resonance angiography because of their less invasive benefits.

Given the close association of LA appendage thrombi and clinical thromboembolism in AF, LA appendage surgical excision, suturing, and stapling[173] are being examined as potential alternatives for patients who are not candidates for warfarin (or dabigatran). Overall, surgical excision is more successful at fully excluding the LA appendage, with a success rate of 73% as compared with only 23% and 0% for suture and stapling, respectively (Fig. 42-13). LA appendage thrombus is common (up to 40%) among those with unsuccessful obliteration of the LA appendage.[173] LA appendage occlusion[174] is another alternative being explored. Each of these procedures is often intraoperatively guided (or confirmed) using 2D or 3D TEE or intracardiac echocardiography.[143]

## Current and Future Areas of Investigation

As the ability of echocardiography to provide detailed structural and functional information about the heart continues to grow, so likely will its role in the evaluation and optimal management of patients with AF. Among the areas of current and future investigation are:

1. Improved methods of assessment of atrial mechanical function with applications of tissue Doppler imaging.
2. Randomized prospective studies to further define the resolution of atrial thrombi using warfarin versus dabigatran (and/or other warfarin alternatives).
3. Prospective studies examining the frequency of silent cerebral embolism after cardioversion using conventional therapy (warfarin versus dabigatran).
4. Assistance in localization of structural abnormalities and foci of abnormal electrical activity, including assistance in radiofrequency ablation of arrhythmic foci.
5. Comparison of 2D and 3D TEE and intracardiac echocardiography for the identification of atrial appendage thrombi.
6. Identification of clinical or echocardiographic indexes that predict recurrence of AF or identify a group at low risk for thromboembolism so as to minimize postcardioversion anticoagulation.

### KEY POINTS

- LA volume (normalized for body surface area) is preferred for characterization of atrial size.
- Increased LA size is a risk factor for the development of AF.
- TEE is highly accurate for identification of atrial thrombi and superior to TTE.
- For patients with AF, TEE risk factors for clinical thromboembolism include LA appendage thrombus, severe spontaneous echocardiographic contrast, depressed (≤0.2 m/s) atrial appendage ejection velocity, and complex aortic plaque. The clinical CHADS2 risk score also correlates with thrombus risk.
- TEE will identify atrial thrombi in approximately 13% of patients presenting with new-onset AF of more than 2 days' duration. The vast majority of thrombi are within or involve the LA appendage.
- In concert with precardioversion therapeutic anticoagulation with unfractionated heparin, low molecular weight heparin, warfarin, or dabigatran, a TEE-guided strategy of early cardioversion is comparable to 1 month of precardioversion warfarin (INR 2.0-3.0) with a risk of clinical thromboembolism of <1%.
- After cardioversion, LA appendage mechanical function may be even more depressed. Depression of LA and LA appendage mechanical function may persist for several weeks after cardioversion, emphasizing the need for therapeutic warfarin (INR 2.0-3.0) or dabigatran for at least 1 month after cardioversion.
- For patients with new-onset, nonvalvular AF who have TEE evidence of atrial thrombi, more than 80% of the thrombi will resolve after 1 month of therapeutic warfarin.
- Recovery of atrial mechanical function after cardioversion is related to the duration of AF before cardioversion.
- Data for atrial flutter suggest that the incidences of atrial thrombi and thromboembolism are slightly reduced compared with AF, but that these patients should likely be treated with AF guidelines.
- TEE is increasingly used to guide interventional therapeutic procedures in the AF population, including pulmonary vein isolation and LA appendage exclusion.

Right Ventricular Type
Other Univentricular Physiology Hearts
**Color and Spectral Doppler Imaging**
General
Intracardiac Shunting
Great Arteries

The population of adults with congenital heart disease (CHD) is growing rapidly in the United States.[1-3] Adult patients with CHD have a variety of heart conditions, from simple "holes in the heart" to complex single ventricle anatomy. Some of these patients have undergone palliation or complete surgical repair, and others remain with their native heart condition or present de novo in adulthood. Many childhood patients have a long lapse in medical follow-up examinations and then present later in adulthood with complications of their underlying condition.[4-7] In all of these situations, echocardiography remains the mainstay of diagnosis for patients with CHD.[8-10] There are many approaches to echocardiographic imaging for adult patients with CHD; one of these methods is discussed in this chapter.

First, the positioning of the heart within the chest is addressed, followed by the definition and morphology of the cardiac chambers, valves, and great vessels. Further analysis is based on the segmental approach, which describes the alignments and relationships of the atria, ventricles, and great arteries. These fundamentals are necessary for recognition of the different morphologic cardiac components in the either usual or unusual anatomic arrangements. Next, the chapter reviews the more common anatomic arrangements that create normal hearts and congenital heart anomalies. This review is followed by a review of issues surrounding the assessment of the univentricular heart. Finally, there is a brief discussion on the use of color and spectral Doppler imaging for identification of shunts and valvular lesions in CHD.

Regardless of the specific disease, repair, technology, or technique at hand, the practitioner must keep certain general principles in mind in the imaging of patients with CHD.

- First, the presence of one congenital abnormality often means that more may exist. Completion of a comprehensive two-dimensional (2D) and Doppler evaluation is crucial in view of the possibility of more than one anomaly.
- Second, there may be exceptions to the "rules" of CHD and cardiac development. Thus, the physician must always describe what is present, even if that information seems inconsistent with what is known about conventional CHD lesions.
- Third, no physician or sonographer should hesitate to get a second opinion. Even the best congenital echocardiographers need assistance at times.
- Fourth, the larger body habitus of adults makes echocardiography more difficult than in children. Imaging may require other strategies to complement the echocardiography. These often include transesophageal echocardiography, magnetic resonance imaging, computerized tomography scanning, and cardiac catheterization.[11-15]

## Basic Principles

The cardiologist should expect that adult patients with CHD may not know specific information regarding their heart disease. Many of the patients may not familiar with the name of their heart condition or the particular aspects of surgical or catheter-based interventions. Some may understand it was a "hole in the heart" or a "narrow valve" or a "single pumping chamber," but many may not be able to describe it in any detail.[16,17]

The clinician, however, can derive a number of clues from basic patient information, and that information can help guide the physician and sonographer. This information includes:

1. Has the patient had surgery?
2. If so, how many surgeries? Were they sternotomies, thoracotomies, or both?

3. Is the patient's condition cyanotic?
4. Has the patient had any catheter-based interventional procedures?

For example, if the patient reports a "narrow valve," has had no surgeries but a catheter-based procedure, and has an acyanotic condition, one might expect aortic or pulmonary stenosis with a small chance of mitral valve disease. Of course, even with this information, the clinician has to keep an open mind in diagnosis of CHD because patients with CHD may have more than one condition. The echocardiography laboratory needs to be familiar with anatomic variations of CHD. However, although most congenital heart anomalies are well described in the pediatric cardiology literature, the nomenclature for some complex anatomic lesions remains disputed. For example, the segmental relationships of the cardiac structures have been variously classified from an embryologic perspective, a physiologic perspective, and even a surgical or interventional perspective.[18-21] In some cases, no universal agreement exists as to the definition of a ventricle, let alone complete segmental anatomy of certain conditions. Some of these controversies are discussed further this chapter. With these terminology disagreements in mind, this text focuses on identification and description of the cardiac chambers and great vessels, their anatomic alignment, and the position of the heart relative to the systemic venous system and other organs.

## Cardiac Position

The heart is normally positioned in the left chest with the apex pointing leftward. Depending on cardiac rotation in development, the heart may take other positions (or malpositions) that include location in the mid chest, the right chest, or even outside the chest (ectopia cordis).[22,23] The spatial position of a particular structure or organ in the body is known as the situs. The condition in which the heart and the other body organs are found in a usual arrangement is termed situs solitus. This includes a left-sided heart, left-sided stomach and spleen, and a right-sided liver. Departures from this normal organ arrangement are specially defined. For example, a complete inversion of the viscera, which results in a heart positioned in the right side of the thoracic cavity, with a rightward-pointing apex, and inversion of the abdominal organs and lungs, is called situs inversus totalis (Fig. 43-1).[18,20,21] Several other combinations can and do occur. For example, patients might have the heart positioned in the right chest but situs solitus of other organs or the heart positioned in the left chest with situs inversus of the other organs. Both of these situations are often associated with a structurally abnormal heart.[24] A small percentage of patients have an unusual and inconsistent arrangement of the viscera, with the heart positioned in either the mid chest or right or left thorax. This is often referred to as heterotaxy syndrome or asplenia and polysplenia syndromes.[25]

### THE LEFT-SIDED HEART

The normal position of the heart is in the left chest with an apex pointing leftward. In certain cases, because of anatomic abnormalities such as hypoplasia of the left lung, the heart may be located in the extreme left chest. This condition is called levoposition. In this situation, however, the heart usually maintains normal segmentation and connections. In some cases of situs inversus or heterotaxy, the heart may remain positioned in the left side of the chest but is then commonly associated with congenital heart defects.[24,25]

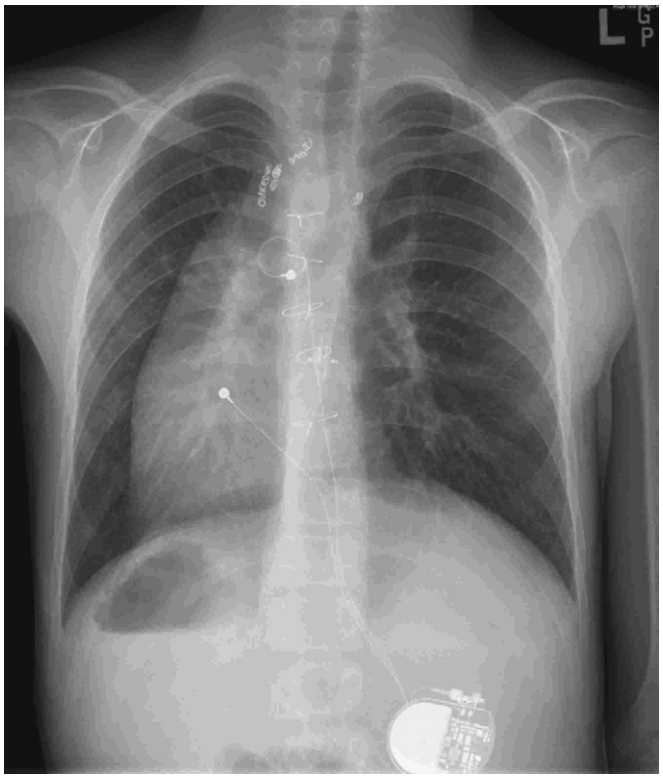

**Figure 43-1 Chest radiograph of a patient with situs inversus totalis.** The cardiac apex *points rightward.* The air bubble of the stomach is visualized in the *upper right abdomen.* The bronchi are also reversed, with a trilobed lung on the left and a bilobed lung on the right. A pacemaker is seen in the abdomen with leads to the atrium and ventricle. Of note, vascular coils are also noted in the *right upper chest.*

### THE RIGHT-SIDED HEART

#### *Anatomy*

A right-sided heart is known as dextrocardia with three basic types: dextroposition, mirror-image dextrocardia, and dextroversion (Fig. 43-2).[22,26]

Dextroposition occurs when mechanical considerations, such as right lung hypoplasia or severe scoliosis, displace the heart to the right side of the thorax. In these cases, the heart retains a leftward-pointing apex. The visceral and atrial positioning is most often situs solitus in this situation. The condition is usually not associated with intracardiac CHD. Mirror-image dextrocardia may be seen with complete situs inversus. In this condition, the heart is positioned in the right thorax with a rightward-pointing apex. The chamber and vessel relationships within the heart are usually normal, but the relative positions of the anatomic components are reversed or "mirror-image" in relation to the normal left-sided heart. A heart with mirror-image dextrocardia often has a right aortic arch and descending thoracic aorta.[23,27] Dextroversion describes a heart that has not rotated the cardiac apex to the left during embryologic development, resulting in a rightward apex with situs solitus or with unusual arrangements of the viscera. As with a leftward heart with situs inversus, these cases have an increased rate of intracardiac congenital heart defects. In some

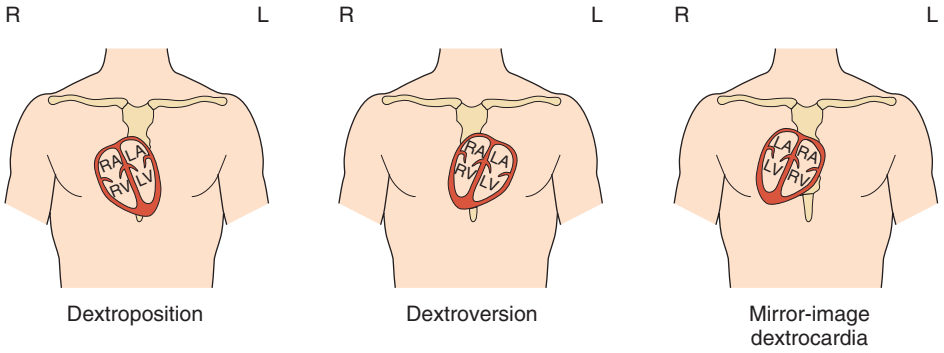

**Figure 43-2 Diagrammatic representation of the types of dextrocardia.** In dextroposition (in situs solitus), the entire heart is shifted to the right chest, either because of a space-occupying mass in the left chest or because of absence of the normal lung volume filling the right chest. Usually, the alignment of the major axis of the heart is normal (pointed toward the left) or rotated slightly vertically; however, the entire heart is shifted to the right of midline or to the retrosternal area. The parasternal long-axis and short-axis views are obtained with the usual orientation of the plane of sound but with the transducer positioned just to the right of the sternum. The apical views are also obtained with the usual orientation of the plane of sound but with the transducer positioned just to the right of the lower sternal border. In dextroversion (in situs solitus), there is failure of apical pivoting. The cardiac apex is to the right of midline, and the atria are usually in their normal positions or shifted slightly to the right. The major axis of the heart is aligned from the left shoulder toward the right hip. The parasternal long-axis view is obtained with the plane of sound oriented in the mirror-image direction of normal. Because the atria are usually normally positioned and the great arteries arise normally from the ventricles, the parasternal short-axis view is obtained with a normal orientation of the plane of sound. In mirror-image dextrocardia (situs inversus totalis), the heart is located in the mirror-image position of normal. Both atria are usually entirely to the right of the sternum, and the cardiac apex is usually in the right fifth or sixth intercostal space at the anterior axillary line; thus, the major axis of the heart is aligned between the left shoulder and right hip. The parasternal long-axis view is obtained from the right second or third intercostal space, with the plane of sound oriented in a mirror-image direction of normal (from left shoulder to right hip). The parasternal short-axis view is obtained from the same transducer location, with the plane of sound also oriented in the mirror-image direction of normal (from right shoulder to left hip). The apical views are obtained with the transducer positioned in the right fifth or sixth intercostal space in the anterior axillary line and with the plane of sound oriented in a mirror-image direction of normal.

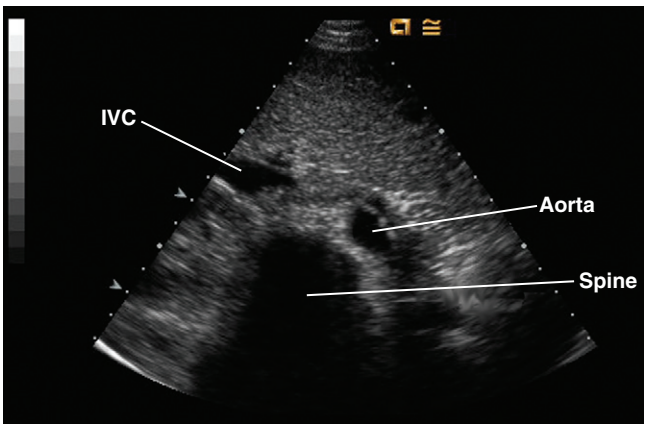

**Figure 43-3 Subcostal short-axis view in a patient with abdominal and atrial situs solitus.** The aorta is leftward and anterior of the spine. The inferior vena cava (*IVC*) is rightward and slightly more anterior.

studies, that correlation reaches 90% of patients with dextroversion having associated congenital heart defects.[25,28]

### *Imaging Approach*

In imaging of the patient with suspected dextrocardia or cardiac malposition, the first step is determination of abdominal situs and cardiac positioning. This is best done by starting with the subcostal view. In the normal subcostal short-axis view, the spine is positioned in the middle with the pulsatile aorta in cross section to the patient's left, just anterior to the spine. The collapsible inferior vena cava is seen in cross section to the patient's right and further anterior of the spine (Fig. 43-3). Ideally, before referral for an echocardiogram for suspected CHD, the patient has had a chest radiograph that shows the liver and stomach bubble and the positioning of the heart within the thorax. In dextroposition, the heart and its segmental connections usually remain normally positioned, albeit located to the right of the midline. The usual echocardiographic views can be used, but they should be adjusted for the rightward positioning and are frequently displaced to the right of the sternum.[23] In mirror-image dextrocardia with visceral and atrial situs inversus, the apex of the heart points toward the right leg and the long axis of the heart is oriented from left shoulder to right leg (Fig. 43-4). The intracardiac connections are often normally related; however, the morphologic right atrium and ventricle are positioned leftward of the morphologic left atrium and ventricle. The apex of the heart is usually positioned as inverted from normal and can be found in the right fifth or sixth intercostal space in the anterior axillary line.

Although further cardiac imaging in this condition can be confusing, the result is that the images either appear normal or are the mirror image of a normally positioned heart. For example, the parasternal long-axis view is obtained with the transducer oriented along the long axis of the heart from left shoulder toward right leg. Once recorded, the images look like those obtained in the usual parasternal long-axis view because there is no right-left orientation, only superior-inferior and anterior-posterior. The parasternal short-axis views are obtained in the orthogonal plane. In the short-axis view, right-left and anterior-posterior orientation is obtained so the image in a patient with dextrocardia looks like the "usual" view, only backwards or right-left inverted. The images obtained in the apical four-chamber view look "backward appearing," similar to the parasternal short-axis view, and they are obtained with the transducer positioned at the apex of the heart. The sonographer or physician should be careful not to invert the image so that it appears normal; this is confusing on later review of the study and misleading regarding the relationship of the heart within the thorax. The imaging positions for dextroversion are similar to that for mirror-image dextrocardia. Often, however, the heart

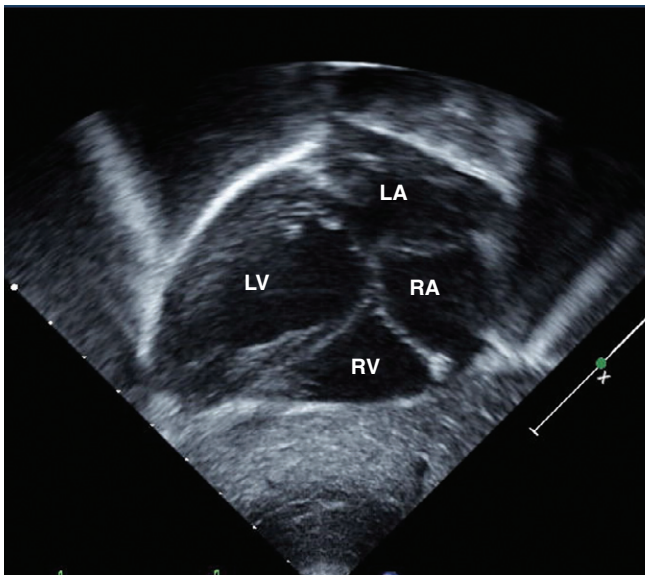

**Figure 43-4 Subcostal four-chamber view of a patient with mirror-image dextrocardia.** The left-sided ventricle has an inferiorly placed atrioventricular valve and is triangular in shape with a trabeculated apex, reflecting a morphologic right ventricle. The right-sided ventricle is more bullet-shaped and smooth walled and consistent with a morphologic left ventricle. The right-sided atrium appears to receive pulmonary veins and is consistent with a morphologic left atrium.

is not positioned as far rightward in the chest; moreover, this condition carries a much higher incidence rate of intracardiac congenital heart abnormalities. In any patient with dextrocardia, views of the aortic arch are obtained in the usual fashion in the suprasternal notch. In these conditions, identification of the presence of right-sided or left-sided arch, descending aorta, and the branching pattern of the head and neck vessels is important.

## Cardiac Morphology

### GENERAL

The heart's anatomic position and function do not always reflect the morphology of a chamber. For example, a left-sided ventricular chamber connected to an aortic outflow is not always a morphologic left ventricle (LV). In certain congenital heart defects, there are absent or atretic valves, chambers, or great vessels. In these cases, identification of the morphology of each chamber becomes more challenging. However, once one is familiar with the usual morphologic landmarks of the cardiac chambers and great arteries, the abnormal anatomic variants and unusual anatomic relationships found in many CHDs become easier to differentiate and recognize (Table 43-1).

### ATRIA

The right atrium is most easily characterized by its appendage, which is a broad-based and triangular structure that lies anterior to the chamber. Often a visible Eustachian valve arises from the orifice of the inferior vena cava, directed toward the mid portion of the interatrial septum. More specifically, the tissue of the valve runs along the inferior portion of the atrium and is directed toward the limbus or the inferior portion of the fossa ovalis (Fig. 43-5). The right atrium is also identified by connections with the suprahepatic portion of the inferior vena cava.

**TABLE 43-1 Morphologic Characteristics of Cardiac Chambers, Valves, and Great Arteries**

| *Morphologic Chamber* | *Identifying Features* |
|---|---|
| Right atrium | Receives inferior vena cava and has Eustachian valve<br>Broad-based and trabecular appendage |
| Left atrium | Receives pulmonary veins (usually)<br>Long and finger-like appendage |
| Tricuspid valve and RV | Atrioventricular valve is trileaflet and has septal attachments<br>Heavily trabeculaed chamber with moderator band<br>Discrete inflow and outflow portions |
| Mitral valve and LV | Atrioventricular valve is bileaflet and attaches to papillary muscles, not septum<br>Chamber is smooth walled |
| Aorta and aortic valve | Trileaflet semilunar valve<br>Gives rise to coronaries, head and neck vessels |
| Pulmonary artery and pulmonary valve | Trileaflet semilunar valve<br>Vessel bifurcates early into right and left branches |

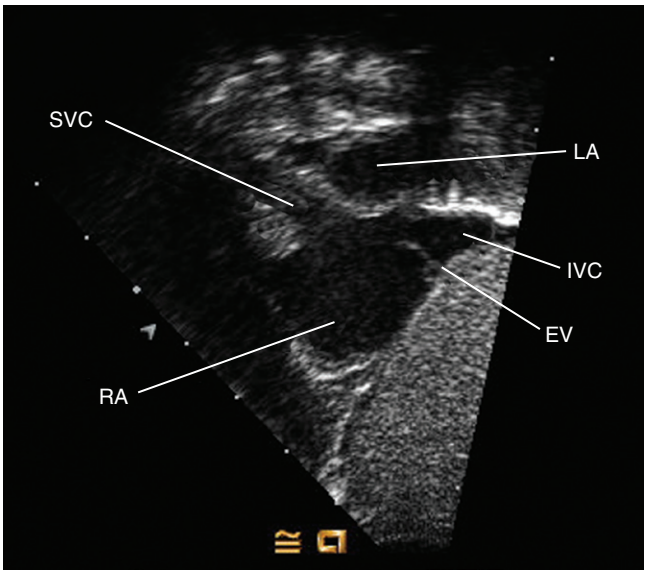

**Figure 43-5 Subcostal sagittal view in a patient with normal return of the superior vena cava (*SVC*) and inferior vena cava (*IVC*) to the right atrium.** The Eustachian valve (*EV*) is visualized near the origin of the inferior vena cava. The left atrium is also shown.

Even with abnormal connections of the superior vena cava, the suprahepatic portion of the inferior vena cava rarely connects anywhere except the morphologic right atrium.[29,30] Finally, the abdominal situs may also help identify atrial anatomy. The atrial situs usually follows the abdominal situs; in situs solitus, with the liver on the right and the stomach on the left, one expects a right-sided morphologic right atrium.[25,28] The left atrium is also best characterized by its appendage, which is a narrow and finger-like or windsock structure that lies anterior to the left atrium. The flap-valve of the foramen ovale, if present, should be found on the left surface of the interatrial septum and is a useful landmark. Finally, the practitioner should look for the connections of at least three individual pulmonary veins, with a minimum of at least one each from the right and left sides, entering an atrial chamber. This finding most always indicates a left atrium.[29,30] However, if the pulmonary veins come to a confluence and empty into an accessory vertical vein before entering an atrial chamber, that chamber is not necessarily a morphologic left atrium.

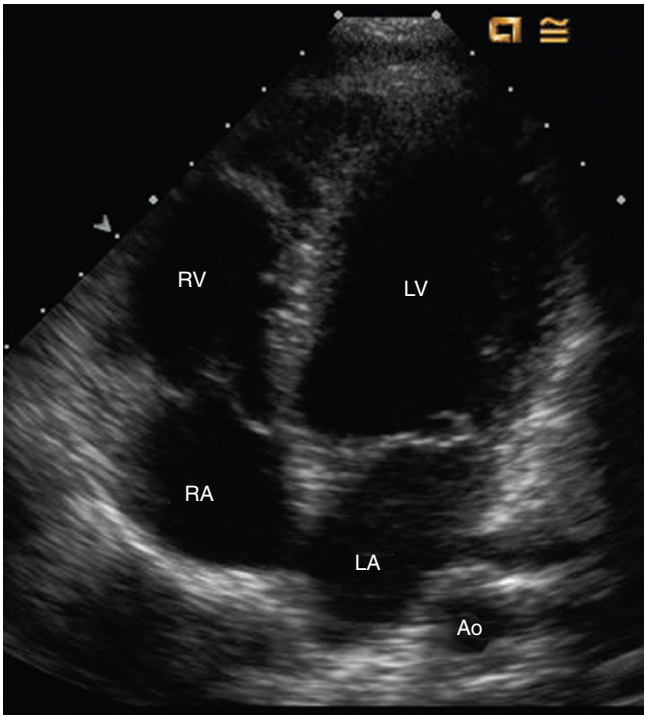

**Figure 43-6 Apical four-chamber view shows the normal relationships of the atria and ventricles.** The moderator band is well seen toward the apex of the trabeculated RV. The tricuspid valve is shown with one leaflet aimed toward the septum and is slightly apically displaced from the mitral valve. The LV is smooth walled. At least two pulmonary veins can be seen entering the left atrium. *Ao,* Aorta.

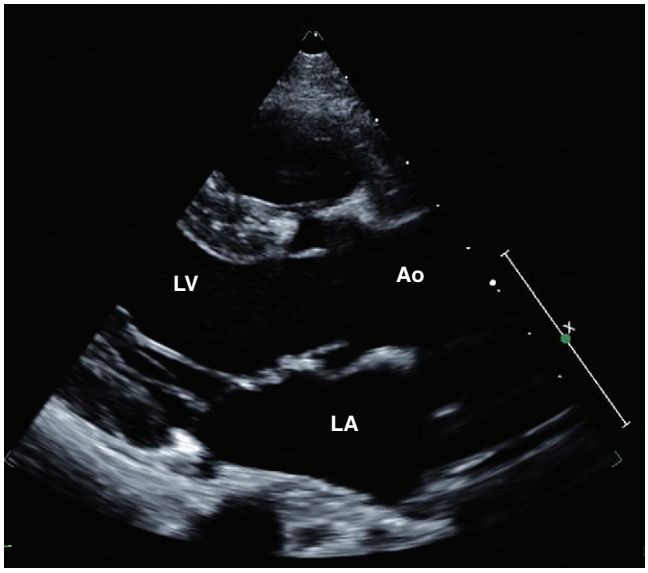

**Figure 43-7 Parasternal long-axis view shows the mitral valve apparatus attaching to papillary muscles away from the interventricular septum.** The mitral annulus is shown in continuity with the aortic valve. *Ao,* Aorta.

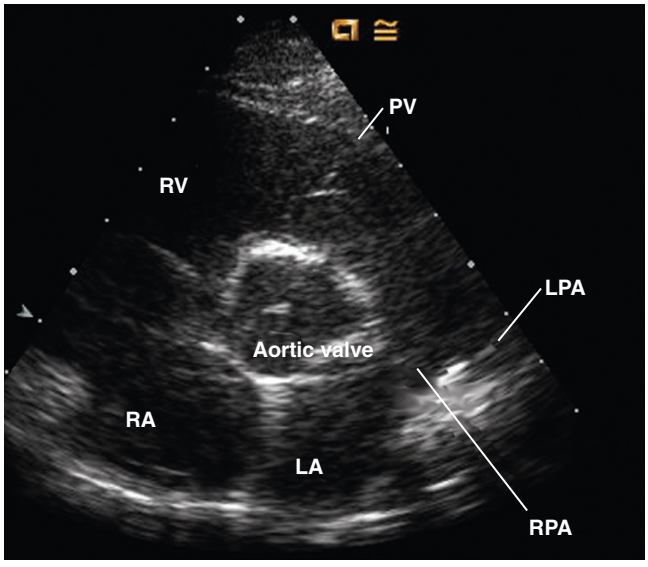

**Figure 43-8 Parasternal short-axis view shows the pulmonary valve anterior and slightly leftward of the aortic valve.** The main pulmonary artery is shown bifurcating into right and left branch pulmonary arteries (*RPA* and *LPA*). *PV,* Pulmonary valve.

## ATRIOVENTRICULAR VALVES AND VENTRICLES

When two atrioventricular valves and two ventricular chambers are found, the valves travel with the morphologically appropriate ventricle. Thus, identification of a tricuspid valve also identifies the right ventricle (RV); identification of a RV signals an associated tricuspid valve. The mitral valve likewise associates with the LV (Fig. 43-6). The tricuspid valve has three leaflets positioned as anterior, posterior, and septal. The leaflets are attached to a network of small papillary muscles on the RV free wall and the interventricular septum. Papillary muscles that arise from the septal surface are distinctive of the RV. As a result, papillary septal attachments are unique to the tricuspid valve and RV. If two distinct atrioventricular valves are present in the heart, then the tricuspid valve is usually the one more apically displaced.[29,30] The RV is also identified by its coarse trabeculations. A number of muscular bands within the chamber cross from the septal to the parietal surface. The most prominent of these is the moderator band, situated in the midcavitary portion of the ventricle (see Fig. 43-6). The relationship of inflow and outflow portions also differentiates the RV from the LV. The RV has a distinct outflow portion that consists of infundibular or conal muscular tissue. Consequently, the outflow semilunar valve and great artery are displaced from the inflow valve, unlike the morphologic LV. The mitral valve is the atrioventricular valve associated with the morphologic LV. The valve has two leaflets, one each in the anterior and posterior positions. Typically, little or no conal tissue separates the LV inflow and outflow, which allows for fibrous continuity of the mitral and LV outflow valve. The mitral valve apparatus is attached to two dominant papillary muscles: the superiorly positioned anterolateral papillary muscles and the more inferior posteromedial papillary muscles. Unlike the situation with the tricuspid valve, neither of the papillary muscles arises from the interventricular septum. The LV chamber itself is smooth walled and bullet shaped in comparison with the trabeculated and somewhat triangular RV. There is no separation of inflow and outflow, so there usually should be continuity between the mitral valve and the LV outflow valve (Fig. 43-7).[29,30]

## SEMILUNAR VALVES AND GREAT ARTERIES

The pulmonary valve is a trileaflet semilunar valve associated with a pulmonary artery (PA). The PA is identified as the great artery that arises from the heart and bifurcates early into right and left branches (Fig. 43-8). In the normal heart, the PA is

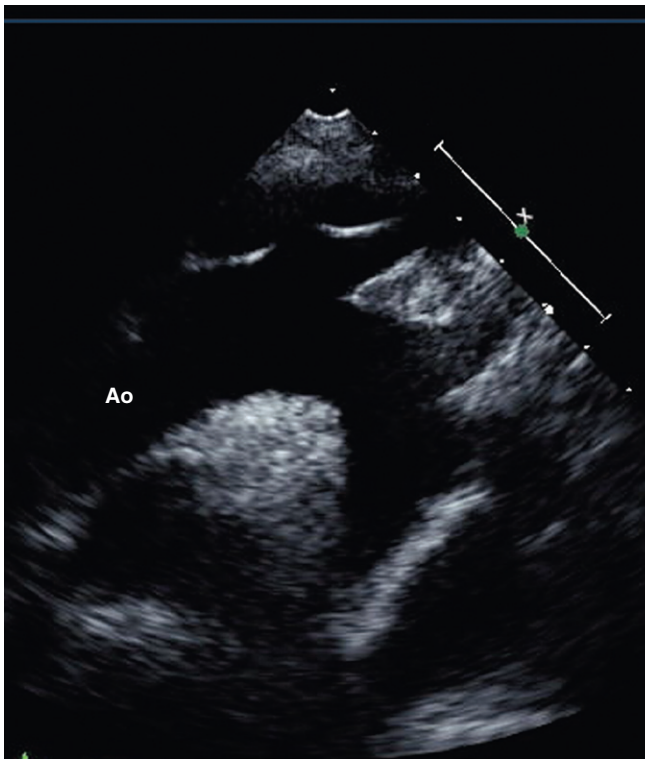

**Figure 43-9 Aortic arch visualized from the suprasternal notch view.** The head and neck vessels are shown arising from the transverse arch. *Ao*, Aorta.

found anterior to the aorta as it arises from the heart. But in CHD, this is not always the case. Thus, the best identification is usually a morphologic description of bifurcation of a vessel. Be aware, however, that there are exceptions. For example, conditions of isolated branch PA atresia are rare but do exist. The aortic valve is a semilunar three-leaflet valve associated with the aorta and aortic arch. The aorta gives rise to the origins of the right and left coronary arteries. The cusps or leaflets of the aortic valve are named right, left, and noncoronary: the right and left cusps are associated with the origins, respectively, of the right and left coronary arteries. About 1% to 2% of people in the United States are thought to have a bicuspid, or two-leaflet, aortic valve.[31] The aorta itself is identified as the great vessel that does not bifurcate early and from which the coronary arteries and head and neck arteries originate (Fig. 43-9). It is a rare case in which the coronary arteries do not arise from the aorta. Although the aortic arch normally arises leftward, it also can be rightward. When the aortic arch arises rightward, it can be associated with mirror-image branching of the head and neck vessels. The sidedness of the arch is most easily identified with evaluation of the direction of the first bifurcating head and neck vessel. If this first artery bifurcates rightward, then the aortic arch is usually leftward; and if the first artery goes leftward, then the aortic arch is most commonly a right arch. If there is no bifurcation of the first head and neck vessel, more involved abnormalities, such as aberrant subclavian arteries that arise from the more distal aorta and vascular rings, should be sought.[32-34] A number of variations on the positioning of the head and neck vessels can exist; they are best defined by tracing each vessel as far as possible in the suprasternal long-axis and short-axis views.

## Cardiac Anatomy

### GENERAL

#### *Segmental Approach*

The heart is anatomically described by the relationships of the atria, ventricles, and great arteries and the relationship of these to the systemic and pulmonary venous connections. Clinically, the segmental approach defines the heart by identifying these relationships within the patient (Table 43-2).

Generally, the easiest way to determine chamber and great vessel alignment is to follow the flow of blood through the heart. In the complete examination, three segments of the heart require description: the atria, the ventricles, and the great vessels. In the normal heart, the concordant arrangement has a right atrium aligned with a RV, the ventricle further aligned with a PA, and a left atrium aligned with LV, further aligned with the aorta. Any other alignment or arrangement between segments is considered discordant.[18,20,21,35]

In the segmental approach, the atria can take three possible configurations. Atrial situs solitus has a normal position, with a morphologic right atrium on the anatomic right side. Atrial situs inversus has reverse positioning, with a morphologic right atrium on the anatomic left side. Atrial situs ambiguous has atrial morphology too difficult to determine, which leaves the sidedness unclear. Often this involves what appears to be two right or two left atria. The atrial situs and abdominal visceral situs are usually similar.[20,21,35]

The ventricular segmental arrangement occurs in one of two positions determined embryologically by the bulboventricular looping of the heart. The first and normal orientation is the dextro-looped ventricles. In this case, the morphologic RV is located more anteriorly and on the anatomic right side. The second possibility is levo-looped, in which the morphologic RV is on the anatomic left side.[20,21,35]

The ventricles give rise to the outflow and great arteries. The description and segmentation of the great artery anatomy is the most confusing and somewhat controversial part of the segmental approach. The usual alignment of the great arteries has the aorta arising from the morphologic LV and the PA arising from the morphologic RV. In that arrangement, the aortic valve is aligned posterior and rightward of the pulmonary valve. In abnormal relations of the great vessels, the aorta arises from a

morphologic RV and the PA arises from a morphologic LV; both great vessels arise from a single ventricular chamber; or only a single outflow is present (truncus arteriosus or atresia of one of the great arteries).[20,21,35] Some definitions of abnormally related or transposed great vessels rely on the orientation of the vessels in relation to each other, noting that transposition occurs when the aorta is anterior to the PA. Other accepted definitions describe transposition as an abnormal alignment of the great vessel with the ventricle. In this definition, vessels are considered transposed if the aorta arises from the morphologic RV and the PA from the LV. Any other relationships of the great vessels to the ventricles, such as double-outlet ventricles, are considered malposed.[20,21,35] Because the morphology may depart in many ways from the normal arrangement, the clinician must describe the anatomy found in the patient, including the relationship of the great arteries to the ventricles and to each other.

### *Concordant and Discordant Arrangements*

Four atrioventricular and ventriculoarterial anatomic or segmental relationships are possible (Table 43-3). Concordance refers to the normal alignments, and discordance refers to abnormal alignments. First, there is normal cardiac alignment with atrioventricular and ventriculoarterial concordance. Second, there is atrioventricular concordance and ventriculoarterial discordance, or d-transposition of the great arteries (Fig. 43-10). Third, one can also have atrioventricular discordance with ventriculoarterial discordance, which is known as congenitally corrected transposition of the great arteries or L-transposition of the great arteries (Fig. 43-11). Fourth, there is atrioventricular discordance with ventriculoarterial concordance. This arrangement is rare; it can occur with different great artery arrangements and includes isolated ventricular inversion, isolated atrial noninversion, and anatomically corrected malposition of the great vessels. As one example, in isolated ventricular inversion, the morphologic right atrium is aligned with a morphologic LV, which is aligned with an aorta. Physiologically it is similar to D-transposition of the great arteries.[18,21,36]

### *Other Nonsegmental Abnormalities*

Apart from the segmental alignment of the heart, two areas of connections between these segments can also contribute to congenital abnormalities. The first is the atrioventricular connection, which consists of the atrioventricular valves and the inlet portion of the interventricular septum. The second is the ventriculoarterial connection, which consists of the semilunar valves and the outflow portion of the ventricular septum.

Abnormalities in the valves or the inlet and outflow regions of the heart require appropriate descriptions along with the segmental anatomy. For example, in common congenital heart anomalies such as a complete atrioventricular canal defect or tetralogy of Fallot, there is usually normal or concordant segmental alignments, but there are inlet or outflow abnormalities. General guidelines regarding such abnormal segmental alignment and segment connections are discussed subsequently.

## DETERMINATION OF ATRIAL SITUS AND VENOUS CONNECTIONS

In many patients with CHD, the segmental anatomy may be unclear or the diagnosis unknown. If so, the cardiac positioning in the thorax and apical direction are best analyzed beginning with the subcostal view. That view also helps determine the situs

**TABLE 43-3 Anatomic Alignments and Relationships**

| *Atrioventricular Connection* | *Ventriculoarterial Connection* | *Congenital Heart Defect* |
|---|---|---|

| Concordant | Discordant | d-TGA |
| Discordant | Discordant | Congenitally corrected TGA |
| Discordant | Concordant | Isolated ventricular inversion or anatomically corrected malposition |

*TGA*, Transposition of the great arteries.

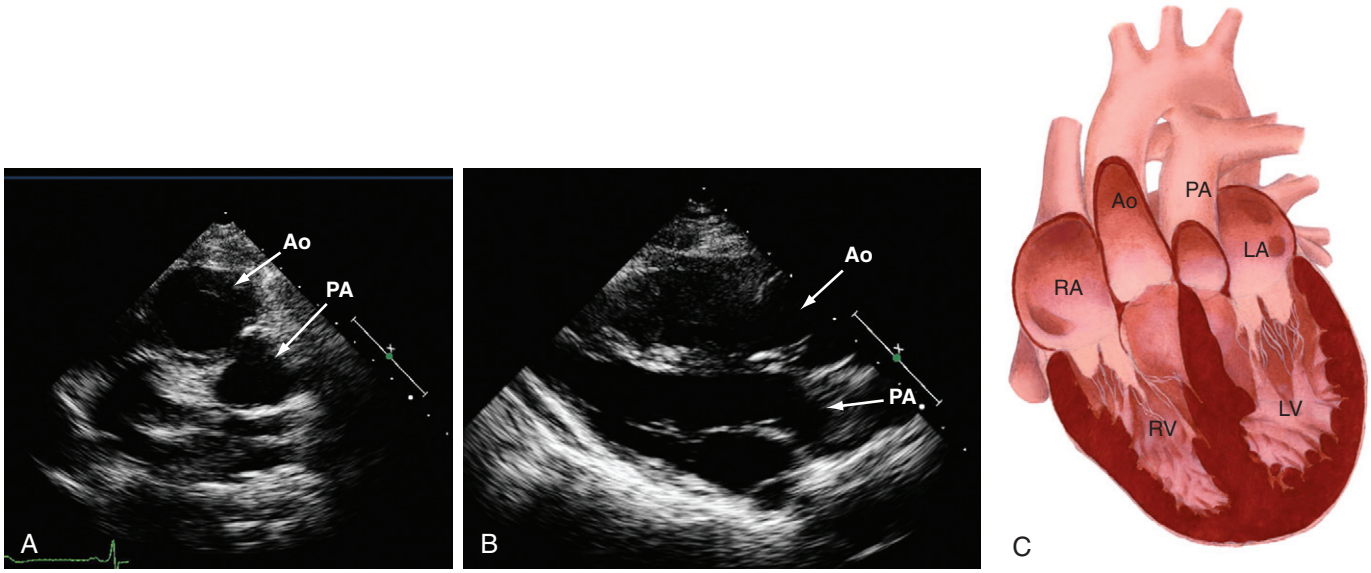

**Figure 43-10 The parasternal short-axis (A) and long-axis (B) views show the great arterial relationships in D-transposition of the great arteries. C,** The pulmonary artery (*PA*) is shown posterior to the aorta (*Ao*). The great vessels are shown as side-by-side in the parasternal long-axis view, which is a typical finding in D-transposition of the great arteries.

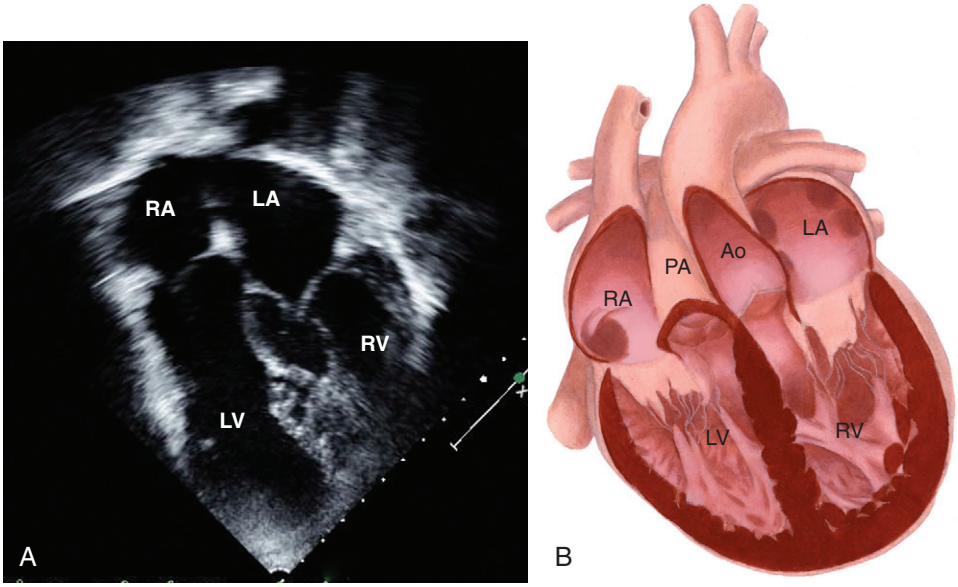

**Figure 43-11 The apical four-chamber view (A) shows the anatomy of L-transposition of the great arteries.** There is atrioventricular discordance. **B,** The morphologic LV is on the anatomic right side and is associated with a mitral valve. The morphologic RV is on the anatomic right side and is associated with a tricuspid valve with a mild Ebstein-like malformation.

of the liver, the position of the inferior vena cava and aorta in relation to the spine, and the relationship of the hepatic portion of the inferior vena cava drainage to the right atrium. In the subcostal short-axis view, the spine, liver, aorta, and inferior vena cava should be identified. In the usual arrangement, the aorta is on the patient's left, whereas the inferior vena cava is noted further anteriorly and rightward (see Figure 43-3). The liver is usually visualized on the patient's right, and often, the air of the stomach can be noted on the left. If the stomach and liver appear reversed, a diagnosis of complete situs inversus or heterotaxy syndrome should be considered. If the inferior vena cava is not present, an azygous or hemiazygous vein, positioned just to the right or left of the aorta, respectively, should be sought. Be aware that in certain cases the aorta may descend on the right side of the spine.[37] The connection of the inferior vena cava to the atrial chamber is often visible with sweeping anteriorly in the subcostal short-axis view. When the hepatic portion of the inferior vena cava is present, the chamber is almost always a morphologic right atrium (see Figure 43-5).[18,20,21] Visualization of the right atrial appendage in the subcostal short-axis view can also help confirm the anatomy, but the appendage may be difficult to see in adults with larger body habitus. The superior vena cava usually is visualized draining into a morphologic right atrium after the transducer is rotated into the subcostal sagittal view. This view may be difficult to obtain in some adults. The right-sided superior vena cava may also be seen in the suprasternal short-axis view aimed rightward of the aorta (Fig. 43-12). If the superior vena cava is not seen in these views or appears small or an innominate vein is absent, consider the diagnosis of a persistent embryologic left-sided superior vena cava. If the right superior vena cava is not visualized in any view entering the right atrium, and the patient has had heart surgery, the superior vena cava has possibly been attached directly to the right PA (Glenn shunt); this anatomy should be investigated. In some cases, particularly in patients with heterotaxy syndrome, both right and left superior vena cavas may be present.[25,28] A persistent left superior vena cava is

**Figure 43-12 The superior vena cava is well seen to the right of the aorta in the suprasternal short-axis view angled rightward.** The right pulmonary artery (*RPA*) is also visualized. *Ao,* Aorta; *SVC,* superior vena cava.

seen with failure of the embryologic left superior vena cava to regress. This has been reported to occur in 0.3% to 0.5% in the general population and in up to 4% to 5% of those with CHD.[24,38,39] A left superior vena cava often explains a coronary sinus that appears prominent in the apical view or is easily visualized in the parasternal long-axis view posteriorly in the

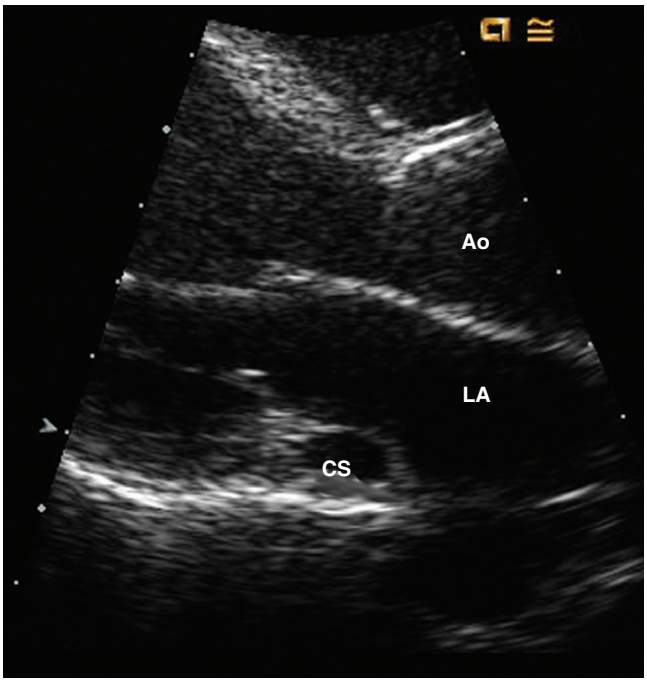

**Figure 43-13 Parasternal long-axis view shows a prominent coronary sinus (*CS*).** The most common association with this finding is a persistent left superior vena cava. *Ao,* Aorta.

left atrium (Fig. 43-13). (If no left superior vena cava is present, the dilated coronary sinus may also be explained by anomalous pulmonary venous drainage into the coronary sinus.) Although the left superior vena cava typically drains to the coronary sinus, it occasionally drains directly to the left atrium.

The subcostal sagittal view with aim leftward or the parasternal short-axis view often best shows the left superior vena cava draining into the coronary sinus near the level of the mitral annulus. In addition, the suprasternal short-axis view aimed to the left of the aorta, following inferiorly toward the coronary sinus, is also useful. Dual superior vena cavas are often best seen in the suprasternal short-axis view.[38,39] Drainage of all four individual pulmonary veins should be defined as well as possible to allow the clinician to evaluate a diagnosis of total or partial anomalous pulmonary venous return and to help determine the morphologic left atrium. Unrepaired total anomalous pulmonary venous return in an adult or older teen is very unusual because this almost always must be diagnosed and fixed in childhood. However, other abnormalities of the pulmonary veins might be diagnosed in adulthood, including partial anomalous venous return (one or two pulmonary veins returning to the systemic venous system or right atrium directly) and cor triatriatum.[40]

Identification of all four pulmonary veins on transthoracic imaging often is not possible in adults; typically, transesophageal imaging or another imaging modality is needed. In infants and children, the individual drainage of the pulmonary veins is best seen in the subcostal four-chamber view, the parasternal short-axis view, or a lower window in the suprasternal short-axis view. Color Doppler imaging is very helpful in identification of the orifice of the individual veins. If drainage of the individual pulmonary veins into the left atrium is not identified, and a right-to-left shunt is identified at the atrial level, a pulmonary venous confluence with a vertical vein connection to the systemic venous system should be sought. In this case of total anomalous pulmonary venous return, the confluence most often lies posterior to the left atrium and is visible in the parasternal long-axis, suprasternal, or subcostal view, depending on whether the drainage is intracardiac, supracardiac, or infracardiac, respectively. Pulmonary veins can also have mixed drainage, with individual veins seen draining to the left atrium, directly to the right atrium or the coronary sinus. In partial anomalous pulmonary venous return, usually two or three veins are seen entering the left atrium. The other veins, most commonly from the right side, usually enter the superior vena cava or the right atrium directly. This may occur in association with an atrial septal defect, particularly of the sinus venosus type. However, the partial anomalous pulmonary venous return is an isolated finding in 20% of cases.[40-42] Patients with partial anomalous pulmonary venous return often present as having right atrial and ventricular enlargement of uncertain etiology.

In rare cases, the pulmonary veins can drain to the left atrium but have incomplete integration with it. This condition is known as cor triatriatum and occurs when a membrane is present in the left atrium that separates and prevents some or all of the pulmonary veins from draining through the corresponding atrioventricular valve. Physiologically, this condition can be asymptomatic until adulthood if mild. However, the condition may mimic mitral stenosis and be symptomatic in childhood if severe.[43,44]

One further distinction regarding atrial anatomy should be mentioned. In rare conditions known as heterotaxy syndromes, the atrial and visceral situs are unusual and may be difficult to define. In some of these cases, the morphology of the two atria may look similar and the two chambers may resemble dual right or dual left atria. These findings are often associated with abnormal visceral anatomy. If dual atria are identified, other congenital heart defects should be sought. Abnormalities of the systemic and pulmonary veins and inflow and outflow anomalies, such as atrioventricular canal defect or double outlet RV, are commonly associated with heterotaxy syndromes.[25,28]

## DETERMINATION OF ATRIOVENTRICULAR VALVES AND VENTRICLES

Once the atrial arrangement has been identified, the alignment with the ventricle or ventricles is next to be defined. This is simplest with two ventricular chambers and two atrioventricular valves. As mentioned, the atrioventricular valve follows the chamber morphology. If there are two well-formed ventricular chambers, attempts are then made to morphologically distinguish a RV from a LV. In identification of ventricles, the evaluation for shape, trabeculations, and a moderator band is best done in the apical four-chamber view, with further use of the parasternal long-axis and short-axis views (see Fig. 43-6). If there are well-formed atrioventricular valves and interventricular septum, then the valve attachments to the interventricular septum may also help differentiate the morphology of the chambers. Only a morphologic RV has an atrioventricular valve with septal attachments. A single dominant ventricle or a univentricular heart poses further difficulties and is covered in more detail subsequently in the chapter. The atrioventricular valves require description and interrogation in their own right, not just in relation to the ventricles. The valves may be

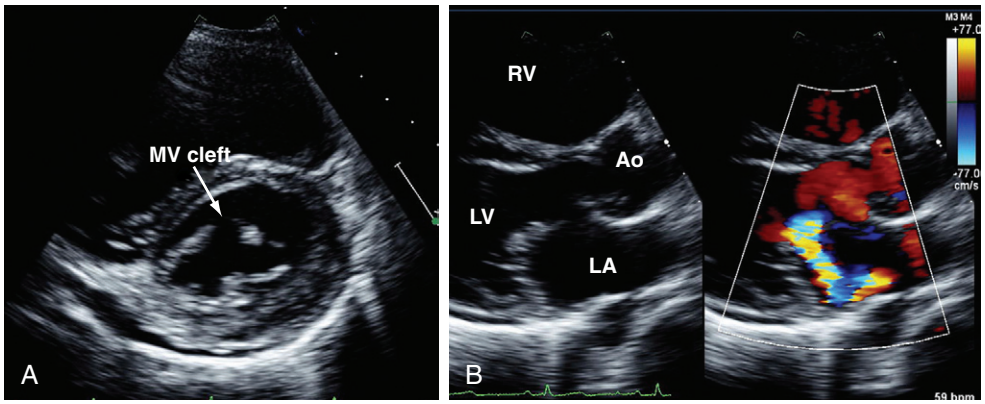

**Figure 43-14 Parasternal short-axis view at the level of the mitral valve shows a small cleft in the anterior leaflet.** Parasternal long-axis view shows mitral regurgitation through the cleft in the anterior leaflet. *MV,* Mitral valve.

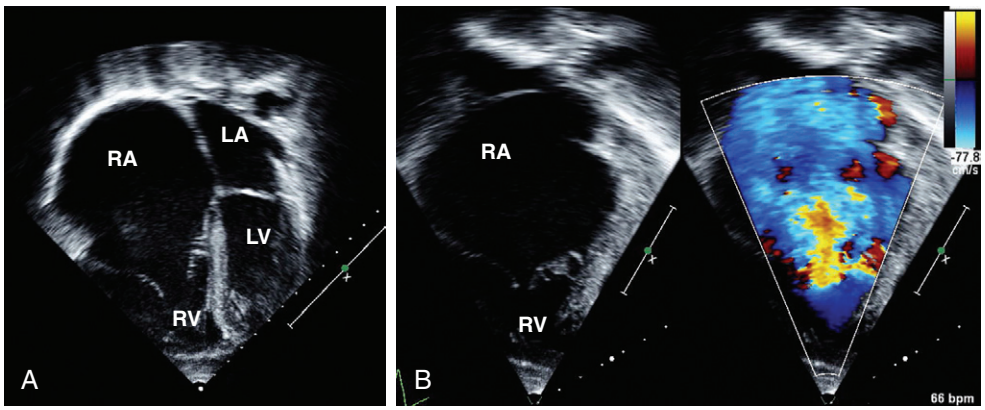

**Figure 43-15 Apical four-chamber view shows a patient with severe Ebstein anomaly of the tricuspid valve.** There is apical displacement of the tricuspid valve. The second image is focused on the right-sided chambers and shows severe tricuspid regurgitation.

morphologically abnormal or abnormally positioned even though the segments are concordant. The valve arrangements and attachments are well seen in the apical four-chamber, parasternal long-axis and short-axis, and subcostal sagittal views. Several arrangements or abnormalities of the atrioventricular valves can occur without corresponding abnormalities of segmentation or other chamber alignments. For example, there may be imperfect closure of the leaflets or abnormalities in the chordal apparatus of one of the two valves. On the mitral side, this can result in cleft, parachute, and arcade valves. A cleft is a separation in the valve leaflet that does not allow for full coaptation and results in mitral regurgitation. A parachute mitral valve involves a single dominant or asymmetric papillary muscle arrangement (Fig. 43-14). An arcade mitral valve is attached by short chords to multiple diminutive papillary muscle heads. The parachutes and arcades can be stenotic, regurgitant, or normally functioning.[45] On the tricuspid valve side, apical displacement and tethering of the septal and posterior leaflets results in Ebstein anomaly (Fig. 43-15).[46]

Another atrioventricular valve abnormality occurs when the patient has a common atrioventricular valve in place of two separate valves, as seen with atrioventricular septal defects. In that case, there is a primum atrial septal defect, an inlet ventricular septal defect, and a single atrioventricular valve with usually five leaflets that separate the atria from the respective ventricles. The most common leaflet arrangements of the single atrioventricular valve are: anterior and posterior bridging leaflets, right and left lateral leaflets, and a right accessory leaflet. Because of the common atrioventricular valve, the right and left sides are notably situated at the same level in the inlet; this differs from the usual position of mild apical displacement of the tricuspid valve relative to the mitral. The common valve may have attachments at the crest of the septum, or there may be no septal attachments at all.[47] In the adult, even if the atrioventricular septal defect has been repaired, the left and right atrioventricular valves remain at the same level.

The partial atrioventricular canal defect, which consists of a primum atrial septal defect and cleft mitral valve, can present unrepaired in adults.[48] The cleft can be best visualized with interrogation of the mitral valve in the parasternal short-axis view. Subaortic obstruction from the typical gooseneck deformity of the LV outflow tract or from accessory septal attachments should be considered in both repaired and unrepaired atrioventricular canal defects.

Other confusing atrioventricular alignments are presented by straddling, overriding, or atretic atrioventricular valves. With straddle or override, the affected atrioventricular valve is at least partially committed to the opposite ventricular chamber, either by the direction of the inflow (straddling) or by the alignment of the valve annulus (overriding).[49,50] When

only one atrioventricular valve is present, and it is not a common atrioventricular valve, the other valve is probably atretic or not fully formed. The most common form of this is atresia of the tricuspid valve with a resultant hypoplastic RV, usually known solely as tricuspid atresia. Congenital heart anomalies with atresia of one atrioventricular valve usually involve very complex anatomy and often a heart with a single dominant ventricular chamber.

With a very rare abnormality of criss-cross atrioventricular valves, the systemic and pulmonary venous flows cross to opposite ventricles in the unoperated heart or the right-sided atrium flows into the left-sided ventricle (and vice versa) without mixing oxygenated and deoxygenated blood. This is an embryologic rotational defect and can occur with atrioventricular and ventriculoarterial concordance or discordance. This defect should be suspected when two atrioventricular valves cannot be visualized in parallel in any of the routine views.[51-53]

### DETERMINATION OF SEMILUNAR VALVES AND GREAT ARTERIES

The relationship of the ventricles to the outflow valve and arteries is most easily described when there are two distinct ventricular chambers and two distinct arterial outflow vessels. In the normally positioned heart, the aortic valve and the origin of the aorta arise from the LV and are posterior and slightly rightward of the pulmonary valve and the PA origin arising from the RV outflow tract. The relationship of the great arteries to the ventricular chambers is well seen in the parasternal long-axis and short-axis views and in the apical four-chamber view (see Figs. 43-7 and 43-8).

From the parasternal long-axis view, the posterior vessel arising from the posterior ventricle should be followed to determine whether it gives rise to an aorta with head and neck vessels or a PA that turns further posteriorly and bifurcates early. These relationships can also be evaluated with sweeping anteriorly from the atrioventricular valves in the apical four-chamber view. The first vessel to come into view is the posterior great vessel; again, one can determine whether it is an aorta or PA on the basis of the early bifurcation or the presence of coronary and head and neck arteries. A great artery can be considered aligned with a ventricular chamber if half or more of that artery orifice is committed to the chamber. The alignment with the ventricular chamber can then be determined as concordant (e.g., aorta with LV) or discordant (e.g., PA with LV). The distinction between concordance and discordance becomes difficult when both great arteries arise from one chamber or there is only a single outflow. As with the atrioventricular valves, this anatomy still requires description. In some of the more recent classifications, these types of great artery relationships are termed malposed rather than transposed. In the double-outlet ventricle, both great arteries arise from a single ventricular chamber that is usually a morphologic RV. In a rare instance, the arteries arise from a morphologic LV. Many definitions and multiple anatomic variations comprise a diagnosis of double-outlet ventricles. In one definition, each great artery has some subarterial conal tissue; thus, neither is in fibrous continuity with the mitral valve. In the simpler definition of the double outlet RV, the anterior vessel arises completely from the RV and the posterior vessel may override the septum but is more than 50% committed from the RV.[53] Truncus arteriosus is another outflow tract abnormality. In this diagnosis, instead of two outflows from one ventricle, there is a single outflow that acts for both ventricles. The single outflow divides into both the aorta and either a main PA or individual branch PAs. As before, this is best diagnosed by following the outflow vessel in the apical four-chamber or parasternal long-axis and short-axis views to determine the branching patterns. In most cases, by the time a patient has reached adulthood, the truncus arteriosus has been repaired in childhood or the patient has severe cyanosis and development of Eisenmenger physiology. Once the individual great arteries have been identified, they must be traced distally as far as possible for examination for additional extracardiac congenital malformations. The imaging of the bifurcation of the normally positioned branch PAs is best performed in the parasternal short-axis view. The pulmonary valve can be seen giving rise to a main PA and the bifurcation of the right and left branches (see Fig. 43-8). The individual branches can also be visualized in the suprasternal notch views, with the right PA best seen in the suprasternal short-axis view (see Fig. 43-12), and the left PA can be seen by tilting slightly leftward of the standard suprasternal long-axis view. The PAs should be interrogated for absence or stenosis of a branch PA or other abnormalities such as a patent ductus arteriosus or aortopulmonary window. The aorta is visualized in multiple views to investigate as many of its segments as possible. The aortic valve and proximal ascending aorta are well seen in the usual parasternal long-axis view. The more distal aortic arch should be visualized from the suprasternal notch long-axis view. Often the entire transverse aortic arch and proximal portion of the descending thoracic aorta can be seen at this angle. It is an excellent view to interrogate for coarctation of the aorta or patent ductus arteriosus. When possible, the descending aorta should also be imaged from the subcostal views in both the short axis and long axis. Examination of abdominal aortic pulsatility can be helpful in determining a more distal coarctation or the severity of a more proximal coarctation.[54] Other extracardiac congenital abnormalities can be seen when imaging the aorta and branch PAs, including a patent ductus arteriosus and an aortopulmonary window. A patent ductus arteriosus is seen as a vascular connection that arises from the aorta, near the typical origin of a left subclavian artery, and enters the left PA. If the ductus is small, it may be difficult to see in 2D imaging but will be visible as continuous left to right shunting from the aorta to the PA with Doppler imaging. If the ductus is large and not discovered until adulthood, it is likely the patient will have elevated pulmonary vascular resistance or Eisenmenger physiology and there may be little residual shunting. An aortopulmonary window is usually seen as a connection between the main PA and the ascending aorta. It is best visualized in the parasternal short-axis view but may be difficult to discern in 2D images; often color and spectral Doppler images are required. As with a large ductus arteriosus, an aortopulmonary window may be hard to diagnose, even with Doppler imaging in adulthood, because the patients with unrepaired conditions have elevated PA pressures and have developed Eisenmenger physiology.

## Univentricular Heart

### GENERAL

As with congenital malformations previously discussed, the univentricular heart engenders its own debate over nomenclature.[18-21,29] Different terms are used to describe these hearts,

including primitive ventricles, univentricular hearts, and univentricular atrioventricular connections. Morphologically, the potential rudimentary chambers include those associated with an outflow vessel (outflow chamber) and those associated with neither an inflow nor outflow vessel (trabecular chamber). Some pathologists prefer to call these types of rudimentary chambers "ventricles" and describe the anatomy from an embryologic perspective. Others define a "ventricle" as a chamber that receives 50% of an inflow valve.[18] Still others describe the anatomy and morphology as found in the heart, such as double-inlet LV or unbalanced atrioventricular canal with hypoplastic LV. For purposes of this section, the univentricular heart refers to a heart in which the atrioventricular connection is predominantly related to a single ventricular chamber that is either morphologically right or left in origin. Occasionally, the morphology of the chamber cannot be determined; these instances should be referred to as univentricular heart of indeterminate type.[55,56] In the adult, the patient with a univentricular heart may present to the echocardiography laboratory either as unrepaired or with a palliative or reparative surgery. Unless one is familiar with all the different nomenclatures, the best practice often is simply to describe the chambers present and the relationship to the valves and great vessels. Determination of the morphology of the dominant ventricular chamber should focus on the anatomic landmarks, the atrioventricular connections, and the ventriculoarterial connections. Although two atrioventricular valves may enter a common chamber, such as in double-inlet LV, there can also be atresia of one of the valves or a common atrioventricular valve.[55-59] In the univentricular heart, the atrioventricular valves are often malformed in some way and may not carry the normal morphologic conditions of a mitral and tricuspid valve. These are more appropriately identified as right and left atrioventricular valves. Moreover, the ventriculoarterial connections can take any arrangement, including normally related, transposed, double outlet, and atresia of one of the vessels.[55-59]

## LEFT VENTRICULAR TYPE

The morphologic LV-type univentricular heart is the more common form of single ventricular chamber found in adults (Fig. 43-16). The rudimentary chamber is usually located at the base, anterior and superior to the ventricle, and often gives rise to the aortic outflow. The orientation of the chambers is most often levo-looped, with the LV somewhat rightward and the rudimentary chamber to the left; dextro-looping, however, also exists.[55-59] The connection between the ventricle and the rudimentary chamber is best seen in the subcostal, parasternal long-axis and short-axis views. In the long-axis view, the opening to the anterior rudimentary chamber is seen leading to an outflow vessel. In the coronal view, both the right and the left atrioventricular valves can be seen opening into the posterior ventricle and the rudimentary chamber is visualized anteriorly.

The atrioventricular valves can also be seen in the apical four-chamber view entering into a common chamber with no intervening inlet septum.[55,56,60] Although there are usually two separate atrioventricular valves, stenosis or atresia of one of the valves can occur, as can entry of a common valve (Fig. 43-17). In most of these patients, the great arteries are transposed, the aorta arises from the rudimentary chamber, and the PA arises from the morphologic LV.[55,56,60]

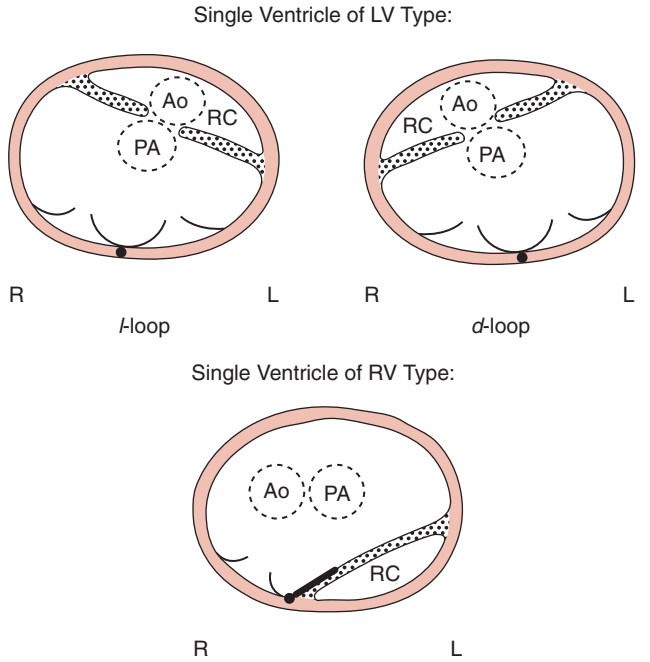

**Figure 43-16 Diagrammatic representation of the anatomic features used to diagnose the type of univentricular heart on 2D echocardiography.** The drawings represent parasternal short-axis projections. In single ventricle of the LV type, the trabecular septum (*stippled*) and rudimentary chamber (*RC*) are anterior to the atrioventricular valves. The trabecular septum runs to the acute or obtuse margin of the heart and not to the crux of the heart (*black circle*). Thus, there is no intervening septum at the crux of the heart between the atrioventricular valves. Most often, the rudimentary chamber is at the left basal aspect of the heart (levo-loop); however, it can also be located less frequently at the right basal aspect of the heart (dextro-loop). Most commonly, the ventriculoarterial connections are discordant with the aorta (*Ao*) arising from the rudimentary chamber and the pulmonary artery (*PA*) arising from the main ventricle (*depicted in the diagram*); however, any ventriculoarterial connection is possible. In single ventricle of the RV type, the rudimentary chamber and trabecular septum are posterior to the atrioventricular valves. The trabecular septum courses to the crux of the heart, and there is usually left atrioventricular valve atresia (*shown*). Most commonly, the ventriculoarterial connections are double outlet from the main ventricle (*shown*); however, any ventriculoarterial connection is possible.

## RIGHT VENTRICULAR TYPE

In adulthood, the less commonly seen condition is the single ventricular chamber of the RV type (see Fig. 43-16). In this case, the rudimentary chamber is located posterior and inferior to the morphologic RV.[55-61] This chamber may be located to the right (levo-loop) or to the left (dextro-loop) of the dominant RV. Some patients with a univentricular heart of the RV type and a common inlet may exhibit other features consistent with heterotaxy syndromes.[25]

The atrioventricular valves may be double inlet, single inlet with atresia of one valve, or a common inlet. The atrioventricular valve communications and the rudimentary chamber are best seen in the apical and subcostal four-chamber views because the valves lie more anteriorly and the rudimentary chamber lies more posteriorly. The rudimentary chamber usually does not give rise to any of the outflow vessels. Most often, the patient has a form of double-outlet RV, with both great arteries arising from the RV, or a single aorta with pulmonary atresia.

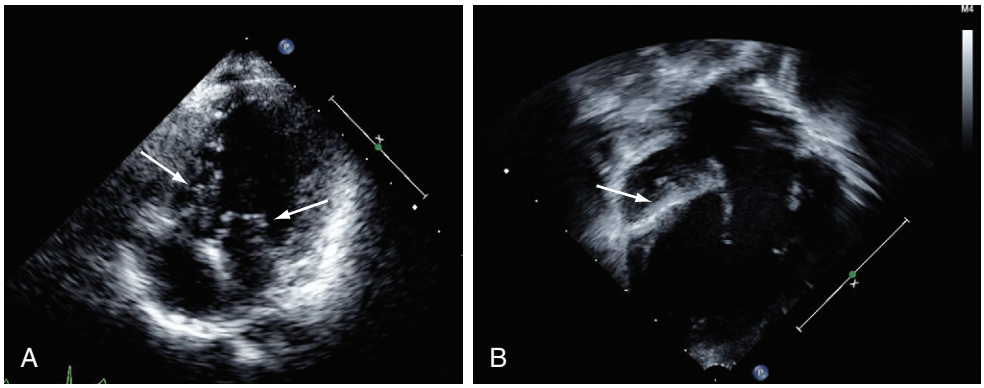

**Figure 43-17 Apical four-chamber views from patients with univentricular hearts of the LV type. A,** The transducer has been tilted posteriorly to image the inlets of the heart. This view is a posterior plane passing through both atrioventricular valve inlets and the crux of the heart; therefore, this plane lies posterior to the trabecular septum and rudimentary chamber. Note the "kissing" atrioventricular valve (*arrows*) with no intervening ventricular septum oriented to the crux of the heart. Both atrioventricular valves empty into the large posterior LV. **B,** Apical four-chamber view showing a univentricular heart with tricuspid atresia. There is a single ventricular chamber and a single left-sided atrioventricular valve. There is a membranous plate (*arrow*) where the right-sided atrioventricular valve would normally be located.

### OTHER UNIVENTRICULAR PHYSIOLOGY HEARTS

Special mention should be made of some subtle differences in describing a few of the univentricular lesions. For example, there are differences in describing a double inlet LV with right atrioventricular valve atresia, as opposed to diagnosing tricuspid atresia, or similarly, the differences between a univentricular heart of the RV type with absent left atrioventricular valve, as opposed to a hypoplastic left heart with mitral atresia. There are anatomic and embryologic differences in the development of these conditions. Visually, however, the differences may be difficult to determine. One echocardiographic distinction can be found in the positioning of the atria and the interventricular septum. In the cases of tricuspid atresia and hypoplastic left heart syndrome, the atria lies over the associated ventricular chamber and the ventricular septum is visualized up to the crux of the heart in the inlet septum. In the other cases of the univentricular heart, the inlet portion of the septum is often missing and the atria is seen over the dominant chamber, not the rudimentary chambers. However, in the adult who has often had multiple surgeries, these distinctions may be quite difficult.

## Color and Spectral Doppler Imaging

### GENERAL

Anatomy is obviously crucial, but it is only one part of the CHD evaluation. Color and spectral Doppler imaging are both critical tools in any comprehensive investigation of congenital heart lesions. In particular, Doppler imaging plays an important role in identification of intracardiac shunt lesions, such as ventricular septal defects; valve abnormalities, such as pulmonary stenosis; and residual embryologic vascular connections, such as a left superior vena cava to the coronary sinus. Similarly, the Doppler techniques help identify the direction of flow. These techniques also quantify flow in intracardiac shunting and valvular abnormalities.

### INTRACARDIAC SHUNTING

Once the anatomy and relationships of the chambers and great artery and venous connections have been determined, abnormalities between those chambers must be investigated.

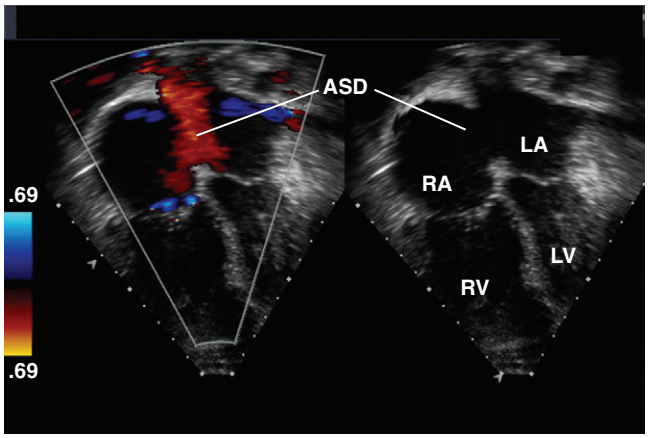

**Figure 43-18 Apical four-chamber view shows large secundum atrial septal defect (*ASD*).** There is also significant RA and RV enlargement.

- The interatrial and interventricular septa are closely examined for intracardiac shunting; and
- The atrioventricular and semilunar valves are interrogated for stenosis and regurgitation, regardless of the positioning within the heart.

Moreover, with univentricular hearts or single ventricles, determination of any connection between the ventricular chamber and rudimentary outflow chamber is crucial. It is important to determine whether there is obstruction in this region. Finally, the aorta and PAs are interrogated for stenosis at any point along the anatomic course. Atrial shunts are sought in the interatrial septum in multiple views. These views include the apical four-chamber, parasternal short-axis, and subcostal sagittal planes (Fig. 43-18). The subcostal view is often helpful because it shows the secundum septum and the venosus septa of the inferior vena cava and superior vena cava. However, in many adults, the subcostal images may not be clear. If an interatrial shunt is identified, the direction and velocity of flow between the interatrial chambers are reported. The degree of shunting can be estimated by the degree of RV enlargement. Alternatively, it can be determined quantitatively by calculating a pulmonary to systemic flow ratio, using the flow across the pulmonary valve and flow across the aortic valve in an otherwise structurally normal heart.[62]

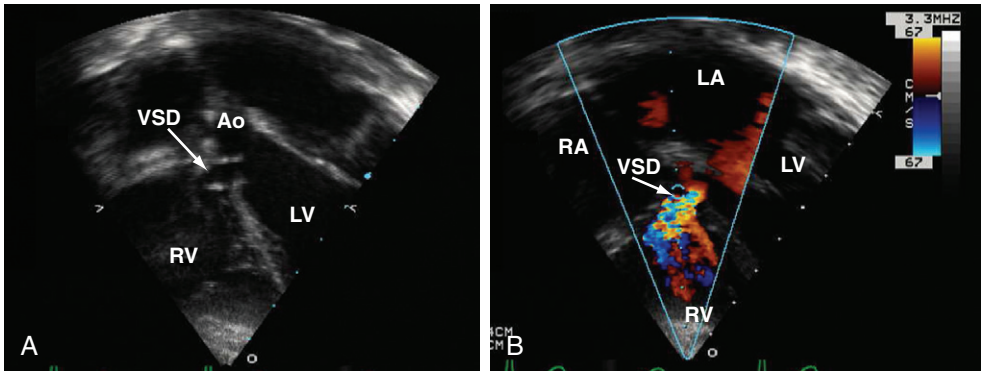

**Figure 43-19 Apical four-chamber views with and without color Doppler imaging show a perimembranous ventricular septal defect (*VSD*) with left-to-right shunting.** *Ao,* Aorta.

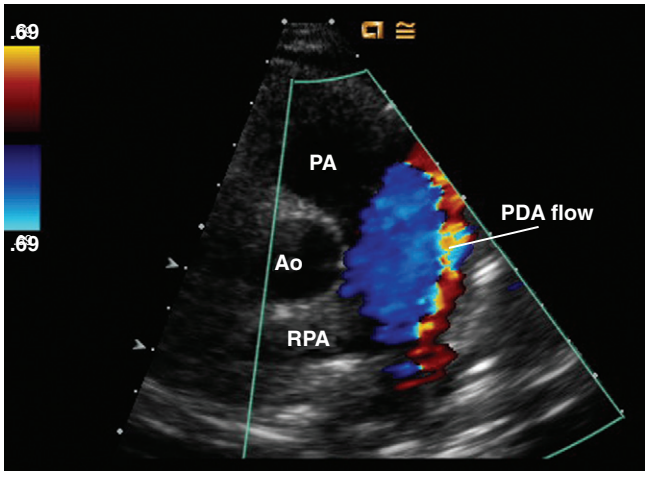

**Figure 43-20 Parasternal short-axis view with color Doppler imaging shows the left-to-right shunt (*red flow*) of the patent ductus arteriosus (*PDA*) into the main pulmonary artery (*PA*).** *Ao,* Aorta; *RPA,* right branch pulmonary artery.

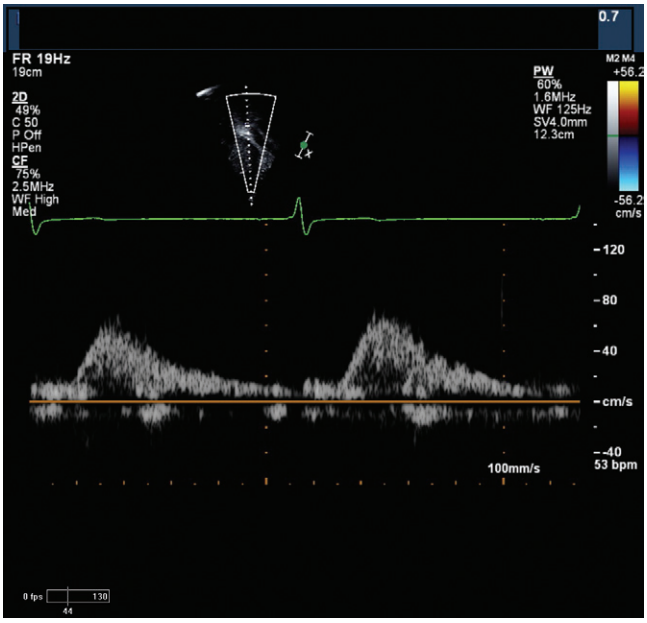

**Figure 43-21 Spectral Doppler profile of the descending aortic flow shows low peak velocity with an antegrade run-off into diastole.**

The interrogation for interatrial defects requires careful attention. With other signs of an intracardiac shunting, such as unexplained RV enlargement, the interrogation needs to include the venosus and primum portions of the septum. If the images are limited by body habitus, a saline solution bubble contrast study may be necessary.

Like the interatrial septum, the interventricular septum is interrogated in multiple views. These include the apical four-chamber, parasternal long-axis, and short-axis views (Fig. 43-19). For each view, imaging from the apex to the base of the septum is important. In the apical four-chamber and parasternal long-axis views, the transducer is aimed anteriorly and posteriorly to interrogate the outflow and inflow portions of the septum, respectively. The sector width should be narrow, and the color gain decreased, to identify smaller shunts. As with atrial level shunting, the direction and velocity of flow should be estimated with both color and spectral Doppler imaging. Note that with some serpiginous, or small, muscular defects, velocity interrogation may be inaccurate.

## GREAT ARTERIES

As with the normal heart, complete evaluation for valvular stenosis and regurgitation with color and spectral Doppler imaging is important. In CHD, several anomalies discussed in relation to the aortic arch and PA are better defined with Doppler interrogation. The aortic arch is best visualized in the suprasternal views. Color and spectral Doppler interrogation are investigated for flow acceleration, particularly in the area of the isthmus just at, or distal to, the left subclavian artery origin. Turbulence in this area may suggest a coarctation or a patent ductus arteriosus. The small ductus is identified as having continuous left to right shunting from the aorta into the PA (Fig. 43-20), whereas the larger ductus may have low velocity or bidirectional shunting if the patient has development of Eisenmenger physiology. In the case of a coarctation, there is increased velocity of flow across the narrowed area with persistent antegrade diastolic run-off. The downstream and abdominal aortic flow is also interrogated in the subcostal view to evaluate for blunting of pulsatile flow or persistent diastolic run-off (Fig. 43-21).

The branch PAs are best interrogated with Doppler imaging in the parasternal short-axis and suprasternal views for stenosis or other flow abnormality. If a patent ductus arteriosus is suspected, the diastolic flow into the PA from the aorta is often seen with color in these views. The PA branches can also be interrogated in the subcostal sagittal view if the patient has good subcostal images.

## KEY POINTS

- The segmental approach begins with the identification of the atrial and abdominal situs and continues with the identification of ventricular and arterial relationships.
  - The atria are defined by the appendages and by the systemic and pulmonary venous connections.
  - The right atrium has a broad appendage and is associated with the suprahepatic inferior vena cava.
  - The left atrium has a narrow appendage and is associated with the pulmonary venous return.
- The RV is recognized by the presence of a moderator band and association with a tricuspid valve, and the LV is bullet shaped and is associated with a mitral valve.
  - The tricuspid valve has three leaflets and attachments to the interventricular septum.
  - The mitral valve has two leaflets attached to papillary muscles opposite the interventricular septum.
  - In the normal heart, the tricuspid valve is more apically displaced.
- The great arteries are denoted by the bifurcation patterns as they exit the heart. Either vessel can be anterior or posterior, and either can be right or left.
  - The aorta bifurcates more distally and gives rise to the coronary arteries and head and neck vessels.
  - The PA bifurcates early into the right and left PA branches.
- Normal segmental alignment is when the right atrium is associated with the RV and the PA and the left atrium with the LV and the aorta.
- The most common abnormalities with discordant relationships are:
  - D-transposition of the great arteries with atrioventricular concordance and ventriculoarterial discordance; and
  - L-transposition of the great arteries or congenitally corrected transposition of the great arteries with atrioventricular discordance and ventriculoarterial discordance.
- Anatomic abnormalities of the atrioventricular and semilunar valves are common, even with normal segmentation.
  - Some of the more frequent findings include bicuspid aortic and pulmonary valves, Ebstein-like tricuspid valves, and cleft mitral valves.
  - Abnormalities can also include common, atretic, straddling, and overriding atrioventricular valves and common, overriding, and atretic semilunar valves.
- The univentricular heart refers to a heart in which the atrioventricular connection is predominantly related to a single ventricular chamber that is either morphologically right or left in origin.
  - In the LV type, the rudimentary chamber is usually anterior and superior and gives rise to the aorta.
  - In the RV type, the rudimentary chamber is usually inferior and posterior and is not associated with an outflow vessel.
- Full functional assessment with color and spectral Doppler imaging is required for:
  - All intracardiac valves for stenosis and regurgitation;
  - The atrial and interventricular septa for evidence of shunting; and
  - The aorta and pulmonary arteries for evidence of flow abnormalities and shunts.

Congenitally Corrected Transposition of the Great Arteries (CCTGA or L-Loop TGA)
Tricuspid Valve Atresia
Functional Univentricular Heart

Adults with congenital heart disease are increasingly coming to medical attention.[1] Caring for adults with congenital heart disease was formally recognized as a subspecialty within cardiology at the 22nd Bethesda Conference of the American College of Cardiology in 1990.[2] In 2001, the 32nd Bethesda Conference addressed the allocation of care of these patients and developed a system for grading the complexity of congenital heart disease lesions in adults (Box 44-1).[3] In managing adults with unoperated congenital heart disease, three clinical subgroups emerge: patients with mild or slowly progressive defects who do not require surgical intervention; patients who have eluded previous diagnosis and are still amenable to surgical or transcatheter intervention; and patients with abnormalities that are deemed inoperable. It is the task of the cardiologist to evaluate each patient thoroughly to determine optimal management. The American Heart Association and the American College of Cardiology have developed guidelines for management of adults with congenital heart disease, which includes adults who have not undergone prior surgical repair of certain congenital heart defects.[4]

Echocardiography has been a major advancement for cardiologists in diagnosing and evaluating the anatomic and physiologic status of the adult with congenital heart disease. The technique is not without challenge or difficulty, however. Echocardiographic windows may be limited by body habitus, including chest wall deformities and scoliosis. Congenital or acquired pulmonary disease and cardiac malpositions lend additional impediment to surface echocardiographic imaging. Transesophageal echocardiography (TEE) is useful in circumventing some of these difficulties and plays a major adjunctive role in evaluating and managing adults with congenital heart disease.[5-7] Increasingly, alternate imaging modalities, such as cardiac magnetic resonance imaging (MRI) and computed tomography (CT), are playing important roles in the complete evaluation of adults with congenital heart disease.[8,9]

This chapter includes the clinical features, echocardiographic evaluation, and management of many of the congenital heart defects that are encountered in the adult patient who has never undergone cardiac surgery. Additional discussion of complex congenital lesions can be found in Chapter 43 and of those with prior surgical procedures in Chapter 45.

## Valvular Abnormalities

### BICUSPID AORTIC VALVE

The congenitally bicuspid aortic valve is the most frequent of all congenital heart defects, occurring in approximately 1% to 2% of the U.S. population, and has a male predominance.[10] This is a highly heritable lesion, though a specific genetic abnormality has only been clearly defined for a small subset of families with autosomal dominant inheritance.[11,12] A bicuspid aortic valve is also associated with an increased risk of other left-sided obstructive lesions among relatives.[13] Morphologically, the bicuspid valve may have two equal cusps with a single central commissure, or the cusps may be disparate in size, with an eccentric commissure and the larger cusp containing a raphe.

Functionally, a bicuspid aortic valve may be nonstenotic and nonregurgitant, particularly in adolescents or young adults, of whom as many as one third have no significant functional impairment (see also Chapter 39). Progression of stenosis is common, however, even in valves with mild dysfunction. By the age of 60 years, 53% of bicuspid valves are stenotic, and by the age of 70 years, 73% are significantly stenotic (see Chapter 23).

**Box 44-1**

## ADULT CONGENITAL HEART LESIONS BY COMPLEXITY

**Simple Complexity**
Isolated congenital aortic valve disease
Isolated congenital mitral valve disease (e.g., except parachute valve, cleft leaflet)
Isolated patent foramen ovale or small atrial septal defect
Isolated small ventricular septal defect (no associated lesions)
Mild pulmonic stenosis
Previously ligated or occluded ductus arteriosus
Repaired secundum or sinus venosus defect without residua
Repaired ventricular septal defect without residua

**Moderate Complexity**
Aorto-LV fistulas
Anomalous pulmonary venous drainage, partial or total
Atrioventricular canal defects (partial or complete)
Coarctation of the aorta
Ebstein anomaly
Infundibular RV outflow obstruction of significance
Ostium primum atrial septal defect
Patent ductus arteriosus (not closed)
Pulmonic valve regurgitation (moderate to severe)
Pulmonic valve stenosis (moderate to severe)
Sinus of Valsalva fistula/aneurysm
Sinus venosus defect
Subvalvular or supravalvular aortic stenosis (except hypertrophic cardiomyopathy)
Tetralogy of Fallot
Ventricular septal defect with:
- Absent valve or valves
- Aortic regurgitation
- Coarctation of the aorta
- Mitral disease
- RV outflow tract obstruction
- Straddling tricuspid/mitral valve
- Subaortic stenosis

**Severe Complexity**
Conduits, valved or nonvalved
Cyanotic congenital heart disease (all forms)
Double-outlet ventricle
Eisenmenger syndrome
Fontan procedure
Mitral atresia
Single ventricle (also called double inlet or outlet, common or primitive)
Pulmonary atresia (all forms)
Pulmonary vascular obstructive diseases
Transposition of the great arteries
Tricuspid atresia
Truncus arteriosus/hemitruncus
Other abnormalities of atrioventricular or ventriculoarterial connection not included above (i.e., crisscross heart, isomerism, heterotaxy syndromes, ventricular inversion)

Adapted from Warnes CA, Liberthson R, Danielson GK Jr, et al: Task force 1: the changing profile of congenital heart disease in adult life. *J Am Coll Cardiol* 37(5):1170-1175, 2001 (the 32nd Bethesda Conference).

Of individuals older than 40 years who require aortic valve replacements, about 30% have evidence of a congenitally abnormal valve.[14] The mechanism of progressive valvular dysfunction appears to be a "wear-and-tear" process leading to fibrosis and calcification.

**Box 44-2**

## ASSOCIATED DEFECTS WITH BICUSPID AORTIC VALVE

Ventricular septal defect
Subaortic stenosis
Aortic coarctation or arch hypoplasia
Aortic dilation
Aortic aneurysm
Turner syndrome
Endocarditis

### *Associated Conditions*

Common associations with a bicuspid aortic valve are listed in Box 44-2. Congenitally bicuspid aortic valves have a known association with abnormalities of the aorta (see Chapter 39). Aortic coarctation occurs in a small percentage of patients with bicuspid aortic valve. Aortic dissection is another abnormality recognized for its association with bicuspid aortic valve. Reported studies have shown that 5% to 9% of patients with dissecting aortic aneurysms also have a bicuspid aortic valve.[15,16] Poststenotic dilatation of the ascending aorta has long been recognized in congenital aortic stenosis and has traditionally been attributed to mechanical impingement of a jet lesion eccentrically directed by the domed leaflets. However, the ascending aorta may be dilated even in functionally normal bicuspid valves, raising the possibility that aortic dilation may be caused by a developmental defect affecting both the valve and the aortic root.[17] In fact, an increase in vascular smooth muscle cell apoptosis and increased metalloproteinase activity has been described in the aortic walls of patients with bicuspid aortic valve, suggesting a genetic abnormality of the aortic wall. Periodic echocardiographic assessment of the ascending aorta is indicated in all patients with bicuspid aortic valve regardless of the functional status of the valve itself.

Another group of malformations associated with a bicuspid aortic valve is Shone complex. This complex comprises several levels of inflow or outflow obstruction to the left heart: supramitral ring, congenital mitral stenosis, discrete subaortic membrane, bicuspid aortic valve, and aortic coarctation.[18] Whereas most patients with this complex have undergone treatment in childhood, milder forms may be seen in the adult population, prompting careful assessment of the mitral valve structure, subaortic region, and aortic arch in the adult with bicuspid aortic valve.

Infectious endocarditis is a significant problem for patients with congenital aortic stenosis (see Chapter 22). Unfortunately, it may be the first mode of presentation for a patient with a previously undiagnosed bicuspid aortic valve. Natural history studies of young adults with congenital aortic stenosis found a 35-fold higher incidence of endocarditis in that group than the general population.[19] Progression of valvular infection to the surrounding aortic root may occur if there is a delay in diagnosis and treatment or in the presence of a particularly invasive organism. In a recent investigation of 310 consecutive patients with native aortic valve endocarditis, the presence of a bicuspid aortic valve was associated with a higher risk of abscess formation and more often required early surgical intervention.[20]

### *Echocardiographic Evaluation*

The distinctive echocardiographic features of congenitally bicuspid aortic valve include systolic doming in the parasternal

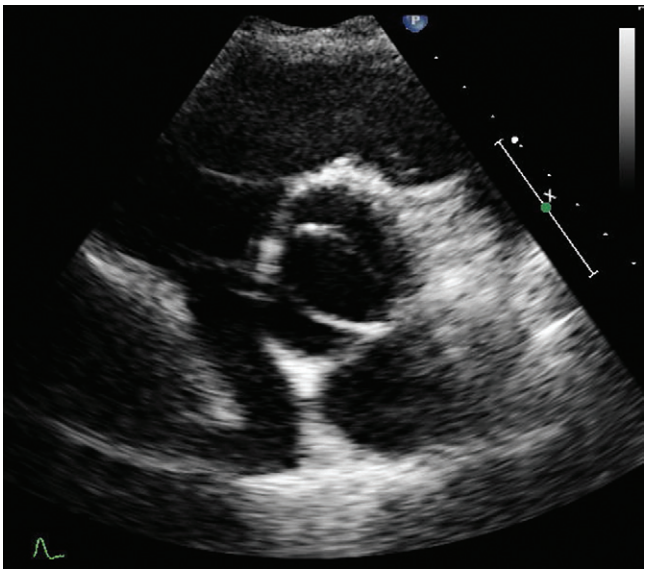

**Figure 44-1** Parasternal short-axis echocardiographic view of a bicuspid aortic valve.

long-axis views and demonstration of a single commissural line with two functional valve cusps in the parasternal short-axis views (Fig. 44-1). Particular care must be taken to assess the valve in systole and in diastole. In patients with asymmetric leaflets and a prominent raphe, the valve may appear tricuspid in diastole; however, the elliptical "football" shape of the systolic orifice indicates that the raphe is not a functional commissure. The valve leaflets often are thickened and fibrotic, more so with increasing age. When extensive calcification occurs, doming may no longer be noted, and the morphology of the cusps in the short-axis views may be difficult to distinguish from calcific stenosis of a tricuspid aortic valve.

Valvular stenosis should be evaluated with pulsed-wave (PW) and continuous-wave (CW) Doppler exactly as one would a stenotic trileaflet aortic valve. Because of the eccentric nature of the stenotic jet in congenital aortic stenosis, Doppler sampling from the right parasternal window may detect the highest systolic velocities and should always be attempted in addition to the usual apical and suprasternal notch sampling. In ongoing follow-up, serial aortic valve areas should be routinely calculated by the continuity equation in addition to peak and mean gradients. The development of left ventricular (LV) dysfunction may mask the progression of stenosis if valve gradients alone are used to assess the severity of stenosis.[21]

Valvular regurgitation is frequently present and may be the predominant functional abnormality in the adolescent and young adult. Careful echocardiographic inspection of the valve leaflets may give an indication as to whether the regurgitation is caused by fibrosis and retraction of the commissural margins of the leaflets, cusp prolapse, aneurysmal enlargement of the root and valve annulus, or valvular destruction secondary to endocarditis. Doppler color flow imaging readily detects the regurgitant flow and can be used for semiquantitation of the degree of aortic regurgitation. Serial assessment of the effect of regurgitation on ventricular size and function should be performed.

The subvalvular left ventricular outflow tract (LVOT) and mitral valve should be carefully investigated for congenital anomalies. Associated coarctation must be excluded, and the size and shape of the ascending aorta should be serially followed.

TEE may be useful if valve morphology is difficult to determine by transthoracic echocardiography (TTE) and if such information would guide a surgical attempt at valve repair. Additionally, more accurate aortic and pulmonary annular dimensions can be measured if a pulmonary autograft (Ross procedure) is planned or to guide the choice of a mechanical valve. Evaluation of endocarditis and aortic root abscess are also indications for a transesophageal study. Quantitative functional assessment of the valve usually is more accurate from the transthoracic approach, although transgastric views usually allow adequate Doppler alignment for valve gradients. Cardiac magnetic resonance angiography or CT can provide additional information regarding the entire aorta and should be considered when echocardiographic windows are nondiagnostic.

### *Management*

Confirmation of the presence of a bicuspid aortic valve and echocardiographic Doppler determination of the severity of stenosis and regurgitation assist in clinical management decisions. Patients with mild to moderate degrees of stenosis or regurgitation require more regular surveillance. The adolescent and young adult with bicuspid aortic valve should have echocardiographic Doppler study every year if the mean gradient is greater than 30 mm Hg, if the peak instantaneous gradient is greater than 50 mm Hg, if the aortic root or ascending aorta measures greater than 3.5 cm, or if root enlargement is progressing at 0.5 cm/year or more.[4,22] First-degree relatives of patients with a bicuspid aortic valve should be screened for its presence.[23] In a large cohort of 642 ambulatory adults with bicuspid aortic valve, 25% experienced a primary cardiac event during a mean follow-up of 9 years, yet the overall mortality rate was not significantly different from population estimates.[24] In a separate analysis of 212 asymptomatic bicuspid aortic valve patients in the community, there was a 42% incidence of cardiac medical or surgical events. Independent predictors of cardiac events included age greater than 50 years and valve degeneration at the time of diagnosis.[25]

Development of chest pain, syncope, heart failure, LV hypertrophy with strain, significant arrhythmia, or a mean Doppler gradient greater than 50 mm Hg are indications for further investigation and possible intervention. In the young adult with supple valve leaflets, balloon valvuloplasty often produces successful results in relieving aortic stenosis.[26,27] Aortic regurgitation, however, generally increases by at least one grade following this procedure in patients with mixed valve disease.[28] Indications for aortic balloon valvuloplasty include the lack of significant valve calcification and a peak-to-peak gradient of greater than 50 mm Hg in a symptomatic patient, or greater than 60 mm Hg in an asymptomatic patient. Intervention is reasonable in the asymptomatic adolescent or young adult with a peak-to-peak gradient of greater than 50 mm Hg when the patient is interested in participating in competitive athletics or wishes to become pregnant.[4]

With newer expertise in surgical aortic valve repair, current indications for surgical intervention in the adolescent and young adult with a bicuspid aortic valve may undergo closer scrutiny. Concerns about valve replacement and anticoagulation in young adults may be unnecessary if initial enthusiasm for aortic valve repair or the Ross procedure is maintained.[29-31] The Ross procedure involves translocation of the patient's native pulmonic valve into the aortic position and replacement of the pulmonic valve with an aortic homograft. The premature calcification and degeneration that have plagued the homograft

and heterologous bioprosthetic aortic valves are not a problem when the patient's own pulmonic valve is used in the aortic position. Some enlargement of the neoaortic sinuses has been observed in the early postoperative period, which does not appear to progress over time. The long-term outcome of an aortic homograft in the place of a translocated pulmonic valve is uncertain, but intermediate follow-up has shown reasonable durability, with a 9% failure rate and a 12% incidence of dysfunction in a large series of patients. The rate of freedom from dysfunction was 87% at 8 years. Use of a pulmonary homograft was associated with lower rates of failure and dysfunction.[32] A recent meta-analysis review of 39 reports of outcomes of the Ross procedure, including 12 adult series, revealed an autograft deterioration rate of 1.14% and right ventricular outflow tract (RVOT) deterioration rate of 0.65%/patient-year.[33]

## PULMONIC VALVE STENOSIS

Congenital valvular pulmonic stenosis is a common anomaly that has a slightly higher prevalence in women. The anomaly generally follows a benign course with increasing age. Because of the benign nature of this lesion, patients with pulmonic stenosis often escape detection during childhood and come to medical attention during their adult years. The second natural history study of congenital heart defects reported the outcomes of 464 adults with pulmonic stenosis and reported that those with mild pulmonic stenosis (peak gradient less than 25 mm Hg) have less than a 5% chance of requiring valvuloplasty during childhood and even less likelihood of requiring intervention in adulthood. Those with moderate degrees of stenosis (peak gradient of 25 to 50 mm Hg) have only a 20% likelihood of requiring an intervention.[34]

Adults with pulmonic stenosis most often have a supple but thickened valve with commissural fusion or a bicuspid valve. Calcification of the valve is uncommon, even in older patients. In a study of 325 patients with congenital pulmonic stenosis, doming was present in 31%, leaflet thickening in 24%, and calcification in 1% to 2%.[35] Poststenotic dilation of the main and branch pulmonary arteries (PA) is common. Pulmonic regurgitation is frequently present but is usually mild. Congenital pulmonic stenosis is often an isolated congenital heart lesion; however, it may be associated with other RVOT lesions, such as acquired infundibular stenosis, supravalvular or branch PA stenosis, or atrial septal defect (ASD). Abnormalities of the pulmonic valve and PA may be present in adults with certain genetic syndromes, such as Noonan syndrome, Williams syndrome, trisomies 13-15 and 18, and congenital rubella syndrome.[36] Specifically in Noonan syndrome, the frequency of pulmonic stenosis is approximately 25%, with 7% of these cases demonstrating a dysplastic pulmonic valve that may not be responsive to balloon angioplasty.[37]

### *Echocardiographic Evaluation*

Acquiring diagnostic two-dimensional (2D) images of the pulmonic valve in adults can be difficult due to the frequent interference of overlying lung tissue. The acoustic windows may be improved by positioning the patient in a high left lateral decubitus position and imaging during held expiration. Apical and subcostal views of the RVOT are also helpful in assessing the patient with pulmonic stenosis. Leaflet thickening may actually enhance echocardiographic visualization of the valve; the presence of poststenotic dilation of the main PA is a helpful clue in previously unsuspected valvular pathology. Classic valvular

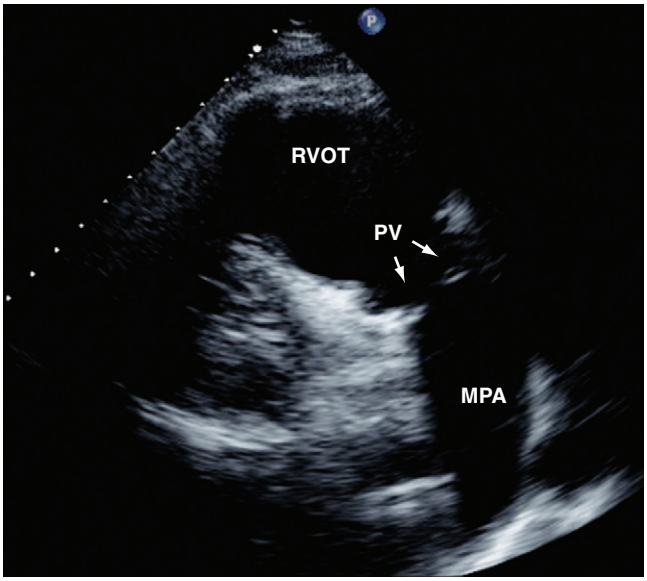

**Figure 44-2 Parasternal long-axis echocardiographic view of the *RVOT* in a patient with valvular pulmonic stenosis.** Valve leaflets are thickened and dome into pulmonary artery during systole (*arrows*). There is a poststenotic dilation of the main pulmonary artery. *MPA*, Main pulmonary artery; *PV*, pulmonic valve; *RVOT*, right ventricular outflow tract.

stenosis causes systolic doming of the leaflets (Fig. 44-2). PW Doppler demonstrates an increase in systolic velocity that begins at the valvular level, and CW Doppler allows estimation of the peak and mean transvalvular gradient. Color flow mapping distinctly delineates the turbulent jet of high-velocity flow into the main PA. Because of the horizontal substernal course of the RVOT, accurate peak Doppler flow velocities may be difficult to obtain from the parasternal approach. Sampling of the highest peak systolic velocity may be more accurate from the apical or subxiphoid approach. In older patients, long-standing valvular obstruction leads to significant RV hypertrophy including the infundibular portion of the ventricle. Dynamic infundibular obstruction thus adds to the valvular gradient over time. Doppler flow patterns sampled within the infundibulum typically demonstrate dagger-shaped, late-peaking systolic signal characteristics of dynamic obstruction.[35]

It is common to use the peak Doppler-derived gradient for assessment of severity of pulmonic stenosis. However, a recent investigation of 132 patients with congenital pulmonic stenosis indicated that Doppler peak gradients may overestimate the clinical severity of pulmonic stenosis, most likely because of pressure recovery effects, and the mean gradient more closely correlates with the measured peak-to-peak gradient by catheter methods.[38,39]

### *Management*

In general, the adult with mild pulmonic stenosis (peak systolic gradient less than 30 mm Hg) requires no specific intervention. Decisions regarding intervention in patients with higher gradients should be individualized based on symptomatology and echocardiographic findings. Box 44-3 summarizes the Class I recommendations for intervention in adults with pulmonic stenosis. Since the first successful report of balloon valvuloplasty for the treatment of pulmonic stenosis, it has now become the

**Box 44-3**

**CLASS I RECOMMENDATIONS FOR INTERVENTION IN ADULTS WITH CONGENITAL PULMONIC STENOSIS**

- Balloon valvuloplasty is recommended for asymptomatic patients with a domed pulmonic valve and a peak instantaneous Doppler gradient greater than 60 mm Hg or a mean Doppler gradient greater than 40 mm Hg (in association with less than moderate pulmonic regurgitation).
- Balloon valvuloplasty is recommended for symptomatic patients with a domed pulmonic valve and a peak instantaneous Doppler gradient greater than 50 mm Hg or a mean Doppler gradient greater than 30 mm Hg (in association with less than moderate pulmonic regurgitation).
- Surgical therapy is recommended for patients with severe pulmonic stenosis and an associated hypoplastic pulmonary annulus, severe pulmonic regurgitation, subvalvular pulmonic stenosis, or supravalvular pulmonic stenosis. Surgery is also preferred for most dysplastic pulmonic valves, and when there is associated severe tricuspid regurgitation or the need for a surgical Maze procedure.

Adapted from Warnes CA, Williams RG, Bashore TM et al. ACC/AHA 2008 guidelines for the management of adults with congenital heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to develop guidelines on the management of adults with congenital heart disease) developed in collaboration with the American Society of Echocardiography, Heart Rhythm Society, International Society for Adult Congenital Heart Disease, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 52:e200, 2008.

treatment of choice for isolated pulmonic stenosis.[40,41] Echocardiographic evaluation is quite helpful, both for determining which patient is most likely to respond favorably and also to follow the results of the dilation. A small pulmonic valve annulus and markedly thickened, cartilaginous leaflets predict a poor response to balloon dilation. In addition, the patient who has acquired significant infundibular hypertrophy may demonstrate a high postprocedural gradient. Regression of hypertrophy does occur in a large percentage of patients after removal of the valvular component of obstruction and does not constitute a contraindication to balloon valvuloplasty.[42] In such cases with apparent residual obstruction, reassessment of Doppler gradients is recommended over the following 6 months before proceeding with a second procedure.

## MITRAL VALVE ANOMALIES

Adults with congenital anomalies of the mitral valve usually present with clinical findings of mitral regurgitation. Thus, when patients are referred for echocardiography of mitral regurgitation, one of several congenital problems in the mitral valve structure may be found. A cleft in the anterior leaflet occurs as either an isolated abnormality or a part of a complex involving defects in the atrioventricular (AV) septum. A double-orifice mitral valve results from abnormal fusion of the endocardial cushions during embryologic development. Patients with this anomaly may have two equal orifices or one large mitral orifice and a smaller vestigial one. Functionally, a double-orifice mitral valve may be either stenotic or regurgitant. A parachute mitral valve has abnormal attachments of the valve leaflets to the papillary muscles. Classically, one large centrally placed papillary muscle is present with all chordae from both leaflets converging on this muscle. Although this arrangement often creates significant inflow obstruction in childhood, the coexistence of redundant leaflet tissue and chordae with strategically placed commissures and clefts may produce a valve that functions with minimal obstruction.[43] A variety of other minor aberrant arrangements of the papillary muscles may be noted echocardiographically in adults that contribute to inadequate coaptation of the mitral valve leaflets during systole. For example, it is common to find an additional posterior papillary muscle with chordal attachments creating a bifid appearance of the posterior leaflet. Hypoplasia of the mural leaflet has been reported.[44] A papillary muscle on the high lateral or anterolateral wall (papillary muscle of Moulaert) may have chordal attachments from the anterior leaflet, resulting in a triangular mitral valve office.[45]

### *Echocardiographic Evaluation*

Echocardiographic assessment of congenital mitral anomalies uses all the usual windows for evaluating the mitral valve. The parasternal short-axis view defines the number of leaflets, a single or a double orifice, the presence of a cleft, and the number and location of the papillary muscles (Fig. 44-3). The orientation of the anterior leaflet cleft is toward the anterior septum in cases of isolated mitral valve cleft and toward the mid or inferior septum in patients with an associated AV canal defect. Long-axis or off-axis views may be needed to follow chordal attachments to their respective papillary muscles. PW, CW and color Doppler all are important to assess the functional significance of these structural anomalies. Doppler quantification of the severity of mitral stenosis and mitral regurgitation is discussed in Chapters 18 and 21. Abnormal flow patterns created by any of the congenital mitral valve lesions predispose to the development of infectious endocarditis. Mitral anomalies are sometimes first detected when a young adult is referred for an echocardiographic search for valvular vegetations in the setting of clinical endocarditis.[46]

### *Management*

Management of congenital mitral stenosis or mitral regurgitation in the adolescent or adult follows similar clinical guidelines to those in acquired mitral valve disease. Intervention for congenital mitral stenosis is indicated for symptomatic patients with a mean mitral valve gradient of 10 mm Hg and for asymptomatic patients with pulmonary hypertension with a mean gradient of at least 10 mm Hg.[47] Balloon mitral valvotomy has been attempted in congenital mitral stenosis but carries a significant risk of valve disruption and should only be attempted in selected cases by centers with experience with this lesion.[48] Intervention for patients with congenital mitral regurgitation should be reserved for those patients with symptomatic severe mitral regurgitation or asymptomatic patients with severe mitral regurgitation and LV dysfunction.[47] With the increasing success of mitral valve repair, delaying surgical treatment to avoid a prosthetic valve has become less imperative.[49,50] Preoperative or intraoperative TEE determination of exact leaflet anatomy and the mechanism of valve dysfunction has been a vital factor in predicting the successful repair.[51] TEE features of interest include the presence and degree of calcification or fibrosis, adequacy and mobility of individual leaflets, site and direction of the regurgitant jet, and presence of leaflet clefts and papillary muscle anomalies.

Note discrepancy in orifice size: Orifice *1* is larger than orifice *2*. **C,** Parachute mitral valve with the anterior and posterior leaflets inserting into the posteromedial papillary muscle (*arrows*). *MV,* Mitral valve.

## TRICUSPID VALVE ANOMALIES

There are several congenital abnormalities that affect the tricuspid valve. The dysplastic tricuspid valve with inflow obstruction and regurgitation is part of the spectrum of hypoplastic right heart. Another congenital abnormality of the tricuspid valve occurs from involvement of the tricuspid leaflets in the septal aneurysm that forms around a perimembranous ventricular septal defect (VSD), resulting in tricuspid regurgitation. The most widely recognized congenital anomaly of the tricuspid valve is Ebstein anomaly. This malformation involves failure of delamination of the septal and posterior leaflets of the tricuspid valve resulting in apical displacement of these leaflets with an enlarged, redundant anterior leaflet. Downward displacement of the functional valve orifice results in an enlarged right atrium (RA) and an atrialized portion of the right ventricle (RV). The functional RV is frequently hypoplastic and functionally impaired. There may be underdevelopment of the infundibular portion of the RV and the PA. An ASD or patent foramen ovale is present in the majority of patients.[52] The clinical presentation of this anomaly is quite variable, ranging from severe cyanosis in the newborn to tricuspid regurgitation and arrhythmia in the adult. Tachyarrhythmias are common, with up to 20% of patients with Ebstein anomaly also demonstrating accessory pathways consistent with Wolff-Parkinson-White syndrome.[53] Diagnosis of Ebstein anomaly in the adolescent or adult is commonly made during echocardiographic evaluation of clicks and murmurs heard on auscultation or as part of clinical investigation for the cause of tachyarrhythmias. Rarely, a patient with unexplained cyanosis or paradoxical embolism is discovered to have Ebstein anomaly.

### *Echocardiographic Evaluation*

Echocardiography is ideally suited for the anatomic delineation of the tricuspid valve. The parasternal inflow view of the right heart, when properly aligned, demonstrates the apical displacement of the posterior leaflet and the elongated sail-like anterior leaflet arising normally from the tricuspid valve annulus. The apical four-chamber plane is optimal for defining the origin of the septal leaflet, the degree of adherence of the anterior leaflet to the free wall, and the size of the atrialized RV (Fig. 44-4). Off-axis apical views may be needed to assess the full extent of the functional RV, because the displacement of the tricuspid leaflets often orients the inflow axis more toward the RV outflow tract. It should be noted that apical displacement of the leaflet coaptation point alone can be seen in conditions that dilate the tricuspid annulus and create incomplete closure of the leaflets, such as an ASD with RV volume overload. These conditions differ from Ebstein anomaly in that the tricuspid valve leaflets all arise normally from the annular plane. To classify a displaced septal leaflet as diagnostic of Ebstein anomaly, the measured distance between the mitral leaflet insertion and the origin of the tricuspid septal leaflet in the apical view should be greater than 8 mm/m$^2$.[54]

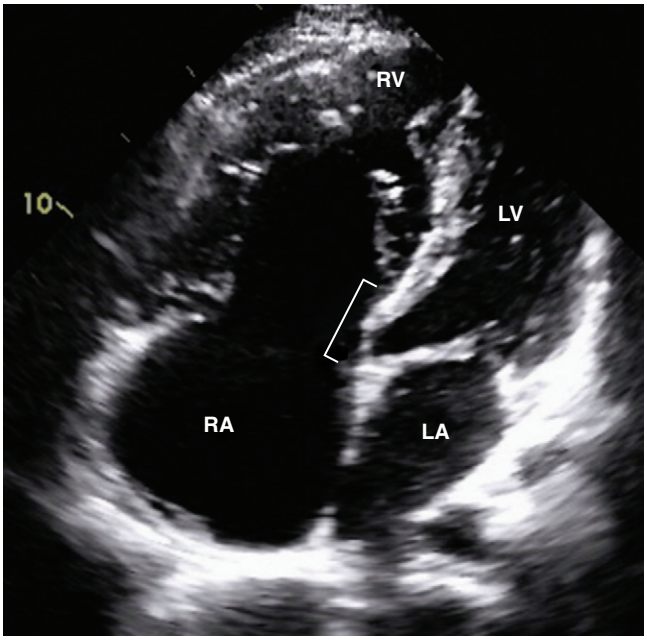

**Figure 44-4 Apical four-chamber echocardiographic view in a patient with Ebstein malformation of the tricuspid valve.** Note marked enlargement of RA with small functional RV. Septal leaflet of the tricuspid valve is apically displaced from the tricuspid valve annular plane (*bracket*).

Echocardiographic evaluation of Ebstein anomaly should also note the relative sizes and contractility of the atrialized and the functional RV. Color flow Doppler detects tricuspid regurgitation, which may be severe or can be present as multiple eccentric jets through commissures in the funnel-like valve

orifice. Inflow obstruction is rarely manifested as an elevated transvalvular gradient; instead, the displaced valve leaflets provide a resistance to forward flow that elevates systemic venous pressure and drives flow right to left across the atrial communication. Careful 2D imaging of the interatrial septum and color Doppler interrogation should demonstrate an atrial septal communication in most patients. Agitated saline contrast injection may be useful if imaging is suboptimal or the shunt is not apparent by color Doppler. TEE provides additional information about the leaflet origins and chordal attachments and better direct imaging of the interatrial septum in adults with difficult TTE studies.

In some individuals with Ebstein malformation, late development of clinical heart failure occurs as a result of LV dysfunction.[55] In some cases, this may be due to myocardial noncompaction.[56] In others, compression of the LV by massive right heart enlargement impairs diastolic filling. With significant distortion of the LV cavity by the enlarged right heart, calculation of the LV volumes and ejection fraction by the simpler echocardiographic methods is difficult. Qualitative estimation of LV function and measures of diastolic function, however, can provide useful clinical information regarding LV performance. Nongeometric indices of ventricular function, such as the myocardial performance index, have also been useful in this patient group.[57] Cardiac MRI is a useful imaging modality to evaluate the RV volume and function (Fig. 44-5).

### *Management*

Patients with Ebstein malformation frequently remain asymptomatic, leading full and active lives despite marked structural abnormality of the tricuspid valve and RA enlargement. Although some centers have suggested that tricuspid valve repair should be considered in the asymptomatic patient if the cardiothoracic ratio is greater than 65%, many centers restrict intervention to those with progressive cyanosis, severe tricuspid regurgitation, ventricular failure, paradoxical embolism, or intractable arrhythmia. Surgical repair of the abnormal tricuspid valve is preferred to valve replacement if the anatomy is favorable, with good results reported.[58] Echocardiographic assessment of the size, mobility, and degree of displacement of the leaflets, attachments of the leaflets to the RV free wall, and function of the RV is critical for the selection of patients most suitable for valve repair.

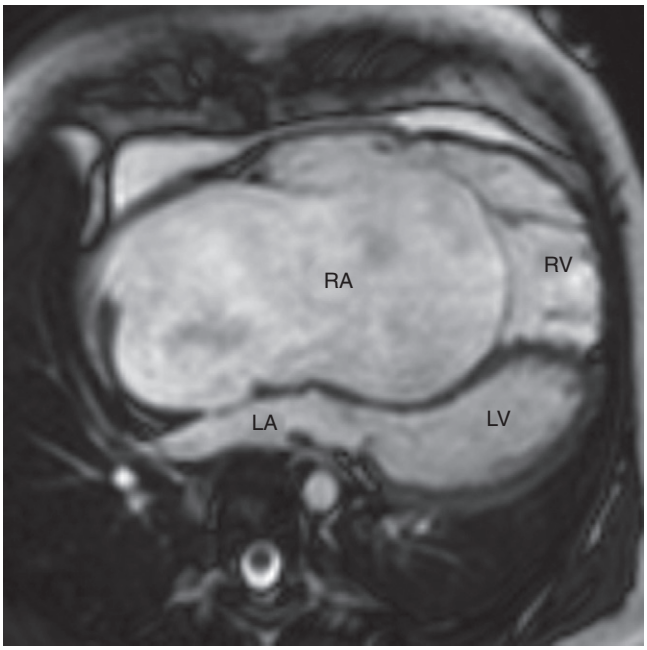

**Figure 44-5** Steady-state free precession cardiac magnetic resonance image in the four-chamber view in patient with Ebstein anomaly.

## Left Ventricular Outflow Tract and Aorta

### SUBAORTIC STENOSIS

Subaortic obstruction in the adult occurs in several forms. A discrete subaortic membrane is a developmental anomaly that is rarely seen in neonates but appears in older children and adults. It has been postulated that turbulent flow in the LV outflow tract stimulates the growth of "rest" tissue in the region of the perimembranous septum, creating discrete outflow obstruction.[59] Discrete subaortic stenosis is usually formed by a thin fibrous membrane attached circumferentially or along a portion of the circumference of the LVOT. It may lie immediately adjacent to the base of the aortic leaflets or be attached more distally near the junction of the muscular and perimembranous portion of the interventricular septum. Occasionally, the entire circumferential structure is composed of muscle, creating a muscular subaortic collar. In older patients, what began as a discrete membrane may be complicated by the development of subaortic hypertrophy. The muscular hypertrophy obscures the thinner membrane, thus masking the true pathophysiology of the obstruction. Long-segment tubular narrowing of the LVOT is more commonly seen in children and usually requires surgical attention before adulthood.

Discrete subaortic stenosis may occur in association with other left-sided obstructive lesions including supramitral ring, bicuspid aortic valve, and coarctation, or as part of a complex including perimembranous VSD and obstructive muscle bundles in the RV.[60] With increasing age, the VSD may close spontaneously, leaving the patient with a discrete obstruction of the LVOT and a muscular collar in the RV. Late development of discrete subaortic stenosis has been described in patients who have undergone surgical repair of AV canal defects.[61]

### *Echocardiographic Evaluation*

Echocardiographic detection of a subaortic membrane is typically made in the parasternal long-axis views of the LV outflow tract in which a linear structure protrudes from the left surface of the interventricular septum and the base of the anterior mitral valve leaflet is tented up by the tension of the circumferential membrane (Fig. 44-6). In some cases, the membrane is difficult to visualize unless the ultrasound beam is directly incident to the plane of the membrane. Low parasternal or apical long-axis views are thus more likely to detect the fine linear structure. When the membrane originates immediately beneath the aortic valve, its detection requires appreciation of subtle abnormality in the excursion of the aortic cusps and observation of a persistent structure in systole when the aortic cusps open into the sinus of Valsalva. Unexplained turbulence and increased flow velocities by Doppler across an apparently normal aortic valve are also a clue to the presence of a high discrete subaortic membrane. Systolic flow acceleration by PW or color Doppler occurs proximal to the aortic valve. Aortic

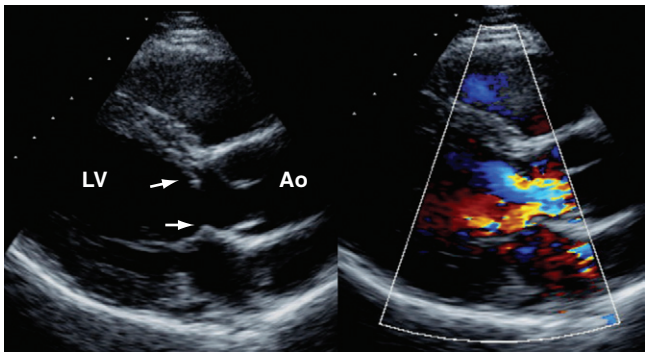

**Figure 44-6 Parasternal long-axis echocardiographic view of the LV in a patient with discrete subaortic stenosis.** Subaortic membrane (*arrows*) is a linear density protruding from upper left septal surface and anterior mitral valve leaflets. Color flow Doppler demonstrates acceleration of blood flow proximal to the aortic valve. *Ao*, Aorta.

**Box 44-4**

**CLASS I RECOMMENDATIONS FOR INTERVENTION IN ADULTS WITH ISOLATED SUBAORTIC STENOSIS**

- A peak instantaneous gradient of greater than 50 mm Hg or a mean gradient of 30 mm Hg on Doppler echocardiography
- Progressive aortic regurgitation and an LV end-systolic dimension of greater than 50 mm or an LV ejection fraction less than 55%

Adapted from Warnes CA, Williams RG, Bashore TM et al. ACC/AHA 2008 guidelines for the management of adults with congenital heart disease. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (writing committee to develop guidelines on the management of adults with congenital heart disease) developed in collaboration with the American Society of Echocardiography, Heart Rhythm Society, International Society for Adult Congenital Heart Disease, Society for Cardiovascular Angiography and Interventions, and Society of Thoracic Surgeons. *J Am Coll Cardiol* 52:e191, 2008.

regurgitation is commonly found in these patients as a result of long-standing subaortic flow disturbance or from infectious endocarditis.

Initial and serial assessment of the outflow tract pressure gradients by Doppler is important because of the progression of both the severity of obstruction and the degree of aortic regurgitation.[62] As with other lesions, TEE may be helpful in the patient with limited transthoracic windows to delineate the exact nature of the LVOT obstruction. This approach is particularly useful in cases with mixed or multiple-level obstruction. Both midesophageal views of the subaortic area and transgastric images of the LVOT are useful for obtaining diagnostic information.[63]

### *Management*

Subaortic stenosis is often a progressive lesion, which can lead to aortic valve damage, ventricular dysfunction, and worsening aortic regurgitation. Risks factors for progression include a peak Doppler gradient across the subaortic stenosis of greater than 30 mm Hg, if the membrane is immediately adjacent to the aortic valve or if there is extension of the membrane onto the mitral valve.[64] The indications for surgical intervention are somewhat controversial. The Class I adult congenital heart disease (ACHD) guidelines for surgical intervention in subaortic stenosis are listed in Box 44-4. Varying outcomes have been reported following surgical resection of subaortic membranes. Some have argued that resection of the membrane preserves the aortic valve from further trauma and prevents progressive aortic regurgitation.[65] However, others report a less predictable course, with up to 55% developing a recurrent membrane over 6 months to 24 years.[66] Still other series have documented that some patients exhibit very slow progression of LVOT obstruction and aortic regurgitation in adulthood.[67] Therefore, caution should be taken in recommending surgery for the asymptomatic patient with only mild hemodynamic abnormalities. When surgical excision is indicated, intraoperative TEE is useful to monitor the success of membrane removal and detect complications, such as mitral valve perforation or iatrogenic creation of a VSD.[68]

Percutaneous balloon dilation has been attempted in patients with discrete subaortic membranes with a substantial reduction in the gradient that persists over 5 years in 48% of patients without significant change in the degree of aortic regurgitation.[69] However, the appropriate selection of patients suitable for percutaneous intervention is essential, and favorable factors include a thin discrete membrane less than 3 mm in width, a sufficient distance between the membrane and the aortic valve to permit a subaortic chamber, and the absence of more than grade 2 aortic regurgitation. Potential damage to the mitral and aortic valves and incomplete relief of obstruction has limited the applicability of this technique, and in many adults with acquired secondary muscular outflow obstruction, percutaneous dilation is unlikely to produce satisfactory results.

## SUPRAVALVULAR AORTIC STENOSIS

Supravalvular aortic stenosis is an uncommon lesion involving a fixed narrowing at the level of the sinotubular junction, which results in an "hourglass" appearance of the aorta (70%), diffuse hypoplasia of the entire ascending aorta (20%) or a discrete supravalvular perimembranous stenosis (10%).[70] This may occur as an isolated abnormality, or as part of Williams syndrome.[71] Other features of Williams syndrome include cognitive disorders, short stature, a "cocktail personality," "elfin facies," and systemic hypertension. A familial autosomal dominant form of supravalvular aortic stenosis that is not associated with developmental delay has also been described.[72] Genetic studies have suggested that the underlying cause of supravalvular aortic stenosis is a mutation of the elastin gene on chromosome 7q11.23, which leads to an arteriopathy of varying severity that is most uniformly expressed in the supravalvular aorta.[73]

Functionally, supravalvular aortic stenosis may occur as an incidental finding with a systolic murmur, often best appreciated in the suprasternal notch. In other cases, the lesion is progressively obstructive or part of a diffuse process affecting the aorta, coronary ostia, brachiocephalic origins, and pulmonary arterial tree. Box 44-5 lists the common associations found with supravalvular aortic stenosis. The aortic valve may be bicuspid or may be distorted by the supravalvular constriction or incorporated into the stenosing ring. Coronary artery issues are not uncommon, and are due to the fact that the coronary ostia are proximal to obstruction, and exposed to high systolic pressures and limited diastolic flow, which may lead to coronary ostial and vessel abnormalities. Pathologic studies on adults with supravalvular aortic stenosis have revealed diffuse or focal intimal and medial fibrosis, hyperplasia, or dysplasia of the

**ASSOCIATED DEFECTS WITH SUPRAVALVAR AORTIC STENOSIS**

Bicuspid aortic valve
Coronary artery abnormalities (ostial stenosis, ostial occlusion, dilation)
Brachiocephalic artery stenosis
Multilevel right-sided obstructive lesions (especially with Williams syndrome)
Renal artery stenosis

coronary arteries.[74] These processes may lead to myocardial ischemia. When progressive obstruction and failure of normal aortic growth occurs, LV hypertrophy and typical symptoms of aortic stenosis develop.

### *Echocardiographic Evaluation*

Echocardiographic detection of supravalvular stenosis relies on careful inspection of the sinotubular junction and proximal ascending aorta, which is possible with cranial angulation in the right or left parasternal windows, or from the suprasternal notch views. The diameter of the normal aorta at the sinotubular junction equals or slightly exceeds that of the aortic annulus. The tubular portion of the ascending aorta should never be smaller than the aortic annulus.[75]

Echocardiographic Doppler study should determine the type of supravalvular lesion and the severity of stenosis. Although routine echocardiographic study now includes imaging the ascending aorta above the sinuses of Valsalva, this portion of the aorta is frequently not imaged, and the diagnosis of supravalvular aortic stenosis may be missed. The impetus to look specifically for this lesion may be a high-velocity turbulent flow detected by CW Doppler across a normal-appearing aortic valve. Accurate assessment of the supravalvular gradient by Doppler is best determined from the right parasternal or suprasternal windows, rather than the apical view. Doppler estimates of the severity of stenosis correlate poorly, however, with catheter-obtained gradients and often overestimate the true degree of obstruction due to pressure recovery in the tubular or long-segment stenosis.[76]

Careful assessment of the aortic arch and brachiocephalic vessels is essential, as there may be ascending or transverse aortic hypoplasia, coarctation, or stenosis of the origins of the head and neck vessels. Additionally, particularly in patients with Williams syndrome, branch pulmonary arteries and renal arteries should be evaluated for evidence of stenosis. An alternative imaging modality, such as cardiac MRI or computed tomography, is often desirable to complete the evaluation. The recently published ACHD guidelines advocate for one of these modalities to complement the echocardiographic assessment in the adult with unoperated supravalvular aortic stenosis. Additionally, these guidelines advocate for periodic screening for myocardial ischemia in these patients.[4]

### *Management*

The decision for surgical intervention for supravalvular aortic stenosis is similar to that for valvular obstruction—significant outflow gradient with LV hypertrophy or symptoms. Box 44-6 lists the Class I guidelines for intervention in adults with supravalvular aortic stenosis. The morphology

**Box 44-6**

**CLASS I RECOMMENDATIONS FOR INTERVENTION IN ADULTS WITH SUPRAVALVAR AORTIC STENOSIS**

- Symptoms and/or mean gradient greater than 50 mm Hg or peak instantaneous gradient by Doppler echocardiography greater than 70 mm Hg
- Surgical repair is recommended for adults with lesser degrees of supravalvular obstruction and the following:
  - Symptoms (i.e., angina, dyspnea, or syncope)
  - LV hypertrophy
  - Desire for greater degrees of exercise or a planned pregnancy
  - LV systolic dysfunction
- Interventions for coronary artery obstruction in patients with Supravalvular aortic stenosis should be performed in ACHD centers with demonstrated expertise in the interventional management of such patients

*ACHD*, Adult congenital heart disease.

of the supravalvular narrowing dictates the type of repair required, varying from patch aortoplasty to partial root replacement. Reconstruction of the coronary ostia or bypass grafting may be required, depending on the anatomy. Associated branch PA stenosis may need to be addressed concurrently. Abnormalities of the aortic valve leaflets may persist after repair and merit clinical and echocardiographic surveillance. The reported surgical outcomes following supravalvular aortic stenosis repair are favorable, with a low mortality and need for reintervention, providing that the associated lesions are addressed at the time of surgery.[77,78]

## SINUS OF VALSALVA ANEURYSMS

The aortic sinus is the part of the aortic root that is delineated proximally by the attachments of the aortic valve leaflet and distally by the sinotubular ridge.[79] Congenital aneurysms of the aortic sinuses of Valsalva are thought to result from a weakness in the aortic media at its junction with the annulus fibrosis. A small diverticulum or finger-like protrusion extends most commonly from the right coronary sinus and arises above the aortic annulus, in contrast to a prolapse of the aortic cusp that occurs below the annular level. The RV is the most common termination site. Aneurysms of the noncoronary sinus usually enter the RA.[80] Over time, the aneurysm may enlarge to become a "windsock," potentially causing obstructive problems in the RV outflow tract or tricuspid valve. Rarely, sinus of Valsalva aneurysms burrow into the interventricular septum and cause AV conduction defects. Protrusion into the LVOT may create outflow tract obstruction.[81] Sinus of Valsalva aneurysms can occur in isolation or with other anomalies, such as VSD, subaortic stenosis, tetralogy of Fallot, or aortic valve abnormalities.[82]

Congenital sinus of Valsalva aneurysms come to clinical attention most typically during adolescence and young adulthood when the protruding structure ruptures into the receiving

chamber. Acute rupture of a large aneurysm causes retrosternal or epigastric pain and severe dyspnea from heart failure. By contrast, perforation of a small aneurysm may go unnoticed until a continuous murmur is auscultated or worsening symptoms of heart failure bring the patient to medical attention. Coronary artery compression by a sinus of Valsalva aneurysm is an unusual mode of presentation.[83]

### *Echocardiographic Evaluation*

Sinus of Valsalva aneurysms may be an incidental finding on echocardiographic study, but they are more often discovered during echocardiographic-Doppler evaluation of a continuous murmur with the suspected diagnosis of patent ductus arteriosus or coronary artery fistula.[84,85] Parasternal long-axis and short-axis views of the aortic sinuses demonstrate the finger-like windsock extending from the base of the sinus toward the site of termination (Fig. 44-7). The originating sinus may be somewhat enlarged, but the native morphology of the root and valve is usually not significantly distorted. It is important to determine that the aneurysm originates from the aortic sinuses above the plane of the aortic valve to distinguish this lesion from the more common aneurysm of the perimembranous interventricular septum. Delineation of a normal coronary artery origin and lumen size distinguishes it from a coronary artery fistula. Acquired aortic fistulas after endocarditis can be differentiated because they lack the extended aneurysmal channel seen with a congenital sinus of Valsalva aneurysm. Color flow Doppler demonstrates continuous turbulent flow within the aneurysm and into the receiving chamber. In patients with a significant left-to-right shunt, cardiac chamber dilation is dependent on the site of termination. Aneurysms that terminate below the tricuspid valve (i.e., RV) result in LA and LV dilation, whereas those that terminate pre–tricuspid valve (RA) result in RV dilation. Aortic regurgitation, often mild, is expected because of distortion of the aortic cusp and aortic root enlargement as a result of long-standing volume overload. Severe aortic regurgitation should raise the suspicion of an aneurysm rupture into the LV outflow tract or endocarditis.

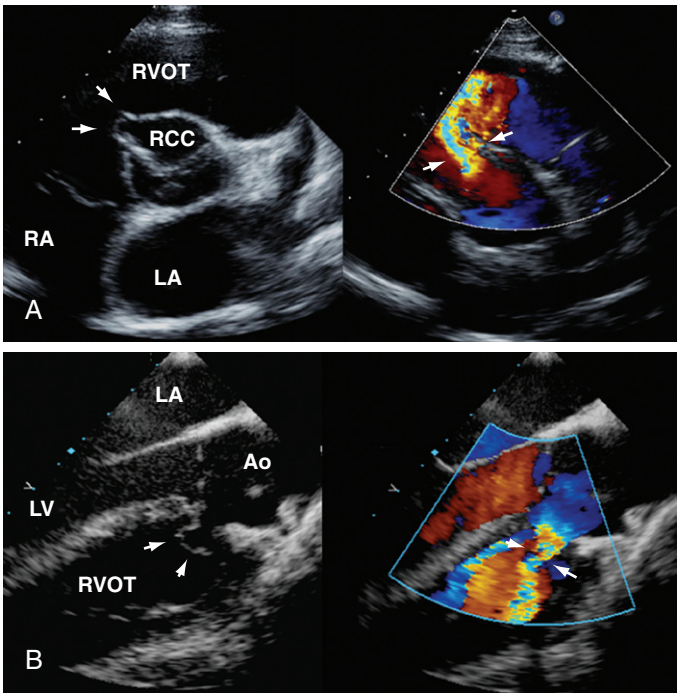

**Figure 44-7 A, Parasternal short-axis echocardiographic view in a patient with a ruptured sinus of Valsalva aneurysm.** Aneurysm of the right coronary cusp (*RCC*) creates a "windsock" protruding into the RV outflow tract (*RVOT*) (*arrows*). Color flow Doppler demonstrates turbulent shunt flow (*arrows*) from aorta into RVOT. **B,** TEE view from this patient further demonstrating this anatomy. *Ao*, Aorta.

### *Management*

Small unruptured aneurysms found incidentally can be followed expectantly. Larger aneurysms or those adversely affecting surrounding structures should be electively excised. Ruptured sinus of Valsalva aneurysms require surgical closure to prevent late congestive symptoms caused by volume overload and to decrease the susceptibility to infectious endocarditis. Surgical repair is highly successful. However, certain risk factors have been associated with poorer outcomes, including presence of infective endocarditis, long cross-clamp time, LV fistula, reoperation, aortic regurgitation, or aortic dehiscence.[86] In one large series of 129 patients with sinus of Valsalva aneurysms, perioperative mortality rate was 3.9%, and the etiology of the 23 late deaths included myocardial infarction, cardiac failure, dissection, and stroke.[87]

## COARCTATION OF THE AORTA

Native coarctation of the aorta in the adolescent and adult is most often discovered during an investigation of systemic hypertension. Weak or absent femoral pulses, LV hypertrophy on electrocardiogram (ECG), or systolic or continuous murmurs auscultated on the back are clues to the diagnosis.

The anatomic lesion most commonly found in the adult is a discrete narrowing of the aortic lumen just inferior to the left subclavian artery origin and opposite the ductus arteriosus or ligamentum arteriosum. Poststenotic dilation of the descending aorta is often present.

Functionally, patients seen as adults are usually asymptomatic because the degree of obstruction created by the coarctation may be mild or moderate, or the obstruction is moderated by the development of collateral vessels between the high-pressure aortic branches proximal to the coarctation and the low-pressure descending aorta.

Approximately 50% of patients with coarctation of the aorta have a bicuspid aortic valve.[88] Other associated cardiac defects include patent ductus arteriosus, VSD, and mitral valve abnormalities. As previously mentioned, it is particularly common in conditions with multiple left-sided obstructive lesions, such as Shone syndrome. Additionally, at least 10% of patients with Turner syndrome have aortic coarctation. The natural history of untreated coarctation of the aorta includes early mortality (mean age 31 years) with complications of cerebrovascular accidents from berry aneurysm rupture, aortic dissection, and endarteritis.[89]

### *Echocardiographic Evaluation*

Echocardiographic diagnosis of coarctation relies on 2D visualization of the anatomy of the aortic arch and Doppler detection of the flow disturbance in the descending aorta. Although the aorta can be imaged in part from a variety of parasternal views, suprasternal notch or right parasternal windows often provide the best visualization of the area of interest. The area of coarctation is often challenging to visualize in the adult, and patient positioning measures to optimize the suprasternal view are important. In the long-axis view of the aortic arch, the

brachiocephalic vessels should be identified and followed distally if possible. Immediately distal to the left subclavian artery, an infolding or posterior shelf of the coarctation narrows the aortic lumen. Poststenotic dilation of the descending thoracic aorta is common.

Color flow Doppler detects a narrowed flow stream at the point of coarctation and systolic flow acceleration, with continuation of flow into diastole in cases of significant obstruction. In fact, when 2D imaging is indistinct, the color flow turbulence may be a clue to the site of obstruction. CW Doppler in patients with discrete obstruction demonstrates a typical pattern of increased systolic flow velocity and a continued gradient in diastole. Doppler gradients (ΔP) estimated from the peak systolic velocity ($V_2$) of the CW Doppler signal usually overestimate the catheter-measured gradients. Better correlations have been shown when the velocity proximal to the coarctation ($V_1$) is included in the modified Bernoulli equation

$$\Delta P = 4\left(V_2^2 - V_1^2\right)$$

or when both the peak systolic velocity and pressure half-time of the diastolic gradient are considered.[90,91] Long-segment narrowing of the aorta without discrete obstruction causes acceleration of flow, giving high peak velocities by CW Doppler. Conversion of these velocities into systolic gradients mistakenly predicts significant coarctation. The lack of a diastolic gradient helps to distinguish flow acceleration from true obstruction. Doppler flow patterns in the descending abdominal aorta are extremely useful in detecting upstream obstruction.[92] Patients with tubular narrowing but without a discrete obstruction demonstrate a normal pattern of abdominal aortic flow: rapid systolic upstroke, relatively laminar flow signal, and no continuation of flow into diastole. With coarctation, the flow profile has a delay in the systolic upstroke, turbulence in systole, and variable degrees of diastolic antegrade flow (Fig. 44-8). Routinely including the Doppler profile of abdominal aortic flow in the clinical examination is an excellent method to screen for unsuspected coarctation. Adults with coarctation may have considerable tortuosity of the transverse arch, making both visualization and alignment for accurate Doppler detection of the gradient impossible. In such cases, a high degree of suspicion is generated by abnormal flow in the abdominal aorta, directing a more diligent search from off-axis views or with stand-alone CW Doppler probe.

Although Doppler flow patterns are relatively easy to obtain in most adults with coarctation, direct imaging of the anatomy of the transverse arch and descending aorta is frequently limited. Alternative imaging modalities are often necessary to further define the details of the obstruction and guide management decisions. TEE can detect the site and configuration of the obstruction. Long-axis views allow quantitation of luminal narrowing; however, Doppler gradients are difficult to obtain because the affected region of the aorta generally lies perpendicular to the interrogating Doppler beam.[93] In addition, visualization of the branch vessels and collaterals is limited with TEE, thus making alternative imaging modalities more useful (Fig. 44-9). The ACHD guidelines recommend that every patient with coarctation (repaired or not) should have at least one cardiac MRI exam or CT scan for complete evaluation of the thoracic aorta and intracranial vessels.[4]

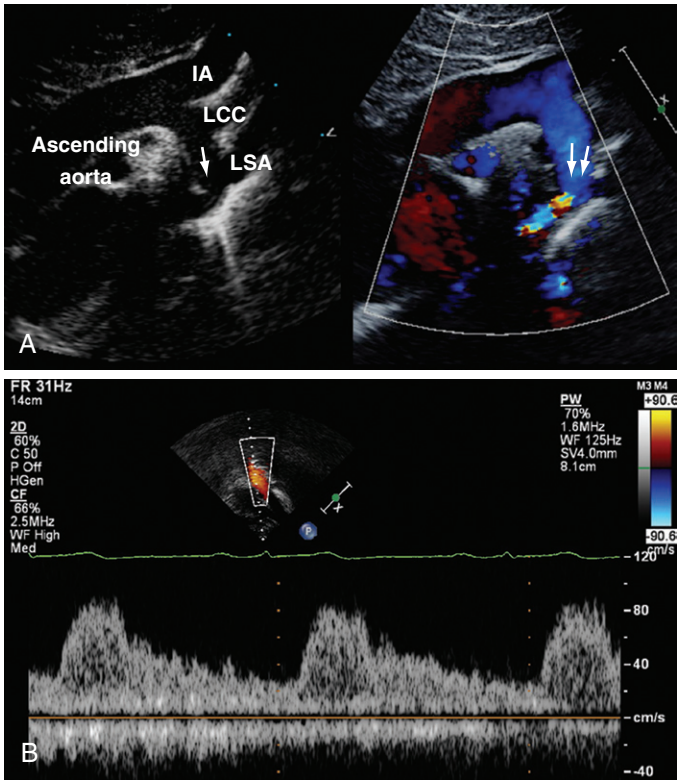

**Figure 44-8** **A, Suprasternal long-axis echocardiographic view of aortic arch demonstrates discrete coarctation at isthmus (*arrow*).** Color flow Doppler reveals aliasing and turbulence beginning at site of discrete obstruction (*double arrows*). **B,** Pulsed-wave Doppler signal in descending abdominal aorta reveals blunting of systolic upstroke and turbulent continuous flow during diastole indicative of significant obstruction to flow located more proximally in aorta. *IA,* Innominate artery; *LCC,* left common carotid artery; *LSA,* left subclavian artery.

**Figure 44-9** **Steady-state free precession cine MRI in oblique sagittal view of aortic arch in adult with discrete aortic coarctation (*arrow*).**

*Management*

Indications for intervention in the adult with coarctation include a peak-to-peak coarctation gradient greater than or equal to 20 mm Hg or the presence of significant coarctation and collateral flow by imaging. The choice of percutaneous catheter intervention versus surgical repair of a native discrete coarctation is sometimes controversial and should be discussed by a team involving ACHD cardiologists, interventionalists, and surgeons. Surgery is often recommended in cases of long-segment coarctation or concomitant hypoplasia of the transverse aortic arch. Percutaneous catheter intervention is indicated for recurrent, discrete coarctation and a peak-to-peak gradient of at least 20 mm Hg.

Balloon angioplasty of native coarctation in adults often results in significant relief of the gradient and improvement in systemic hypertension.[94] In an analysis of 970 percutaneous angioplasty procedures for coarctation, 81% of patients with native coarctation and 75% of those with recurrent aortic obstruction experienced early successful relief of obstruction without a major complication.[95] Small saccular aneurysms may occur at the site of dilation. The long-term outcome of these iatrogenic aneurysms is unknown. Intravascular echocardiography performed immediately after dilation can demonstrate an intimal tear that commonly occurs during balloon angioplasty.[96]

Intravascular stents are now routinely used in the treatment of aortic coarctation. Early and intermediate follow-up suggests excellent relief of stenosis without a significant incidence of stent migration, fracture, restenosis, or thromboembolic complications.[97] In one series of 153 patients with aortic coarctation who had undergone intravascular stenting procedures, serious injuries to the aortic wall were uncommon, and these investigators advocated for predilation of the coarctation site before stent placement.[98]

Coarctation in the adult can be surgically repaired with low operative mortality and good intermediate outcome. Attention to the degree of collateral formation is important to ensure adequate perfusion during cross-clamping and to prevent spinal cord injury. Prosthetic bypass grafts or other alternatives to mobilization and end-to-end anastomosis may be required in adults with less elastic tissue or with unfavorable anatomy such as hypoplasia of the transverse arch.

Residual hypertension is very common and occurs despite the absence of residual obstruction.[99] Patients with repaired aortic coarctation may have a normal resting blood pressure, yet demonstrate an exaggerated systolic blood pressure response to exercise.[100] There is increasing evidence that patients with aortic coarctation exhibit impaired vascular reactivity.[101] Lifelong cardiology follow-up is recommended for all patients with aortic coarctation. Box 44-7 lists the recommendations for key issues to evaluate in follow-up.

**Box 44-7**

**RECOMMENDATIONS FOR FOLLOW-UP IN ADULTS WITH COARCTATION OF THE AORTA**

- Lifelong cardiology follow-up is recommended for all patients with aortic coarctation (repaired or not), including consultation with a cardiologist with expertise in ACHD
- Patients who have undergone surgical repair or percutaneous intervention for coarctation of the aorta should have at least annual follow-up
- Even if the coarctation repair appears satisfactory, late postoperative thoracic aortic imaging should be performed to assess for aortic dilatation or aneurysm formation
- Patients should be observed closely for the appearance of resting or exercise-induced systemic arterial hypertension, which should be treated aggressively after recoarctation is excluded
- Evaluation of the coarctation repair site by MRI/CT should be performed at intervals of 5 years or less, depending on the specific anatomic findings

## Septal Defects and Shunt Lesions

### PATENT FORAMEN OVALE

The most frequent atrial communication is a patent foramen ovale, which is prevalent in approximately 25% of adults.[102] During embryologic development, the atrial septum forms with a septum primum extending inferiorly toward the endocardial cushions. Concurrently, the septum secundum forms, and the defect in this structure, the foramen ovale, allows blood to flow from the fetal RA to left atrium (LA). Following birth, fusion of the two septa often occurs, closing the foramen completely in 75% of patients.

However, in the remaining individuals with incomplete fusion, the flap of septum primum covering the fossa ovalis may open transiently with changes in the transatrial pressure gradient, allowing communication of blood between the two atria. Additionally, this thin perimembranous layer may have small septal perforations or develop into a septal aneurysm with or without an atrial shunt.

Improved detection of patent foramen ovale has generated great interest in the association of this defect with cerebrovascular events, migraine headaches, and other conditions, such as sleep apnea. Although there is no definite consensus as to the risk of stroke implied by the presence of a patent foramen ovale, it is clear that the potential for a right-to-left embolus exists when there is any form of communication in the interatrial septum.

### ATRIAL SEPTAL DEFECTS

ASDs are one of the most common congenital heart lesions discovered in adults. The most common type of ASD is the secundum defect, followed by primum defects, and then sinus venosus defects. A much rarer type of defect is the coronary sinus septal defect, in which the roof of the coronary sinus is partially or completely absent, allowing left-to-right shunt from the LA into the coronary sinus and into the RA. The various types of ASDs are depicted in Figure 44-10.

Patients with shunting at the atrial level are often asymptomatic until middle to late adult years. Physical exam findings may

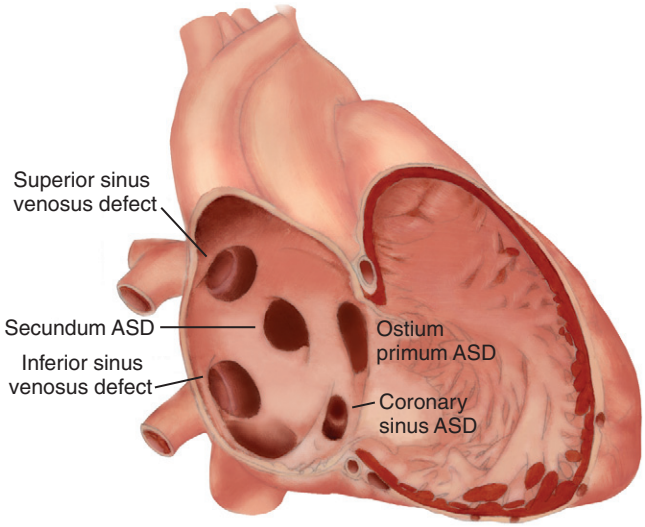

**Figure 44-10 Diagrammatic representation of interatrial septum as viewed from cutaway view of right heart to demonstrate various defect locations.** Superior and inferior sinus venosus defects are located near entry of superior vena cava and inferior vena cava, respectively. Secundum atrial septal defect (*ASD*) is centrally positioned. Primum ASD is inferiorly located near atrioventricular valves and coronary sinus septal defect.

**TABLE 44-1 Associated Defects with Atrial Septal Defect**

| *Type of Defect* | *Associated Lesion* |
|---|---|
| Secundum atrial septal defect | Mitral valve prolapse, pulmonic stenosis, partial anomalous pulmonary venous return |
| Primum atrial septal defect | Cleft mitral valve, inlet ventricular septal defect, septal aneurysm |
| Sinus venosus defect | Partial anomalous pulmonary venous return |
| Coronary sinus septal defect | Unroofed coronary sinus, left superior vena cava, partial anomalous pulmonary venous return |

include a widely split second heart sound and a systolic ejection murmur of increased flow across the pulmonic valve. Symptoms often develop during the third decade of life and beyond and include fatigue, exercise intolerance, dyspnea with exertion, and atrial arrhythmias. RV failure, pulmonary arterial hypertension, and paradoxical embolism are rare modes of presentation for older patients with unrepaired ASDs.[103,104]

### *Echocardiographic Evaluation*

Patients with ASDs require echocardiographic assessment of the anatomic abnormality of the atrial septum, the hemodynamic effect of shunt flow, and the presence of any associated defects (Table 44-1). Imaging of the atrial septum is best performed with subxiphoid views when possible. The apical four-chamber view is unreliable because false-positive dropout often occurs in the midatrial septum. An off-axis four-chamber view obtained by sliding midway between the apical and subxiphoid views, however, yields a more perpendicular interface between the interrogating ultrasound beam and the interatrial septum. Parasternal short-axis and right parasternal views are supplemental windows for imaging the atrial septum. The septum primum covering the fossa ovalis is thinner than either the superior or inferior limbic bands of the septum secundum. Mobility of the septum primum or aneurysmal deformity (greater than 1 cm deviation from the plane of the basal septum) raises the suspicion for a patent foramen ovale. True ASDs should have a distinct edge visible at the blood-tissue interface. All aspects of the atrial septum should be inspected, including the superior rim, with visualization of the superior vena caval entry. Right parasternal views are particularly helpful in imaging this area. When the atrial defect can be imaged directly, measurement of its dimensions in orthogonal planes, the septal rims, and its size relative to the entire atrial septal length should be made.

PW and color flow Doppler add diagnostic power to the transthoracic examination. The passage of flow across an apparent atrial defect confirms the presence of an atrial communication. When the right heart pressures are normal, a clear stream of flow occurs in late systole with accentuation in diastole. Elevation of right heart pressures decreases the transseptal pressure gradient, and shunt flow then may be difficult to distinguish from other low-velocity atrial flows.

Contrast echocardiography plays an important diagnostic role in cases in which the imaging and Doppler findings are equivocal. With rapid intravenous injection of several milliliters of agitated saline (or saline mixed with a small amount of the patient's blood), highly reflective microbubbles appear in the right side of the heart. Contrast passes into the LA within three to five cardiac cycles in the presence of an interatrial communication. Even when left-to-right shunting is predominant, there is a period of transient right-to-left shunting during which contrast can pass into the LA. The right-to-left pressure gradient can be augmented by having the patient cough or perform a Valsalva maneuver. A negative contrast effect occurs with left-to-right shunts when unopacified blood enters the densely opacified RA. Negative contrast is a less reliable diagnostic feature, however, because flow from the inferior vena cava or coronary sinus may create the same appearance. Sensitivities of 92% and above have been reported for detection of ASDs by contrast TTE.[105,106] It has been suggested that injection from the leg may improve the sensitivity of the contrast technique because the Eustachian valve tends to direct inferior vena cava flow across the fossa ovalis.[102]

TTE study also helps to define the hemodynamic effects of shunt flow. RA and RV enlargement and dilation of the main PA are expected with shunts of 1.5:1 or greater. The pulmonary veins are prominent, but the LA is usually normal in size unless there is a primum ASD present, with cleft mitral valve and mitral regurgitation. The interventricular septum in the short-axis views is flattened in diastole and moves paradoxically toward the RV in systole.

Specific quantification of shunt volume by echocardiographic-Doppler techniques has been attempted by several methods, all of which remain semi-quantitative in clinical use. PW Doppler determination of cardiac output has been validated with a high degree of accuracy in the experimental setting.[107] The ratio of PW Doppler–determined cardiac output across the pulmonic and aortic valves gives an estimate of pulmonary-to-systemic flow ratio ($Q_p/Q_s$). This technique is not accurate if the flow across either valve is influenced by something other than the intracardiac shunt, such as valvular stenosis, subvalvular obstruction, or significant valvular regurgitation. Application of this method to the clinical arena has been less successful, partly because of the difficulty of obtaining accurate dimensions of the pulmonary annulus in adults.

When color flow mapping became a part of the echocardiographic diagnostic armamentarium, there was initial enthusiasm for its quantitative potential. Planimetry of the area of the flow stream within the RA has been compared with shunt volumes, but with poor correlation. Better correlation has been shown when the diameter of the color flow stream at the atrial defect is compared with shunt ratios. However, this remains semiquantitative, with considerable overlap between patients with small, moderate, and large shunts. This result might be expected because the color flow diameter simply reflects the anatomic dimension of the atrial defect, and although it bears a gross relationship to the size of the shunt, factors such as RV compliance and PA pressures cause variation in the volume of shunt for a given ASD size.

Estimation of PA pressure is an important part of the echocardiographic assessment of atrial shunts. The pressure is easily and reliably determined by applying the modified Bernoulli equation to the peak velocity of the tricuspid regurgitation jet to obtain the pressure difference between the RA and RV.[108] If the patient does not have tricuspid regurgitation, other subjective signs of pulmonic hypertension may be present. For example, the interventricular septum is flattened in systole if the RV systolic pressure is greater than half the systemic pressure. Systolic notching on the pulmonic valve M-mode or the PA Doppler flow profile also indicates significant elevation in PA pressure. Applying the modified Bernoulli equation to the end-diastolic velocity of the pulmonic regurgitation jet provides quantitative information about the PA diastolic pressure.

The drainage of all the pulmonary veins should be established in any patient with an ASD. Anomalous return of the right superior and middle lobe veins is found in the majority of patients with sinus venosus defects and a small percentage of patients with secundum ASDs. From an anatomic standpoint, sinus venosus defects are not true ASDs, as they do not allow direct communication between the RA and LA, but rather the interatrial communication is through one or more pulmonary veins. These defects frequently result in significant RV volume overload.[109] Echocardiographic Doppler detection of sinus venosus defects in adults is difficult but can be attempted with long-axis and short-axis right parasternal views of the superior vena cava and occasionally can be appreciated in subcostal views of the superior vena cava. A turbulent flow stream entering the superior vena cava laterally and posteriorly represents the pulmonary vein inflow. In a superior sinus venosus defect, the right pulmonary veins drain to the superior vena cava either at the junction or more distally along the course of the superior vena cava (Fig. 44-11). A less common defect is the RA type, or inferior sinus venosus defect. This is also difficult to image and may be mistaken for an inferiorly located secundum ASD. The RA type sinus venosus defect is characterized by anomalous drainage of the right inferior and/or middle pulmonary veins into the inferior aspect of the RA or inferior vena cava. Right parasternal views that focus on the inferior vena caval entry to the RA may be helpful to search for the anomalous pulmonary venous inflow.

Primum ASD is an endocardial cushion defect, actually considered a type of partial AV canal defect with two separate AV valves and no VSD (Fig. 44-12). This type of ASD is usually accompanied by a cleft in the mitral valve, and patients may present with significant mitral regurgitation.

TEE has proven to be superior to TTE study in adult patients for detecting patency of the foramen ovale, secundum ASDs, sinus venosus defects, and anomalous pulmonary venous return.[110-112] Particularly in the case of patent foramen ovale and secundum ASD, TEE is very useful for defect sizing and determining specific anatomic details, such as presence of acceptable septal rims for percutaneous closure. With real time three-dimensional (3D) TEE it is possible to create an en face view of the interatrial septum in which the rims of the defect can be seen in one view (Fig. 44-13).

**Figure 44-11 Steady-state free precession cine MRI in axial view of superior sinus venosus defect.** Posterior wall of superior vena cava (*SVC*) is absent, allowing oxygenated blood from right superior pulmonary vein (*RPV*) to return to right side of heart. *Ao*, Aorta.

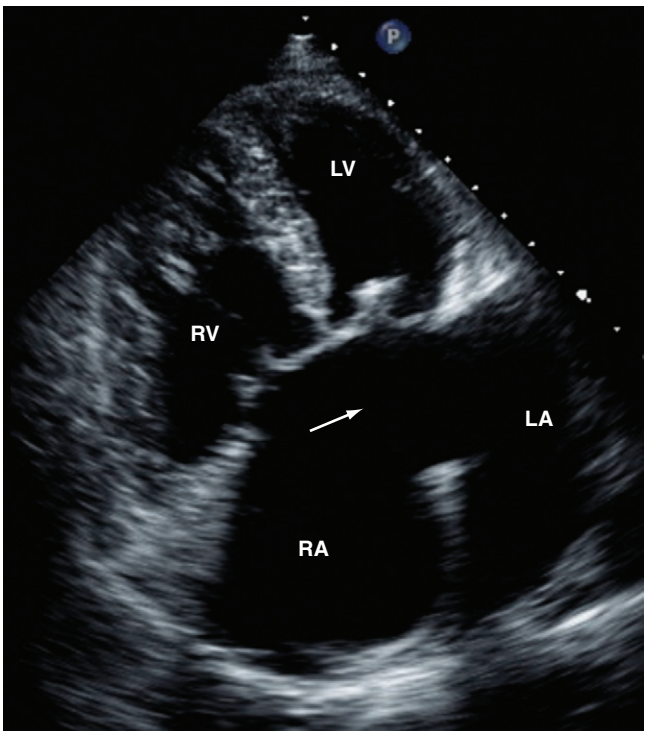

**Figure 44-12 Apical four-chamber echocardiographic view from a patient with a primum atrial septal defect (*arrow*).**

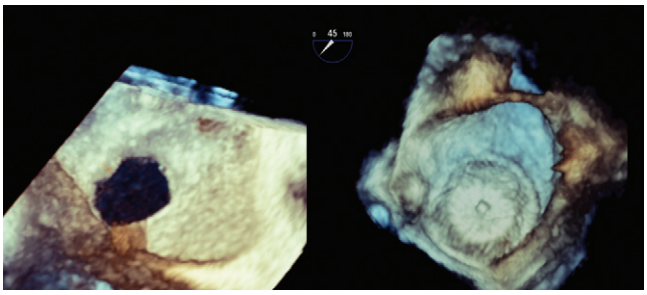

**Figure 44-13** 3D TEE image of en face view of a secundum atrial septal defect (*left*) and similar view following percutaneous device closure of defect (*right*).

The interatrial septum is easily imaged with the probe in the midesophageal position. At 0°, the crux of the heart is well seen, and ostium primum and secundum atrial defects are apparent. From the 90° bicaval view, the superior vena cava entry into the RA is clearly defined and superior sinus venosus defects can be detected. The flaplike opening of the patent foramen ovale can also be appreciated in this view. ASDs vary in shape, making the measurements of the defect in two orthogonal views important. The pulmonary veins can be identified from both the transverse and longitudinal planes.

Color flow mapping confirms the presence of shunting, and saline contrast injection may be useful. However, it is important to recognize that contrast injections may yield false-negative results with TEE imaging. Criteria necessary for an adequate contrast injection include the simultaneous presence of both leftward bulging of the interatrial septum and dense contrast filling of the RA, adjacent to the interatrial septum.[113]

### *Management*

Patients with an isolated ASD and evidence of RA or ventricular enlargement should have elective closure of the defect regardless of presence of symptoms. Small ASDs with a diameter less than 5 mm and no evidence of RV overload do not require closure unless associated with paradoxical embolism. Closure of larger ASDs is indicated to prevent long-term complications, such as atrial arrhythmias, reduced exercise tolerance, tricuspid regurgitation, right-to-left shunting and embolism during pregnancy, overt cardiac failure, or pulmonary vascular disease that may develop in up to 5% to 10% of affected patients.[4] Surgical mortality for this lesion is quite low, and long-term follow-up reveals improvement in symptoms, stabilization of pulmonary hypertension, and near-normal long-term survival rates in patients repaired before the age of 25 years.[114-116]

There is some divergence of opinion regarding closure of ASDs in older adults. One natural history study found no difference in survival or symptoms and no difference in the incidence of new arrhythmias, stroke, emboli, cardiac failure, or progressive pulmonary hypertension between medically and surgically treated patients over the age of 25 years.[117] A subsequent large series of adults over the age of 40 years, however, demonstrated a significant reduction in mortality and dramatic improvement in functional class after ASD closure compared with a similar group managed medically. The risk of atrial arrhythmias and attendant embolic complications was not altered by ASD closure.[118] Thus, with low surgical morbidity and mortality and with the availability of transcatheter closure devices, closure of ASDs with a significant shunt is recommended regardless of age.[119]

At present, patients with an incidentally detected patent foramen ovale do not require intervention. The occurrence of an embolic stroke or peripheral embolus in the patient with a patent foramen ovale and no other obvious embolic source may be considered justification for anticoagulation or for surgical or device closure, particularly in a younger adult. However, the results of several ongoing clinical trials are needed to determine if anticoagulation or antiplatelet agents alone are as effective as patent foramen ovale closure in preventing recurrent embolic events (see Chapter 41).

Many secundum ASDs in adults may be referred for percutaneous closure. Several transcatheter closure devices have been designed and are approved by the U.S. Food and Drug Administration for this purpose, such as the Amplatz Septal Occluder (AGA Medical, Golden Valley, Minn.) and the Helex ASD device (W.L. Gore, Flagstaff, Ariz.). The basic device is a flexible wire framework, covered with fabric or filled with foam, that folds inside a catheter delivery system. One portion of the device is extruded on the LA side of the ASD, the delivery sheath is withdrawn across the defect, and the other side of the device is employed along the RA side. Newer generation devices have a thick central core that allows the device to be self-centering within the defect. This characteristic provides better immediate closure rates and permits closure of larger ASDs because less overlap is required to ensure that the device remains well seated. For any of the current devices, the best results are achieved when the defect is centrally located in the interatrial septum because extension of the device beyond the edges of the defect may impinge on the AV valves or extend into the superior vena cava, right superior pulmonary vein, or coronary sinus. Therefore, sinus venosus and primum defects are not suitable for device closure with current technology.

Echocardiography plays an essential role in the selection of patients most suitable for device closure. Assessment of defect size, the overall length of the interatrial septum, the amount of septal rim around the defect, and the degree of mobility or aneurysm of the septum primum are all important factors in evaluating a patient for device closure. Although TTE can provide some of this information, TEE generally is more accurate in adults. The balloon-stretched diameter is the most reliable measurement in selecting a device size, as some traction is placed on the atrial septum in the process of placing the device. Thus, in clinical practice, TTE is used to diagnose the shunt at the atrial level, characterize the location of the defect and its approximate size, determine shunt size, and detect any associated defects. If device closure is considered, TEE before or during catheterization can further define the anatomy, and the balloon-stretched diameter can be measured. TEE guidance in the catheterization laboratory has greatly facilitated the optimal placement of the closure device parallel to the plane of the interatrial septum and centered across the defect (see Chapter 5). In addition, deployment in the atrial appendage or within the mitral valve orifice can be avoided under direct TEE observation. The fully deployed device can then be observed for a period of time before the procedure is completed to ensure that it remains in a good position (Fig. 44-14). Color flow Doppler and contrast echocardiography determine residual patency immediately after deployment. Some centers prefer the use of intracardiac echocardiography to monitor device placement (see Chapter 6). The ultrasound-tipped catheter can be inserted intravenously with local anesthesia

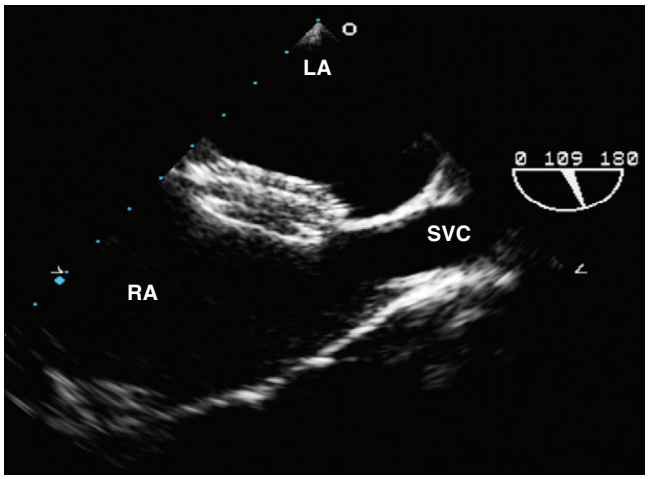

**Figure 44-14 TEE image of interatrial septum with Amplatzer occluder device in place.** *SVC,* Superior vena cava.

and manipulated by the interventionalist, avoiding the need for anesthesia and a separate TEE procedural staff. In experienced hands, intracardiac echocardiographic monitoring has been shown to be equally reliable for delineating the ASD or patent foramen ovale and for assessing device deployment.[120]

Follow-up studies of device closure of ASDs have shown a high rate of successful placement. Residual patency rates are small, with a continued decrease in shunting over time. Although a number of complications have been reported (device embolization, malposition, device erosion through the atrial wall or aorta, endocarditis, and thrombotic emboli), the complication rate is low.[121,122] Endothelialization of the device is thought to occur within 6 months when properly aligned flush with the native septum.[123]

## ANOMALOUS PULMONARY VENOUS CONNECTIONS

Connection of some or all of the pulmonary veins to the systemic circulation results in a left-to-right shunt and RV volume overload. Embryologically, these anomalies are the result of persistence of early fetal connections between the developing lung buds and the systemic venous pathways, with subsequent failure of incorporation of the common pulmonary venous confluence with the LA. Total anomalous pulmonary venous return almost always presents in infancy or early childhood, because of the marked hemodynamic derangement. However, there are rare reports of patients with this condition surviving to adulthood.[124,125] Partial anomalous pulmonary venous connections are occasionally discovered in adults with unexplained right heart dilation. Although there are a myriad possible anomalous connections (Fig. 44-15), the right pulmonary veins are more often involved than the left veins.[126] Commonly, the right pulmonary veins enter the superior vena cava, the superior vena cava–RA junction, or directly into the RA, with or without an associated sinus venosus defect. Anomalous right pulmonary venous connection of the right inferior pulmonary veins is frequently associated with scimitar syndrome, so named because the radiographic appearance of the anomalous pulmonary venous connection to the inferior vena cava resembles a Turkish sword. Anomalous drainage of the left pulmonary veins usually terminates via an ascending vertical vein into the innominate vein.

The clinical presentation of this anomaly is similar to that of an ASD, with a pulmonic flow murmur, RV volume overload, dyspnea, and exercise intolerance. In theory, the amount of left-to-right shunt with partial anomalous pulmonary venous connections should be small because each pulmonary vein carries only 25% of the total pulmonary blood flow. However, the lower resistance encountered in the RA causes preferential shunting of flow to the pulmonary segments that drain anomalously, thereby creating a larger left-to-right shunt.

### *Echocardiographic Evaluation*

As mentioned previously, partial anomalous pulmonary venous connections should be suspected whenever a sinus venosus defect is present and should be carefully considered in patients with a secundum ASD as well. The presence of right heart enlargement without an atrial shunt or other obvious cause of an RV volume overload is also a signal to inspect the pulmonary venous return carefully. Pulmonary venous entry to the LA should be sought in the parasternal short-axis views of the LA, the apical four-chamber view, the subxiphoid views of the LA, and the suprasternal "crab view" of the LA using color flow Doppler to demonstrate the venous inflow streams. If some of the pulmonary veins do not appear to enter the LA, attention should be directed to the known systemic venous entry points. Suprasternal or right parasternal views of the superior vena cava and innominate vein may demonstrate enlargement and more vigorous flow if this is the pathway for the anomalous drainage. Alternatively, the inferior vena cava or coronary sinus may be dilated if pulmonary venous flow is diverted into these systemic venous channels. Direct visualization of the pulmonary vein entry is often difficult in the adult patient by TTE but is occasionally possible when the potential sites of entry are carefully inspected using color Doppler. In experienced hands, TEE is accurate in diagnosing partial anomalous pulmonary venous connections and delineating the sites of anomalous entry.[126] MRI and CT are excellent adjuncts to echocardiography for visualizing pulmonary venous anatomy.[127,128]

### *Management*

Partial anomalous drainage of a single pulmonary vein usually does not create a significant hemodynamic disturbance and often does not require intervention. Anomalous pulmonary veins that cause RV volume overload, or that occur in association with an ASD, should undergo surgical correction. The surgical repair is individualized for the type of anomalous drainage, but whenever possible, anomalous veins are redirected to the LA via a baffle with closure of any associated septal defects.

## VENTRICULAR SEPTAL DEFECTS

VSDs are the most common congenital anomaly recognized at birth, but they account for only about 10% of cases of congenital heart disease in the adult. This decrement in prevalence is in part the result of a high rate of spontaneous closure during the first years of life.[129] In addition, moderate and large lesions generally cause symptoms of heart failure, dyspnea, and failure to thrive in childhood, requiring medical and surgical intervention before adulthood. The VSDs that persist into adult years, therefore, are either small defects, larger defects that have diminished in size, or large defects with irreversible pulmonary vascular disease. Spontaneous closure of VSDs after adolescence is very uncommon. Associated defects are listed in Table 44-2.

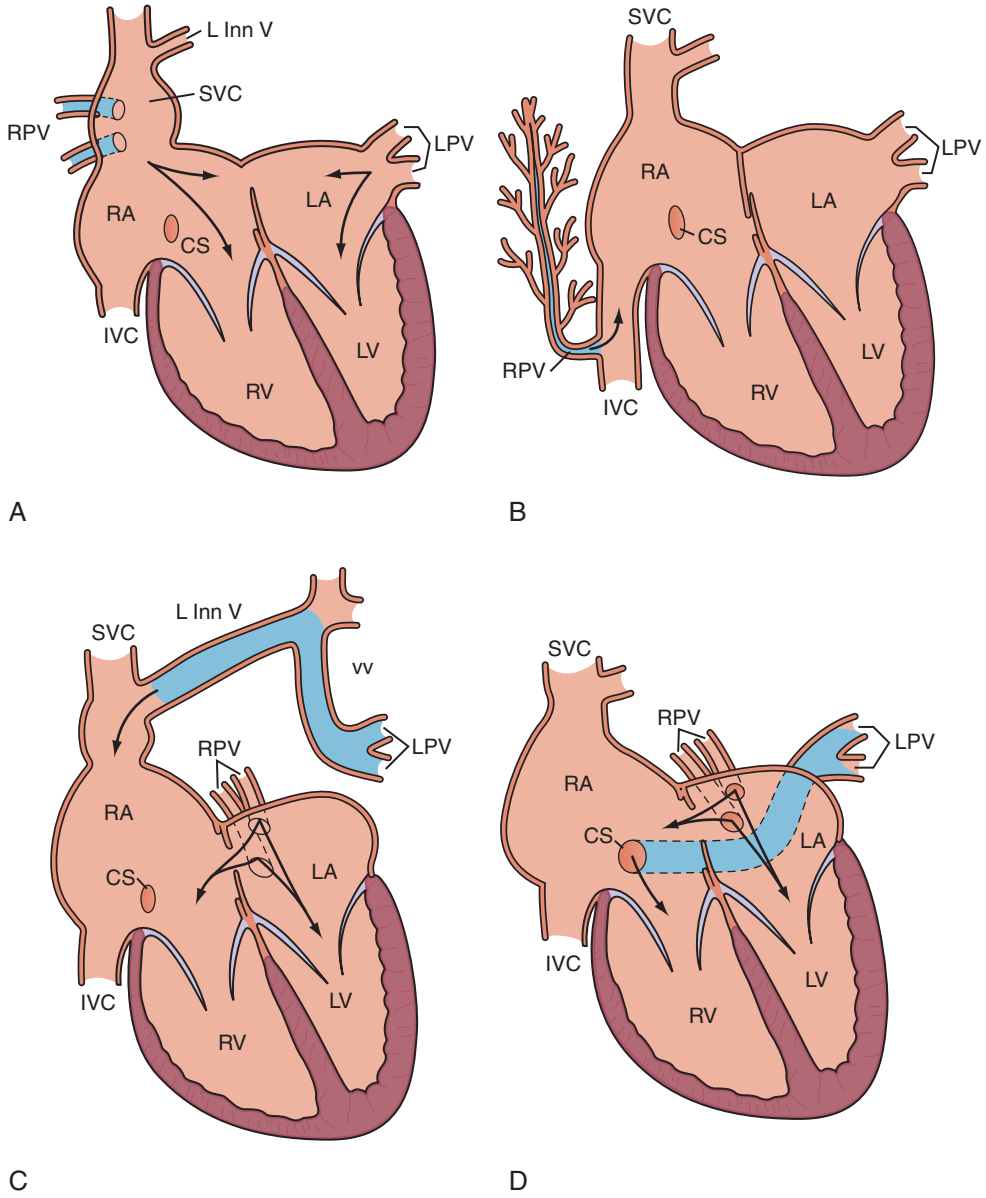

**Figure 44-15** **Diagrammatic depiction of several different types of partial anomalous pulmonary venous return. A,** Right pulmonary veins (*RPV*) drain to superior vena cava (*SVC*). **B,** Right pulmonary veins drain to inferior vena cava (*IVC*). **C,** Anomalous drainage of left pulmonary veins (*LPV*) via ascending vertical vein (*vv*) to left innominate vein (*L Inn V*). **D,** Drainage of left pulmonary veins to coronary sinus (*CS*). *(From Adams FH, Emmanoulides GC, Riemenschneider TA, editors:* Heart disease in infants, children, and adolescents, *ed 4. *Not all conoventricular defects are in the perimembranous septum.

There are four anatomic types of VSDs, with multiple synonyms for each type (Table 44-3). The most common location for adult VSDs is the perimembranous ventricular septum (VSD locations, Fig. 44-16). Shunt flow passes from the LV outflow tract to the RV just beneath the septal leaflet of the tricuspid valve. Perimembranous septal aneurysm formation may occur by fibrous tissue proliferation and incorporation of

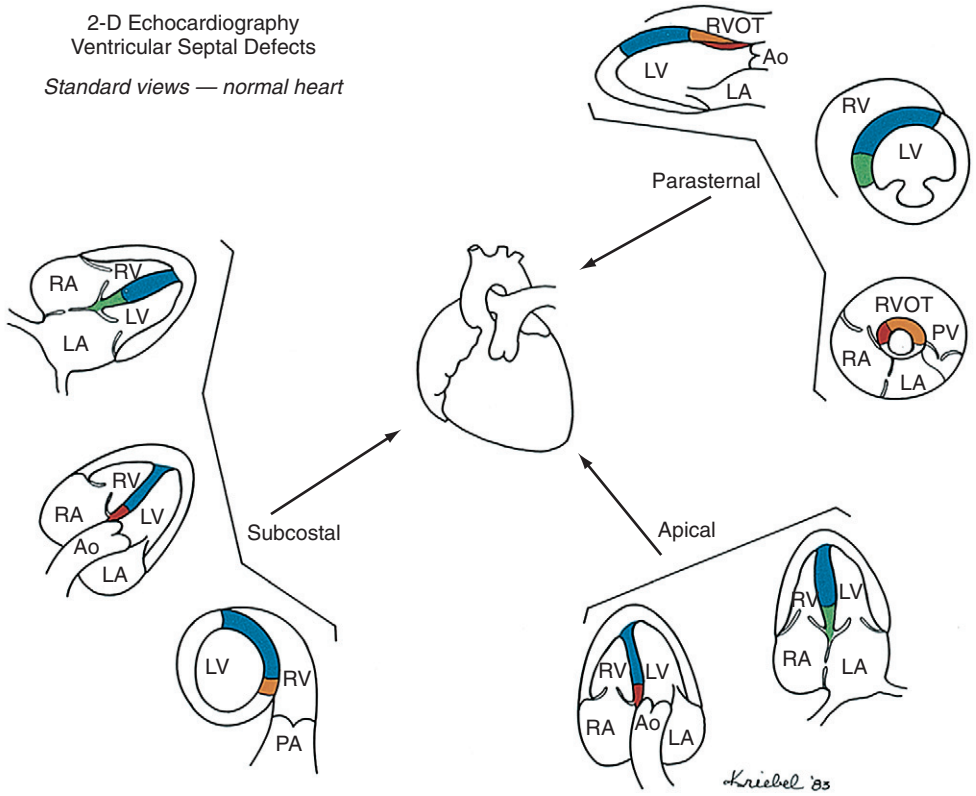

**Figure 44-16 Standard 2D echocardiographic views with color coding of the location of the common types of ventricular septal defects.** Perimembranous septum is coded in *red*, supracristal or infundibular septum in *orange*, inlet septum in *green*, and muscular septum in *blue*. *Ao*, Aorta; *PA*, pulmonary artery; *PV*, pulmonic valve; *RVOT*, right ventricular outflow tract. *(From Levine RA, Gillam LD, Guyer DE, et al: Echocardiography: principles and clinical applications. the septal tricuspid valve leaflet. The aneurysm limits shunt flow and occasionally closes the defect entirely (Fig. 44-17). Aneurysms may become quite large and have been noted to cause turbulence and obstruction in the RV outflow tract. Distortion of the septal leaflet from incorporation into the septal aneurysm may create a communication from the LV outflow tract into the RA, a Gerbode defect. Over time, this defect leads to RA and RV volume overload and atrial arrhythmias. In some perimembranous VSDs, the support of the right aortic cusp is undermined, leading to prolapse of this cusp into the defect. Progressive aortic regurgitation often becomes a more important hemodynamic issue than the ventricular shunt. Subaortic membranes may also develop in association with perimembranous VSDs. Another important associated finding in patients with perimembranous VSDs is double-chamber RV. A low-lying obstructive muscle bundle develops between the inlet and outlet portions of the RV and may lie either proximal or distal to the VSD. This RV outflow obstruction results in RV hypertension, which may be mistaken for pulmonary hypertension from the VSD shunt if the muscle bundle is not detected.

Muscular VSDs are the next most common type of septal defect. The smaller muscular defects often close spontaneously, and the ones that persist into adulthood are generally quite large, sometimes multiple, and associated with pulmonary vascular obstructive disease (Eisenmenger syndrome). These patients may present with cyanosis from reversal of shunt flow. Pulmonary hypertension is avoided in a few individuals by the development of muscular hypertrophy of the RVOT, a sort of natural pulmonary banding referred to as the Gasul

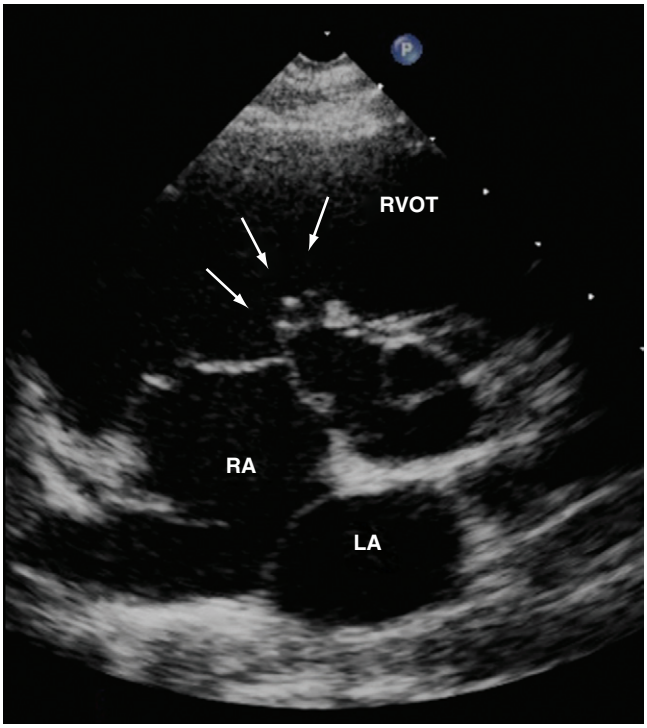

**Figure 44-17 Parasternal short-axis echocardiographic view from patient with perimembranous ventricular septal defect and perimembranous septal aneurysm.** The aneurysm protrudes into the right ventricular outflow tract (*RVOT*) and has associated tricuspid valve septal leaflet tissue.

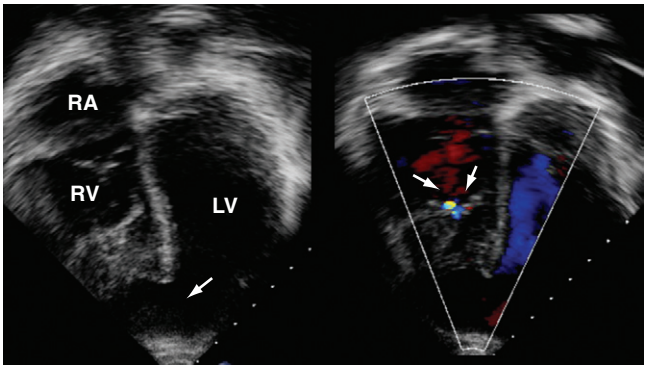

**Figure 44-18 Four-chamber echocardiographic view from patient with large apical muscular ventricular septal defect (VSD) (*arrow*).** Color flow Doppler reveals small area of aliasing (*arrows*) that represents turbulent flow from RV apex through moderator band, which has hypertrophied and effectively closed the large apical VSD shunt.

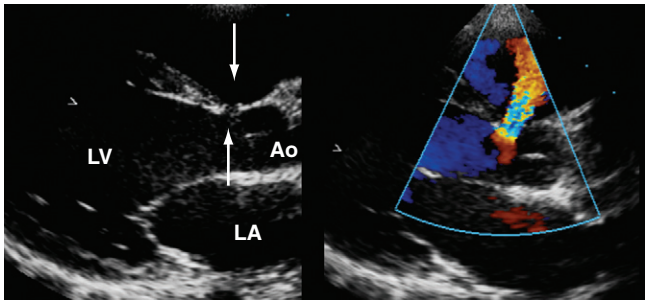

**Figure 44-19 Parasternal long-axis echocardiographic view from a patient with a perimembranous septal defect (*arrows*).** Color flow Doppler reveals shunt flow. *Ao*, Aorta.

phenomenon.[130] Hypertrophy of the moderator band also can restrict shunt flow across sizable apical muscular defects, and when this occurs, the LV and the RV apex become one chamber, giving the cardiac apex an aneurysmal appearance (Fig. 44-18).

Conal septal defects are found more commonly in patients of Asian descent and are frequently associated with aortic regurgitation. Prolapse of the right or left coronary cusp into the VSD may actually decrease the VSD shunt while creating more severe aortic regurgitation.[131] Occasionally, the aortic sinus is extruded through the defect and ruptures, causing a fistula from the aorta to the RV outflow tract.

Defects in the inlet septum are usually the result of a defect in formation of the AV septum. The formation of this portion of the septum is intimately associated with the development of the AV valves and the crux of the heart; therefore, associated AV valve anomalies and a primum ASD are common. Clefts in either the mitral or tricuspid valves may occur. The tricuspid valve occasionally straddles the inlet VSD, with chordal insertions that cross the defect into the left ventricle (LV). When the VSD is small, dense chordal tissue crossing the defect may effectively obstruct flow, limiting the shunt size. Fibrous aneurysms also occur with AV septal defects, decreasing or closing the ventricular septal communication. In most cases, however, an inlet VSD is large and rarely closes spontaneously. AV septal defects are frequently seen in adults with Down syndrome.

### *Echocardiographic Evaluation*

The interventricular septum is a complex fibrous and muscular structure requiring careful interrogation of all aspects by 2D imaging and color Doppler to detect VSDs. Perimembranous VSDs (Fig. 44-19) are best seen in the parasternal long-axis and short-axis views as echo dropout beneath the aortic valve and near the attachment of the septal leaflet of the tricuspid valve. Apical or subcostal five-chamber views also demonstrate the position of the defect in relation to the LV outflow tract and tricuspid valve. Associated abnormalities of the right aortic cusp, subaortic region, and septal aneurysm formation should be delineated. Interrogation for the presence of an obstructive muscle bundle in the RV must be performed. The conal septal VSD can be appreciated in the parasternal long-axis view at the base of the heart, located immediately proximal to the pulmonic valve. If the right aortic cusp has become distorted and prolapses into the VSD, the defect itself may not be detected without color or PW Doppler. Muscular septal defects may be located anywhere within the trabecular septum. Careful scrutiny of parasternal short-axis sweeps and apical, off-axis apical, and subcostal views is required to detect muscular defects. Inlet VSDs are most apparent in apical or subcostal four-chamber views directed posteriorly toward the crux of the heart.

Assessment of the LA and LV chamber size and function is important. Long-standing volume overload is associated with enlargement of left heart structures and may cause LV failure in the adult. In the clinical setting of endocarditis, vegetations can be detected on the aortic valve, the perimembranous septal aneurysm, or the tricuspid valve septal leaflet. Endarteritis at the site of the jet lesion within the RV or RV outflow tract is usually not detectable by 2D imaging unless vegetations are extensive.

Color flow mapping greatly enhances the sensitivity of detection of all forms of VSDs. Left-to-right shunts are readily detected as turbulent jets crossing the septum into the RV when the PA pressures are normal. Ambiguity may occur when there is little difference between left and right heart pressures because shunt flow is low in velocity and difficult to distinguish from other low-velocity flow within the right heart. PW and CW Doppler studies are helpful to confirm the timing and velocity of shunt flow. With small perimembranous and conal septal VSDs, low-velocity diastolic shunt flow may precede the high-velocity systolic jet, presumably owing to the slight differences in late diastolic pressures between the RV and LV. This diastolic flow is sometimes mistaken clinically for aortic regurgitation or another aortic runoff lesion such as a sinus of Valsalva fistula or coronary artery fistula.

CW Doppler measurement of the VSD peak jet velocity allows estimation of RV systolic pressures, and consequently PA systolic pressures. By applying the modified Bernoulli equation, one can calculate the pressure gradient between the left and RV from the VSD peak velocity. Subtracting this gradient from the cuff systolic blood pressure yields the RV systolic pressure (Fig. 44-20). Alignment as parallel as possible to the direction of the VSD jet prevents underestimation of the gradient between the ventricles. Sampling from multiple windows or off-axis views may be required to achieve the best alignment.

Shunt quantification by PW Doppler can be performed in the same way as with ASDs. Measurement of cardiac output across the pulmonic and aortic valves is made, and the pulmonic-to-systemic flow ratio ($Q_p/Q_s$) is computed. The turbulence created in the PA by shunt flow from nearby perimembranous and conal septal defects may make measurement of the pulmonary velocity-time integral inaccurate.

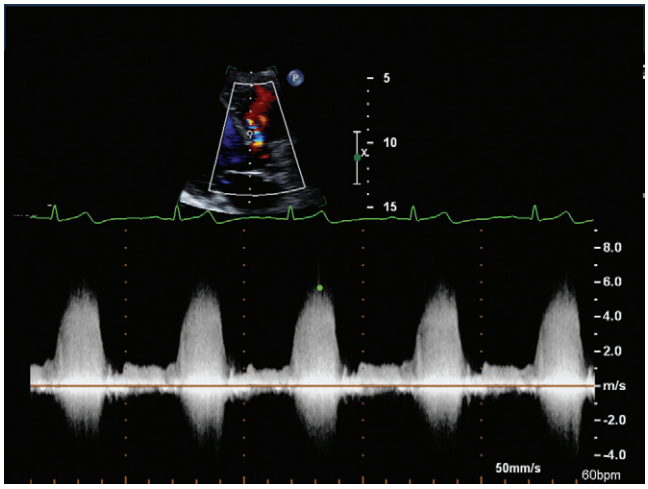

**Figure 44-20 CW Doppler spectral tracing of a ventricular septal defect shunt flow.** RV systolic pressure can be estimated by subtracting LV to RV pressure difference from systolic blood pressure. In this example, transseptal pressure gradient is $4V^2 = 4(5)^2 = 100$ mm Hg. With systolic blood pressure of 130 mm Hg, estimated RV systolic pressure is normal at 30 mm Hg.

An alternative method for deriving shunt ratios involves calculating the volumetric shunt flow across the VSD and adding it to the systemic cardiac output to get the pulmonary flow:

$$Q_p = Q_s + \text{VSD shunt}$$

The VSD shunt volume is the product of the cross-sectional area of the color flow jet at the defect and the velocity-time integral of the CW Doppler systolic flow signal. In one study, this method had better correlation with shunt ratios determined by the Fick method than the standard PW Doppler calculation of $Q_p/Q_s$.[132] It may prove particularly useful in patients with pulmonic stenosis or in whom the pulmonary annulus or pulmonary flow profile is difficult to measure.

### *Management*

The outcome of asymptomatic adults with small VSDs that have not been closed during childhood is excellent.[133,134] Surgical intervention for the adult with a small VSD with no significant LV volume overload and normal PA pressures is not necessary. Periodic follow-up is important, to reassess ventricular size and function and to follow PA pressures. Closure of a small VSD may be indicated when intervention is needed for associated abnormalities, such as significant aortic regurgitation or RV outflow tract obstruction. Surgical closure of a VSD is indicated for patients with a $Q_p/Q_s$ of greater than 2.0 and clinical evidence of LV volume overload or a history of infective endocarditis.[4]

Patients with large VSDs and irreversible pulmonary vascular obstructive disease should be managed medically. In select cases, small VSDs in adults may be closed percutaneously. Indications include residual defects after surgical closure, a history of bacterial endocarditis, or a hemodynamically significant left-to-right shunt. Appropriate placement requires a sufficient distance from the aortic valve or the AV valves to avoid damaging these structures. Acquired heart block, device embolization, and endocarditis have all been described as infrequent complications following device placement.[135,136]

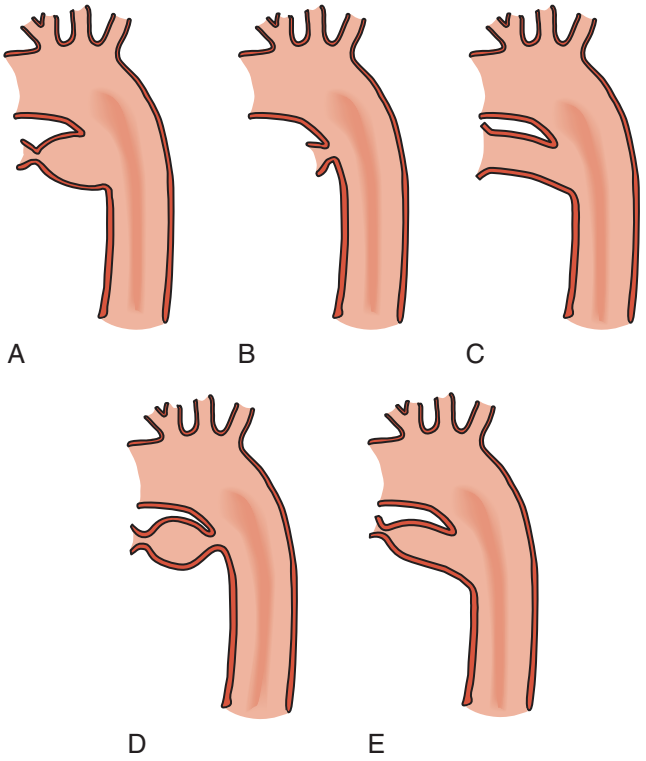

**Figure 44-21 Various shapes of patent ductus arteriosus as seen angiographically.** Ductus is shown arising from lesser curvature of aortic arch. Its configuration varies from window-like communication to long tortuous channel (**A** to **E**). Knowledge of ductal shape is important in choosing best method of transcatheter closure. *(Modified from Krichenko A, Benson L, Burrows P, et al: Angiographic classification of the isolated, persistently patent ductus arteriosus and implications for percutaneous catheter occlusion.* Am J Cardiol *63:878, 1989. Reprinted by permission of the publisher. Copyright 1989 by Excerpta Medica Inc.)*

## PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a normal fetal cardiac structure that functionally closes within the first days of life. It arises from the PA bifurcation near the origin of the left PA and inserts into the lesser curvature of the descending thoracic aorta. Ductal shape is quite variable, sometimes being a long, tortuous channel or a conical connection or even a short window-like communication (Fig. 44-21). The ductus arteriosus normally closes spontaneously within the first 24 to 48 hours of life. Persistence beyond the neonatal period is abnormal, and spontaneous closure after the first year of life is distinctly uncommon. This lesion is found only in about 2% of adults with congenital heart disease. It is usually an isolated anomaly, but it can occur in association with complex lesions, VSD, or coarctation. The ductal tissue becomes more friable and calcified with increasing age. Aneurysms of the ductus arteriosus or the closed ductal diverticulum also occur and may rupture.

The clinical presentation of an adult with a patent ductus arteriosus depends on the size of the shunt. Trivial shunts may be clinically silent, detected by an echocardiographic Doppler study that was requested for an unrelated lesion. Small ductal shunts produce a continuous murmur at the left upper sternal border, which can be confused with the murmur of a coronary artery fistula, mixed aortic valve disease, or a VSD with aortic regurgitation. Patients with moderate or large shunts develop heart failure and atrial arrhythmias from the long-standing LV

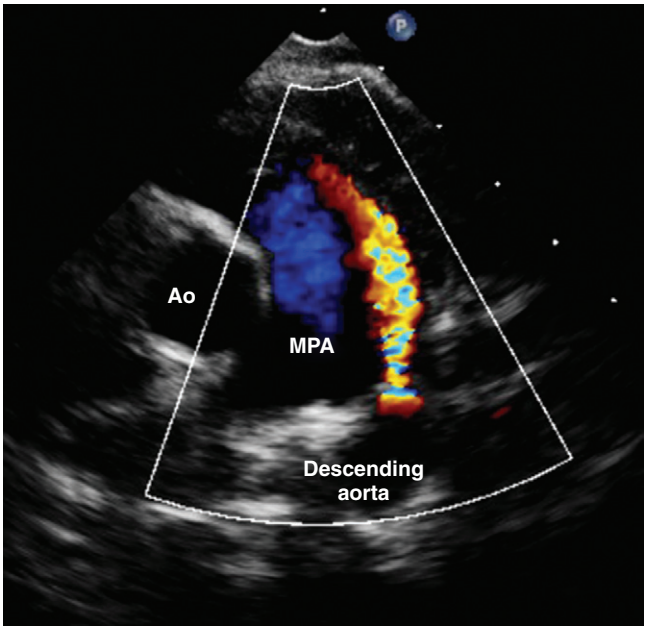

**Figure 44-22 Parasternal short-axis echocardiographic view of base of heart demonstrating small patent ductus arteriosus.** Stream of left-to-right shunt flow is show in color as it passes from descending thoracic aorta to the main pulmonary artery (*MPA*). *Ao*, Aorta.

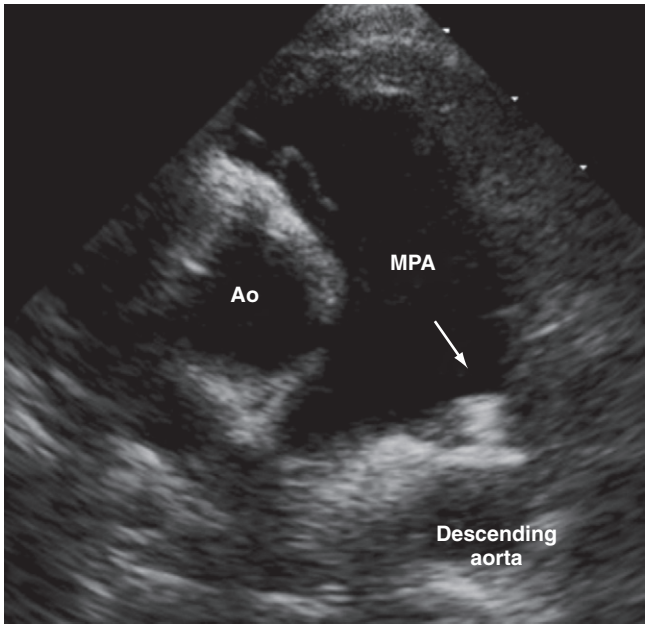

**Figure 44-23 Parasternal short-axis echocardiographic image from patient following patent ductus arteriosus occluder device closure.** Occluder device (*arrow*) is seen near origin of left pulmonary artery. *Ao*, Aorta; *MPA*, main pulmonary artery.

volume overload. With the onset of pulmonary hypertension and reversal of the shunt, the murmur decreases in intensity or disappears and differential cyanosis of the extremities may be noted.

### *Echocardiographic Evaluation*

2D imaging of the ductus arteriosus is accomplished with ease in the neonate and young child, but it becomes more challenging in older adolescents and adults. The direct view of the ductal channel is best obtained in a high left parasternal window at the PA bifurcation where the left PA crosses the descending thoracic aorta. The main PA appears to "trifurcate" with the third channel being the ductus. Visualization is possible in the suprasternal notch views of the aorta focused on the lesser curvature of the aorta opposite to the left subclavian artery. Diagnosis of a patent ductus arteriosus in the adult usually is made with color flow Doppler imaging rather than direct 2D imaging. The left-to-right flow stream appears as a red jet in diastole entering the main PA near the left PA origin (Fig. 44-22). Although patent ductus arteriosus shunt flow is continuous, the systolic component is usually washed along with the systolic flow in the main PA. If flow can be visualized within the ductus itself, however, a continuous Doppler signal is present. As the PA pressure rises, the velocity of the patent ductus arteriosus shunt decreases, and it becomes more difficult to distinguish a discrete patent ductus arteriosus jet from other low-velocity flows within the dilated pulmonary vessel. Adults with a dilated main PA often have a low-velocity retrograde flow in late systole from swirling of flow within the enlarged vessel. PW Doppler can distinguish this from ductal flow by the difference in timing. Continuous flow into the PA also is seen with coronary artery fistulas and with an aortopulmonary window. Demonstration of the color Doppler flow stream emanating from the bifurcation and originating within the descending thoracic aorta should confirm that the shunt comes from a patent ductus arteriosus.

CW Doppler sampling of ductal shunt flow is important for estimation of PA pressure. When the ultrasound beam is aligned from the high left parasternal window directly into the mouth of the patent ductus arteriosus, systolic and diastolic flow velocity can be recorded. Applying the modified Bernoulli equation, the peak systolic velocity of the patent ductus arteriosus jet can be used to calculate the systolic gradient between the aorta and the PA. Subtracting this gradient from the cuff systolic aortic blood pressure yields the PA systolic pressure.

### *Management*

Indications for patent ductus arteriosus closure include LA and/or LV enlargement, net left-to-right shunting, or prior endocarditis.[4] A patent ductus arteriosus discovered in the adult is often friable and calcified, and percutaneous device closure is often feasible. If the patent ductus arteriosus is associated with other cardiac lesions that require surgical correction, the ductus may be closed at the time of surgery; however, percutaneous closure before surgery may also be entertained. Percutaneous closure of a patent ductus arteriosus in an adult is usually technically successful, with a low rate of complications.[137] Several types of devices are currently in use, including a pluglike occluder within the ductus, umbrella devices that occlude the orifices at each end of the ductus, and coils that are extruded within the ductus and thrombose the channel.[138] TEE guidance of device placement has not played as critical a role for the ductus arteriosus as for ASD closure. The difficulty in imaging the anatomic details of the ductus arteriosus by TEE limits the usefulness of this modality, and fluoroscopic monitoring alone is sufficient for accurate placement.

TTE Doppler assessment after device closure is quite helpful to ensure appropriate device position and assess residual shunting. The highly reflective device can be appreciated by 2D imaging of the pulmonary bifurcation and along the lesser curvature of the aorta (Fig. 44-23). Malpositioning of the patent ductus arteriosus devices can result in protrusion of a portion of the occluder into the aortic lumen or into the main PA.[139] Feasibility and efficacy of device or coil occlusion of the patent ductus arteriosus are excellent. Complication rates are low but include device or coil embolization, hemolysis, and left PA stenosis.

## CORONARY ARTERY FISTULAS

A coronary artery fistula is an abnormal communication of a coronary artery with a cardiac chamber, great vessel, or other vascular structure without passing through the myocardial capillary bed. Most coronary artery fistulas are congenital, resulting from persistence of embryonic channels between cardiac chambers and the developing coronary circulation. Coronary artery fistulas are rare, reported in 0.2% of coronary angiograms, and are often discovered incidentally.[140] The clinical presentation depends on the site of termination of the fistula and the degree of shunting. Over 90% of coronary artery fistulas terminate in the right heart—RV, RGA, PA, coronary sinus, or superior vena cava. A continuous murmur is caused by shunting from the aorta to the right heart. When the fistula communicates to the LV, the murmur is audible only in diastole. Shunting is usually modest; in a review of a single-center experience with coronary artery fistulas, the median pulmonary-to-systemic flow ratio was 1.3 : 1.[141] Signs of RV volume overload and heart failure may appear later in life from the long-standing left-to-right shunt. The shunt is rarely large enough to cause severe pulmonary hypertension. Angina related to myocardial ischemia has been reported in a small number of patients as a result of "coronary steal" as the fistula diverts flow from the normal coronary circulation.[142]

### *Echocardiographic Evaluation*

Echocardiographic Doppler diagnosis of coronary artery fistula begins with the detection of enlargement of the proximal coronary artery involved in the abnormal communication. The affected coronary vessel is diffusely enlarged and can often be traced to the site of termination with knowledge of the expected coronary course and the usual sites of fistulous communication. Aneurysmal lakes develop near the communication with the receiving chamber or vessel, appearing as large sonolucent regions (Fig. 44-24). Enlargement of the heart chambers give an indication of the amount of left-to-right shunting.

Color flow Doppler demonstrates continuous flow with the involved coronary artery and helps to localize the exit site.[143,144] When a small fistula from the left coronary artery to PA is present, a tiny stream of continuous flow may be found incidentally in the proximal main PA. Larger fistulas are diagnosed by scanning the RA, RV, and LV for a continuous turbulent flow signal.

TEE can also detect coronary enlargement and visualize the enlarged and aneurysmal channels of the fistula. It is particularly helpful intraoperatively to assess residual fistulous flow and segmental wall motion after ligation of the feeding coronary vessel.[145]

Contrast echocardiography has been used in conjunction with angiography to detect fistulous communication when there are multiple entry sites of a coronary artery fistula.[146] If the fistula terminates in both the RV and LV, angiographic contrast may stream preferentially to the lower-pressure chamber. Faint opacification of the LV easily may be overlooked. With injection of agitated saline into the arterial catheter, however, even a trace of contrast in the LV is obvious echocardiographically.

### *Management*

Small, clinically silent fistulas do not require closure. Patients with fistulas that are large enough to cause coronary dilation should be followed clinically for development of symptoms of myocardial ischemia or ventricular volume overload. Coronary angiography is generally necessary to completely evaluate the coronary circulation for coexistent atherosclerotic disease and for complete anatomic delineation of the fistula. Closure of large fistulas may be approached surgically or with transcatheter coil occlusion or devices, depending on the specific anatomy of the lesion.[147,148]

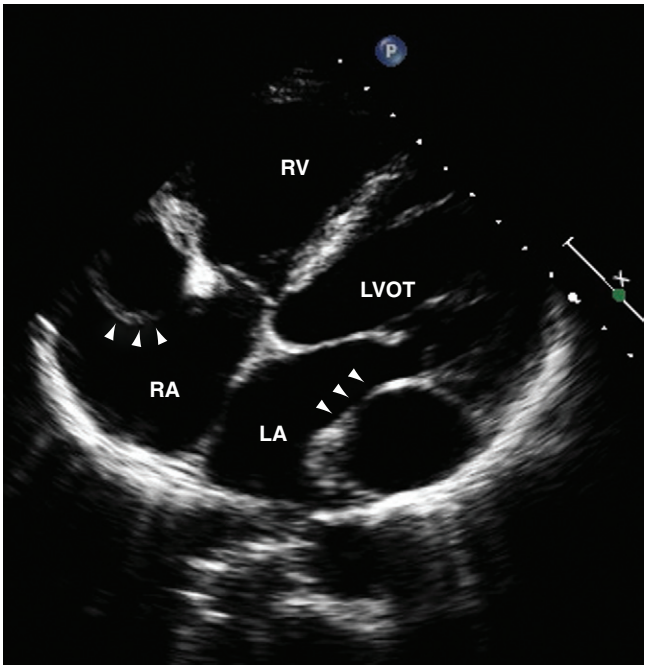

**Figure 44-24 Off-axis apical four-chamber echocardiographic view from patient with coronary artery fistula demonstrating large venous lakes (*arrowheads*) seen along atrial surfaces.** *LVOT,* Left ventricular outflow tract.

# Complex Congenital Heart Disease

Adults who survive with complex congenital heart defects represent a small but intriguing fraction of an adult cardiology practice. In the current surgical era, the vast majority of patients with complex lesions have had palliative surgeries during childhood (see Chapter 45). The rare patient reaches adulthood without prior intervention and seeks medical attention for symptoms that may be typical of acquired heart disease—heart failure, angina, arrhythmias, endocarditis—only to be found to have complex congenital heart disease when an echocardiographic study is performed. A brief consideration is given here to some of the complex lesions that permit natural survival into adulthood.

## TETRALOGY OF FALLOT

Originally described by Stensen in 1671, the anatomic features of "la maladie bleue" as detailed by Fallot in 1888 included a large VSD, an overriding aorta, pulmonic stenosis, and RV hypertrophy (Fig. 44-25). Approximately 15% of patients have an ASD (pentalogy of Fallot) and 25% have a right aortic arch. Anomalous origin of the left anterior descending coronary artery or bilateral left anterior descending vessels occur in up to 9% of patients, which may complicate the patch repair of the RV outflow tract as the anomalous vessel passes over it.[149,150]

Physiologically, the clinical picture with tetralogy of Fallot is that of a VSD with RV outflow obstruction of variable severity. Most patients develop severe cyanosis within the first year of

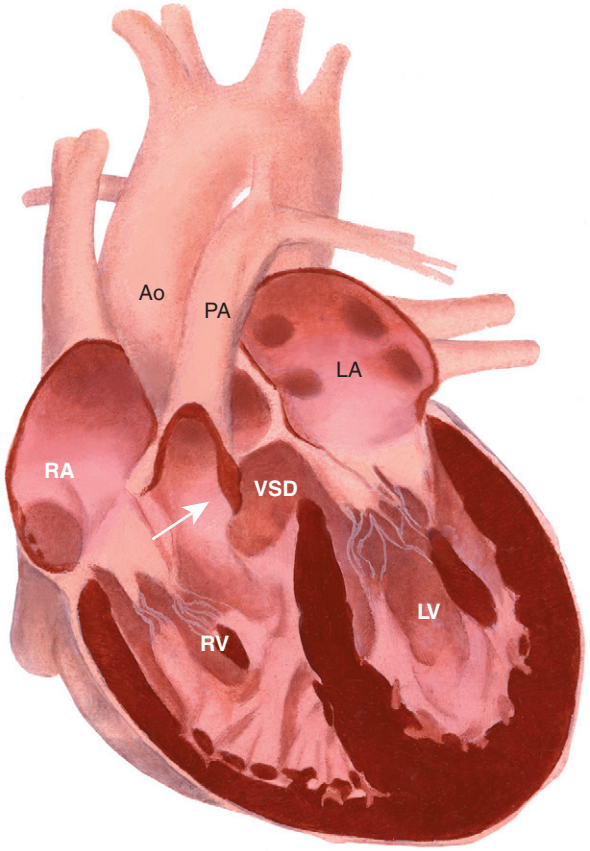

**Figure 44-25 Anatomic features of tetralogy of Fallot.** There is a large subaortic ventricular septal defect (*VSD*), aorta (*Ao*) straddling ventricular defect, and deviation of conal septum (*arrow*) into RV outflow tract creating subpulmonic stenosis.

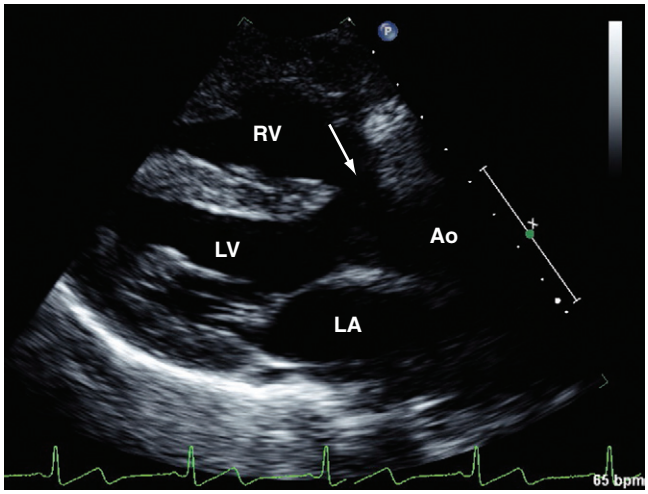

**Figure 44-26 Parasternal long-axis view from patient with tetralogy of Fallot demonstrating large conoventricular septal defect (*arrow*) and aortic (*Ao*) override of interventricular septum.**

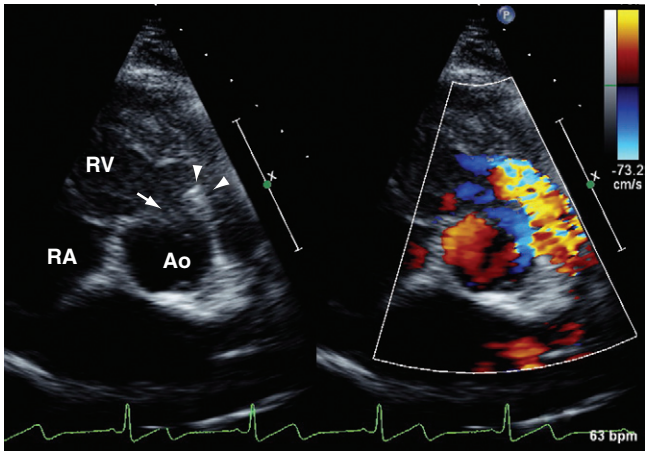

**Figure 44-27 Parasternal short-axis views from patient with tetralogy of Fallot demonstrating anterior deviation of conal septum (*arrowheads*).** *Arrow* indicates ventricular septal defect. Color flow Doppler reveals acceleration of blood flow at this level. *Ao*, Aorta.

life, requiring surgical palliation or correction. Only 11% of patients will survive to adulthood without intervention.[151] With only a modest degree of pulmonic stenosis, patients may survive with few symptoms into adult years. Paradoxically, the other group of late survivors without surgery includes patients with complete obstruction to blood flow. This subgroup of patients, those with pulmonic valve atresia and VSD, has multiple aortic-to-pulmonary arterial collaterals that supply the pulmonary circulation with only a modest amount of systemic desaturation. Morbidity and mortality in this group of patients is commonly due to symptoms from chronic hypoxia and secondary erythrocytosis and includes cerebrovascular accidents, brain abscess, endocarditis, and arrhythmias.

### *Echocardiographic Evaluation*

Echocardiographic Doppler evaluation can accurately define the characteristic features of tetralogy of Fallot. The conoventricular VSD usually is large and lies immediately beneath the dilated overriding aortic root (Fig. 44-26). In the parasternal views of the LV, the size of the VSD can be appreciated. The direction and velocity of shunt flow across the defect are easily determined in these planes by color flow and PW Doppler imaging. Unless the VSD has become restrictive over time, the shunt is low velocity and predominantly right-to-left. Parasternal short-axis views of the RVOT and aorta demonstrate the typical anterior deviation of the conal septum and narrowing of the RVOT (Fig. 44-27). A small pulmonary annulus, valvular pulmonic stenosis, and hypoplasia of the main and branch pulmonary arteries also are visible in this view. The systolic gradient across the stenotic outflow tract should be measured by CW Doppler imaging. In patients with native or acquired pulmonary atresia, the RVOT is filled with muscle and ends blindly with no visible pulmonic valve leaflets and no detectable flow by PW Doppler. When the parasternal views are not able to visualize the PA because of chest wall or lung interference, scanning from the suprasternal notch or high left subclavicular area may provide the necessary access to the branch pulmonary arteries. The proximal right PA is measurable in nearly all patients with confluent pulmonary arteries. Suprasternal or high parasternal views of the ascending aorta are most accurate for measuring the right PA, which passes behind the aorta as a small cross-sectional lumen in the long-axis plane. Aortopulmonary collaterals can be detected but are not fully delineated by 2D echocardiography. Apical and subcostal five-chamber views depict the large VSD and the overriding aorta. Aortic root dilation and regurgitation can also be evaluated at this point in the examination. Moving the scan plane even more anteriorly from the five-chamber view brings the RVOT into view. This approach may provide better alignment of the Doppler cursor for sampling the RV outflow tract gradient.

In the cross-sectional views of the aortic root at the base of the heart, attempts should be made to visualize the coronary arteries. Enlargement of the right coronary orifice hints at a larger blood supply through this vessel, perhaps caused by the anomalous origin of the left anterior descending coronary artery. Careful attention should be directed to the cross-sectional lumen seen anterior to the RV outflow tract in the high parasternal views and to anteriorly coursing vessels arising from the proximal right coronary artery. Although some success has been reported with TTE study of the coronary arteries in adults with tetralogy of Fallot,[152] an alternative imaging modality is often needed in preoperative adults.

Transesophageal imaging in tetralogy of Fallot can provide nearly all the important diagnostic information. Malalignment of the conal septum is apparent in the midesophageal longitudinal views of the RV outflow tract or from the transgastric approach. The pulmonic valve anatomy and the sizes of the main and right PA can be determined from the transverse views in the midesophagus or high esophagus. The left PA is often more difficult to image. The VSD and overriding aorta can be appreciated in transverse views from the midesophagus and from transgastric views.

### *Management*

Some adults with tetralogy of Fallot will be candidates for complete repair. Surgery for this lesion can be accomplished in the adult with acceptable mortality and with gratifying relief of cyanosis and improvement in functional class. In the subgroup with pulmonary atresia, decisions regarding surgical correction are based on the confluence and size of the PAs and the size and distribution of aortopulmonary collaterals.

## CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES (CCTGA OR L-LOOP TGA)

Also known as "physiologically corrected transposition of the great arteries," this is a malformation in which the great arteries are transposed but the ventricles are inverted and discordant relative to the atria (Fig. 44-28; see also Fig. 43-11). In the absence of associated lesions, L-loop TGA (Fig. 44-29) may not be clinically recognized and is compatible with a normal life span.[153,154] Complete heart block is increasingly prevalent with increasing age.[155] Several associated lesions may be present and are listed in Box 44-8.

Even with associated lesions, L-loop TGA is often compatible with survival into adulthood. The limiting factor is often the degree of systemic RV dysfunction and tricuspid regurgitation.[156,157] Severe tricuspid regurgitation is associated with poor long-term outcomes in this patient population.

### *Echocardiographic Evaluation*

The anatomic features and echocardiographic diagnosis of this lesion are reviewed in Chapter 43. Clinical echocardiographic-Doppler follow-up in patients with L-loop TGA is directed toward monitoring systemic RV function and systemic AV valve regurgitation. Ventricular shunting and pulmonary outflow obstruction also require serial assessment. Standard geometric models for assessing LV volumes and ejection fraction do not accurately model the unusual shape of the systemic RV; therefore the Simpson's rule method using two orthogonal apical planes may be a more accurate echocardiographic method for calculating systemic ventricular volume and function in this

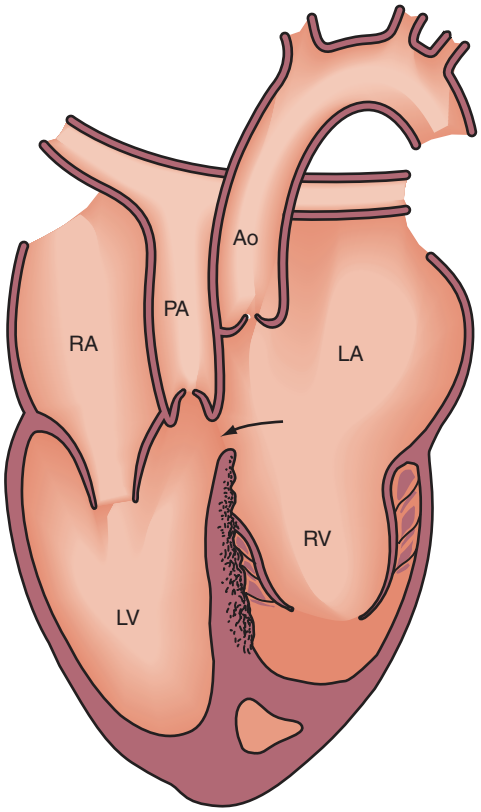

**Figure 44-28 Anatomic features of congenitally corrected transposition.** Aorta (*Ao*) lies anterior and to left of pulmonary artery (*PA*). It arises from morphologic RV, which is left sided. Most commonly associated lesions include pulmonic stenosis, ventricular septal defect (*arrow*), and Ebstein-like malformation of left-sided tricuspid valve. *(From King ME: Complex congenital heart disease II: a pathologic approach. In Weyman AE, editor:* Principles and practice of echocardiography, *ed 2, Philadelphia, 1994, Lea & Febiger, p 1038.)*

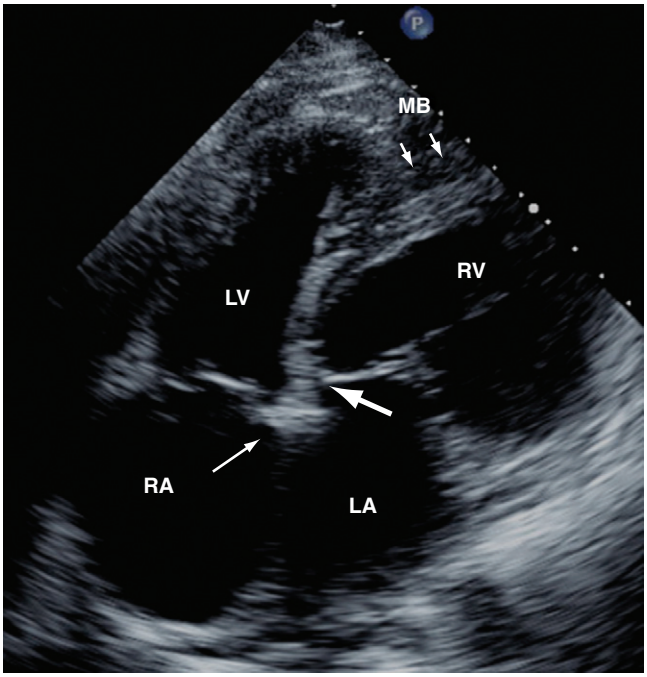

**Figure 44-29 Congenitally corrected transposition of the great arteries.** Off-axis apical four-chamber echocardiographic view shows that the anatomic RV has tricuspid valve (*large arrow*), which is more apically positioned than the mitral valve (*small arrow*). Prominent moderator band (*MB*) is visualized in RV (*double arrows*).

**Box 44-8**

**ASSOCIATED DEFECTS WITH CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES**

Ventricular septal defect
Pulmonary outflow obstruction
Ebstein malformation of the tricuspid valve
Dextrocardia
Ventricular noncompaction
Atrioventricular conduction abnormalities

group. Three-dimensional echocardiography does not require geometric assumptions and is an alternative modality for evaluating this anatomy.[158] Magnetic resonance imaging is also useful in following systemic RV function.[159,160] An alternative nongeometric means of serially following systemic ventricular function in this group of patients is the myocardial performance index, which uses Doppler measures of isovolumic time intervals and ejection time.[161]

### *Management*

The diagnosis of L-loop TGA may be made for the first time in adulthood; in one cohort the initial diagnosis was made in adulthood in 66% of patients, 17% of whom were more than 60 years of age at the time of diagnosis.[154] The asymptomatic adult patient with L-loop TGA requires no intervention. The incidence of complete heart block increases with age, and caution must be taken during any invasive cardiac procedures. The electrocardiogram demonstrates deep Q waves in the right precordial leads that can be mistaken for ischemic injury. The prevalence of systemic RV failure is difficult to determine, as the definition of systemic RV failure is widely variable in the literature, and this group is often discussed in combination with people who have undergone atrial switch procedures for complete (D-loop) transposition of the great arteries (see Fig. 43-10 and Chapter 45). Medical management of systemic RV dysfunction is appropriate, although studies are limited documenting the benefits of medical therapies proven for LV dysfunction, such as angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.[162]

Patients with associated VSD and pulmonic stenosis should be managed in a similar fashion to those with normally related great arteries. If pulmonary outflow tract obstruction is severe enough to require operative correction, or if the systemic tricuspid valve requires surgical attention, the options for repair are either physiologic or anatomic. Physiologic repair would entail simply repairing or replacing the tricuspid valve, closing the VSD, or bypassing the pulmonic stenosis with an LV-PA conduit. This, however, leaves the anatomic RV as the systemic ventricle, which is problematic for long-term survival. Anatomic repair requires a double switch procedure, with an atrial switch, a Rastelli procedure to connect the LV to the aorta, and an RV-PA conduit. This anatomic approach is a more extensive surgery, and the result is an anatomic LV as the systemic ventricle and unloading of the RV with its abnormal tricuspid valve. In order for this anatomic surgery to be successful, the LV must be adequately trained to accept systemic pressures (through native pulmonic stenosis or placement of a PA band). This is most often performed in a young age group. The choice of surgical approach must be individualized to the patient's anatomy and physiology.[163,164]

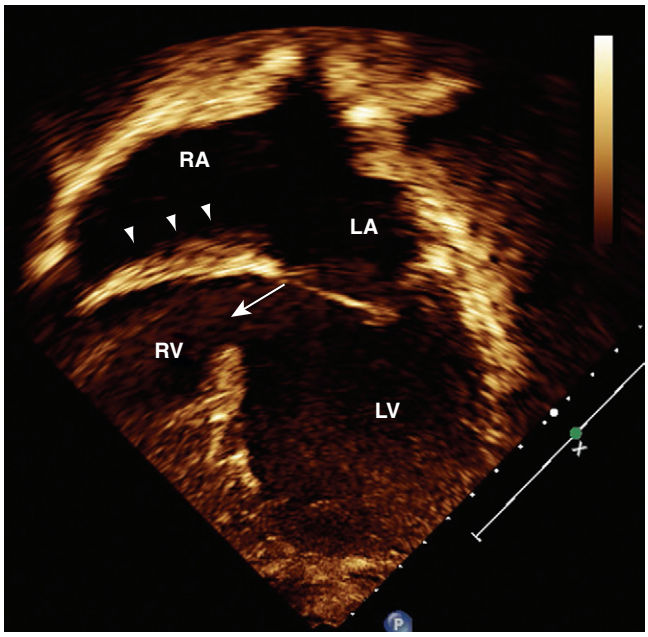

**Figure 44-30 Apical four-chamber echocardiographic view from patient with tricuspid atresia.** Atretic tricuspid valve is a thick, fibrous ridge (*arrowheads*) at base of enlarged RA. Ventricular septal defect (*arrow*) is present, which leads into a tiny RV chamber.

Adults with L-loop TGA should have regular follow-up with a cardiologist who has expertise in ACHD. Echocardiographic Doppler study and/or cardiac MRI should be performed yearly or at least every other year by staff trained in imaging complex congenital heart disease.[4]

## TRICUSPID VALVE ATRESIA

Tricuspid valve atresia constitutes 1% to 3% of all congenital heart defects, and fewer than 10% of patients survive beyond childhood without surgery.[165] In this malformation, the atrioventricular valve of the morphologic RV is absent or imperforate. The RV is variably underdeveloped and there is compensatory left heart enlargement. An atrial septal communication is present to allow egress of blood from the blind RA, and a VSD of variable size is usually present. Most commonly, the great vessels are normally related, but in up to 35% of cases, they are malposed, with or without obstruction to pulmonary blood flow. The physiology in the adult is that of a central mixing lesion creating cyanosis, with VSD and pulmonic stenosis, or VSD and pulmonary vascular disease. The adult with uncorrected tricuspid atresia is susceptible to multiorgan dysfunction due to the complications from chronic cyanosis.

### *Echocardiographic Evaluation*

In the place of the tricuspid valve, a thick band of fibromuscular tissue is recognized by 2D imaging (Fig. 44-30). No evidence of flow can be demonstrated by color or PW Doppler. The RA is enlarged, often with a prominent Eustachian valve. The size of the RV is related to the size of the VSD during fetal development. It may be vestigial and slitlike with a small VSD, or nearly normal in size with a large VSD. Progressive restriction of the VSD may occur.[166] When the great vessels are normally related, progressive VSD closure creates further obstruction to pulmonary blood flow. In patients with transposed great arteries, the systemic blood flow is jeopardized.

Thus, serial determination of the VSD size by 2D imaging and VSD gradient by Doppler is an important part of the echocardiographic evaluation.

The LV in this anomaly is enlarged, and systolic function may be impaired from long-standing volume overload. Quantitative assessment of ventricular function is performed by the usual echocardiographic methods and is an important factor in determining surgical options.

Echocardiographic study in the patient with tricuspid atresia also must focus on the presence, size, and origin of the aorta and PA. The orientation and relative size of the great arteries and associated abnormalities of the valvular and subvalvular region all can be appreciated from parasternal windows. Apical and subcostal images are particularly useful in establishing ventriculoarterial relationships and measuring gradients across the semilunar valves and outflow tracts.

The interatrial septum in the adult with uncorrected tricuspid atresia generally has a large, unrestricted ASD. Apical, subcostal, or right parasternal windows optimally should delineate the atrial septum and demonstrate right-to-left shunting by PW and color Doppler.

### *Management*

Patients with tricuspid atresia and restricted pulmonary blood flow may be candidates for a Fontan procedure, which diverts systemic venous return directly to the PA. The optimal candidate must have good LV function, no significant mitral regurgitation, and normal branch PA anatomy and pulmonary resistance. Natural survivors with tricuspid atresia and pulmonary vascular disease who are not amenable to surgical correction may be considered for heart-lung transplantation.[167]

## FUNCTIONAL UNIVENTRICULAR HEART

The basic element of the functional univentricular heart is communication of both AV valves, or a single common AV valve, with a single ventricular chamber.

Natural survival of adolescents and adults with this complex congenital anomaly depends on fortuitous streaming of oxygenated and unoxygenated blood and protection of the pulmonary circulation by an optimal degree of pulmonic stenosis.

### *Echocardiographic Evaluation*

The important aspects to ascertain echocardiographically in patients with this anomaly are listed in Box 44-9.

### *Management*

Adults with functional univentricular heart who are well balanced may not require surgical intervention, as long-term survival in the unoperated state in some cases equals that of corrective surgery.[168] Particularly, adults with double-inlet LV and well-balanced circulation may survive into their sixth decade of life with good functional capacity and preserved ventricular function.[169] However, operative strategies aimed at relieving the complications from cyanosis and preservation of late ventricular function may be entertained.[170] This consideration of a "late Fontan" surgery requires adequate PA size and confluence, low PA resistance, competent systemic AV valves, good ventricular function with low end-diastolic pressure, and unobstructed ventricular outflow. Palliative surgeries may also be considered, such as cavopulmonary or aortopulmonary shunts, in cases where the foregoing criteria are not met.[171]

**Box 44-9**

**IMAGING CHECKLIST IN THE EVALUATION OF ADULTS WITH FUNCTIONAL UNIVENTRICULAR PHYSIOLOGY**

- Presence and location of an accessory chamber
- Number and functional status of the atrioventricular valves
- Number and orientation of the great vessels and their relation to the main or accessory chamber
- Presence and severity of outflow tract obstruction
- Functional performance of the systemic ventricle
- Nature and adequacy of venous return in the case of atresia of one of the atrioventricular valves

**KEY POINTS**

- Adults with congenital heart disease may escape detection during childhood because their lesion is mild or slowly progressive, because their physiology is well balanced or protected, or because of poor access to medical care.
- The mode of presentation of the adult with unoperated congenital heart disease is often similar to that of adults with acquired heart disease—heart failure, arrhythmia, murmur, hypertension, or endocarditis.
- Bicuspid aortic valve is the most common form of congenital heart disease in the adult and requires continued follow-up for progressive stenosis or regurgitation and aortic root dilation.
- Despite marked structural abnormality, patients with Ebstein anomaly are often able to live active lives, but may experience adverse events such as tachyarrhythmias, paradoxical emboli, progressive tricuspid regurgitation, and heart failure.
- Discrete subaortic stenosis may be masked by development of septal hypertrophy, requiring careful TTE and TEE studies to elicit the correct pathophysiology.
- Aortic coarctation may be missed by transthoracic imaging, but PW Doppler in the abdominal aorta may alert the examiner to the flow disturbance more proximally in the aorta.
- Doppler gradients in supravalvular aortic stenosis and long-segment aortic coarctation often overestimate the true gradient because of flow acceleration in a tubular vessel with pressure recovery.
- Sinus venosus defects are the most frequently missed septal defect by TTE resulting from incomplete imaging of the most superior aspect of the septum; TEE or cardiac MRI is often required to detect the defect and partial anomalous pulmonary venous drainage.
- In the cyanotic adult with unoperated congenital heart disease, detecting the presence of pulmonic stenosis at any level may convert the clinical status from inoperable to surgically treatable.
- Alternative imaging modalities, such as cardiac MRI and CT, are important adjuncts to echocardiography in the complete assessment of the adult with congenital heart disease.

# 45 Echocardiographic Evaluation of the Adult with Postoperative Congenital Heart Disease

JAMIL A. ABOULHOSN, MD | JOHN S. CHILD, MD

**General Postoperative and Postinterventional Congenital Heart Disease Issues**
- Atrial and Ventricular Incisions and Devices
- Anatomic and Valvular Residua and Sequelae
- Ventricular Function
- Conduits, Patches, and Prosthetic Materials

**Palliative Procedures**
- Pulmonary Artery Banding
- Palliative Aortopulmonary Shunts
- Glenn Shunts

**Corrective Procedures for "Simple" Lesions**
- Atrial Septal Defects
- Ventricular Septal Defects
- Patent Ductus Arteriosus
- Bicuspid Aortic Valve
- Subaortic Stenosis
- Coarctation of the Aorta
- Ebstein Anomaly
- Pulmonic Stenosis
- Anomalies of the Coronary Arteries

**Repair of "Complex" Malformations**
- Atrial Switch Surgery
- Arterial Switch Surgery
- Total Anomalous Pulmonary Venous Connection
- Fontan Atrial Surgery
- Atrioventricular Septal Defects
- Biventricular Repairs
- Tetralogy of Fallot
- Complete Transposition of the Great Arteries
- Congenitally Corrected Transposition of the Great Arteries
- Double-Outlet Right Ventricle

The incidence of moderate and severe forms of congenital heart disease is approximately 6 per 1000 live births (19 per 1000 if a bicuspid aortic valve is included).[1] In the past 60 years, advances in diagnosis and in catheter and surgical treatment have resulted in nearly 1 million adult survivors with congenital heart disease in the United States.[2-6] Most surgically modified congenital heart diseases leave behind (residua) or cause (sequelae) problems ranging from trivial to serious.[6,7] An explosion in transcatheter interventions for congenital heart disease over the past three decades has obviated the need for surgery in an ever-growing list of native and postoperative lesions.

The evaluation and management of adult congenital heart disease requires detailed knowledge of the

1. Original anatomy and physiology;
2. Dynamic changes in anatomy and physiology that occur with time;
3. Effects of "adult" diseases (e.g., systemic arterial hypertension, coronary artery disease) or conditions (e.g., pregnancy) on that physiology;
4. Types of operative repair (both past and present) for each complex of lesions;
5. Presence and extent of possible postoperative residua, sequelae, and complications;
6. Types of transcatheter interventions and devices, their echocardiographic appearance, expected sequelae, and potential complications; and
7. Proper selection, performance, and interpretation of modalities required for anatomic imaging and hemodynamic assessment.[8]

It is impractical to repetitively catheterize these individuals; combined two-dimensional (2D), three-dimensional (3D), and Doppler echocardiography is often more useful than angiography in providing details of valvular anatomy and in visualizing patches and ventricular wall thickness.[8] In patients who have undergone transcatheter interventions, echocardiography can noninvasively evaluate device position (Fig. 45-1), residual shunting, and device impingement on valves, veins, and other structures. It can also assess for the presence of pericardial effusion and tamponade physiology following device placement.[9] Transthoracic, transesophageal, and intracardiac echocardiographic techniques are complementary and can be invaluable tools in the selection, procedural guidance, and long-term follow-up of transcatheter interventions.[9-11]

Transesophageal echocardiography (TEE) images areas often not seen on transthoracic echocardiography (TTE) and provides more complete depiction of complex anatomy.[8,12,13] It allows good visualization of the origins of the coronary arteries, main pulmonary artery branches, and entire aorta. TEE is essential in the evaluation of the atrial septum, characterization of septal defects, and assessment of rim adequacy and adjacent structures when considering device closure; the addition of 3D capability further improves the accuracy and utility of TEE in the guidance of device closure.[14-16] TEE is the standard for intra- and postoperative evaluation of complex congenital heart disease surgery.[8,12,13] In the postoperative care unit, TEE elucidates causes of general complications (e.g., hypotension, tamponade, ventricular dysfunction) or complications of specific congenital heart disease surgeries such as the Fontan procedure

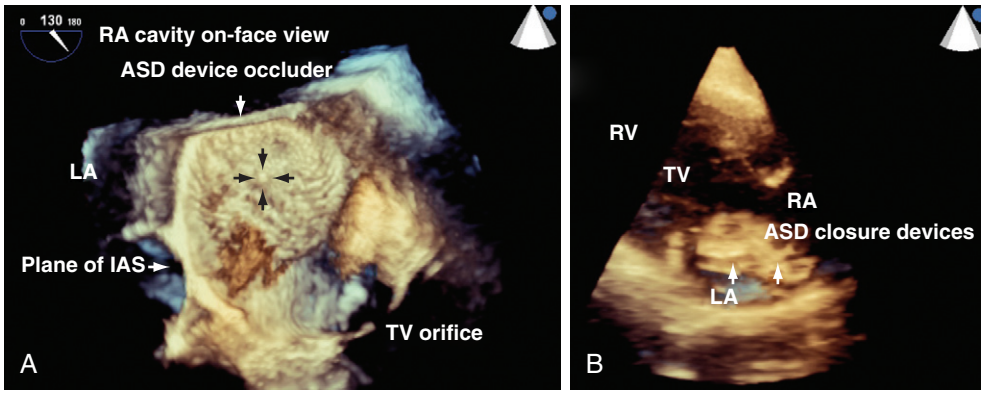

**Figure 45-1** **A, Live 3D TEE demonstrating an Amplatzer Septal Occluder straddling the intraatrial septum (*IAS*) as seen from the RA side. B,** 3D TTE of two Amplatzer Septal Occluders as seen from a parasternal RV inflow view. *ASD*, Atrial septal occluder; *TV*, tricuspid valve.

(e.g., lateral tunnel thrombus). TEE is widely used to guide transcatheter interventions, including closure of atrial and ventricular septal defects, aortic valvuloplasty, mitral valvotomy, pulmonary venous angioplasty and stenting, and Fontan fenestration creation or closure.

Intracardiac echocardiography is gaining popularity as an alternate means of structural imaging for procedural guidance.[11] The advantages of intracardiac echocardiography over TEE include the ability of a single operator to perform both the catheterization/intervention and the crucial guiding echocardiography. However, the major disadvantage is a more limited scope of imaging (typically from the right atrial location in intracardiac echocardiography as opposed to the length of the esophagus and the transgastric views by TEE).

## General Postoperative and Postinterventional Congenital Heart Disease Issues

### ATRIAL AND VENTRICULAR INCISIONS AND DEVICES

Electric instability may occur after atrial or ventricular incisional scars or aneurysms, or after insertion of intracardiac patches or conduits with possible disruption of the conduction system[6,7,17,18] (Table 45-1). Patients with intraatrial baffles or conduits (e.g., Mustard and Fontan procedures) frequently suffer atrial arrhythmias; superimposed pressure overload on a ventriculotomy site may cause ventricular arrhythmias.[7] Because certain subgroups of postoperative congenital heart disease often require pacemaker therapy, there are concerns about diminished ventricular contractility over the long term with pacing via one ventricle (usually the right).[19,20] Thus, ventricular resynchronization by biventricular or multisite pacing may be of value and is amenable to evaluation by Doppler echocardiography.[21,22] Transcatheter device closure of atrial septal defect (ASD) is associated with an early risk of atrial arrhythmias and/or sinus dysrhythmia.[23] The risk of heart block is low, and patients rarely require pacemaker implantation. The risk of heart block is higher in patients who undergo transcatheter closure of membranous/perimembranous ventricular septal defects (VSDs), with published rates ranging from 1% to 17%. The risk is highest in infants and young children.[24-28] Transcatheter device closure of muscular VSD does not carry a significant risk of heart block given the lack of proximity to the bundle of His.[29] However, all VSD devices do carry the risk of ventricular arrhythmias, mostly noted at or early after time of device placement and consisting largely of isolated premature ventricular contractions without clinical morbidity or mortality.

**TABLE 45-1 General Postoperative Issues in Congenital Heart Disease**

| *Postoperative Issue* | *Examples* |
|---|---|
| Electric instability | Atrial arrhythmias after intraatrial baffle procedures<br>Ventricular arrhythmias after ventriculotomy<br>Heart block and ventricular arrhythmias following device closure of VSD<br>Atrial dysrhythmias following device closure of ASD |
| Residual anatomic defects | Bicuspid aortic valve in patient with aortic coarctation<br>Residual mitral regurgitation after cleft leaflet or primum ASD repair<br>Pulmonic regurgitation after tetralogy of Fallot repair<br>Dilated aortic root<br>Residual shunt post surgical or device closure of ASD and/or VSD<br>Pulmonic and aortic valve regurgitation post balloon valvuloplasty |
| Impaired ventricular function | Chronic volume overload due to valve regurgitation<br>Anatomic RV functioning as the systemic ventricle<br>Single functioning ventricle<br>Coronary artery kinking post aortic root repair or replacement or post RV to PA conduit stenting |
| Prosthetic materials | Degeneration of septal patches, intracardiac and extracardiac conduits<br>Prosthetic valve dysfunction<br>Thrombus formation<br>Risk of infective endocarditis<br>Obstruction or leaking of conduits<br>Device embolization or migration<br>Device erosion into adjacent tissue (aorta or atrial wall) |

*ASD*, Atrial septal defect; *PA*, pulmonary artery; *VSD*, ventricular septal defect.

### ANATOMIC AND VALVULAR RESIDUA AND SEQUELAE

Postoperative anatomic and valvular sequelae and residua must be sought.[6,7] Bicuspid aortic valves, common with aortic coarctation, continue to pose risks of progressive stenosis, regurgitation, and endocarditis despite coarctation repair. Variations on a parachute mitral valve, also associated with coarctation and other stenoses in sequence on the left-sided circulation, are detected by imaging a decreased interpapillary muscle distance and Doppler evidence of inflow obstruction. Repair of an ostium

primum ASD with cleft mitral leaflet may leave residual mitral regurgitation or the sequel of mitral stenosis; subaortic stenosis due to anomalous chordal attachments should be sought. Transcatheter static balloon pulmonic valvuloplasty has supplanted surgery as the treatment of choice in isolated pulmonic valve stenosis.[30] Although effective at relieving stenosis, this technique can result in pulmonic regurgitation.[31,32] Similarly, balloon valvuloplasty of stenotic bicuspid aortic valves carries the risk of creating aortic regurgitation with resultant left ventricular (LV) volume overload.[33] In repaired tetralogy of Fallot, pulmonic regurgitation is a sequel to valvotomy or transannular incision and patch. Mild to moderate low-pressure pulmonic regurgitation is common and well tolerated. Severe pulmonic regurgitation may cause right ventricular (RV) dilation and tricuspid regurgitation, particularly if there is residual RV outflow obstruction. Muscular VSDs may have been missed and should be sought by color flow imaging. Residual shunting is common immediately following device occlusion of atrial or ventricular septal defects, patent ductus arteriosus, and many other congenital cardiac or extracardiac communications. However, with currently available devices that combine Nitinol and polyester, the majority of these residual shunts close within days to weeks of device implantation. The likelihood of complete VSD closure of perimembranous or muscular VSDs after device closure is less given the high-velocity shunt present at the ventricular level[27,29] (Fig. 45-2). A dilated aortic root or trunk may occur in tetralogy of Fallot, transposition of the great arteries, or single ventricle in association with pulmonic stenosis, and late aortic regurgitation is common in adults. Aortic aneurysms or pseudoaneurysms are not uncommon in patients with coarctation of the aorta following surgical repair (most commonly seen in those with patch augmentation) or following balloon angioplasty.[34,35] The rate of aneurysm or pseudoaneurysm formation is much lower when stents are employed and is essentially nonexistent with the use of covered stents.[36,37] Atrioventricular valve regurgitation, common preoperatively in Fontan patients, may progress postoperatively.

### VENTRICULAR FUNCTION

Valvular lesions pose a risk for endocarditis and, if severe, affect long-term ventricular performance.[38] Operative myocardial preservation often was faulty in earlier decades. The later in life the patient is operated, the less the regression of ventricular hypertrophy. Long term, a subaortic right ventricle (RV) operating at systemic pressures or a single functioning ventricle in a "univentricular" heart—even after a Fontan—may have an irreversible decline in contractility. Ventricular function may suffer if a prosthetic patch or conduit origin is large, if an incisional aneurysm acts as a "windkessel," or if valvular or conduit obstruction and regurgitation or large shunt overloads the heart. Procedures that involve manipulation or reimplantation of the coronary arteries carry the risk of coronary artery kinking, torsion, or obstruction with resultant downstream myocardial infarction and/or ischemia. This is an important clinical consideration in patients with complete transposition of the great arteries who have undergone the arterial switch operation, those who have undergone the Ross procedure, or those with anomalous coronary arterial anatomy who have undergone arteriotomy, reimplantation, or bypass. Transcatheter stent placement within an RV-to-pulmonary-artery conduit carries the risk of coronary compression (typically left main or proximal left anterior descending).

### CONDUITS, PATCHES, AND PROSTHETIC MATERIALS

Septal patches, prosthetic valves, and conduits may degenerate.[7,8] Foreign bodies such as pacer wires or mechanical valvular prostheses risk thrombus formation or endocarditis (Fig. 45-3). Bioprosthetic valves and conduits often develop obstruction and/or regurgitation due to degenerative changes and calcification or by intimal ingrowth, particularly in adolescents and young adults. External conduits may be kinked by compression between the heart and sternum. Obstruction can occur at the exit from the ventricle, at a bioprosthetic valve, or at the distal insertion site. An internal conduit may develop leaks, internal obstruction, or kinking, or it may partially obstruct the chamber within which it sits. Some conduits have unusual courses due to altered great artery relationships; therefore, multiple precordial and subcostal transducer positions or multiplane TEE may be required for an adequate anatomic-hemodynamic evaluation. Continuous-wave (CW) Doppler is directed into the conduit from multiple angles to predict the pressure gradient; most conduits curve, and the proper angle to record the true peak velocity may be difficult to obtain.[8] CW Doppler of atrioventricular valve regurgitation quantitates ventricular systolic pressure and estimates significant conduit stenosis. Transcatheter devices carry a small risk of erosion into adjacent structures. This is of greatest concern with large ASD occluders and may result in aortic root to atrial fistulas and/or hemopericardium. The risk of device embolization is low and highly operator dependent. Appropriate device sizing, device testing before deployment, and observation after device deployment reduce the risk of this dreaded complication. Device retrieval is feasible and effective in the majority of cases. Rarely, device embolization results in large pulmonary embolism, stroke, or limb ischemia. When imaging a patient with a history of device placement, every effort should be made to locate and interrogate the device. Intracardiac devices should be clearly visible by TTE. If they are not visualized on routine postprocedural surveillance (we typically perform this 12 to 24 hours after transcatheter device implantation), then we recommend further imaging to locate the device (fluoroscopy, computed tomographic [CT] angiography, or magnetic resonance imaging [MRI]). Devices or coils placed in the great arteries or extracardiac veins (e.g., patent ductus arteriosus occluder) may not be readily visible by TTE in the adult patient.

## Palliative Procedures

### PULMONARY ARTERY BANDING

Pulmonary artery banding may be used to decrease the volume and pressure effects of a large shunt at the ventricular level to avoid heart failure or pulmonary hypertension (Fig. 45-4). The band site is evaluated by echocardiographic anatomic imaging, the best band placement being the midportion of the pulmonary artery. A band that is too close to the valve may interfere with valve function, and a band that has slipped onto the bifurcation may cause branch artery stenosis. Inadequate banding allows pulmonary hypertension (Table 45-2). Band stenosis gradient is quantitated by aligning the CW Doppler beam with the color flow jet via the iatrogenic stenosis (see Fig. 45-4). Because most lesions that require banding have large VSDs, pulmonary artery systolic pressure can be

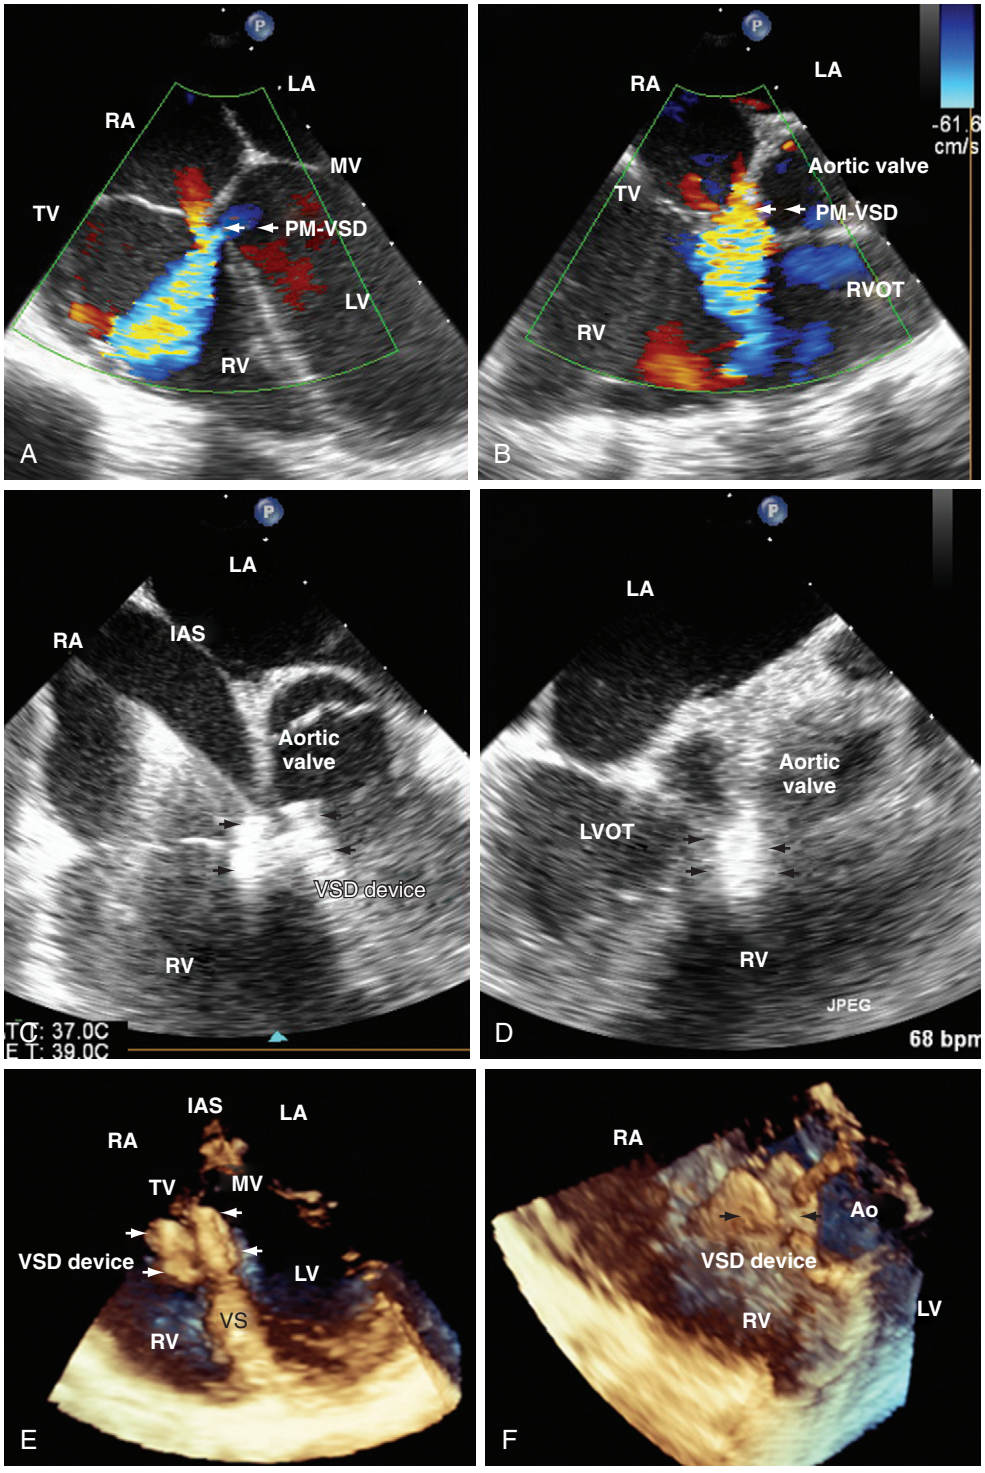

**Figure 45-2** **A** and **B, X-plane simultaneous orthogonal images from TEE with 2D and color flow Doppler demonstrating a moderate degree of high-velocity left-to-right systolic shunting across a perimembranous ventricular septal defect (*PM-VSD*). C** and **D,** Muscular VSD device attached to a cable is straddling the VSD just below the aortic valve. **E** and **F,** Live 3D TEE after VSD device release demonstrates its relationship to the mitral valve (*MV*), tricuspid valve (*TV*), and aortic valve. *IAS*, Intraatrial septum; *LVOT*, left ventricular outflow tract; *RVOT*, right ventricular outflow tract.

estimated as systolic systemic blood pressure minus the peak pressure gradient across the band (provided that there is no LV outflow tract obstruction). Transcatheter pulmonary artery "banding" is feasible with the use of flow restrictors. These are essentially occlusion devices with fenestrations that allow for continued but lessened flow. There is very little experience with such devices in adult congenital heart disease patients. Clinical investigation has focused on a neonatal population with single-ventricle physiology and excessive pulmonary blood flow.

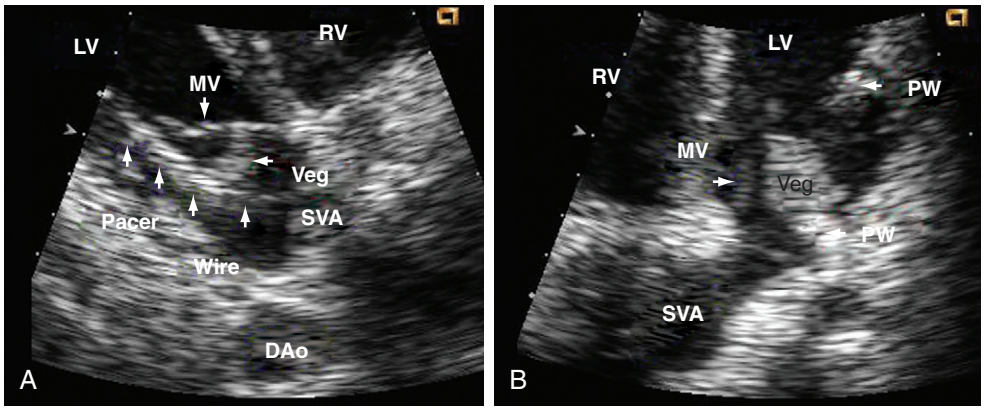

**Figure 45-3 Complete transposition of the great arteries late post Mustard with pacemaker previously inserted for sick sinus syndrome.** Patient presented with fevers and bacteremia. TTE views (**A,** modified parasternal long-axis view; **B,** zoomed portion of four-chamber apical view) reveal a vegetation (*Veg*) on the pacer wire (*PW*), which passes via the systemic venous atrium (*SVA*) from the superior vena cava to the LV. Vegetation resolved after 6 weeks of antibiotic therapy. *DAo*, Descending aorta; *MV*, mitral valve.

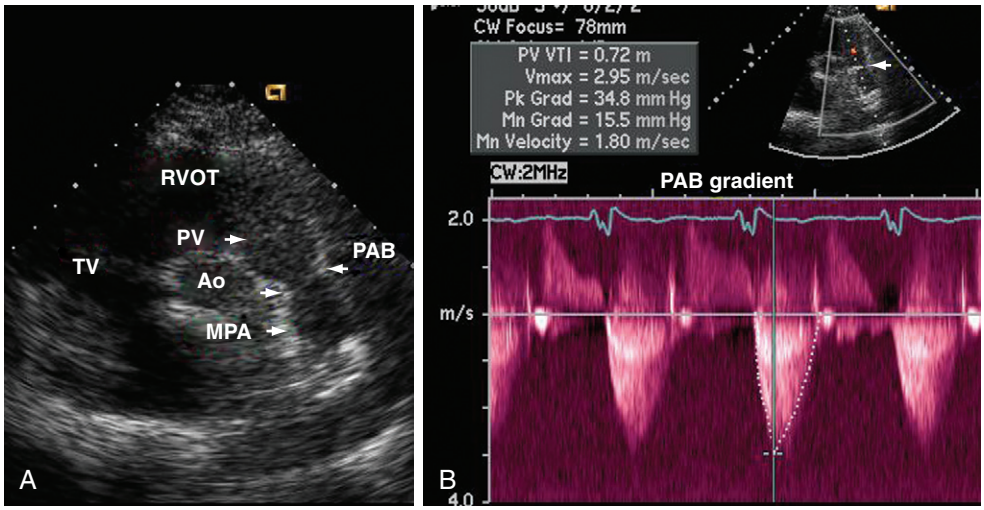

**Figure 45-4 Pulmonary artery band (*PAB*).** This patient had a previous PAB as a neonate before subsequent repair of an atrioventricular septal defect as an infant. **A,** Parasternal long-axis TTE view shows that PAB was not completely removed. **B,** Accompanying CW Doppler study reveals residual "stenosis" with a mean systolic gradient of 15.5 mm Hg. *Ao*, Aorta; *MPA*, main pulmonary artery; *RVOT*, right ventricular outflow tract; *TV*, tricuspid valve.

**TABLE 45-2 Palliative Procedures for Congenital Heart Disease**

| *Name of Procedure* | *Description* | *Complications* |
|---|---|---|
| Pulmonary artery banding | Constriction of main pulmonary artery | Inadequate band with consequent pulmonary vascular disease<br>Branch pulmonary artery stenosis<br>Pulmonic valve dysfunction |
| Waterston shunt | Ascending aorta to right pulmonary artery | Pulmonary hypertension due to too large a shunt |
| Potts shunt | Descending aorta to left pulmonary artery | Kinking of branch pulmonary arteries |
| Blalock-Taussig shunt | Subclavian artery to branch pulmonary artery | Inadequate shunt to maintain pulmonary blood flow |
| Modified Blalock-Taussig shunt | Gore-Tex graft from subclavian artery to pulmonary artery | Excessive shunt resulting in pulmonary hypertension |
| Glenn shunt | Superior vena cava to right pulmonary artery with division of main pulmonary artery | Postoperative cyanosis due to increased collaterals from superior to inferior vena cava or pulmonary arteriovenous fistulas |
| Bidirectional Glenn shunt | Superior vena cava to both (undivided) pulmonary arteries | Postoperative cyanosis due to increased collaterals from superior to inferior vena cava or pulmonary arteriovenous fistulas |

## PALLIATIVE AORTOPULMONARY SHUNTS

Palliative systemic arterial to pulmonary arterial shunts are performed for congenital heart disease characterized by decreased pulmonary arterial flow (e.g., tetralogy of Fallot) (Fig. 45-5). The shunts from the high-pressure aorta to the low-pressure pulmonary artery can be evaluated for patency by CW Doppler, which should reveal nonlaminar flow in both systole and diastole toward the pulmonary artery in the absence of pulmonary hypertension.

The Waterston (ascending aorta to right pulmonary artery) and Potts (descending aorta to left pulmonary artery) shunts are discrete side-to-side connections. Potts and Waterston anastomoses are now rarely performed because of problems with

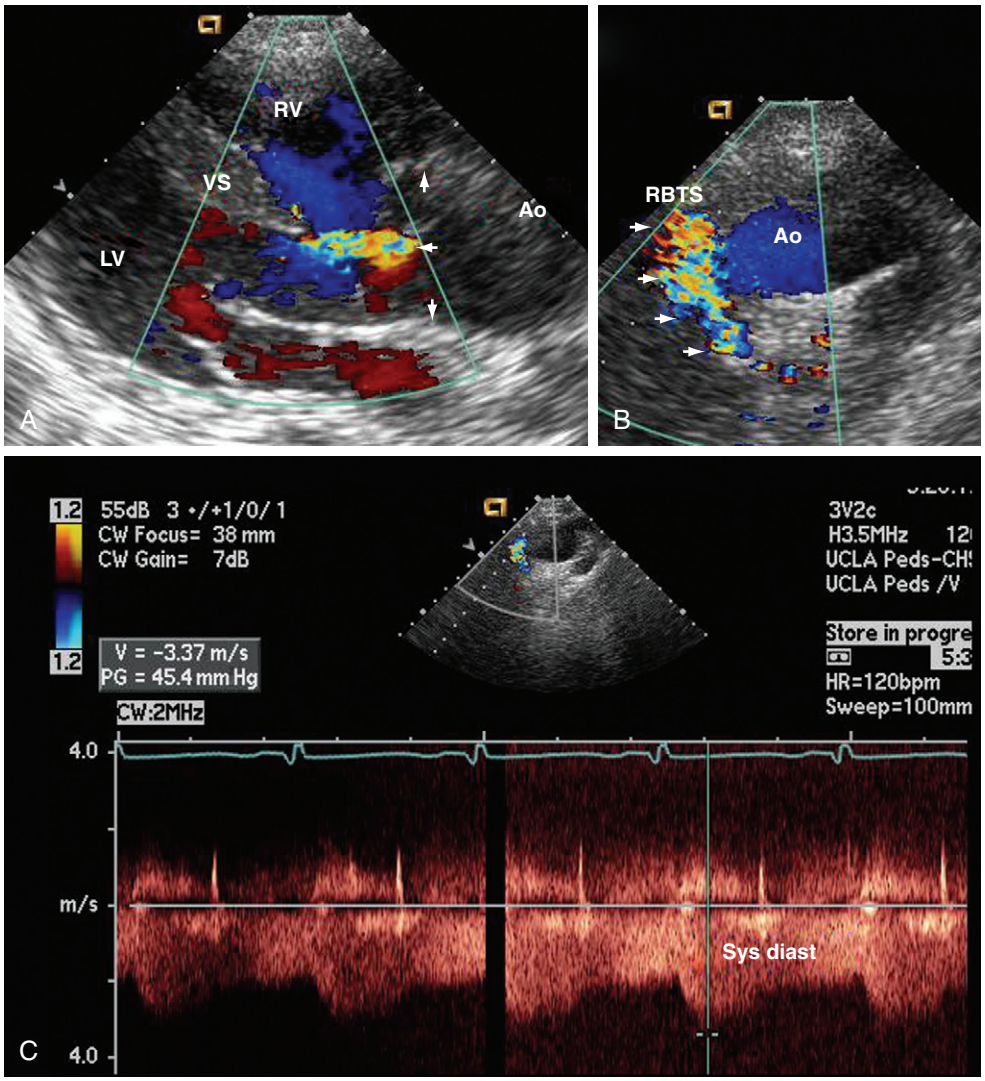

**Figure 45-5** **Right Blalock-Taussig shunt (*RBTS*) palliation in tetralogy of Fallot. A,** Underlying tetralogy anatomy of aorta overriding (*vertical arrows*) malaligned defect of ventricular septum (*VS*). Color flow shows jet of aortic regurgitation. **B,** Suprasternal notch view of RBTS descending (*horizontal arrows*) rightward along the transverse aorta (*Ao*). **C,** CW Doppler of RBTS with "continuous" high-velocity flow with peaking in systole (*Sys*) but persisting throughout diastole (*diast*), indicating low pulmonary vascular resistance.

precise control of size and possible pulmonary hypertension or kinking of branch pulmonary arteries, which may complicate further repair. TTE imaging of these anastomoses is often difficult in adults and may require TEE, where proper Doppler alignment with color flow imaging makes it possible to calculate the Bernoulli equation gradient. Pulmonary artery systolic pressure is estimated by subtracting the peak systolic pressure gradient from the brachial artery systolic peak pressure. As pulmonary artery pressures rise, diastolic flow decreases more than systolic flow; diminutive diastolic flow indicates increased diastolic pulmonary pressure.

A classic Blalock-Taussig shunt is a direct end-to-side anastomosis between a subclavian artery and a branch pulmonary artery, usually on the side opposite the aortic arch (see Fig. 45-5). A modified Blalock-Taussig shunt uses a 4- to 5-mm Gore-Tex tube or vein graft from the aorta or subclavian artery to the pulmonary artery. Imaging of a Blalock-Taussig shunt uses suprasternal and supraclavicular views augmented by color flow imaging. Estimation of pulmonary artery pressure may be unreliable in a long, curving connection. A low gradient may be seen in the presence of adequate flow and normal pulmonary artery pressures. The flow should be virtually continuous; thus, it must be distinguished from a patent ductus (see Fig. 45-5). If the shunt is small or occluded, flow decreases or is lost. Doppler is helpful in the early postoperative period in a patient who continues to have cyanosis, in order to assess adequacy of the shunt versus other causes of postoperative cyanosis (e.g., atelectasis). If the shunt is too large and results in pulmonary hypertension (fortunately an uncommon event), the diastolic flow decreases first, with decreased systolic flow later as pulmonary vascular resistance rises to equal systemic resistance.

## GLENN SHUNTS

A classic Glenn shunt is anastomosis of the end of the superior vena cava to the side of the right pulmonary artery divided from the main pulmonary artery and superior vena caval ligation as it enters the right atrium (RA). A bidirectional Glenn allows superior vena cava flow to both pulmonary arteries, causing improved systemic oxygen saturation without

ventricular volume overload, useful as definitive palliation or as a staging for subsequent Fontan procedures in complex congenital heart disease not amenable to biventricular repair. Echocardiographic imaging from right supraclavicular or suprasternal notch windows can show the course of the superior vena cava and the size of the connection to the right pulmonary artery. TEE imaging in at 90° to 110° alignment identifies the RA and upper stump of the superior vena cava and then, with rotation of the probe rightward, the superior vena cava–right pulmonary artery connection. Combined color flow and spectral Doppler evaluate anastomosis patency.[8,12,13]

Recurrent late postoperative cyanosis may be via collateral venous flow from the superior vena cava to the inferior vena cava or from pulmonary arteriovenous fistulas. Echocardiographic contrast detects these extracardiac shunts; after injection into an arm vein, late flow into the left atrium (LA) identifies pulmonary arteriovenous fistulas, whereas prompt appearance in the RA reveals azygous-venous collaterals to the inferior vena cava.[2] Fistulas and venous collaterals are amenable to catheter-directed coil embolization or device closure.

## Corrective Procedures for "Simple" Lesions

Simple lesions are isolated shunts, obstructive malformations, or regurgitant lesions. Complex malformations have two or more simple lesions, often with malpositions of veins, chambers, or great arteries and associated cyanosis.[8] Corrective procedures for simple lesions are listed in Table 45-3.

### ATRIAL SEPTAL DEFECTS

ASDs are among the most common unoperated and postoperative congenital heart defects. A secundum ASD, the most common, has conventionally been closed by direct surgical repair with good results even in adults more than 40 years old.[39-41] Recently, transcatheter device closure for secundum defects of appropriate size and rim for current devices has been successful with a low rate of complications (see Fig. 45-1).[23,42-45] Both TEE and intracardiac echocardiography are valuable in guiding proper insertion of ASD closure devices.[46,47] Echocardiographic exam after ASD closure searches for residual shunting, associated mitral abnormalities, pulmonary hypertension, and degree of resolution of right heart chamber enlargement.[8,48] Immediate residual shunting through the device is common after transcatheter ASD closure and usually resolves over a period of weeks to months as the device endothelializes. Surgical patch leaks are infrequently seen, provided that severe pulmonary hypertension was not present. A previously sizable shunt will have a decrease in but not necessarily normalization of RV size and increased LV size plus improved RV and LV myocardial performance index.[48] LV diastolic dysfunction, especially restrictive physiology, bears special consideration in the older adult with a secundum ASD; device or surgical closure of the defect results in increased LV preload and therefore increased filling pressure of a poorly compliant ventricle.[49] In patients with evidence of elevated LA pressure at baseline, test occlusion of the defect with continuous LA pressure assessment may reveal further increase in LA pressure and warrant device fenestration and further medical therapy (e.g., intravenous diuretic use).[50] TTE with color flow Doppler can be effective in monitoring device appearance and position as well as fenestration patency following the procedure.

Sinus venosus ASD, often associated with anomalous pulmonary venous connections to the superior vena cava, often requires TEE for precise diagnosis (Fig. 45-6). Repair requires patching of the defect with autologous pericardium so as to also baffle the anomalous pulmonary venous drainage to the LA via the ASD. TEE is valuable to evaluate the adequacy of patch closure of the defect with attention to possible superior vena caval or pulmonary venous obstruction (Fig. 45-7).

Atrioventricular canal–type ASD is considered in the section on "complex" repairs. A coronary sinus ASD, the rarest form, consists of partial or complete absence of the coronary sinus

**TABLE 45-3 Corrective Procedures for "Simple" Congenital Heart Lesions**

| *Lesion* | *Corrective Procedure* | *Complications and Residual Abnormalities* |
|---|---|---|
| Atrial septal defect | Suture repair, patch closure, or transcatheter closure | Residual shunting<br>Associated mitral valve abnormalities<br>Persistent pulmonary hypertension<br>Right heart chamber enlargement |
| Ventricular septal defect | Surgical repair (via right transatrial approach) | Residual patch leak<br>Arrhythmias if ventricular incision needed |
| Patent ductus arteriosus | Surgical ligation or catheter device closure | Residual shunting (more likely if calcified) |
| Bicuspid aortic valve | Surgical or balloon valvuloplasty<br>Pulmonic autograft<br>Valve replacement | Associated lesions (ventricular septal defect, coarctation)<br>Restenosis<br>Prosthetic valve dysfunction |
| Subaortic stenosis | Excision of membrane or fibromuscular ridge | Aortic regurgitation<br>Iatrogenic ventricular septal defect<br>Mitral valve injury<br>Recurrent stenosis |
| Coarctation of aorta | Multiple repair procedures | Residual or recurrent coarctation<br>LV hypertrophy<br>Associated lesions (e.g., bicuspid aortic valve, supramitral ring) |
| Ebstein anomaly | Surgical repair | Residual tricuspid regurgitation<br>Associated lesions (patent foramen ovale, atrial septal defects, pulmonic stenosis, ventricular septal defects) |
| Pulmonic stenosis | Balloon dilation<br>Surgical repair | Residual stenosis<br>Pulmonic regurgitation<br>Dynamic RV outflow obstruction (early postoperative) |
| Coronary artery anomalies | Various repair procedures | LV dysfunction<br>Mitral regurgitation |

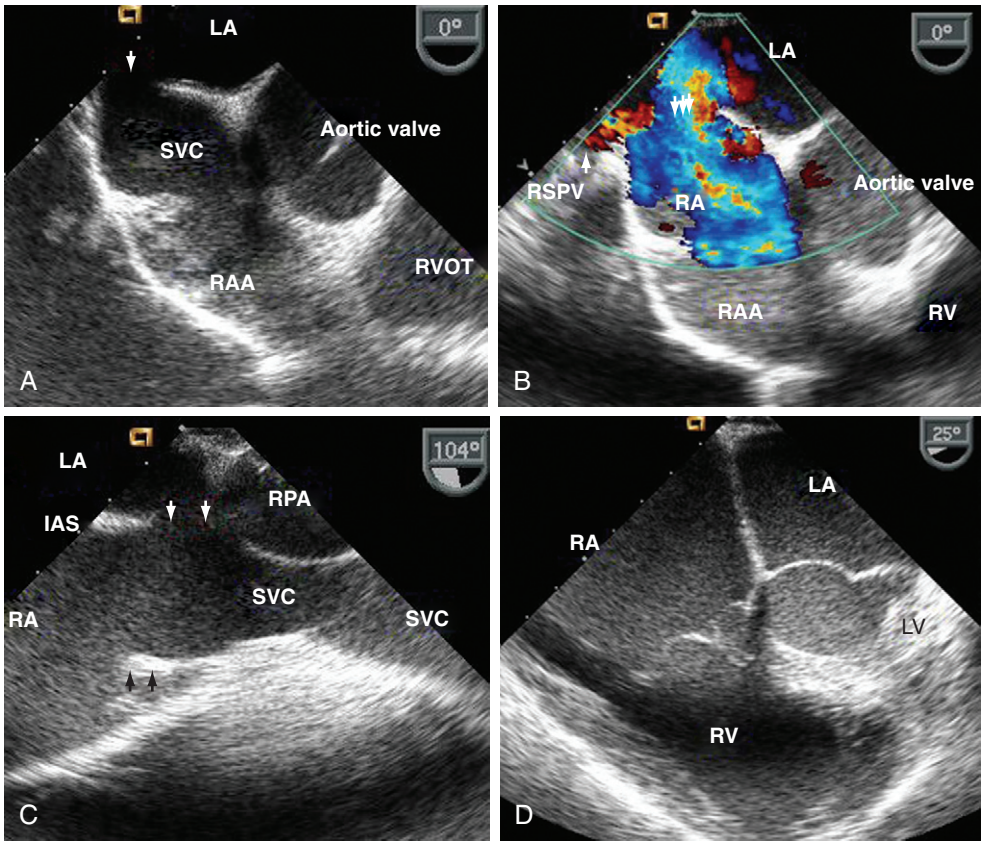

**Figure 45-6** **Sinus venosus atrial septal defect on preoperative multiplane TEE. A,** The horizontal plane demonstrates a communication (*arrow*) between LA and superior vena cava (*SVC*) at its entrance into RA at the level of the RA appendage (*RAA*). **B,** TEE color flow imaging shows a shunt from LA into SVC and RA. Also shows entrance of partial anomalous pulmonary venous connection of right superior pulmonary vein (*RSPV*) into RA rather than LA. **C,** Vertical plane of defect (*white arrows*) between LA and SVC; mouth of SVC to RA is seen on vertical plane with crista terminalis (*black arrows*). **D,** Horizontal plane below level of defect demonstrates severely dilated RA and RV. *IAS*, Interatrial septum; *RPA*, right pulmonary artery; *RVOT*, right ventricular outflow tract.

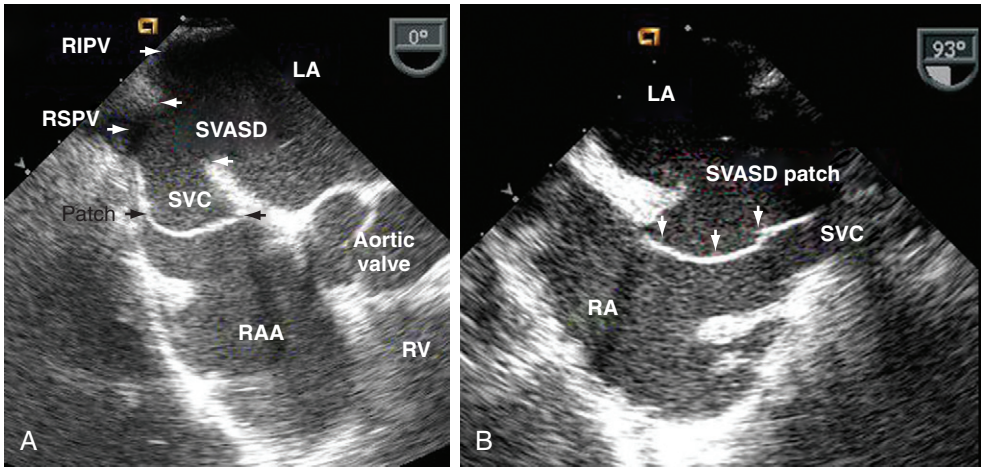

**Figure 45-7** **Sinus venosus atrial septal defect (*SVASD*) with partial anomalous pulmonary venous connection.** Intraoperative TEE in patient from Figure 45-6 after patch repair (*SVASD patch*) of defect where patch redirects right superior pulmonary vein (*RSPV*) flow to LA via defect that is left open. Superior vena cava (*SVC*) is mildly narrowed but patent. Right inferior pulmonary vein (*RIPV*) is seen to enter LA normally.

with connection of the LA to the RA via the usual location of the coronary sinus ostium, usually with a persistent left superior vena cava that joins the roof of the LA.[24] A coronary sinus ASD may be associated with complete atrioventricular septal defects or tricuspid atresia (and may first be detected after a Fontan repair).

## VENTRICULAR SEPTAL DEFECTS

VSD, a common congenital lesion alone or in combination with other anomalies, may occur anywhere in the ventricular septum. VSD may be classified as perimembranous, muscular, inlet, outlet, or malaligned. VSD may be characterized as

restrictive or nonrestrictive according to whether there is a significant systolic pressure gradient from LV to RV. In adults, substantial left-to-right shunt due to a nonrestrictive VSD is rare as a result of pulmonary vascular disease (Eisenmenger syndrome). Spontaneous closure of perimembranous VSD occurs frequently, mainly by adherence of septal tricuspid leaflet tissue but occasionally by prolapse of an aortic cusp into the defect. Tricuspid regurgitation may develop. Aortic regurgitation (especially with outlet supracristal defects) may occur; operative closure of the VSD usually prevents progression. Small defects risk infective endocarditis. Once endocarditis occurs, it may be argued that closure of the VSD will diminish subsequent risk. Nine of 296 patients who underwent closure of isolated VSD developed endocarditis; 3 of the 9 had no known residual shunt.[51]

A simple VSD is closed by right transatrial approach to avoid electrical and mechanical consequences of ventricular incisions. Multiple muscular VSDs may require left ventriculotomy for visualization, with the risks of ventricular arrhythmia and ventricular dysfunction. Investigation for patch leaks is imperative, preferably in the operating room at the time of closure to allow re-repair at that time. Color flow imaging after closure of a large VSD may show previously undetected smaller defects. Transcatheter device closure has been helpful for multiple muscular VSDs, for persistent postoperative VSD in complex conotruncal malformations, and for acquired postinfarction VSD and recently has been applied to perimembranous VSD.[24] TEE or intracardiac echocardiography during the procedure decreases fluoroscopy time, determines the device position relative to the defect and adjacent valves, and detects residual shunting.

## PATENT DUCTUS ARTERIOSUS

Patent ductus arteriosus is ordinarily detected in childhood, but undiagnosed cases are seen each year during routine echocardiography for other reasons. Operative closure of patent ductus arteriosus in the young leaves few residua; in adults, calcification is common and can tear during ligation. Catheter device closure is effective provided the size is less than 7 mm and previous endarteritis at the site has not occurred, which could weaken the vessel wall. TEE is useful in verifying complete uncomplicated closure. Color flow imaging search for residual shunting is essential to confirm success or the need for further device closure and for advice on antiinfective endocarditis prophylaxis.

## BICUSPID AORTIC VALVE

Bicuspid aortic valve, the most common congenital cardiac malformation, may initially be functionally normal, but with time most develop significant stenosis or regurgitation.[52,53] Associated lesions (e.g., VSD, aortic coarctation) should be sought. There is an associated tissue defect of the aortic wall with a tendency to aneurysm and ascending aortic dissection.[54]

Surgical or balloon catheter valvuloplasty can palliate young adults but can may cause aortic regurgitation. Most patients ultimately require valve replacement with a mechanical or bioprosthetic valve (homograft or heterograft or Ross procedure) or repair (Fig. 45-8). The Ross procedure (pulmonary autograft to the aortic position, heterograft or homograft to the pulmonary position, with or without reimplantation of the coronary arteries) reduces bioprosthetic degeneration in the aortic position, decreases the reoperation rate, and avoids long-term anticoagulation. Bioprosthetic pulmonic valve degeneration is often well tolerated, but late valve replacement is likely.

Concerns about pulmonary root autografts in the aortic position include potential for dilation of the wall of the pulmonary artery with continued exposure to systemic arterial pressure and the development of progressive "neoaortic" valvular regurgitation. Because cardiopulmonary bypass time is longer than for simple valve replacement, meticulous attention to myocardial preservation and to the technique of coronary reimplantation is required. Precise measurement of the pulmonary and aortic annuli to ensure parity and demonstration of only mild or no pulmonic regurgitation are helpful in deciding on the Ross procedure. Intraoperative TEE achieves these goals and verifies valvular and myocardial function and normal flow at coronary reimplantation sites.

## SUBAORTIC STENOSIS

Subaortic stenosis, most commonly due to a discrete fibromuscular ridge, may be isolated or may complicate perimembranous VSDs before or after closure.[55-57] Aortic valve regurgitation is more likely the closer the membrane is to the aortic valve. Excision of the membrane or fibromuscular ridge in association with focal septal myectomy is the treatment of choice to reduce the likelihood of recurrence. If associated aortic regurgitation is moderate or less, surgical repair may avoid replacement. Intraoperative TEE verifies relief of obstruction, lack of mitral injury, absence of iatrogenic VSD, and only mild or absent aortic regurgitation.[8] Surveillance for recurrence with stenosis and development or progression of aortic regurgitation is mandatory.

## COARCTATION OF THE AORTA

There are many survivors of coarctation surgical repair; the numbers of those treated with catheter balloon dilatation or stenting are steadily increasing (Fig. 45-9).[58,59] Residua, sequelae, or complications are frequent and require lifelong follow-up.[6,60-64] Bicuspid aortic valve, aortic medial defects, abnormal medium-sized arterial reactivity, and intracranial aneurysms are commonly associated with coarctation, suggesting a common developmental abnormality with diffuse arteriopathy.[6,65-69] Repairs include resection of coarctation with end-to-end anastomosis, patch, or subclavian flap aortoplasty or interposition conduit (see Fig. 45-9). If the condition is symptomatic, repair is best done in infancy. Otherwise, timing is "elective," but the later in life repair is performed, the more likely persistent hypertension and accelerated coronary artery disease. Suprasternal notch echocardiographic views are useful for imaging of residual or recurrent coarctation narrowing or aneurysm formation. Color flow imaging shows the narrowed site with proximal acceleration; CW Doppler is necessary to show the systolic gradient.[8] Continued diastolic forward flow through the zone of narrowing denotes significant obstruction (see Fig. 45-9). Exercise Doppler echocardiography is useful for follow-up of repaired coarctation to detect exercise-related hypertension and coarctation gradients. TEE is more effective than surface echocardiography in evaluating the extent and degree of coarctation. Doppler peak systolic velocity in the descending aorta correlates better with residual narrowing of the aortic isthmus or distal aortic arch than does the systolic blood pressure gradient between the upper and lower limbs.

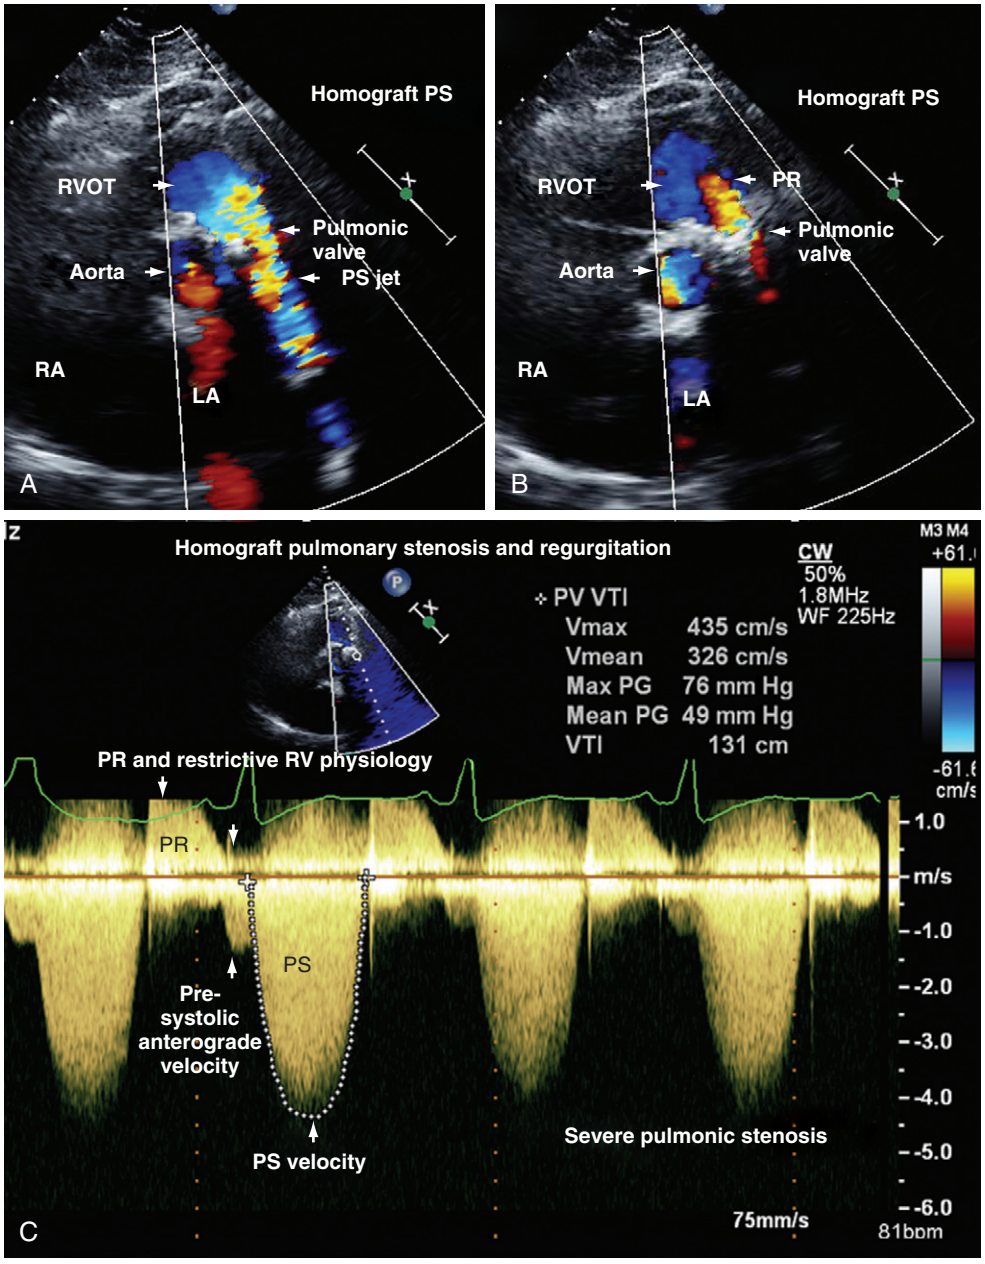

**Figure 45-8** **Homograft pulmonic stenosis. A,** TTE, systolic parasternal short-axis frame with color Doppler across stenotic pulmonary homograft in patient who has undergone Ross procedure. Note that the pulmonic stenosis jet (*PS jet*) is within the homograft and at pulmonic valve level. **B,** Diastolic frame demonstrating moderate pulmonic valve regurgitation (*PR*). **C,** CW Doppler demonstrating severe pulmonic stenosis (*PS*) with a peak and mean gradient of 76 mm Hg and 49 mm Hg, respectively. There is also evidence of moderate pulmonic regurgitation (*PR*) and restrictive RV physiology as evidenced by presystolic anterograde flow in the right ventricular outflow tract (*RVOT*).

Peak velocities greater than 2.5 m/s effectively detect greater than 25% narrowing. Prolongation of anterograde flow during diastole indicates a significant morphologic abnormality, such as restenosis or aneurysmal dilation.

LV hypertrophy and function should be quantified; associated left-sided obstructive lesions (e.g., bicuspid aortic valve, supramitral ring) must be sought. Postoperative endarteritis is rare but can result in a pseudoaneurysm. Balloon catheter dilation and stenting are often applied to recurrent or residual postoperative coarctation, but are effective and safe in native coarctation.[58] Balloon angioplasty alone carries a higher risk of aneurysm/pseudoaneurysm formation or dissection when compared to stenting. The use of covered stents essentially nullifies these risks, as well as the very low but dreaded risk of aortic rupture. Intravascular or transesophageal echocardiography during balloon dilation or stenting and intraoperatively is useful to show a good result and detect tear or dissection.[8]

## EBSTEIN ANOMALY

Ebstein anomaly has significant morbidity due to arrhythmias and right heart failure and even sudden death, possibly due to ventricular arrhythmias arising in the pathology of the atrialized RV.[70-73] It is characterized by apical displacement of the septal tricuspid leaflet with adherence of the septal and posterior tricuspid leaflets to the underlying myocardium, resulting

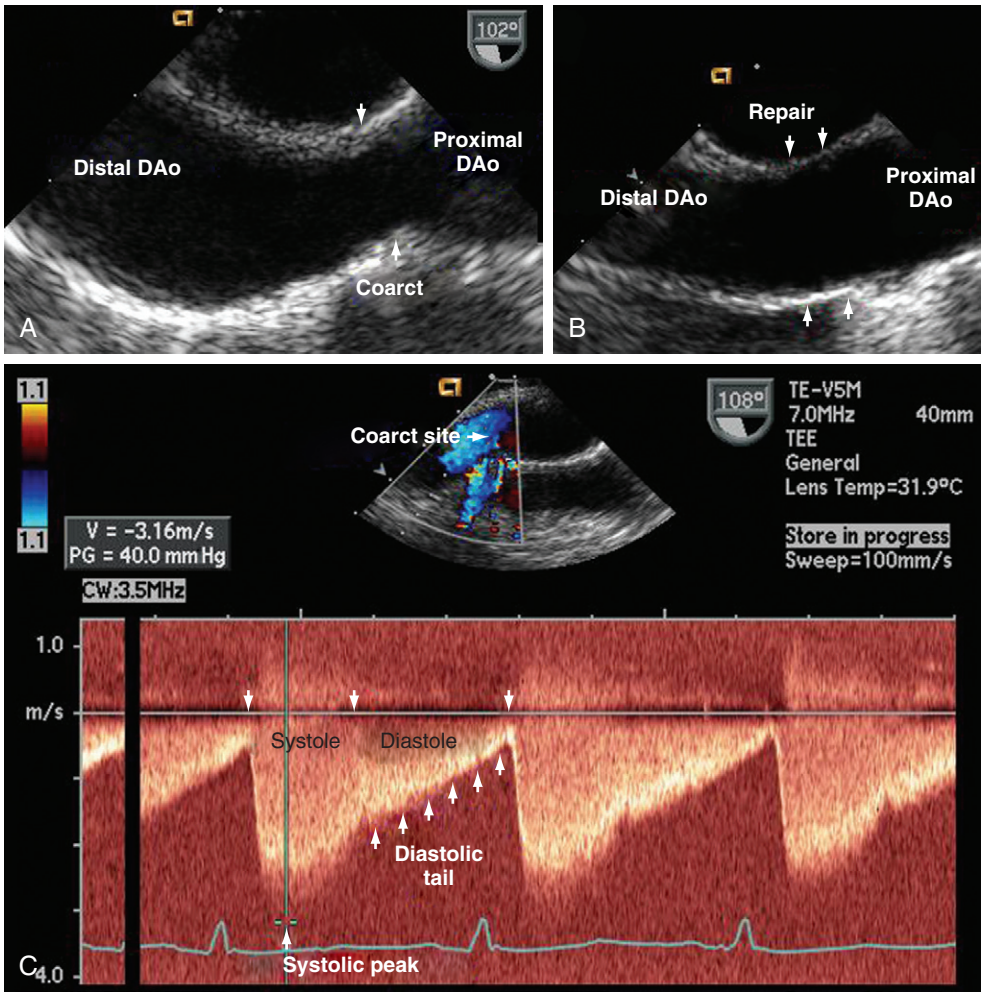

**Figure 45-9 Aortic coarctation. Intraoperative TEE. A,** Prerepair coarctation anatomy (*Coarct*) with dilatation of distal portion of descending aorta (*DAo*) that was nonpulsatile in contrast to excessively pulsatile proximal DAo. **B,** After coarctation repair (resection and end-to-end anastomosis), there is no residual stenosis. **C,** CW Doppler before coarctation repair that is not able to be precisely aligned with true angle of the coarctation. Thus peak recorded velocity of 3.16 m/s is underestimate of true peak instantaneous systolic gradient. Regardless, the continued diastolic tail reveals that this is significantly obstructive coarctation.

in downward displacement of the functional annulus and an "atrialized RV chamber" in its inflow portion. The anterior leaflet is redundant and may have abnormal fenestrations or tethering to ventricular myocardium. The true tricuspid annulus is dilated; tricuspid regurgitation is usual. Comprehensive echocardiographic definition of the tricuspid anatomy is usually adequate for diagnosis and prediction of suitability for repair and avoids the need for preoperative catheterization.[8,12,74,75] Associated anomalies include patent foramen ovale, ASD, pulmonic valve stenosis or atresia, VSDs, and tetralogy of Fallot. LV function can be decreased.[76] Tricuspid valve repair and annuloplasty with RV plication and RA reduction are preferable to valve replacement.[7,77-84] An anterior leaflet that is elongated, untethered, and freely mobile is necessary for best repair; a dysplastic, tethered, or fenestrated valve is undesirable. Intraoperative TEE verifies satisfactory reduction in tricuspid regurgitation without stenosis, repair of associated defects, and adequacy of myocardial preservation.

## PULMONIC STENOSIS

Pulmonic stenosis may be subvalvular, valvular, or supravalvular. Management requires elucidation of severity and site of stenosis and of associated abnormalities such as VSD or ASD. Some adults are still seen with previous surgical valvuloplasty for isolated valvular pulmonic stenosis. Balloon catheter dilatation is now usual in isolated valvular stenosis, but less so with dysplastic valves.[7] Immediately after valvuloplasty, the severely hypertrophied RV outflow tract may develop dynamic subpulmonic stenosis manifest by late-peaking high velocities that typically regress over time. Follow-up of residual stenosis or sequelae of pulmonic regurgitation is required.

Double-chambered RV, a variation of subpulmonic stenosis, due to aberrant muscle bundles at the junction of the inlet and outlet portions of the RV proximal to the infundibulum, is often associated with VSD and occasionally subaortic stenosis.[8] Only the inlet RV is under pressure from the "pulmonic stenosis" and, despite hypertrophy of that portion, the electrocardiogram shows remarkably low-voltage RV forces. Resection of the obstructing muscle bundles is indicated when there is more than mild stenosis.

## ANOMALIES OF THE CORONARY ARTERIES

Coronary artery anomalies include abnormal origin of the right, left main, or left coronary artery branches from one

coronary cusp or the other; associated abnormal courses of the anomalous artery; and abnormal connections to other vessels or chambers (e.g., coronary arteriovenous fistula or anomalous origin of the left coronary artery from the pulmonary artery).[7,8,12] Some of these anomalies are benign; others may result in myocardial ischemia, ventricular dysfunction, arrhythmias, and sudden death. Abnormalities of the course of the coronary arteries seen in tetralogy of Fallot or transposition complexes are important in relation to the technique of surgical repair. Echocardiography, particularly TEE, has had success in identifying coronary abnormalities.

Anomalous origin of the left coronary artery from the pulmonary artery is often associated with myocardial ischemia, congestive heart failure, mitral regurgitation, and arrhythmias. Surgical approaches include simple ligation of the left coronary artery at its attachment to the pulmonary trunk, saphenous vein or internal mammary artery bypass grafting, direct reimplantation of the coronary to the aorta, and (via a surgically created aortopulmonary window) fashioning of a tunnel that directs blood flow from the aorta to the left coronary ostium. Postoperative imaging of this connection in the operating room is necessary. Long-term echocardiographic evaluation includes quantitation of global and regional LV function and degree of mitral regurgitation.

## Repair of "Complex" Malformations

### ATRIAL SWITCH SURGERY

Atrial switch surgery (e.g., Mustard and Senning) is the reason most born with complete transposition of the great arteries are adolescents and young adults today (Table 45-4).[7] A combination of atrial septal tissue, pericardium, or synthetic material is used to fashion a baffle that reroutes systemic venous return to the subpulmonary morphologic left ventricle (LV) and pulmonary venous return to the subaortic morphologic RV (Figs. 45-10, 45-11, and 45-12). The atrial cavity is therefore divided into two portions: an anterior chamber receiving the systemic venous return and a posterior chamber receiving the pulmonary venous return. Sequelae and complications include dysrhythmias (sinus node dysfunction and atrial arrhythmias are frequent) and conduction disturbances, baffle leaks or obstruction, vena caval and pulmonary venous obstruction, tricuspid regurgitation, dysfunction of the RV, and even sudden death.[6,18,85-90] RV dysfunction may be due to ischemia or fibrosis.[91-93] Residual defects may include pulmonic stenosis, LV outflow tract obstruction, VSD patch leaks, and pulmonary hypertension.

Transthoracic Doppler echocardiography from multiple windows routinely allows imaging of the intraatrial pulmonary venous and systemic venous portions of the atrial switch (see Figs. 45-10, 45-11, and 45-12).[8] Presystolic flow reversal with atrial contraction into the hepatic venous confluence and superior vena cava provides indirect evidence of caval anastomotic patency. If echocardiographic contrast injected into a peripheral arm vein promptly enters the systemic venous atrium, the superior vena caval anastomosis is patent. In obstruction at the superior vena caval connection, azygous or other venous collaterals to the inferior vena cava will cause contrast to first enter the inferior vena cava and then the systemic venous atrium. Tricuspid regurgitation may occur with or without diminished RV function. Long-term performance of the systemic RV is often abnormal, especially in the VSD repair subgroup. In addition to evaluating RV size and ejection fraction, measuring RV myocardial performance index is useful.[8,94] TEE may be needed for accurate imaging of the entrance site of all four pulmonary veins and for imaging of the caval junctions with the systemic venous baffle.[12,13] Peripheral venous contrast injections help

**TABLE 45-4 Corrective Procedures for "Complex" Malformations**

| *Lesion* | *Corrective Procedure* | *Complications and Residual Abnormalities* |
|---|---|---|
| Transposition of the great arteries (TGA) | Atrial switch surgery (Mustard procedure) | Rhythm and conduction disturbances<br>Baffle leaks and obstruction<br>Vena caval and pulmonary venous obstruction<br>Tricuspid regurgitation<br>RV dysfunction |
| TGA | Arterial switch procedure | Supravalvular pulmonic stenosis<br>Supravalvular aortic stenosis (less common)<br>Regional wall motion abnormalities of the LV |
| Tricuspid atresia or double-inlet single ventricle | Fontan repair (RA to pulmonary artery or RV) | Cavoatrial shunting, atrial septal shunting, thrombus, RA-to-pulmonary-artery obstruction |
| Atrioventricular canal defects | Patching of atrial and/or ventricular septal defects combined with valve repair | Residual mitral regurgitation<br>Iatrogenic mitral stenosis<br>Subaortic stenosis<br>Patch leaks |
| Tetralogy of Fallot | VSD patch and relief of infundibular pulmonic stenosis | Pulmonic regurgitation<br>RV aneurysms (with older repairs)<br>Residual RV outflow obstruction<br>Ventricular septal patch leaks |
| TGA with ventricular septal defect (VSD) and pulmonic stenosis | Rastelli repair (conduit from RV to pulmonary artery with VSD patch directing subaortic flow) | VSD patch leak, subaortic obstruction<br>Prosthetic valve dysfunction |
| TGA with VSD and subaortic stenosis | Damus-Kaye-Stansel procedure | VSD patch leak<br>Pulmonic regurgitation |
| Congenitally corrected TGA | Various repairs, depending on associated defects | Left-sided atrioventricular valve regurgitation<br>Heart block<br>Systemic (anatomic right) ventricular systolic dysfunction |
| Double-outlet RV | Rastelli repair | Obstruction of LV to aortic baffle<br>Residual VSDs<br>Obstruction in right-sided conduit |

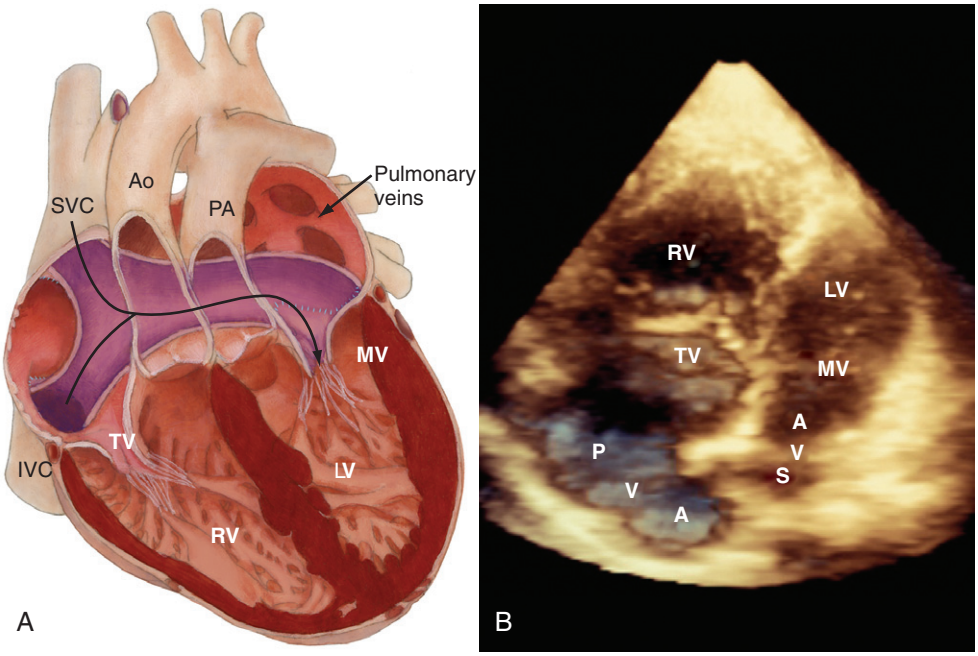

**Figure 45-10** **Complete transposition of great arteries (D-TGA) after atrial switch repair (Mustard or Senning). A,** Deoxygenated systemic venous return via superior vena cava (*SVC*) and inferior vena cava (*IVC*) is directed via intraatrial baffle (*curved arrow*), across mitral valve (*MV*), into subpulmonic LV and thereafter to pulmonary artery (*PA*) for oxygenation in lungs. Oxygenated blood returns from lungs via left-sided pulmonary veins that are baffled to tricuspid valve (*TV*). Oxygenated blood crosses TV into RV, which is connected to aorta (*Ao*). **B,** 3D echocardiography, apical four-chamber view, demonstrating widely patent pulmonary venous atrium (*PVA*) directing pulmonary venous return to TV and systemic RV. Systemic venous atrium (*SVA*) is typically not as well visualized as PVA.

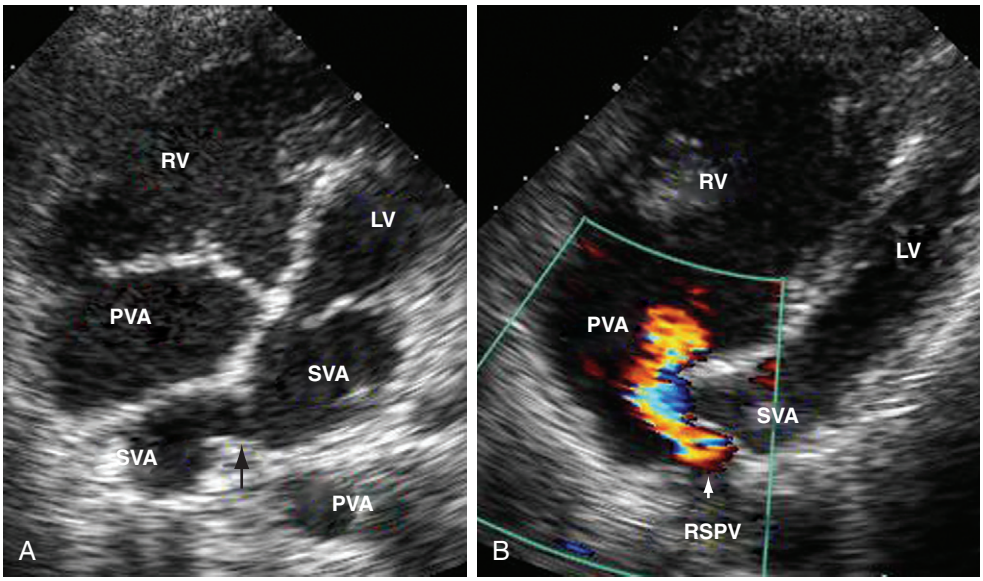

**Figure 45-11** **Pulmonary venous baffle stenosis in complete transposition of great arteries (D-TGA) late after Mustard procedure. A,** The TEE apical 2D four-chamber view shows the systemic venous atrium (*SVA*) with minimal narrowing in midportion (*arrow*); pulmonary venous atrium (*PVA*) wraps around SVA and thus is seen only in two parts. SVA connects vena cavae with LV via a portion of previous LA, and PVA connects posterior LA and pulmonary veins to RV via a portion of previous RA. **B,** Color flow imaging of PVA demonstrates color flow acceleration at narrowing of origin of right superior pulmonary vein (*RSPV*). PVA now courses obliquely across SVA, which is only incompletely seen. In both images, subaortic systemic RV is dilated.

detect baffle leaks. With TEE, obstructed caval-baffle, midbaffle, or pulmonary venous baffle sites are diagnosed by an increased peak velocity of continuous systolic and diastolic flow in combination with documented turbulent flow. TEE and/or intracardiac echocardiography are used in the catheterization laboratory to guide transcatheter interventions to relieve stenosis and/or to close baffle leaks.

## ARTERIAL SWITCH SURGERY

Because of late problems after atrial switch surgery, the arterial switch operation is preferred when possible. Issues include supravalvular aortic or pulmonary artery stenosis at the great arterial anastomoses as well as abnormalities of the proximal coronary arterial anastomoses with potential kinking and abnormal myocardial perfusion.[95-99] Postoperative

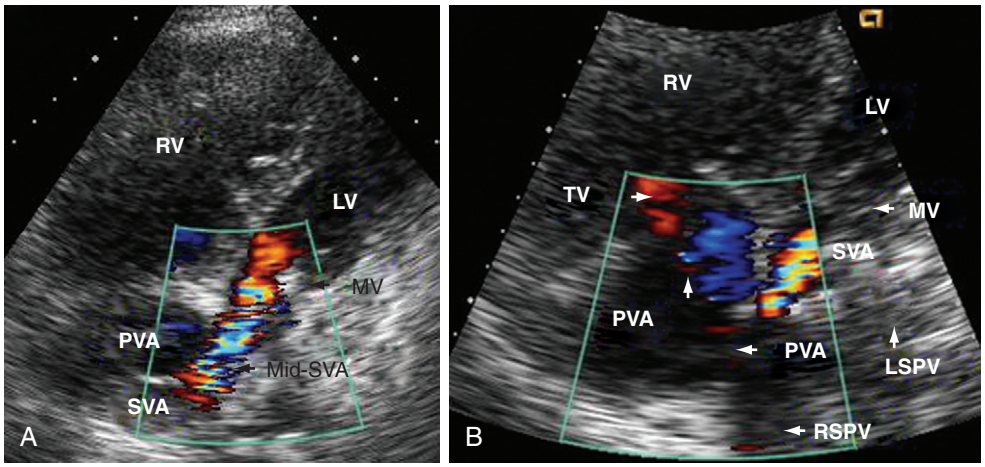

**Figure 45-12 Systemic venous return baffle obstruction in complete transposition of great arteries (D-TGA) late after Mustard procedure.** **A,** The TEE apical view shows the narrowed superior limb of systemic venous atrium (*SVA*) with color flow acceleration. **B,** Pulmonary venous atrium (*PVA*) is widely patent, and entry of pulmonary veins is well seen. *LSPV*, Left superior pulmonary vein; *MV*, mitral valve; *RSPV*, right superior pulmonary vein; *TV*, tricuspid valve.

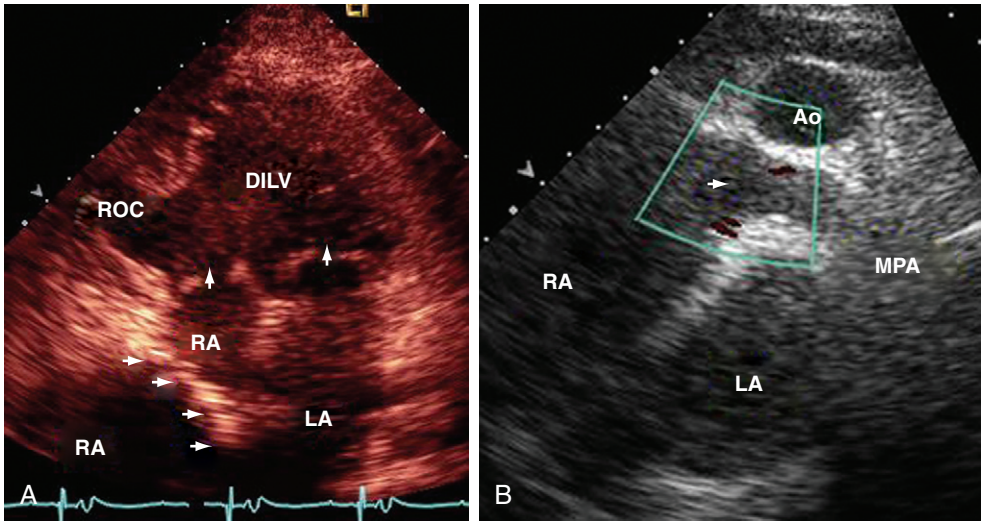

**Figure 45-13 A, TTE of double-inlet left ventricle (*DILV*) with hypoplastic RV forming right outflow chamber (*ROC*).** There is a modified RA to pulmonary artery (PA) Fontan with RA divided by a patch (*arrows*). Note inflow from both RA and LA to single ventricle. **B,** RA-to-PA connection from suprasternal notch view. *Ao*, Aorta; *MPA*, main pulmonary artery.

echocardiography plays an important role in evaluating the arterial anastomoses. Supravalvular pulmonic stenosis is the most frequent complication of the arterial switch operation. Neoaortic root dilatation as well as adequacy of the neoaortic (anatomic pulmonic) valve is a long-term concern. Proximal coronary artery torsion or kinking can be confirmed by intraoperative echocardiography. Myocardial perfusion defects are relatively common after the arterial switch operation; coronary events after the operation are not uncommon, usually occur early, and may be a cause of sudden death.[98,100] Regional wall motion abnormalities have been seen after two-stage repairs and correlate with myocardial perfusion defects.[101]

## TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION

Total anomalous pulmonary venous connection is due to lack of development of communication of the common pulmonary vein and the LA. Most adults arrive already diagnosed and corrected with connection of the common pulmonary vein to the LA and closure of the obligatory ASD. After repair of total anomalous pulmonary venous connection, color flow and pulsed Doppler provide useful information regarding the presence of pulmonary venous obstruction.

## FONTAN ATRIAL SURGERY

Fontan-type atrial surgery, used when biventricular repair is not possible (e.g., tricuspid atresia or double-inlet single ventricle or complex straddling of atrioventricular valves, or crisscross relationships and superior-inferior ventricles—where two functioning ventricles cannot be established) has frequent short- and long-term morbidity and mortality.[102-105] The several variants of the Fontan repair all result in complete or near-complete (hemi-Fontan) separation of the pulmonary and systemic circulations. The RA was an integral part of the original Fontan anatomy. Many adults still living had the old-style direct RA–pulmonary artery anastomosis (Fig. 45-13).[103] In the past two decades, various modifications of the Fontan operations have been used. The RA-to-pulmonary-artery Fontan has been

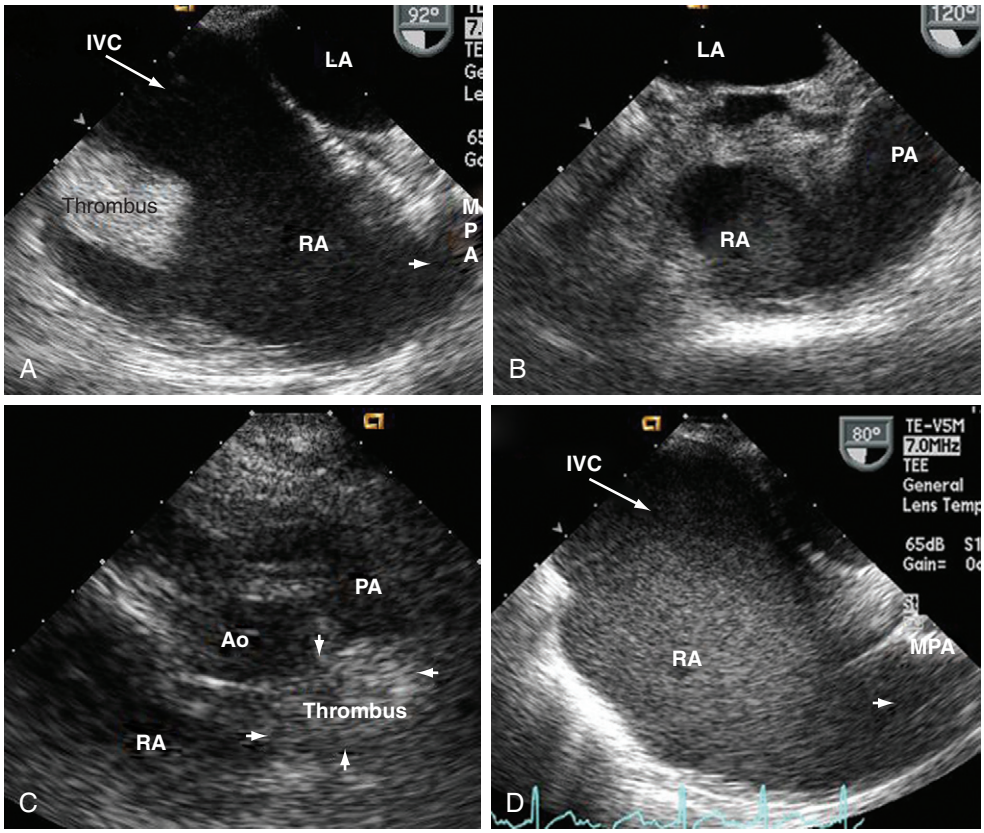

**Figure 45-14** **A, 2D TEE in patient with RA to main pulmonary artery (*MPA*) Fontan.** Note large thrombus near entry of inferior vena cava (*IVC*) to RA. **B,** Short-axis view demonstrating widely patent RA-to-PA connection. **C,** Patient desaturated dramatically the next day and urgent 2D TTE demonstrated embolization of large RA thrombus to RA-to-PA connection. **D,** TEE following treatment with thrombolytic therapy and anticoagulation for 4 weeks demonstrates complete resolution of thrombotic material in RA and RA-to-PA connection. *Ao*, Aorta.

abandoned, mainly because of the unacceptably high risk of arrhythmias and thromboembolism (Fig. 45-14). The two most widely encountered contemporary Fontans are the extracardiac conduit and the lateral or intraatrial tunnel (Fig. 45-15). In high-risk Fontan patients, an adjustable ASD or fenestration may be performed (see Fig. 45-15, *B*).[106,107] In double-inlet single ventricle, a direct atriopulmonary connection with patch exclusion of the right atrioventricular valve was a common modification of the Fontan procedure. The current total cavopulmonary connection is more hemodynamically efficient.[108] The total cavopulmonary connection is either an extracardiac tube connecting inferior vena cava to right pulmonary artery plus connection of superior vena cava to pulmonary artery, or an intracardiac tube or lateral tunnel using the lateral wall of the RA to bring the inferior vena cava to the pulmonary artery with the superior vena cava attached to the right pulmonary artery (see Fig. 45-15).[108-112] In adults whose Fontan circulation is failing or atrial arrhythmias are difficult to control, conversion to either a modern total cavopulmonary connection often with a modified maze procedure with RA size reduction is considered.[113] Patch exclusion of the RA may result in right atrioventricular valve regurgitation. Postoperative subaortic stenosis (dynamic or fixed—at the bulboventricular foramen in single ventricle, at the subaortic conus in tricuspid atresia with transposed great arteries) must be sought (Fig. 45-16).[8,12,13,114] The most common complications in the atrial portion of the Fontan circulation include cavoatrial shunting, atrial septal shunting, thrombus, and RA-to-pulmonary-artery obstruction; atrial arrhythmias are frequent.[102,103,105,111,112] Surgical sequelae purposely left behind in high-risk patients include atrial fenestrations and adjustable ASDs.[107] These communications are often closed later in the catheterization laboratory under TEE or intracardiac echocardiographic guidance.[115,116]

In adults, RA-RV conduits are occasionally seen by TTE examination but RA-pulmonary connections can be difficult to visualize (see Figs. 45-13 and 45-14).[8,12,13] Evaluation of ventricular hypertrophy and systolic and diastolic is important as they are determinants of long-term outcome.[117,118] Multiplane TEE consistently images the Fontan anastomosis, although not always with the necessary alignment to allow accurate spectral Doppler assessment of peak velocity profiles.[8,12,13]

In the Fontan patient, an important determinant of outcome is the systolic and diastolic function of the systemic ventricle and its atrioventricular valve, both of which are readily evaluated by transthoracic Doppler echocardiography studies.[2,12,13,119,120] TEE is useful when directed at suspected complications or known residua of the Fontan atrial anatomy (baffle shunts, thrombi, stenotic connections).

With no functioning subpulmonary RV in most with the Fontan repair, pulmonary artery flow shows a bi- or triphasic pattern with diastolic velocities equal to or greater than systolic, with accentuation of diastolic velocity at the time of RA contraction in those with RA-PA variants; this is not as appreciated in total cavopulmonary shunts (Fig. 45-17).[121] Inspiration augments pulmonary artery flow velocities (see Fig. 45-17), and pulmonary and systemic venous flow profiles remain relatively

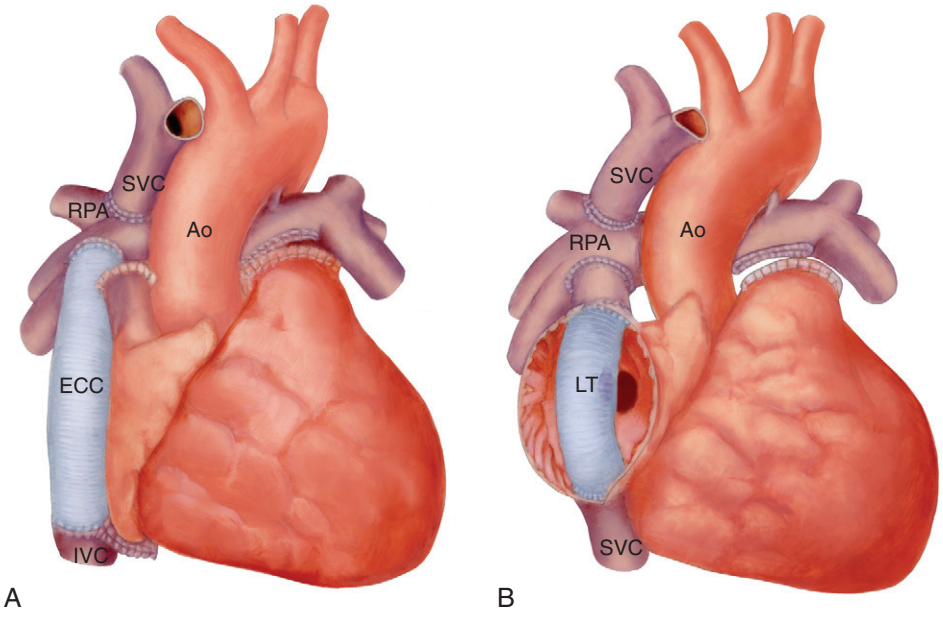

**Figure 45-15 Two most commonly employed Fontan modifications in the current era. A,** Extracardiac conduit (*ECC*) from inferior vena cava (*IVC*) to right pulmonary artery (*RPA*). Glenn connection from superior vena cava (*SVC*) to pulmonary artery is noted. **B,** Lateral tunnel (*LT*) Fontan running within RA with fenestration and atrial septal defect (*ASD*) left in place or created. *Ao*, Aorta.

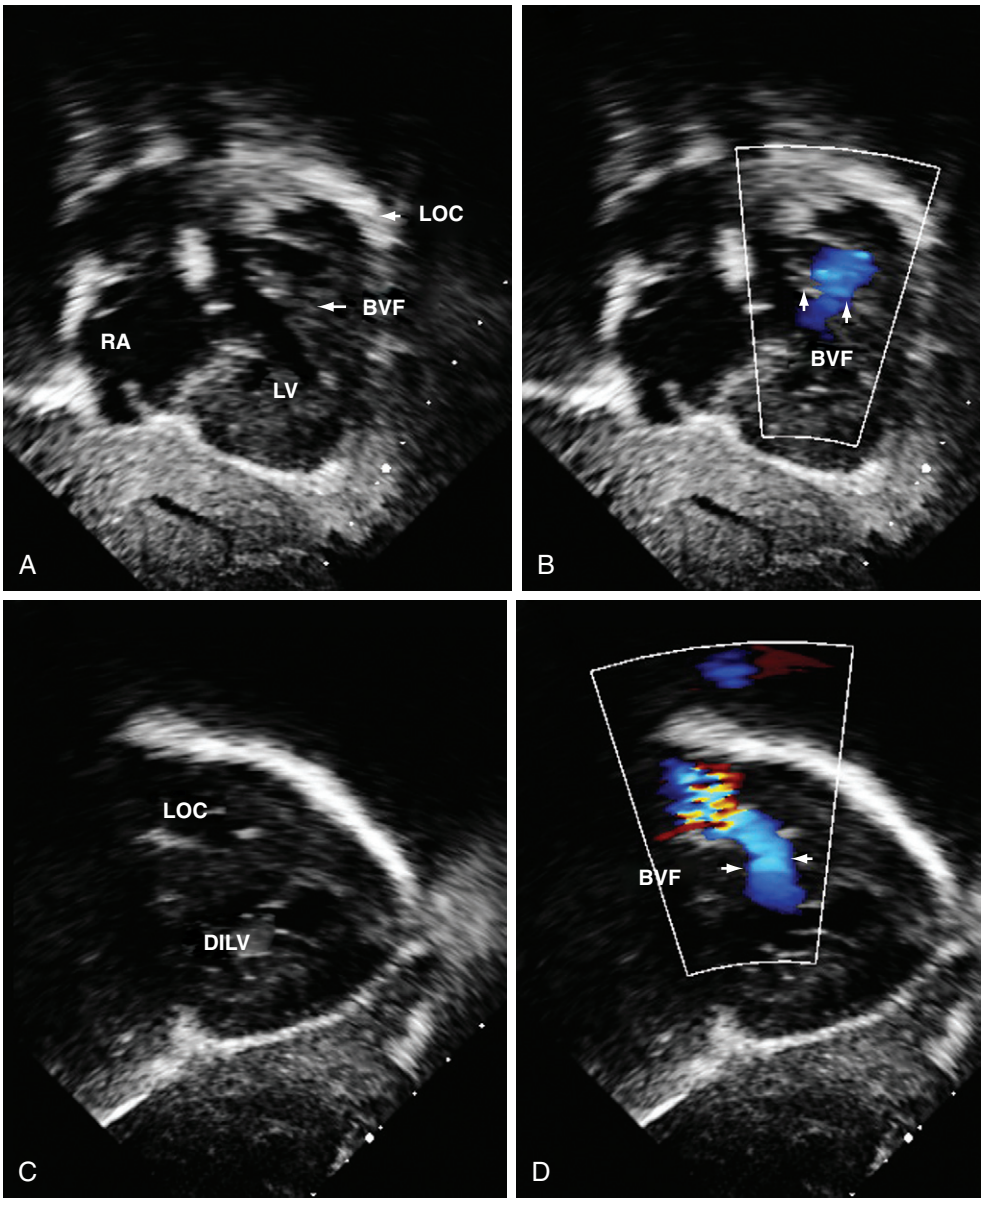

**Figure 45-16 Double-inlet LV (DILV).** Modified subcostal views show a narrowed bulboventricular foramen (*BVF*) into hypoplastic morphologic RV that forms left outlet chamber (*LOC*) This results in flow acceleration and subaortic stenosis.

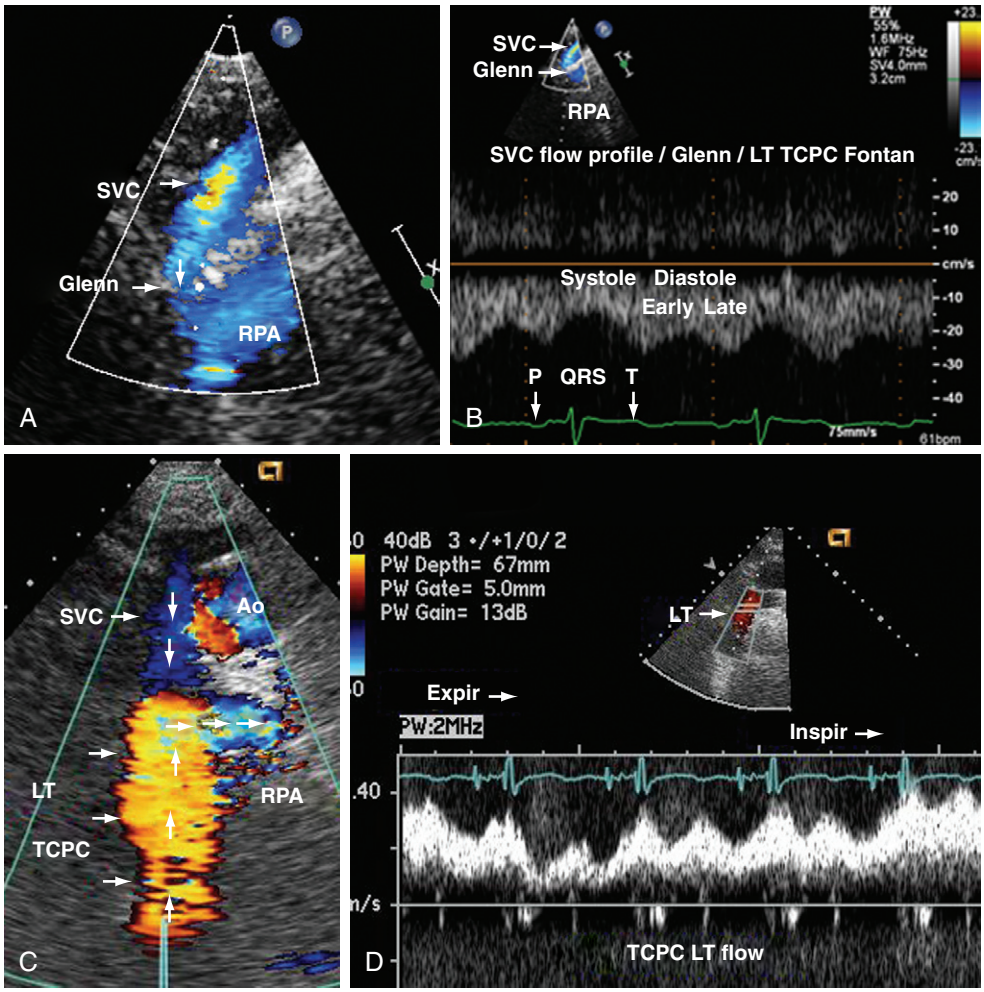

**Figure 45-17** **Single ventricle physiology with a total cavopulmonary connection (*TCPC*) using a lateral tunnel (LT) from inferior vena cava to the PA plus a Glenn anastomosis from the superior vena cava (*SVC*) to right pulmonary artery (*RPA*). A,** Suprasternal notch view with color Doppler demonstrating SVC-to-RPA Glenn connection. **B,** Pulsed-wave (PW) Doppler demonstrates continuous flow that is accentuated in early and late diastole. **C,** Color Doppler from suprasternal notch view clearly demonstrating flow from EC and Glenn into RPA. **D,** PW Doppler within ECC-to-RPA connection demonstrates continuous flow that is accentuated with inspiration. *Ao*, Aorta.

normal in patients with normal left (or single) ventricular function. Abnormal systemic ventricular performance is reflected in a reduced pulmonary arterial flow pattern velocity with decreased change on inspiration and a predominantly systolic profile.

Intraoperative TEE ensures patent connections and helps in sizing any surgical ASD or fenestration. Postoperative TEE may be required in the intensive care unit in Fontan patients to search for known complications (e.g., increasing pulmonary artery pressures with decreased cardiac output and "right heart failure" due to lateral tunnel Fontan thrombus embolization). TEE and intracardiac echocardiography can be used in the interventional catheterization laboratory to guide postoperative closure of surgical ASDs or fenestration.

## ATRIOVENTRICULAR SEPTAL DEFECTS

Atrioventricular septal or canal defects (AVSD) are a group of anomalies that share a defect at the site of the atrioventricular septum and abnormalities of the atrioventricular valves.[8,12,13,119] They are considered "complex" lesions because of the usual association of two or more abnormalities. These defects may be partial (partial endocardial cushion or primum ASDs, cleft mitral leaflet, and/or inlet VSD) or complete and will usually have been corrected in childhood or adolescence. The usual partial AVSD in adults is a primum ASD plus an anterior mitral leaflet cleft with abnormal chordal attachments to the LV outflow tract and variable degrees of mitral regurgitation. Repair requires primum ASD patching and mitral valve repair. Complete AVSDs, rarely first diagnosed in adults, are seen in patients surviving to adulthood after childhood repair. A complete AVSD has a large septal defect with interatrial and interventricular components plus a common atrioventricular valve that connects both atria and both ventricles.

Follow-up imaging examines adequacy of mitral repair, amount of regurgitation, and presence of iatrogenic mitral stenosis or subaortic stenosis. Subaortic stenosis may be due to a discrete fibromuscular narrowing or abnormal LV outflow tract attachments of anomalous chords and leaflet tissue, or may develop postoperatively because of reduction of LV outflow size as the cleft in the mitral leaflet is apposed.[8] Owing to combined preoperative RV and LV volume overload, the size and function of both ventricles must be quantified postoperatively. Occasionally, tricuspid regurgitation can be substantial, and tricuspid valvular repair requires postoperative evaluation. In addition, in complete AVSD repairs, the VSD patch must be evaluated.

Some patients, especially those with Down syndrome, can have pulmonary vascular disease; tricuspid and pulmonic regurgitant jets should quantify pulmonary artery pressure. To minimize significant residual defects (e.g., valvular regurgitation, patch leaks), intraoperative TEE should be used.[8,12,13]

## BIVENTRICULAR REPAIRS

Biventricular repairs result in two well-formed functional ventricles with a subpulmonic ventricle and a subaortic ventricle that are able to provide a circulation in series without an admixture of venous and systemic blood. Most complex congenital cardiac malformations amenable to biventricular repair are cyanotic and consist of a mixture of septal defects; obstructive and regurgitant valvular, subvalvular, or supravalvular lesions; and malpositions of the cardiac chambers and great arteries.[7] Anatomic substrates that are typical candidates include tetralogy of Fallot, pulmonary atresia with VSD, transposition complexes of the great arteries, and double-outlet ventricles.[7,8] The basic theme includes patch closure of a VSD and reconstitution of ventricular to pulmonary arterial blood flow (Fig. 45-18). If pulmonic stenosis cannot be directly repaired for anatomic or conduction system reasons, the pulmonary artery must be ligated or the valve oversewn and a conduit placed from the ventricle to pulmonary artery (see Fig. 45-18). Long-term postoperative survival is affected by age at operation, degree of relief of the loading conditions imposed on the ventricular myocardium, myocardial protection during operation, electrophysiologic sequelae, and the durability of prosthetic materials, especially valved or nonvalved conduits.

## TETRALOGY OF FALLOT

Tetralogy of Fallot is the most common complex congenital malformation with cyanosis at birth in which patients live to adulthood.[7] Tetralogy of Fallot is due to anterior deviation of the outlet septum with infundibular narrowing and a malaligned VSD. Echocardiography shows the malaligned VSD with aortic override plus a spectrum of RV outflow tract and pulmonary artery obstructive lesions from mild to complete pulmonary atresia (see Fig. 45-5).[8,12,13,119] Numerous associated defects must be identified for proper surgical and postoperative management—for example, ASDs, endocardial cushion abnormalities, Ebstein malformation, muscular VSDs, absent pulmonic valve or left pulmonary artery, abnormal origin of one pulmonary artery from the aorta, systemic and pulmonary

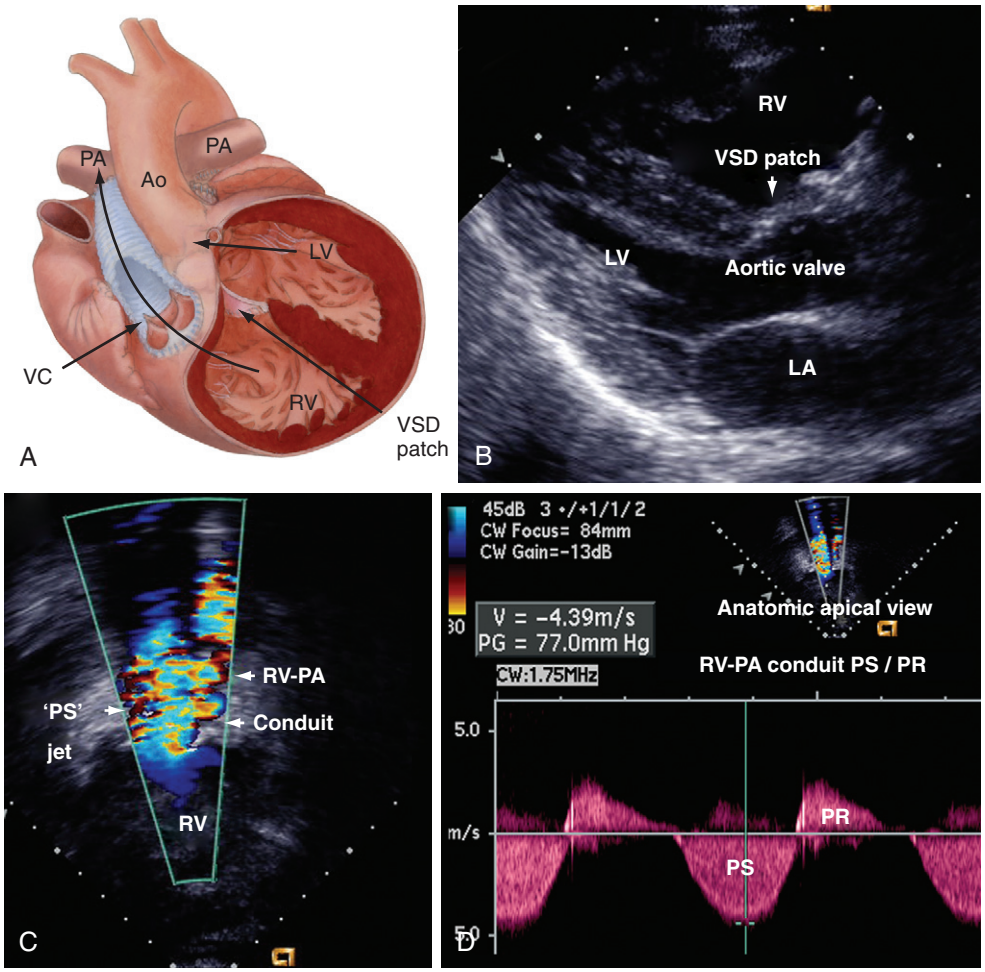

**Figure 45-18 A, Rastelli repair in patient with double-outlet RV with severe pulmonic stenosis involves patching of ventricular septal defect (*VSD*) to form internal tunnel from LV to aortic valve.** Valved conduit (*VC*) is placed from RV to pulmonary artery (*PA*). **B,** TTE parasternal long-axis view demonstrating VSD patch and internal tunnel from LV to aortic valve. **C,** Short-axis subcostal color flow Doppler demonstrating flow acceleration consistent with pulmonic stenosis (*PS*) within anteriorly located RV-to-PA conduit. **D,** CW Doppler from subcostal position demonstrates severe PS with estimated peak instantaneous systolic gradient of 77 mm Hg along with moderate pulmonic regurgitation (*PR*).

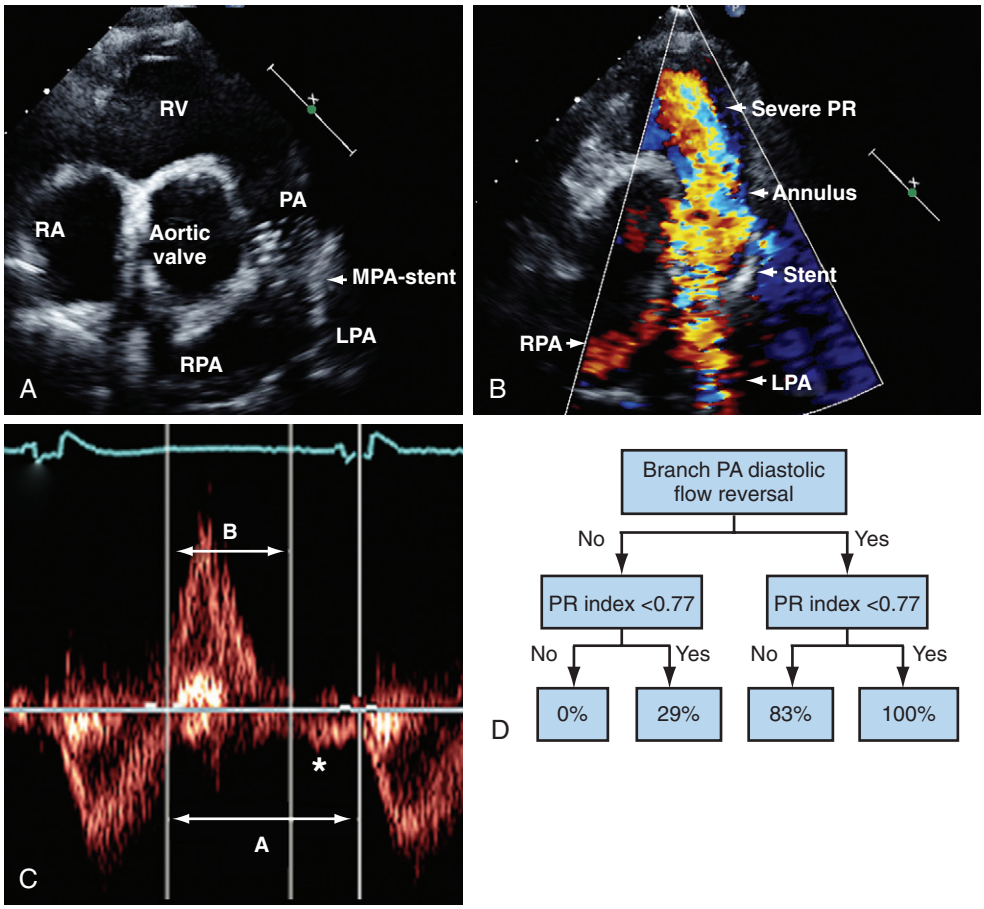

**Figure 45-19** **Tetralogy of Fallot with pulmonary atresia status post transannular patch placement from RV to pulmonary artery (*PA*). A,** TEE parasternal short-axis view shows residual stenosis of distal main pulmonary artery (*MPA*) that was treated with stent without obstructing right pulmonary artery (*RPA*) or left pulmonary artery (*LPA*) ostia. **B,** Color Doppler in diastole demonstrates severe pulmonic regurgitation (*PR*) with branch pulmonary artery flow reversal (*RPA* and *LPA*). Note that stent is well above level of pulmonic valve annulus. **C,** The PR index is the ratio of the duration of regurgitant flow (*arrow* in B) to the total duration of diastole (*arrow* in A). In this case, the PR index is <0.77, suggesting severe PR. End-diastolic forward flow (*) is sign of restrictive RV physiology. **D,** Flow chart for the likelihood of severe PR on velocity encoded MRI imaging, based on the presence of diastolic flow reversal in the branch pulmonary arteries and a PR index less than 0.77. When both are present, the likelihood of severe PR is 100%; if neither is present, the likelihood of severe PR is 0%. *(With permission from Renella P, Aboulhosn J, Lohan DG, et al: Two-dimensional and Doppler echocardiography reliably predict severe pulmonic regurgitation as quantified by cardiac magnetic resonance.* J Am Soc Echocardiogr *23:880-886, 2010.)*

venous anomalies, discrete subaortic stenosis, right-sided aortic arch, aortopulmonary window, aortopulmonary collaterals, and coronary artery anomalies.[8]

Tetralogy of Fallot repair includes patch closure of the VSD and usually an RV outflow tract incision to relieve infundibular stenosis. The RV incision at times must extend through the pulmonary annulus thus requiring a transannular patch. Pulmonic valve, trunk, or branch artery stenosis should be relieved (Fig. 45-19). If there is extreme pulmonic stenosis or pulmonary atresia, a valved conduit connects the RV to the pulmonary artery. After tetralogy of Fallot repair, long-term concerns focus on the RV and its outflow tract, the pulmonic valve and pulmonary artery, the LV, the aortic valve and ascending aorta, and electrophysiologic residua and sequelae (see Fig. 45-19).[6,7,17,122-158]

When tetralogy of Fallot is repaired in the first 5 years of life, late RV function remains normal in the absence of significant RV outflow obstruction provided low-pressure pulmonic valve regurgitation is only mild to moderate. Severe pulmonic regurgitation (see Fig. 45-19) causes RV enlargement and failure and tricuspid regurgitation, particularly if there is any residual RV outflow tract, pulmonic valve, or pulmonary artery (e.g., branch stenosis) obstruction (see Fig. 45-19; Fig. 45-20). Postoperative RV outflow tract scars and aneurysms may be present and lead to risk of ventricular arrhythmias and sudden death. 2D echocardiography with color flow and spectral Doppler examines the RV outflow and pulmonary artery anatomy for obstruction or regurgitation (see Fig. 45-19)[159]; CW Doppler tricuspid regurgitant jet velocities reflect RV systolic pressure.[8] VSD leaks, usually eccentric, may occur anywhere along the patch and require color flow imaging for detection. RV restrictive physiology late after repair of tetralogy is common as detected by Doppler hemodynamics. The A wave contributes to forward pulmonary flow and shortens the duration of pulmonic regurgitation, resulting in less RV enlargement and better exercise tolerance (see Fig. 45-19).[8,118,133,138,160] When severe pulmonic regurgitation results in impaired exercise performance, increasing RV size with decreasing RV systolic function, and increasing tricuspid regurgitation, pulmonic valve replacement is necessary. Aerobic capacity has been shown to improve after pulmonic valve replacement for severe pulmonic regurgitation after previous tetralogy of Fallot repair even if

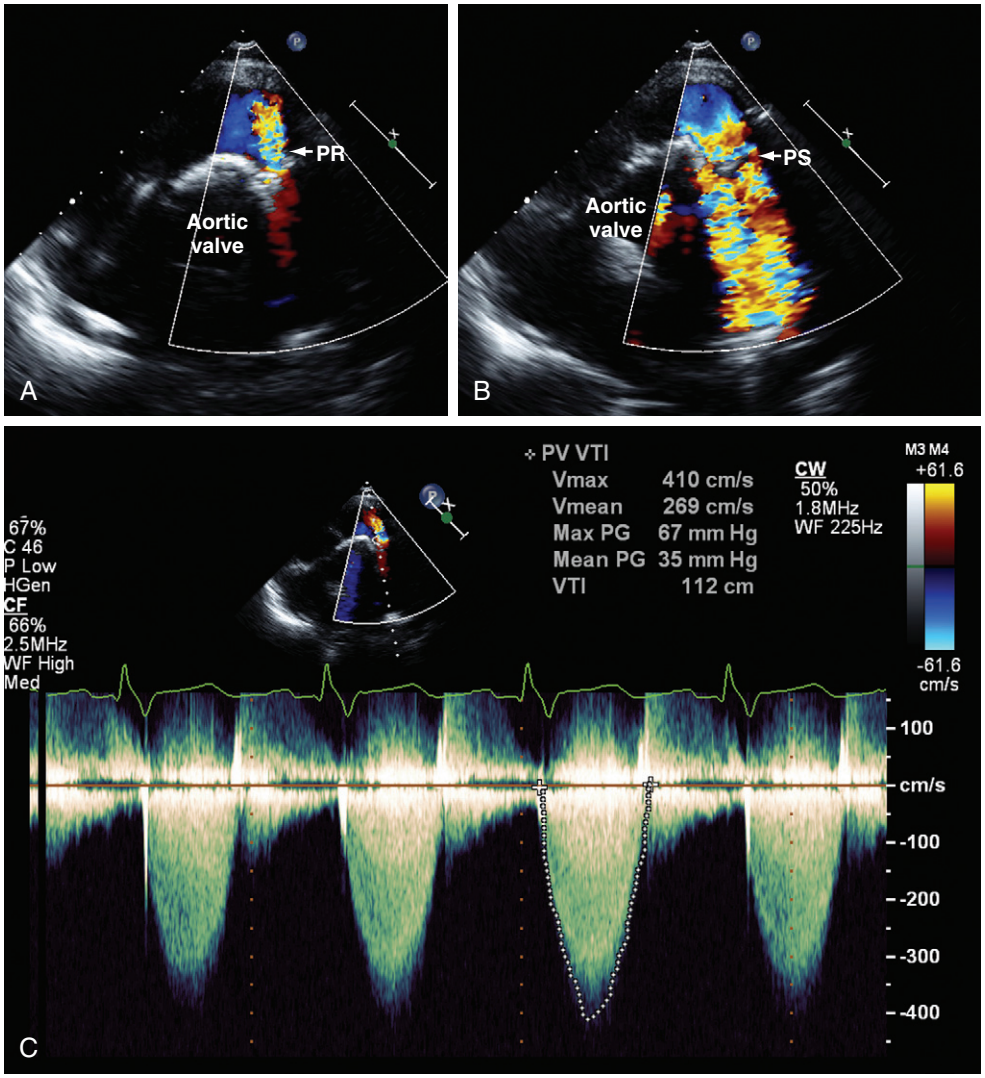

**Figure 45-20** **Bioprosthetic pulmonic valve dysfunction 14 years after tetralogy of Fallot surgery. A,** Residual moderate pulmonic regurgitation (*PR*) seen with color Doppler in a TTE parasternal view. **B,** Residual pulmonic stenosis (*PS*) with color flow acceleration at level of bioprosthetic valve. **C,** CW Doppler demonstrates estimated peak instantaneous systolic gradient of 67 mm Hg.

the RV size and function does not. The use of transcatheter pulmonic valve replacement is expected to increase dramatically as this technology becomes more widely available (Fig. 45-21).

Late postoperative LV function in tetralogy of Fallot is related to age at the time of repair and to previous volume overload from palliative shunt procedures. Patients with severe cyanotic tetralogy of Fallot have decreased left heart volumes and decreased LV ejection fractions related to the reduced pulmonary arterial blood flow. Repair in the first 2 years of life allows LV mass and volume to normalize; with repair after 2 years of age, left heart volumes increase but LV function remains subnormal. Medial aortic disease can cause a dilated aortic root or trunk; aortic regurgitation is common and at times has resulted in biventricular failure.[54] Any combination of persistent VSD patch leaks, ventricular-to-pulmonary outflow obstruction, and significant valvular regurgitation may cause serious ventricular overload. Inadequate operative myocardial preservation or the preexistence of volume overload (as with large palliative shunts before more complete hemodynamic repair) may cause ventricular failure over the long term.[7]

## COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

Transposition complexes have each great artery arising from the wrong ventricle (ventriculoarterial discordance) (see Chapter 43). This definition is independent of the spatial relationships of the great arteries and the presence or absence of a subaortic infundibulum. In complete transposition of the great arteries (D-TGA), each atrium connects to its anatomically appropriate ventricle (atrioventricular concordance), but that ventricle gives rise to an anatomically inappropriate great artery (ventriculoarterial discordance). The aorta arises from the RV (with aortic-mitral discontinuity) and usually sits to the right of and anterior to the pulmonary artery, which emerges from the LV. This results in two separate and parallel circulations, and some communication between the two circulations must exist or be made iatrogenically after birth to sustain life.[7]

Echocardiographic imaging must define the course of each of the great arteries and

1. Identify the size and location of a VSD;
2. Confirm the presence and severity of pulmonic stenosis;

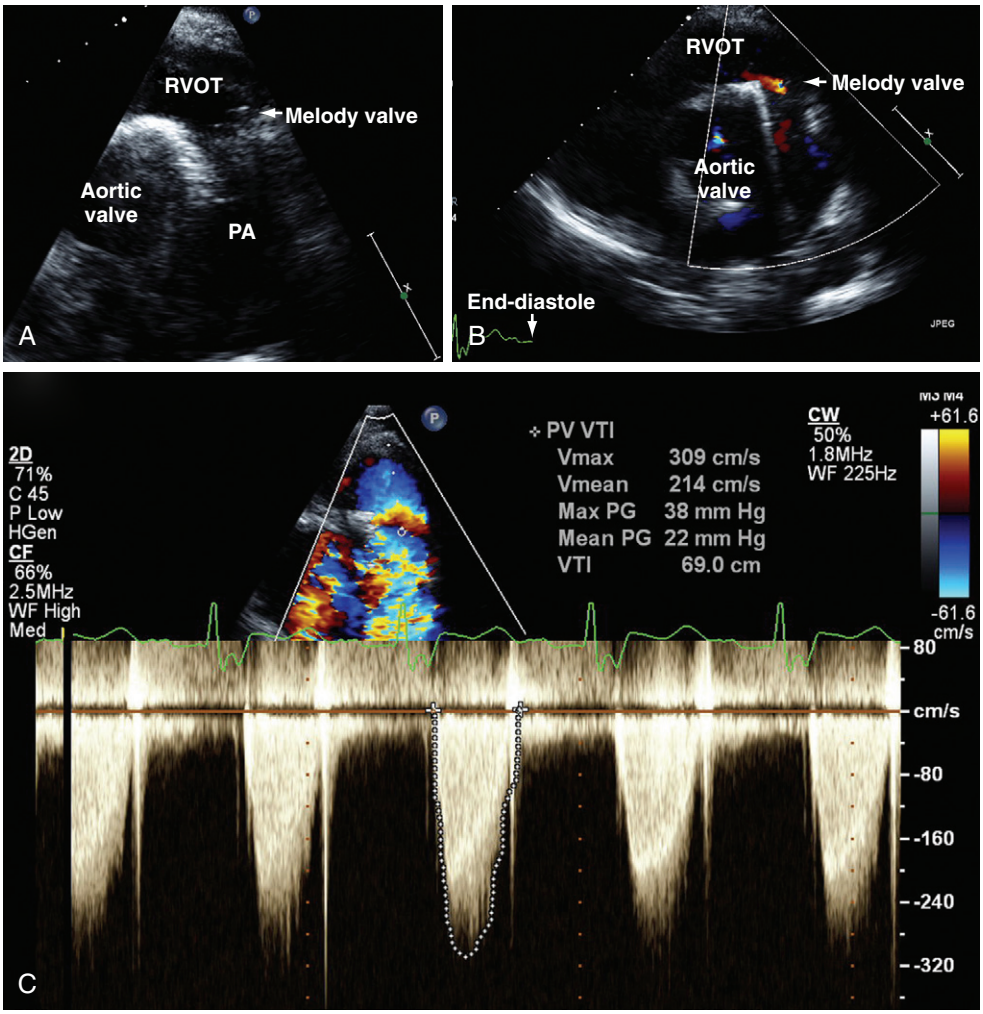

**Figure 45-21** **Transcatheter pulmonic valve replacement with 22-mm Melody valve in patient described in Figure 20. A,** Leaflets of Melody valve are seen are seen coapting appropriately in diastole. **B,** Color Doppler in diastole demonstrating minimal pulmonic regurgitation. **C,** CW Doppler demonstrating mild to moderate residual flow acceleration with peak instantaneous gradient of 38 mm Hg, a reduction of ~50% compared to pre-Melody assessment. *PA*, Pulmonary artery; *RVOT*, right ventricular outflow tract.

3. Detect other shunts; and
4. Evaluate the presence and severity of valvular regurgitation.[8,12,13]

Dynamic subvalvular pulmonic stenosis can be due to systolic anterior mitral motion into the LV outflow tract or dynamic subpulmonic septal contraction with obstruction versus fixed subvalvular stenosis. The pulmonic valve may be the site of obstruction. The location of the obstruction affects surgical planning; if not addressed, these problems contribute to postoperative morbidity and mortality.

Long-term outcome of surgical intervention for D-TGA, with or without VSD and pulmonic stenosis, depends on the type of repair.[4-6] In the past, most patients underwent intraatrial baffle procedures (e.g., Mustard or Senning), causing persistence of a systemic subaortic RV and tricuspid valve (see Figs. 45-10 and 45-11). In contrast, the arterial switch operation is now used and the LV is the systemic ventricle. Rastelli repair, whether for transposition of the great arteries (TGA) or for double-outlet right ventricle with VSD and pulmonic stenosis, uses an external conduit from RV to pulmonic artery and an intraventricular "tunnel" via the VSD from LV to aorta (see Fig. 45-18). An internal tunnel may develop a patch leak or obstruction due to kinking, or it may partially obstruct the chamber through which it transits. Long-term concerns include durability of a bioprosthesis, patency of conduits, VSD patch leaks, and postoperative electrophysiologic residua and sequelae.[7]

The Damus-Kaye-Stansel procedure, as applied to D-TGA with a VSD without pulmonic stenosis but with subaortic stenosis, consists of end-to-side anastomosis of the proximal pulmonary artery to aorta, oversewing of the aortic valve or proximal aorta, and a VSD patch. The RV is connected to the distal main pulmonary artery, now separated from the proximal main pulmonary artery, by a valved conduit. A variation of the Damus-Kaye-Stansel procedure is used in single ventricle with TGA and "subaortic stenosis" (bulboventricular foramen obstruction). Imaging of the pulmonic arterial to aortic anastomosis establishes lack of obstruction, pulmonary regurgitation, conduit patency, or VSD patch leaks.

## CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

Congenitally corrected transposition of the great arteries (CCTGA) consists of discordant atrioventricular and ventriculoarterial connections with ventricular inversion (RA enters the LV via a mitral valve, LA enters the RV via a tricuspid valve; LV

gives rise to the pulmonary artery, RV gives rise to the aorta). The atrioventricular valves follow their ventricles, revealing the left-sided systemic ventricle as the anatomic RV and vice versa. Echocardiographic crux anatomy shows the left atrioventricular valve more apically placed than the right atrioventricular valve, identifying tricuspid and mitral valves, respectively. The aorta leaves the RV leftward and anterior (L-TGA) and LV connects to a rightward and posterior pulmonary trunk, well shown on short-axis parasternal views or angulated apical or subcostal views.[7,8] Associated anomalies include ASD, Ebstein-like abnormality of the left-sided tricuspid valve and tricuspid regurgitation (physiologically equivalent to mitral regurgitation), VSD, and subvalvular (fixed or dynamic) or valvular pulmonic stenosis. A large VSD with significant pulmonic stenosis or severe systemic atrioventricular valve regurgitation prompts consideration of surgery. A Rastelli procedure may be used in CCTGA with a VSD and subvalvular pulmonic stenosis. The LV may be connected to the pulmonic artery via a valved conduit, whereas the RV supplies the aorta once the VSD is patched. The subpulmonary stenosis is often not resected because of the high incidence of complete heart block.

Three issues materially influence long-term postoperative survival:

1. Progressive tricuspid regurgitation;
2. High incidence of heart block often caused by operation; and
3. Progressive decrease in systemic subaortic morphologic RV function.[6,7,161,162]

Atrioventricular valve regurgitation is common preoperatively, is difficult to repair (often requiring replacement instead), may progress postoperatively, poses a continuing risk of endocarditis, and may affect long-term ventricular performance.

## DOUBLE-OUTLET RIGHT VENTRICLE

Double-outlet right ventricle, a heterogeneous category, has both great arteries committed to the RV; the VSD may be committed to the aorta (subaortic, infracristal), to the pulmonary artery (subpulmonic, supracristal), to both (doubly committed, subarterial), or to neither. The VSD location affects the streaming characteristics of blood, the degree of cyanosis, and the capacity for and type of repair.[7] The presence or absence of pulmonic stenosis or increased pulmonary vascular resistance is a determinant of outcome. Double-outlet right ventricle with a subpulmonary VSD and an RV or biventricular pulmonary trunk (Taussig-Bing anomaly) may clinically resemble complete TGA with a nonrestrictive VSD. Cyanosis is usually mild initially but progresses as pulmonary vascular resistance rises. Favorable regulation of pulmonary blood flow occasionally establishes adequate but not excessive flow, with consequent amelioration of LV volume overload.

Echocardiography must address the spatial relationships between the great arteries, the outflow tract for each artery, the location and type of VSD, and the relationship of the VSD to the aorta. Associated anomalies must be sought (e.g., malpositions or atrioventricular canal or septal defects).

Rastelli repair for double-outlet RV with subaortic VSD and pulmonic stenosis consists of an external RV-to-pulmonary-artery conduit and an intraventricular LV to the aorta via the VSD tunnel (see Fig. 45-18). The intraventricular course of the LV to the aortic baffle can be long and kinking may occur; this is best evaluated intraoperatively with TEE. An RV-to-pulmonary artery valved conduit can develop obstruction. In double-outlet RV of a tetralogy of Fallot type with normally related great arteries and a subaortic VSD, the repair may use a septal patch and primary repair of the site of pulmonic stenosis without resort to a conduit. Residual defects in the native ventricular septum or around the patch may be more frequent in repair of double-outlet RV than in tetralogy of Fallot, presumably because the distance from the VSD to the aorta is greater and more complex as a result of both the proximity of tricuspid valve tissue and anomalies of the ventricular septal musculature. "Intramural" residual interventricular defects seen after repair of conotruncal malformations, most commonly double-outlet RV, are found around the anterior portion of the patch between the neosystemic outflow tract and RV and require careful color flow imaging to detect. In such cases, device occluder placement has reduced the shunt; successful surgical closure may require removal and reattachment of the anterior portion of the patch.

### KEY POINTS

- Advances in surgical and catheter treatments have resulted in more adults than children with congenital heart disease in the United States.
- Many adult echocardiographic laboratories are unprepared for the full range of previously operated or complex congenital heart disease. Echocardiographic studies in these patients should be done where expertise is best, whether in an adult or a pediatric laboratory.
- Echocardiographic imaging with color and spectral Doppler recordings provides comprehensive anatomic, functional, and hemodynamic details in adults with congenital heart disease.
- For best results, imaging and hemodynamic study requires detailed knowledge of: (1) the anatomic and hemodynamic faults of the original defect; (2) the types of operative repairs (both past and present) available for each complex of lesions; and (3) the potential residua, sequelae, and complications of the "old" and "new" repairs.
- Echocardiographic data are integrated with other imaging and hemodynamic modalities (MRI, CT, and cardiac catheterization) for optimal management of adults with congenital heart disease.

- Intraluminal Venous Extension

**Differential Diagnosis**

**Newer Echocardiographic Techniques**

## Background

Although cardiac tumors are rare, with an autopsy frequency of only 0.001% to 0.03%,[1,2] they represent an important group of cardiovascular abnormalities because an early and accurate diagnosis may permit a curative procedure or, in some circumstances, may even avoid unnecessary surgery.[3-5] Before the introduction of two-dimensional (2D) echocardiography in the 1970s, ante mortem diagnosis of cardiac tumors was exceptionally unusual.[6] However, with the advent of 2D transthoracic echocardiography, the ability to identify cardiac tumors ante mortem has been possible. Moreover, ante mortem diagnosis of cardiac masses and tumors has steadily increased. This has been brought about by improvements in imaging technology that include higher frequency transthoracic imaging transducers, harmonic imaging, and refinements in transesophageal echocardiography (TEE), including multiplane TEE and three-dimensional (3D) imaging.[7,8] Echocardiography is well suited as the initial imaging modality in patients suspected of having a cardiac tumor because it is a simple noninvasive technique with widespread availability and relatively low cost (Box 46-1). Computed tomographic (CT) scan and magnetic resonance imaging (MRI) provide additional diagnostic information and should be seen as ancillary complementary techniques[9] because they can provide information for staging and treatment planning, particularly when surgical resection is being considered.[10]

Patients with cardiac tumors may present with cardiovascular-related or constitutional symptoms. However, more often than not, a cardiac mass is discovered incidentally during an echocardiographic examination performed for an unrelated indication. These incidental masses usually represent thrombi or vegetations and often occur in a particular clinical milieu with associated unique concomitant echocardiographic abnormalities.[5] If a mass is indeed a tumor, it is most likely malignant as a result of a known malignant process elsewhere, usually from the breast or lung or malignant melanoma. Much less likely, the mass represents a primary cardiac tumor. In this case, it is most likely benign, with a nearly 50% likelihood of being a myxoma. Malignant primary cardiac tumors are very rare and represent only approximately a quarter of primary cardiac tumors. These are most often a variety of sarcoma.

Clinical symptoms and signs are often determined by location of the tumor rather than its histologic type.[11,12] Thus, the clinical significance of a "benign" tumor may be just as important as a "malignant" type. Benign tumors may be locally invasive and impair myocardial contractility or cause valve dysfunction presenting with heart failure or conduction system disease or fatal arrhythmias. Systemic or pulmonary tumor embolization is an important and relatively common complication that occurs in up to a quarter of cases and is related to specific structural and anatomic tumor characteristics. Tumors of the aortic valve and left atrium (LA) pose the highest embolic risk. In addition, and somewhat paradoxically, patients with minimal symptoms, hemodynamic alterations, and smaller tumors have higher embolic complications than patients with larger symptomatic tumors.[13] Often, tumors present with pericardial effusions with or without tamponade; others may present with constitutional or systemic symptoms.

The benefit of echocardiography lies in its ability to show precise anatomic details and pathology. It delineates the morphologic appearance, location, and motion of tumors and determines the hemodynamic consequences of the tumor, if any.[14] The sensitivity of echocardiography is greatest for endocardial lesions, where the contrast between the tumor and the

echolucent chamber is greatest, permitting accurate characterization of the size and mobility of the mass. Intramyocardial lesions are less well appreciated, and pericardial tumors are the most difficult to detect, mainly because of the increased pericardial echo density and its far-field position. MRI and CT scan offer benefits over echocardiography in defining lesions in these locations[15] and are also helpful in staging tumors, assessing degree of mural infiltration, and detecting pericardial involvement and presence of tumor extension or metastases (Table 46-1). MRI and CT scan are also particularly good at evaluating tumor vascularity and fat composition.

Transthoracic echocardiography and TEE have unique attributes and limitations in evaluation of cardiac tumors. Although the availability of transthoracic echocardiography is widespread and it is simpler to perform, multiplane TEE generates higher resolution images of structures, particularly near the esophagus. It is thus not only better suited to detection of tumors in the superior vena cava, right atrium, pulmonary arteries, LA, and descending thoracic aorta but also helpful in distinguishing these masses from thrombi and vegetations.[16,17] Overall, TEE has better sensitivity and specificity than transthoracic echocardiography, especially in identification of smaller tumors.[18] It is also particularly useful in distinguishing true pathology from normal or normal variant cardiac anatomy (e.g., a prominent crista terminalis or lipomatous hypertrophy of the interatrial septum).[4] However, TEE is not as good at identification of left ventricular (LV) apical masses; if this is a clinical concern, transthoracic echocardiography should be performed.[16,19]

The following discussion reviews the clinical scope of cardiac tumors and their incidence. A clinical classification and a diagnostic approach are presented, and the echocardiographic and pathologic correlation of the most common individual tumors is addressed in descending order of their prevalence. Alternative and complementary imaging techniques are also briefly discussed. Finally, conditions that mimic cardiac tumors and newer emerging echocardiographic technologies with potential for better evaluation of cardiac tumors are also discussed.

## CLASSIFICATION OF CARDIAC MASSES

A classification of cardiac masses is presented in Table 46-2, and diagnostic approach is presented in Figure 46-1. The most likely etiology of a cardiac mass is thrombus or vegetation. The clinical setting provides diagnostic clues. For example, thrombi are most likely associated with atrial fibrillation or a LV apical infarct, and vegetations may be seen in patients with native valve disease or prosthetic valves. However, if a cardiac mass really represents a tumor, its etiology can often be determined with consideration of four factors:

1. the histology-based likelihood
2. the age of the patient at time of presentation
3. the tumor location; and
4. noninvasive tissue characterization

With this approach, and integration of the clinical data, an accurate diagnosis and treatment strategy is usually possible without the need for percutaneous or open surgical biopsy.

### *Histology-Based Likelihood*

Secondary malignant disease of the heart and pericardium is considerably more common than primary cardiac malignant disease; in some estimates, it is 30 to 1000 times more common.[2] In a random autopsy series, the frequency of metastatic involvement is 0.4%; and in patients with diagnosed cancer cardiac involvement, it is as high as 20%.[9] Spread to the heart is generally via direct tumor extension, venous/lymphatic spread, or arterial metastasis. The most common underlying malignant diseases with secondary cardiac involvement are carcinoma of the lung, breast, esophagus, stomach, and kidneys and melanoma, lymphoma, and leukemia.

Primary cardiac tumors are much rarer than secondary malignant lesions. Almost 90% of primary cardiac tumors excised surgically are benign, with nearly 80% of these tumors representing myxomas.[6] In a report of 323 consecutive patients undergoing surgical resection of primary cardiac tumors between 1957 and 2006 at the Mayo Clinic, 94% of tumors were benign, and 50% of these were myxomas. The remaining benign

tumors in descending order of frequency included papillary fibroelastomas (26%), fibromas (6%), lipomas (4%), and others, including calcified amorphous tumors, hemangiomas, teratomas, unilocular developmental cysts, and rhabdomyomas.[7] Although papillary fibroelastoma traditionally have been considered less frequent than myxoma, it is increasingly recognized in our clinical experience that papillary fibroelastoma may in fact now represent the most common form of benign cardiac tumor. This fact underscores the increasing ante mortem diagnosis of cardiac masses resulting from the widespread use of echocardiography and the enhanced images newer echocardiographic technology affords.

In contrast to benign primary cardiac tumors, only about 10% of primary cardiac tumors excised at surgery are malignant, of which more than 90% are sarcomas. The remaining few are represented by lymphomas.[7] To illustrate just how rare malignant primary cardiac tumors are, only 34 patients were identified at the Mayo Clinic between 1975 and 2007. All had sarcomas, and the commonest histologic type was angiosarcoma (41%).[8]

## DIAGNOSTIC APPROACH

### *Age at Presentation*

Because the incidence rate of cardiac tumors varies with age (Table 46-3), age at presentation provides a clue to the diagnosis. For example, rhabdomyomas and fibromas are the most common benign cardiac tumors in children.

### *Location*

Particular cardiac tumors have a predilection for certain locations (Fig. 46-2), which enables characterization by their location. Myxomas most commonly arise in the LA, usually from a stalk attached to the atrial septum. Sarcomas can also present as a LA mass and are commonly mistaken for a myxoma before surgery.[8] Angiosarcomas, in particular, tend to arise in the right atrium. Rhabdomyomas and fibromas are located within the ventricles. Papillary fibroelastomas are generally located on cardiac valves. Metastatic disease often affects the pericardium by direct invasion, present within the cardiac muscle if spread hematogenously and emanating from the pulmonary veins or inferior vena cava by intraluminal spread.

### *Noninvasive Tissue Characterization*

Echocardiography provides limited but useful information regarding tissue characteristics (Table 46-4), including echogenicity of the mass and whether calcification is present. Vascularity can also be assessed with color flow Doppler imaging and echocardiographic contrast. Strain imaging also has potential in identification of the noncontractile nature of masses, such as fibromas. CT scan provides information regarding vascularity by contrast enhancement, presence of calcification, and presence of fat. MRI also provides information regarding vascularity, presence of fat, degree of tissue edema, and possibly iron content.

## Cardiac Myxomas

Three quarters of all primary cardiac tumors are benign, and nearly half of these are myxomas. Myxomas occur in all age groups, most frequently between the third and sixth decades of life (with an approximate incidence rate of 45% in adults and 15% in children).[20] Women are more commonly affected.[21-26] Although myxomas usually occur sporadically as an isolated tumor in the LA, familial myxomas have been reported (accounting for 7% of myxomas).[27-30] The familial myxomas occur as an inherited autosomal dominant disorder, in combination with two or more of the following conditions: skin myxomas (single or multiple), cutaneous lentiginosis, myxoid fibroadenomas of the breast, pituitary adenomas, primary adrenocortical micronodular dysplasia with Cushing syndrome, and testicular tumors (characteristically large cell calcifying Sertoli cell tumors). Although multiple acronyms (LAMB and NAME) have been used to describe these associations in the past, these syndromes are now grouped under the broader category of Carney complex, named after the physician who first described the familial nature of the disorder.[31] These patients tend to be younger and may have the germ-line mutation PRKAR1A.[32]

They are also more likely to have multiple myxomas and have an increased risk of recurrence after resection.[21]

## CLINICAL SETTING

The clinical features of myxomas, like most cardiac tumors, are determined by their location, size, and mobility. These characteristics are easily addressed with echocardiography. Most patients present with one or more features of the triad of embolism, intracardiac obstruction, and constitutional symptoms. Dyspnea may occur as a result of atrioventricular valve obstruction. Occasionally, there are no symptoms, particularly with small tumors. Myxomas may recur after surgical resection. The overall risk of recurrence after resection is 13%, but it is much more common with familial myxomas than with sporadic tumors (22% versus 3%). The hazard of recurrence increases linearly for 4 years after resection, after which risk of recurrence is low. On the basis of this observation, semiannual surveillance echocardiographic follow-up examination has been recommended for 4 years after surgery.[33]

## LOCATION

Cardiac myxomas usually develop in the atria, with 75% originating in the LA and 15% to 20% in the right atrium. They characteristically arise from or near the interatrial septum at the border of the fossa ovalis membrane.[11,22-24,34] Occasionally they may grow through the fossa ovalis and into both atria. Myxomas may also originate (in descending order of frequency) from the posterior atrial wall, anterior atrial wall, and atrial appendage. Three percent to 4% of myxomas originate in the LV, and 3% to 4% in the right.[20,34] Tumors are usually solitary. Multiple tumors or atypical locations suggest familial myxoma. Myxomas of the heart valves have been reported but are extremely rare (Figs. 46-3 and 46-4).

## GROSS APPEARANCE

The gross appearance of cardiac myxomas is variable. The tumors range in size from 1 to 15 cm in diameter but most frequently measure 5 to 6 cm in diameter.[20] Myxomas are generally polypoid and often pedunculated, frequently arise from a narrow stalk, and are rarely sessile. They are usually round or ovoid in shape with a smooth or gently lobulated surface (Fig. 46-5). The mobility of the tumor depends on its consistency, which varies in part depending on the extent of attachment and the length of its stalk. Polypoid myxomas are usually compact and show little tendency towards spontaneous fragmentation. The less common villous or papillary myxomas have a surface that consists of multiple fine villous extensions that are fragile and tend to break off. The risk of embolization is greatest with these tumors (Table 46-5).[35-38] Adding to their embolic potential, they frequently have organized thrombi on their surface.

**TABLE 46-4 Features of Benign Primary Cardiac Tumors**

| *Type of Tumor* | *Patient Age at Diagnosis* | *Associated Syndromes* | *Most Common Location* | *Typical Morphologic Characteristics* | *Echocardiographic Features* | *CT Features* | *MRI Features* |
|---|---|---|---|---|---|---|---|
| Myxoma | 30-60 years (younger if associated with Carney complex) | Carney complex | Interatrial septum at fossa ovalis, LA more common than right | Gelatinous, attached to stalk; calcification common; hemorrhage or necrosis common | Mobile tumor, narrow stalk | Heterogeneous, low attenuation | Heterogeneous, bright on T2WI; heterogeneous enhancement |
| Papillary fibroelastoma | Middle-aged, elderly | None | Cardiac valves | Small (<1 cm), frond-like, narrow stalk; calcification rare; no hemorrhage or necrosis | "Shimmering" edges | Usually small pedunculated mass; may have calcifications and frond-like appearance when large | Usually small pedunculated mass; may have frond-like appearance when large |
| Lipoma | Variable | Multiple fatty lesions in tuberous sclerosis may be lipomas or angiomyolipomas | Pericardial space or any cardiac chamber | Large, broad-based; no calcification, hemorrhage, or necrosis | Usually hypoechoic in the pericardial space, echogenic in a cardiac chamber | Homogeneous fat attenuation (low attenuation) | Homogeneous fat signal intensity (increased T1); no enhancement |
| Hemangioma | All ages; mean, fourth decade | None | Anywhere; one third in RV, one third in LV; one fourth in right atrium | Multilobulated, unilocular, cystic, <1-8 cm | "Solid" echodense | Intense central contrast enhancement | Rapid enhancement increased T2WI signal |
| Rhabdomyoma | Infants, children <4 years | Tuberous sclerosis | LV, RV in walls on aortic valves outflow tract | Mural pedunculated multiple, variable size, spontaneous regression | Brighter than surrounding myocardium | Hypodense on contrast CT | Isointense to myocardium T2WI; hyperintense to myocardium T2WI |
| Fibroma | Infants, children, young adults | Gorlin syndrome | Ventricles | Large, intramural; calcification common; no hemorrhage or necrosis | Intramural, calcified | Low attenuation, calcified | Isointense on T1WI; dark on T2WI; usually little to no enhancement |
| Paraganglioma | Young adults | Many possible but almost always sporadic | LA, coronary arteries, aortic root | Broad-based, infiltrative or circumscribed; calcification rare; hemorrhage or necrosis common | Echogenic, relatively immobile | Low attenuation; avidly enhancing | Typically isointense or heterogeneous on T1WI, bright on T2WI; marked enhancement |

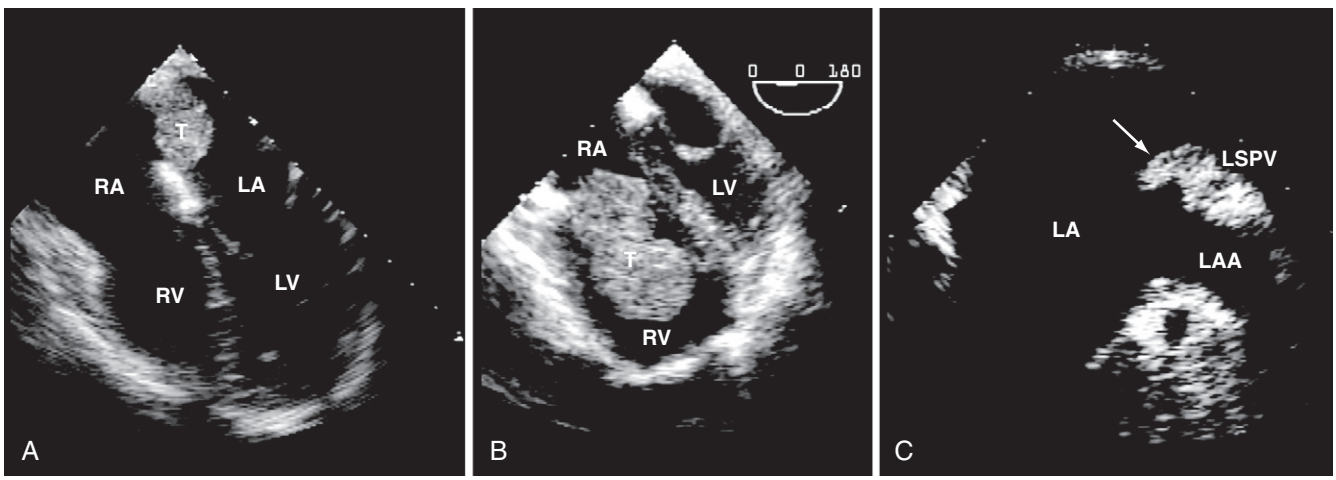

**Figure 46-3 Locations of myxomas. A,** TEE four-chamber view shows a 3.5-cm lobulated LA myxoma (*T*) arising from the fossa ovalis membrane. A mass at this location typically represents an atrial myxoma. At surgery, several "streamers" were attached to the tumor, not seen on echocardiography. **B,** A TEE four-chamber view shows a RV myxoma (*T*) measuring 7 × 4 cm that arises from the anterior tricuspid valve leaflet. This tumor extended through the RV outflow tract and pulmonic valve (not shown). Myxomas arising from unusual locations or from multiple sites should raise suspicion of Carney complex (see Figure 46-2). **C,** TEE in a 70-year-old woman presenting with a stroke. An 8-mm LA myxoma (*arrow*) is seen attached to the "Q tip" (junction of the left superior pulmonary vein [*LSPV*] and LA appendage orifice [*LAA*]). A lesion at this location may be confused with a thrombus. The mass did not resolve with anticoagulation therapy. At surgery, an additional smaller friable lesion was identified inferior to the primary lesion shown.

**Figure 46-4 A 19-year-old woman presented with a stroke.** On examination, there were cutaneous myxomas and lentigines of the lips (*bottom panel*). A TEE shows multiple intracardiac myxomas. Tumors are seen in the LA near the fossa ovalis (*double arrow*) and related to the anterior tricuspid valve leaflet (*single arrow*). A LV myxoma attached to the anterior septum is also present but is poorly seen in this still frame image (*top panel, arrowhead*). At surgery, an additional small RV apical myxoma was also identified with a thoracoscope. This was not appreciated on preoperative or intraoperative echocardiography. This patient was diagnosed with Carney complex. A repeat echocardiogram 4 years after tumor excision showed no recurrence. This case also stresses the importance of a careful search for additional lesions.

**TABLE 46-5 Morphologic Features of Myxomas Related to Embolism**

| | Emboli | | |
|---|---|---|---|
| *Morphologic Features* | *Yes (n = 10)* | *No (n = 27)* | P *Value* |
| Villous surface | 90 | 37 | .007 |
| Diameter (mm) | 48 ± 17 | 62 ± 26 | .132 |
| Gross calcifications | 0 | 15 | .557 |

Values given as percentage or mean plus or minus standard deviation, unless otherwise specified.

Adapted from Acebo E, Val-Bernal JF, Gomez-Roman JJ, Reveulta JM: Clinicopathologic study and DNA analysis of 37 cardiac myxomas: a 28-year experience.*Chest* 123:1379-1385, 2003.

Internally, myxomas often contain cysts and areas of necrosis and hemorrhage. Calcification has been observed but is rare, found only in 10% to 20% of cases.[20,39] Occasionally, myxomas may become infected.[40-43]

## ECHOCARDIOGRAPHIC FEATURES

Echocardiography accurately defines the location, size, shape, attachment, and mobility of the myxoma.[20,38] Multiple myxomas may be missed, particularly if the imager is distracted by finding the index tumor. Careful evaluation of all cardiac chambers is necessary to exclude multiple tumors. The characteristic narrow stalk is the most important distinguishing feature, followed by tumor mobility and distensibility.[9] When these features of a LA mass are seen, a diagnosis of cardiac myxoma can be made with a high degree of confidence,[44] especially if the stalk originates from the atrial septum. The internal echocardiographic appearance may be homogeneous or have central areas of hyperlucency, which represent necrotic foci and hemorrhage.[45,46] Internal areas of calcification may be present. Depending on their size and mobility, myxomas may result in LV or right ventricular (RV) inflow obstruction, the degree of obstruction sometimes varying with body position (see Fig. 46-5). TEE may provide additional important information in detecting the precise site of insertion and morphologic features of atrial and ventricular myxomas. It is also more sensitive for identification of small tumors (1 to 3 mm in diameter) and satellite tumors.[16,18,44,47-49]

## OTHER IMAGING MODALITIES

Tumor mobility, tumor distensibility and the thin delicate stalk are not as well seen with CT scan or MRI.[9] However, unlike echocardiography, CT scan and MRI can differentiate tissue composition, for better identification of solid, liquid, hemorrhagic, and fatty space-occupying tumors. CT scan and MRI findings of cardiac myxomas are variable, usually reflecting their gross pathologic features. Because of their gelatinous consistency, they have heterogeneous low attenuation at CT scan and calcification, if presence is also seen. They have markedly increased signal intensity on T2-weighted MRIs.[50,51] Presence of calcification or hemosiderin may result in areas of decreased signal intensity. Contrast enhancement is usually heterogeneous, reflecting the presence of necrotic areas.[9,52]

## DIFFERENTIAL DIAGNOSIS

Differentiation of cardiac myxoma from vegetations or thrombi is important. Usually, the echocardiographic appearance of a cardiac myxoma is quite distinctive. Sometimes, however, the diagnosis may be less certain, particularly when the myxoma has an unusual location or attachment, such as the LA appendage. In these instances, the clinical scenario (atrial fibrillation), associated echocardiographic findings (impaired ventricular function, LA enlargement, and spontaneous echocardiographic contrast), and CT/MRI findings are helpful in distinguishing thrombus from tumor. Sometimes, if the mass is small, a diagnostic trial of anticoagulation therapy can be attempted and imaging repeated to confirm resolution.

# Papillary Fibroelastoma

The true prevalence of papillary fibroelastomas is unknown. The reported prevalence of papillary fibroelastoma varies and is likely underreported because this condition is asymptomatic and thus underrepresented in surgical series, sometimes not appearing at all.[53] However, in a surgical series from the Mayo Clinic[39] and the Armed Forces Institute of Pathology,[53] papillary fibroelastomas accounted for 10% of primary cardiac tumors and were thus the second most common primary cardiac tumor.[5] Also, with the advent of echocardiography

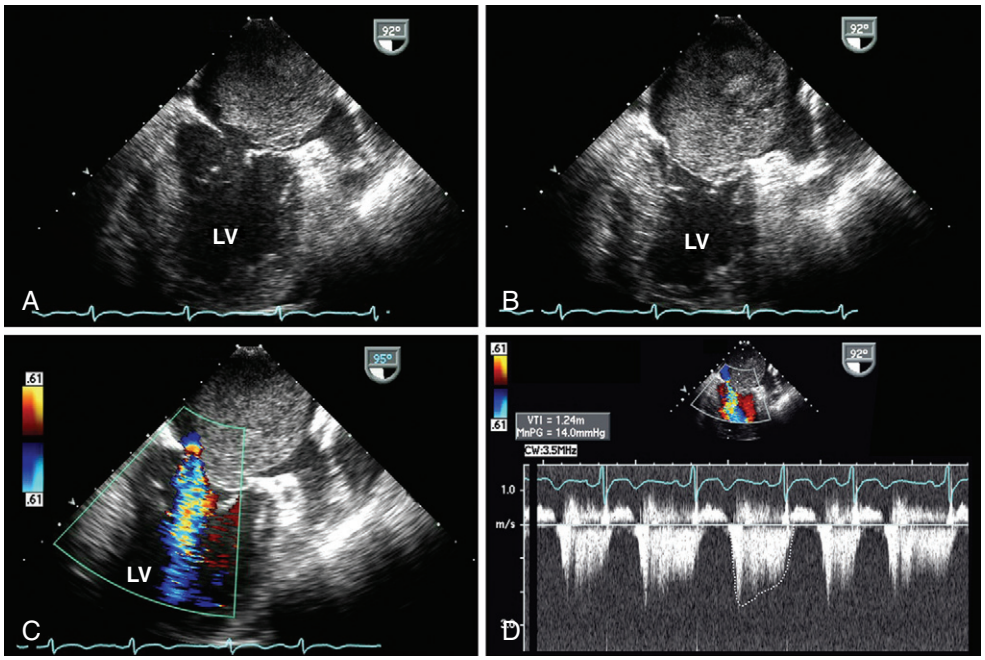

**Figure 46-5 A 64-year-old woman presented with exertional and resting chest heaviness and shortness of breath for 3 months.** The TEE shows the typical echocardiographic appearance of a large LA myxoma. **A,** A systolic frame shows a large 5 × 7 cm ovoid mass in the LA arising from a narrow stalk attached to the fossa ovalis (*not shown*). **B,** A diastolic frame shows the myxoma prolapsing through the mitral valve resulting in functional mitral valve stenosis (**C** and **D**). The mean gradient across the mitral valve is 14 mm Hg.

and improving imaging techniques, cardiac papillary fibroelastoma is detected earlier and increasingly reported.[6] These benign endocardial papillomas predominantly affect the cardiac valves and account for three quarters of all cardiac valvular tumors.[5] Patients with papillary fibroelastomas are often asymptomatic (30%) and diagnosed incidentally.[5,54] However, the clinical consequences of papillary fibroelastomas are significant and have been increasingly recognized as causes of stroke, transient ischemic attack, systemic embolism, and sudden cardiac death.[5,54]

## CLINICAL SETTING

Cardiac papillary fibroelastomas occur in all age groups but are predominantly identified in adulthood, particularly between the fourth and eighth decades of life.[5,54] The mean age of detection is approximately 60 years, which may reflect the increased use of echocardiography in older patients. Men and women are equally affected. There is a strong association with hypertrophic obstructive cardiomyopathy, and surgical, radiation, and hemodynamic.[33] The natural history of these tumors has not been characterized because serial studies with echocardiography have not been performed. They are considered generally slow-growing tumors but are clinically important because they may serve as a nidus for thrombus formation and potential thromboembolism.

## GROSS PATHOLOGY

Grossly, papillary fibroelastomas are small, usually less than 1 cm in diameter (mean, 9 cm), but they can be as large as 7 cm.[5] When these tumors occur in the cardiac chambers, they are larger than those found on the aortic and mitral valves.[54] These tumors have a characteristic flower-like appearance with multiple papillary fronds attached to the endocardium by a short pedicle; when immersed in saline solution, they exhibit the typical "sea anemone" appearance.[54,55] The papillary fronds are narrow, elongated, and branching and merge imperceptibly into the substance of the valve. Sometimes, the gross appearance of the characteristic papillary structure may be obscured by attached thrombi.[53,56] Calcification rarely occurs and has been reported in only two cases.[56]

## LOCATION

Papillary fibroelastomas usually develop on cardiac valves (75% to 90%) but may arise anywhere in the heart, originating from the LV, ostium of the right and left coronary arteries, LA appendage, atrial and ventricular septum, right atrium, LV outflow tract, Eustachian valve, and Chiari network. They have also been found in the right atrial appendage and RV outflow tract (Fig. 46-6).

Left-sided valves are affected 95% of the time, with aortic valve involvement slightly more common than mitral valve.[5,54] Valvular papillary fibroelastomas usually arise from the mid portion of the valve rather than the free edge (a distinguishing characteristic from Lambl excrescences; see subsequent discussion). Those that originate from the semilunar valves most often project into the arterial lumen but sometimes project into the ventricular cavity or even prolapse across the valve in diastole. Those that originate on the atrioventricular valves project into the atria. Rarely, they may arise from the subvalvular apparatus of the mitral and tricuspid valves.[57,58] Papillary fibroelastomas are usually solitary but can occur at multiple sites (9%).[5,54]

## CLINICAL MANIFESTATIONS

Nearly 50% of papillary fibroelastomas are discovered incidentally during echocardiography for unrelated reasons or during

evaluation of a cardiac source of embolism.[13,33] Like most cardiac tumors, their clinical presentation depends on many factors, including tumor location, size, growth rate, and tendency for embolization. The most common clinical presentations include cerebral and systemic embolization and coronary artery occlusion. Patients may also present with heart failure and sudden cardiac death. Embolism is thought to occur from superimposed thrombi or fragmentation of the papillary fronds themselves (sometimes both) because, on occasion, confirmed tumor fragments have been isolated in embolic material.[5,54]

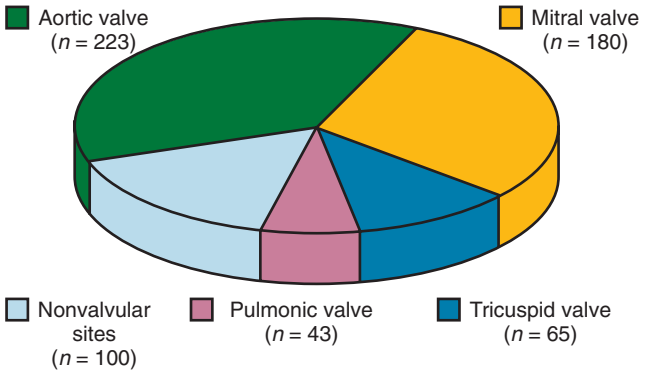

**Figure 46-6 Location of cardiac papillary fibroelastoma in 611 patients.** *(With permission from Gowda RM, Khan IA, Nair CK, et al: Cardiac papillary fibroelastoma: a comprehensive analysis of 725 cases.* Am Heart J *146:404-410, 2003.)*

## ECHOCARDIOGRAPHIC DIAGNOSIS

Papillary fibroelastomas are easily detected with echocardiography. Although transthoracic echocardiography can readily detect these tumors, the superior resolution of TEE makes this the definitive imaging modality for confirmation of the characteristic appearance of these usually small, highly mobile tumors and plays a central role in the search for multiple lesions.[5,59,60]

On 2D echocardiography, papillary fibroelastomas are characterized by a small, mobile, pedunculated valvular or, less commonly, endocardial mass, which on many occasions, flutters or prolapses into the cardiac chamber during systole or diastole (Fig. 46-7). Usually they have a well-defined "head," but they may appear as elongated strand-like projections. Characteristically, they have a stippled edge with a "shimmer" or "vibration" at the interface of the tumor with the surrounding blood, a finding that may distinguish them from thrombi.[5,61] Rather than being pedunculated and mobile, the tumors may be sessile. Sometimes, the tumors may be missed because they are small, the examination is not performed carefully enough because the clinical index of suspicion is low, or they are masked by an associated lesion or degenerative valvular disease.[54] If a papillary fibroelastoma is suspected as a source of embolism, a TEE should be performed. A proposed treatment algorithm based on imaging characteristics is presented in Fig. 46-8.

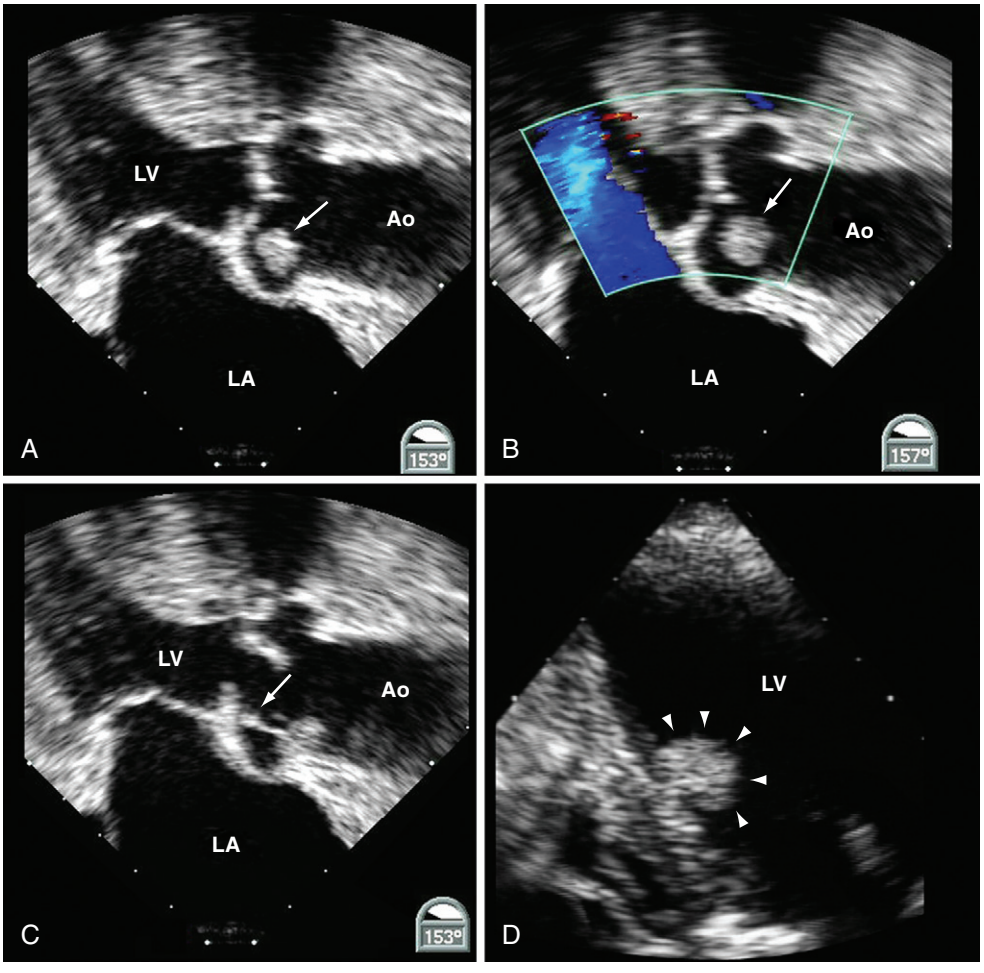

**Figure 46-7 An incidental mass was identified in an 80-year-old woman undergoing a routine transthoracic echocardiogram.** The TEE shows a 14 × 10 mm globular mass with an irregular border (*arrows,* **A** and **B**) attached to the aortic surface of the aortic valve noncoronary cusp by a thin stalk (*arrow,* **C**). Apart from aortic valve sclerosis, there were no associated valvular abnormalities or evidence of valvular destruction. **D,** Multiple papillary fibroelastomas were seen on transthoracic echocardiography in a 33-year-old woman with Hodgkin lymphoma and radiation-induced heart disease. In this zoomed apical two-chamber view image, one papillary fibroelastoma is seen attached to the endocardial surface of the mid inferior LV wall. The fimbriated surface can be appreciated (*small arrows*) Although papillary fibroelastomas are most commonly found on valves, they may arise anywhere in the heart. *Ao,* Aorta.

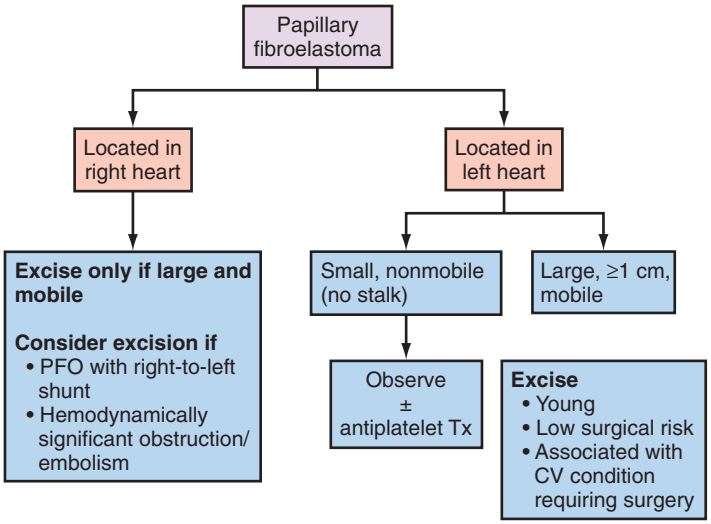

**Figure 46-8 Proposed management of papillary fibroelastomas based on echocardiography findings.** *CV,* Cardiovascular; *PFO,* patent foramen ovale; *Tx,* therapy.

## OTHER IMAGING MODALITIES

Although CT scan and MRI are getting faster and better at evaluation of cardiac valves, they are still less useful than echocardiography. The temporal and spatial resolution is often still inadequate because most of these tumors are small and attached to moving valves. The main disadvantage of MRI is susceptibility to motion artifact.[5,9]

## DIFFERENTIAL DIAGNOSIS

Again, the differential diagnosis includes thrombi, vegetations, other heart tumors, degenerative valvular calcification, and Lambl excrescences (Fig. 46-9). Lambl excrescences may be difficult to distinguish from papillary fibroelastomas.[62] These filiform fronds, first described by Lambl in 1856,[63] occur by definition at the sites of valve closure and are thought be the result of wear and tear lesions that originate as small thrombi on the endocardium of the contact margins of the valves at the site of minor endothelial damage, akin to the frayed edges of an old shirt cuff. In atrioventricular valves, Lambl excrescences are found at the site of valve closure on the atrial surface, but on semilunar valves, they can occur anywhere on the valve. Unlike papillary fibroelastomas, they usually do not occur on the arterial side of the semilunar valves or on the mural endocardium.[5] Unlike papillary fibroelastomas, Lambl excrescences are much

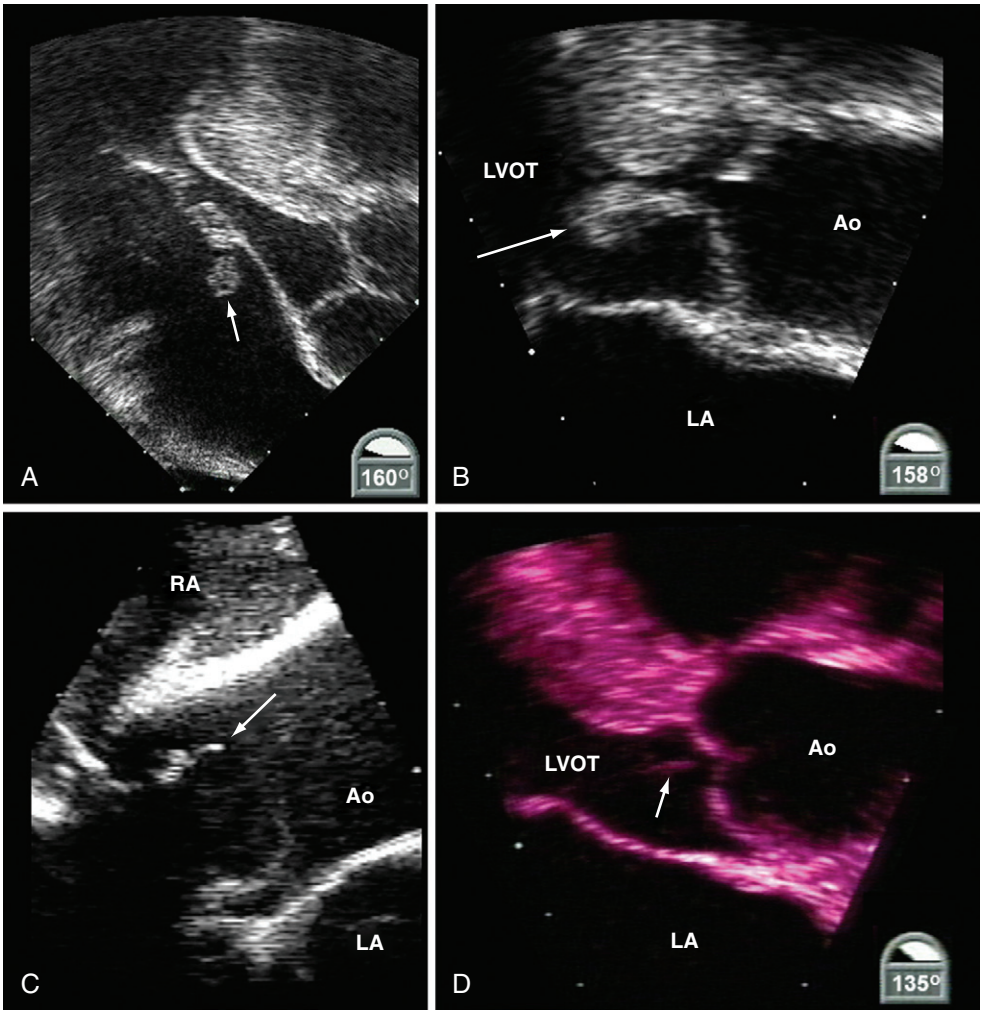

**Figure 46-9 Vegetations and Lambl excrescences may be confused with papillary fibroelastomas.** The *upper panels* show vegetations of the mitral (**A**) and aortic (**B**) valves in two patients with culture-positive enterococcal faecalis endocarditis. The vegetation on the aortic valve (*arrow*) is attached to the left ventricular outflow tract (*LVOT*) aspect of the aortic valve. It is highly mobile and, like the mitral vegetation, is associated with valve destruction and severe aortic regurgitation (*not shown*). Unlike papillary fibroelastomas, these vegetations do not have a characteristic thin stalk and fimbriated shimmering edge. Papillary fibroelastomas are usually not associated with valve destruction. Examples of a Lambl excrescence are shown attached to the aortic valve (*arrows*) in systole (**C**) and diastole (**D**). This fine filamentous highly mobile strand-like structure prolapses through the valve into the LV outflow tract in diastole. Unlike a papillary fibroelastoma, there is no globular "head" component at its distal end, and unlike a vegetation, apart from associated degenerative valve disease, overt valve destruction is unusual. *Ao,* Aorta.

more common, reported in up to 85% of adults, with multiple tumors present in more than 90% of cases. Papillary fibroelastomas, in contrast, are typically larger and more gelatinous and are present on valves away from the valvular lines of closure. They may also be found on endocardial surfaces of the atria and ventricles.[64-68] Despite these reported differences, noninvasively distinguishing these two abnormalities can sometimes be difficult.

## Other Benign Cardiac Tumors

### LIPOMA AND LIPOMATOUS HYPERTROPHY

Lipomatous hypertrophy of the atrial septum is a benign condition and is not a true tumor. It is discussed here because it is often confused with a lipoma. Lipomatous hypertrophy is defined as "any deposit of fat in the atrial septum at the level of the fossa ovalis which exceeds 2 cm in transverse dimension."[53] Lipomatous hypertrophy involves the interatrial septum, sparing the fossa ovalis membrane[53] and resulting in a characteristic dumbbell shape (Fig. 46-10). It results from adipose cell hyperplasia and is associated with increasing age and obesity.[69,70] It is a nonneoplastic condition and may be associated with atrial arrhythmias. It may very rarely result in superior vena cava obstruction.[71] Echocardiographically, the atrial septum may measure up to 3 cm in thickness and appears hyperechoic. Unlike lipomatous hypertrophy, lipomas are much less common. Unfortunately, the number of reported cases is not clear from the literature because some series do not differentiate between lipomas and lipomatous hypertrophy.[53] These homogeneous fatty encapsulated tumors usually arise from the epicardial surface, most often from a broad pedicle, and grow into the pericardial space.[9] Subendocardial lipomas are often small and sessile, whereas subepicardial lipomas tend to be larger. Subendocardial lipomas may also grow as broad-based pedunculated masses protruding into the cardiac chambers. Lipomas are usually asymptomatic but may cause symptoms from local compression (rarely, lipomas become quite large, weighing as much as 4.8 kg)[72] or cause arrhythmias; they occasionally may arise from the interatrial septum and extend into the LA cavity, mimicking a cardiac myxoma. Lipomas, unlike myxomas, however, have a broad base of attachment and are not as mobile as myxomas.[73,74] An unusual observation is that the echocardiographic appearance of lipomas varies depending on their particular location. In the pericardial space, they may appear echogenic or entirely hypoechoic or have hypoechoic regions.[75-77] Intracavitary lipomas, on the other hand, are homogeneous and hyperechoic.[74,78] The reason for this difference is not known (Fig. 46-11).[9]

If diagnostic uncertainty exists, with respect to identification of lipomatous hypertrophy or lipoma, CT scan and MRI are diagnostic because of their high specificity in identifying fat.[9,79-81] In fact, because the dumbbell appearance is so characteristic for lipomatous hypertrophy and noninvasive imaging is so specific for fat, a percutaneous tissue biopsy or surgical biopsy is unnecessary.[82]

### HEMANGIOMA

Hemangiomas are benign vascular tumors that represent only 2.8% to 10% of primary cardiac tumors.[83,84] They can arise anywhere in the heart and have been found in both ventricles and both atria, on the epicardial surface, and in the pericardium.[85-89] These tumors are seen more frequently in

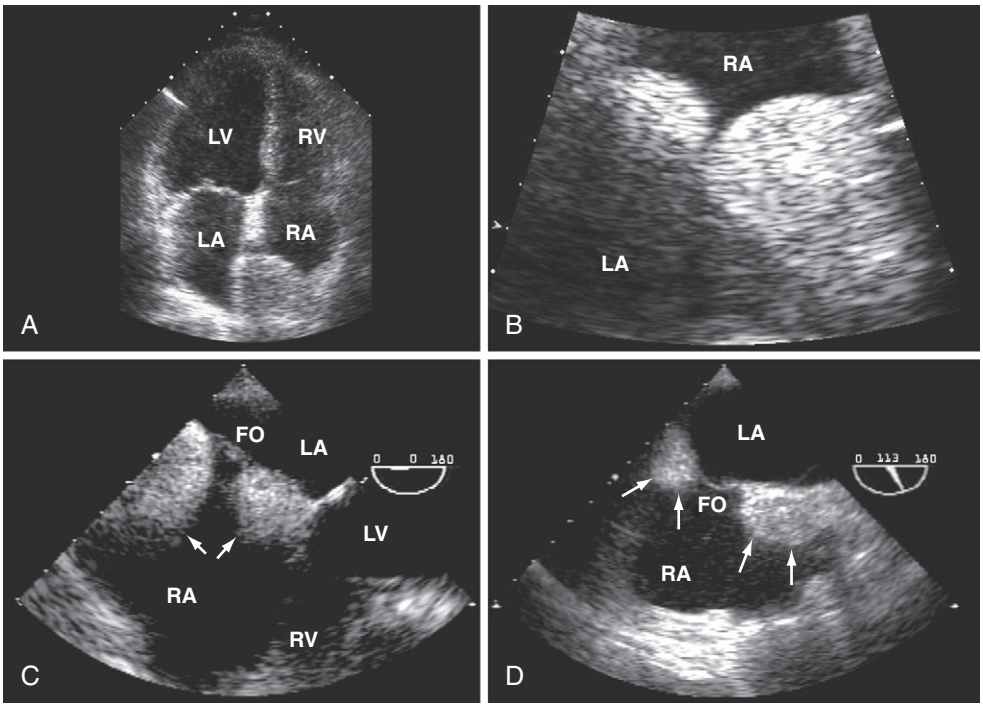

**Figure 46-10** **Typical appearance of exuberant lipomatous hypertrophy of the atrial septum. A,** Transthoracic echocardiogram, apical four-chamber view, shows a dumbbell-shaped mass in relation to the interatrial septum. The fossa ovalis membrane, which is characteristically spared in this condition, is thin, with most of the hypertrophy involving the superior limbus, resulting in a "mass-like" lesion in the roof of the right atrium. **B,** A zoomed image from a subcostal transthoracic echocardiographic view in the same patient. **C** and **D,** TEE views of lipomatous hypertrophy (*arrows*). Again, characteristically, the fossa ovalis membrane is spared. *FO,* Fossa ovalis membrane.

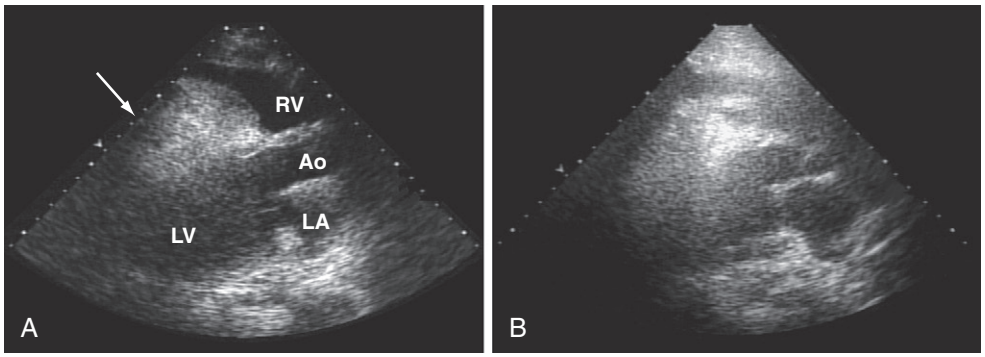

**Figure 46-11 Parasternal long-axis view images from a transthoracic echocardiogram in a 40-year-old woman with syncope and ventricular tachycardia are shown. A,** A large, poorly defined hyperechoic homogeneous intracardiac mass (*arrow*). involving the anterior interventricular septum is present. This mass also involved the anterior wall and extended to the apex. The size of the mass could not be accurately assessed because of acoustic shadowing, typical for a lipoma in this location (**B**). There was no evidence of significant outflow tract or valvular obstruction. MRI of the heart was diagnostic and showed the typical appearance of a lipoma. *Ao,* Aorta.

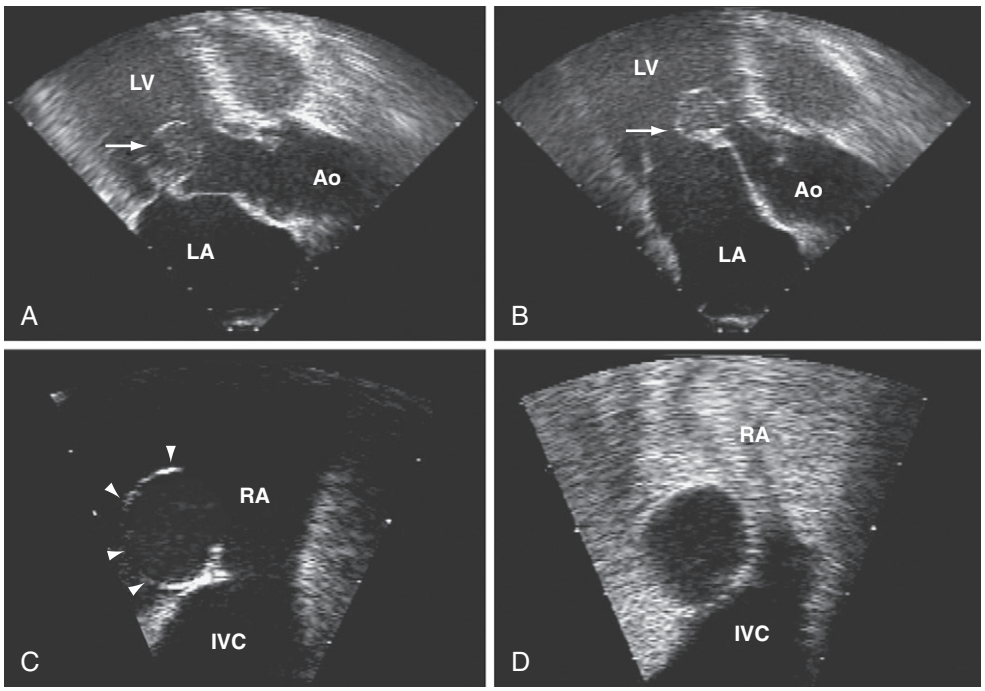

**Figure 46-12 Examples of cardiac hemangioma.** An incidental finding noted on transthoracic echocardiography in a 53-year-old man with ischemic heart disease led to this TEE (**A** and **B**). A 2-cm thin-walled echolucent mass (*arrow*) consistent with a hemangioma is seen attached to the ventricular aspect of the anterior mitral valve leaflet. Echocardiographic contrast administered intravenously is seen within the tumor, confirming its vascular nature. **C** and **D,** Another example of a hemangioma measuring 1.7 × 1.5 cm involving the Eustachian valve at the inferior vena cava–right atrial junction. The outline of the hemangioma is clearly demarcated with administration of agitated saline contrast injection via an antecubital vein. *Ao,* Aorta; *IVC,* inferior vena cava.

males than females, presenting at all ages, with a mean age at diagnosis of 43 years.[90] These tumors are usually asymptomatic and are discovered incidentally with echocardiography, CT scan, or MRI or at autopsy.[91] Symptoms depend on anatomic location and size of the tumor. They may cause arrhythmias, pericardial effusions, congestive heart failure, RV outflow tract obstruction, coronary insufficiency, and sudden cardiac death.[86] From a review of 56 reported cases, the localization of these tumors is approximately a third in the RV, a third in the LV, and a quarter in the right atrium. Other locations include the interatrial septum and interventricular septum and LA in 10% of cases. In a third of cases, multiple extensive tumors are present. The size of cardiac hemangiomas ranges from less than 1 cm to more than 8 cm.[86] Morphologically, the tumors have been variably described as a solid echodense bulge of the interventricular septum, a large multilobulated mass, or a unilocular mass with a cystic structure.[88] Although echocardiography can detect the tumor and its location, unfortunately no uniform diagnostic echocardiographic criteria exist (Fig. 46-12).[88] TEE provides incremental information regarding the accurate localization of the tumor and estimation of intracardiac and extracardiac extension and determination of the attachment site. It is also useful in assessment of whether there is extension of right atrial tumors into the great veins.[17] Cardiac catheterization and MRI are considered superior complementary diagnostic techniques. Cardiac catheterization reveals a characteristic "tumor blush"

that results from the tumor vascularity, and MRI can show the increased vascularity of the hemangioma with rapid enhancement during first pass gadolinium contrast infusion.[92-95]

The natural history of cardiac hemangiomas is poorly documented. Nevertheless, because the hemodynamic consequences of the tumor cannot be predicted, resection is recommended when feasible.

## RHABDOMYOMA

This intramyocardial tumor is the most frequent cardiac neoplasm of childhood, representing 60% of pediatric cardiac tumors,[15] and is often diagnosed in the first year of life, and increasingly in utero with the use of fetal echocardiography (Fig. 46-13).[83,85,86,89,96,97] There is a well-described and common association with rhabdomyoma and tuberous sclerosis, an autosomal dominant syndrome characterized by hamartomas in several organs, epilepsy, mental deficiency, and characteristic skin lesions. In fact, nearly 50% of infants with tuberous sclerosis are reported to have a rhabdomyoma.[98-100]

These tumors are almost always multiple and occur with equal frequency in the LV and RV, growing in the ventricular walls or on the atrioventricular valves. They vary in size from a few millimeters to a few centimeters and may be pedunculated, often obstructing ventricular inflow or outflow. Hemorrhage and calcification are uncommon.[53] Echocardiographically, they appear well circumscribed and slightly brighter than the surrounding normal myocardium (Fig. 46-14).[15]

Rhabdomyomas appear hypodense on contrast CT scan, isointense to myocardium on T1-weighted images, and hyperintense on T2-weighted images.[101] In contrast, fibromas (also a common childhood cardiac tumor; see subsequent discussion) appear as dark solitary masses, often with calcification on T2-weighted images.[102]

A characteristic and peculiar feature of rhabdomyomas is spontaneous regression (Fig. 46-15). The tumors usually regress in size or number or both in most patients less than 4 years of age. This phenomenon occurs less so in older patients, which probably accounts for their higher incidence in children and why, if found in adults, they are usually smaller than those

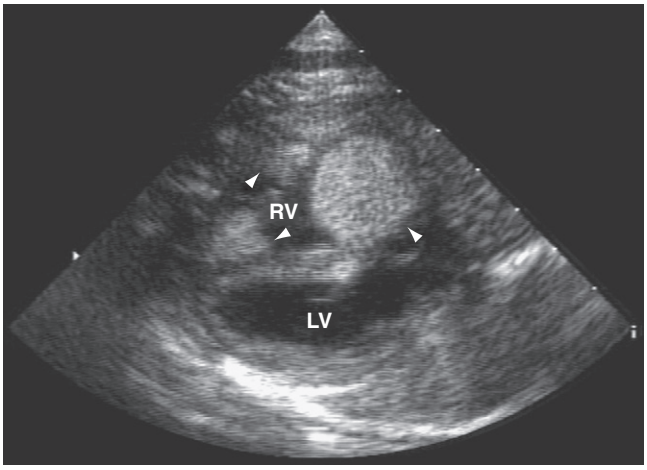

**Figure 46-13 Rhabdomyoma.** This fetal echocardiogram, longitudinal axis view, shows multiple well-circumscribed large and small tumors (*arrowheads*), typical for rhabdomyomas. These masses result in near obliteration of the RV cavity.

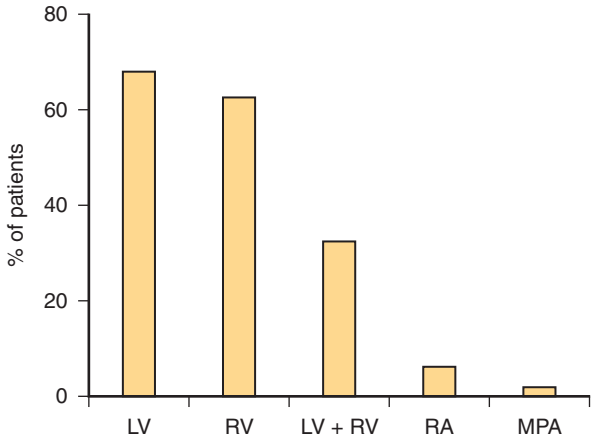

**Figure 46-15 Echocardiographic location of cardiac rhabdomyoma in the various cardiac chambers in 47 patients with tuberous sclerosis.** Some patients had tumors in more than one cardiac chamber. *MPA,* Main pulmonary artery. *(With permission Nir A, Tajik AJ, Freeman WK, et al: Tuberous sclerosis and cardiac rhabdomyoma.* Am J Cardiol *76:419-421, 1995.)*

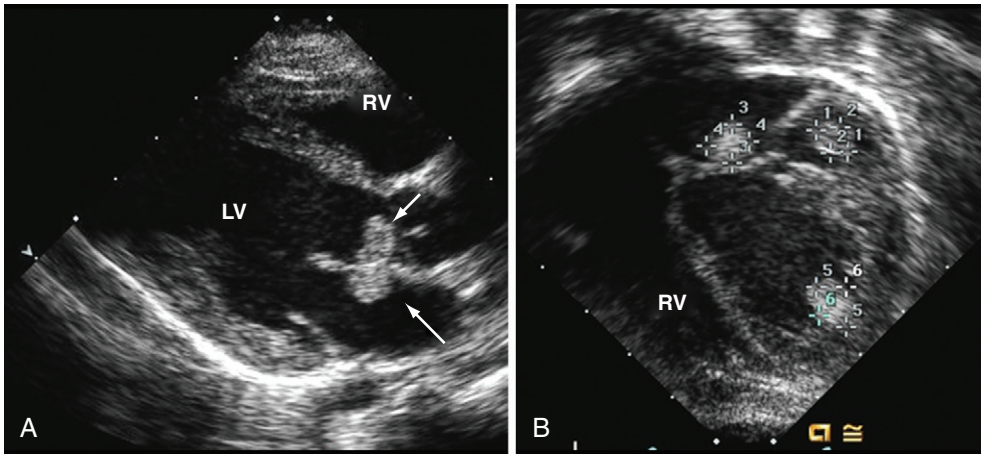

**Figure 46-14 A transthoracic echocardiogram, parasternal long-axis view (A) and oblique short-axis view (B), shows multiple intracardiac tumors attached to the endocardial surface within the LV, LA (*long arrow*), and left ventricular outflow tract (LVOT, *short arrow*).** The tumor in the LVOT resulted in mild outflow tract obstruction. An additional tumor was present in the RV (*not shown*). The patient was a 10-month-old child with tuberous sclerosis, seizures, and Wolf-Parkinson-White syndrome. These lesions in this clinical setting are typical for rhabdomyomas, and their size can be expected to regress with time.

typically seen in children.[100] These tumors are associated with a higher incidence of ventricular preexcitation and Wolff-Parkinson-White syndrome and may increase the risk of arrhythmia.[100] Because spontaneous tumor resolution is common, management is expectant in asymptomatic patients. Occasionally, surgical resection is necessary if the tumors are large and result in structural or hemodynamic complications.[103-107]

### CARDIAC FIBROMA

Cardiac fibroma is a congenital neoplasm that typically affects children, a third of whom are younger than 1 year at presentation. Like rhabdomyomas, they may also be detected in utero. It is the most common resected cardiac neoplasm in children and the second most common benign primary cardiac tumor found at autopsy in children.[53,108] Fibromas have been rarely reported in adults.[109] Males and females are equally affected, with a mean age at presentation of 13 years. There is an increased prevalence of cardiac fibromas in Gorlin syndrome, an autosomal dominant condition associated with multiple basal cell carcinomas, jaw cysts, skeletal anomalies, and tendency for development of neoplasms in several organ systems.[110-112] Patients with fibromas usually present with arrhythmias, heart failure, cyanosis, syncope, chest pain, or sudden death. One third may be asymptomatic.[53,108]

Cardiac fibromas are usually located in the ventricles and most often involve the LV free wall, the intraventricular septum, the RV, and rarely, the atria.[113,114] The tumors are characteristically solitary (unlike rhabdomyoma), circumscribed, and often centrally calcified without cystic change, necrosis, or hemorrhage (although this may be present in large tumors).[39,53,115-117] The typical echocardiographic appearance is of a discreet, often obstructive, echogenic, noncontractile mass that ranges in size from 1 to 10 cm in diameter (mean, 5 cm) in a ventricular wall.[53] The tumor may be nodular and discreet and may even mimic hypertrophic cardiomyopathy or ventricular septal hypertrophy (Fig. 46-16).[113,117-119]

With CT scan, fibromas appear as homogenous masses with soft tissue attenuation that may be either infiltrative or sharply marginated. Calcification is often seen. On MRI, they are homogeneous and hypointense on T2-weighted images and isointense relative to muscle on T1-weighted images. They show little or no contrast material enhancement.[9,116] MRI also shows the extent of myocardial infiltration, which can guide tumor resection.[120]

Surgery appears to be the optimal treatment in patients with symptomatic resectable tumors. The role of surgery in the patient with asymptomatic tumors is less clear because cardiac fibromas can remain dormant for many years and even regress.[116] However, because of fatal arrhythmias, surgery is often recommended, despite absence of symptoms. Transplantation is considered for large and unresectable tumors.

### CARDIAC PARAGANGLIOMA

Cardiac paraganglioma is an exceeding rare tumor, with only 30 cases reported before 1992 and 20 cases in the subsequent 10 years. Patients may present with symptoms of catecholamine excess or compression of adjacent structures. Echocardiography, particularly TEE, identifies ovoid, well-demarcated tumors characteristically within the atrioventricular groove adjacent to the epicardial arteries near the tricuspid and mitral annuli (Fig. 46-17).[121] MRI, CT scan, and nuclear medicine techniques for localizing extraadrenal paragangliomas are also useful in detecting and characterizing these tumors.

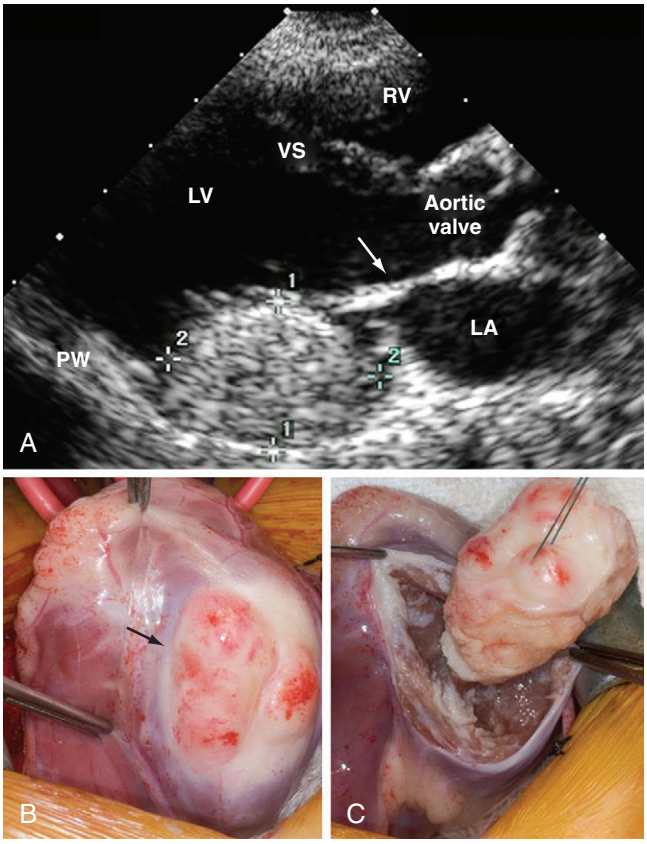

**Figure 46-16 Fibroma.** This 3-year-old girl presented with a cardiac mass diagnosed at 18 months of age when an incidental heart murmur was appreciated. She was entirely asymptomatic. **A,** A transthoracic echocardiogram, parasternal long-axis view. A large solitary homogeneous echodense mass measuring 3.5 cm × 4 cm is seen within the posterior wall, just beneath the mitral valve (*white arrow*), extending from the base to the apex of the LV. The mass did not involve the atrioventricular groove or papillary muscles. Surgery was recommended because of the risk of ventricular arrhythmias and sudden death. **B** and **C,** At surgery a white mass was visualized in the posteroinferior aspect of the free wall of the LV (*black arrow*). The tumor was completely shelled out without difficulty with sharp dissection and without having to enter the LV cavity. *(With permission from Bruce CJ: Cardiac tumours: diagnosis and management.* Heart *97:151-160, 2011.)*

## Malignant Primary Cardiac Tumors

Malignant primary tumors are rare. Metastatic disease or secondary cardiac malignant disease, on the other hand, is 30 times more common. Only approximately 15% of primary cardiac tumors are malignant. The vast majority (95%) of these primary malignant tumors are sarcomas, and the remaining 5% is made up of primary cardiac lymphomas and mesotheliomas.[122]

### SARCOMA

Sarcomas are most frequently diagnosed between the third and fifth decades of life and are found equally in men and women. Although they can arise at any part of the heart, they more commonly affect the left side of the heart, most commonly the LA.[123] The clinical course is dismal, rapidly progressive with death from widespread local infiltration, intracavitary

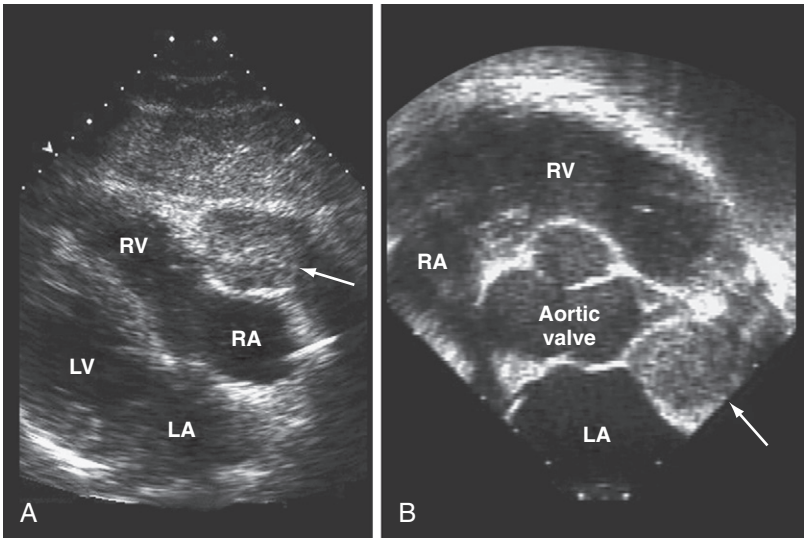

**Figure 46-17 Cardiac paragangliomas. A,** Transthoracic echocardiogram, subcostal view, shows an echogenic, ovoid well-demarcated intrapericardial 6 × 5 cm mass in the right atrioventricular groove producing mass effect but without invading the right atrial wall (*arrow*). There is no associated pericardial effusion. **B,** Transthoracic echocardiogram in a different patient, parasternal short-axis view, shows a mass (*arrow*) adjacent to the aortic valve, immediately beneath the aortic arch and adherent to the left pulmonary artery. Masses in these locations (**A** and **B**) are characteristic of this rare tumor.

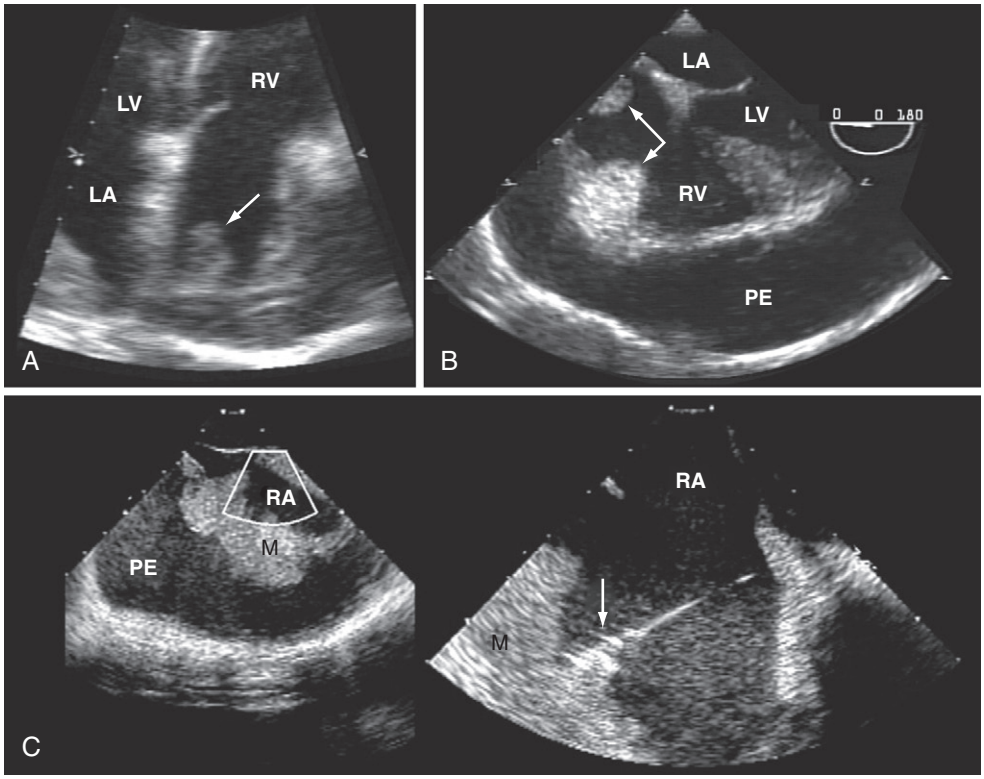

**Figure 46-18 A 33-year-old woman presented with pleuritic chest pain. A,** Transthoracic echocardiogram, apical four-chamber zoomed view, shows an irregular mass in the right atrium (*arrow*) with an associated posterior pericardial effusion predominantly located around the RV. **B,** A TEE image shows the same right atrial mass (*arrows*). Associated abnormal thickening of the right atrial wall and atrioventricular groove is appreciated. **C,** Intracardiac ultrasound imaging guides percutaneous pericardial effusion drainage and biopsy of the tumor. The intracardiac ultrasound probe tip is located within the body of the right atrium. The bioptome (*arrow*) is seen facilitating biopsy of tumor tissue and avoiding the uninvolved thin right atrial wall. Pathology confirmed angiosarcoma. *M,* Mass; *PE,* pericardial effusion.

obstruction, or metastases, often already present at the time of initial presentation. Although sarcomas can be differentiated histologically, their echocardiographic characteristics are not significantly unique to permit a reliable noninvasive histologic distinction (Figs. 46-18 and 46-19). Furthermore, to date, there is no conclusive evidence that histologic classification of sarcomas has any bearing on outcome or treatment.[124,125]

Angiosarcomas are the most common histologic subtype, with a male to female ratio of about two to one. Unlike other sarcomas, they usually arise in the right atrium or pericardium. The presenting signs and symptoms are nonspecific and may include right-sided heart failure, symptoms of pericardial involvement, or vena caval obstruction.[19,126,127] Echocardiography usually shows a broad-based right atrial mass near the inferior vena cava. Epicardial, endocardial, and intracavitary extension is common. On CT scan and MRI, they have avid, arterial phase enhancement that permits a definitive diagnosis. At surgery, local spread of the tumor to

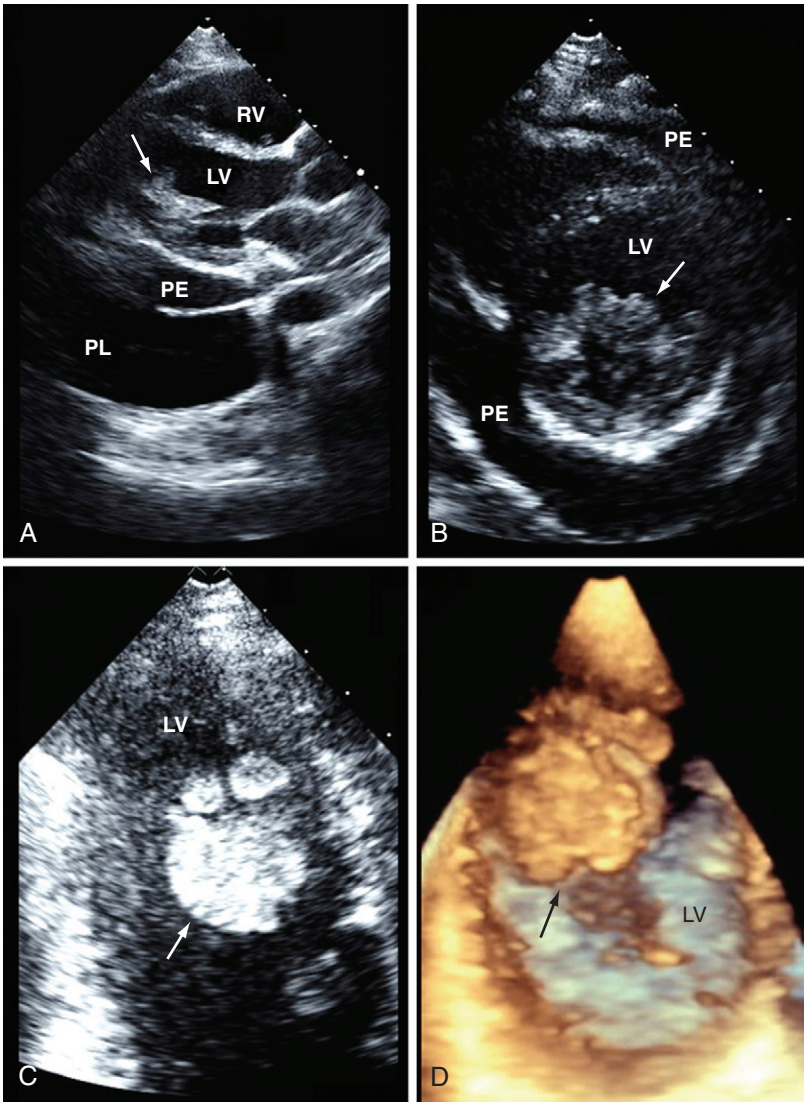

**Figure 46-19 Sarcoma.** This 48-year-old man presented with progressive dyspnea and syncope. A transthoracic echocardiogram was performed, and the parasternal long-axis view (**A**) and short-axis view (**B**) are shown. A large, 4 cm × 2 cm × 2 cm complex multilobulated intracavitary LV mass is readily appreciated on the short-axis view (*arrow*) and is less well appreciated on the accompanying long-axis view (*arrow*). Large pleural and pericardial effusions are also seen. Pericardial tamponade developed that necessitated emergency pericardiocentesis. A total of 800 mL of frankly bloody fluid was aspirated. The presence of hemorrhagic pleural and pericardial effusions with this echocardiographic appearance is suspicious for malignant disease. **C** and **D,** Zoomed 2D view of the complex mobile intraventricular mass arising from the apex of the LV with corresponding 3D image. Whole body CT scan documented widespread metastases. The cardiac tumor was considered unresectable. *PE,* Pericardial effusion; *PL,* plural effusion. *(With permission from Bruce CJ: Cardiac tumours: diagnosis and management.* Heart *97:151-160, 2011.)*

the pleural mediastinum is often found. Pulmonary metastases are frequent, and survival after diagnosis rarely exceeds 6 months.

Rhabdomyosarcomas account for 20% of sarcomas.[128] Multiple sites of myocardial involvement are common without predilection to any particular cardiac location.[31] Fibrosarcomas, histiosarcomas, and osteosarcomas constitute the remaining histologic subtypes of sarcomas. Osteosarcomas characteristically develop near the junction of the pulmonary veins and can extend into these vessels, a feature readily appreciated with TEE.[4]

## PRIMARY CARDIAC LYMPHOMA

The diagnosis of primary cardiac lymphoma requires the following:

1. Absence of lymphoma outside the pericardial sac (after a complete autopsy examination); and
2. The bulk of the tumor residing within the pericardium or cardiac symptoms that arise from lymphomatous cardiac infiltration at the time of initial diagnosis.

Although the incidence is exceedingly rare (1% of primary cardiac tumors in the Armed Forces Institute of Pathology Series report),[129] the incidence of cardiac lymphoma is increasing because of lymphoproliferative disorders related to viral infections (Epstein-Barr virus and HIV) and immunocompromise in transplant cases.[130-136] Cardiac lymphomas usually present during the fourth decade, with a slight predominance in men. All areas of the heart can be involved, including the pericardium. The lymphoma may become intracavitary and produce obstruction. The lesions appear as nodules and rarely as polypoid growths on the endocardial surface. Although echocardiography is a sensitive imaging technique, a definitive tissue diagnosis is still required.[137]

## MESOTHELIOMAS

Pericardial mesotheliomas are malignant tumors of the pericardium, which present clinically either as pericarditis, a pericardial effusion, or both. Some may present with features of constrictive pericarditis and signs of right heart failure (Fig. 46-20).[15] These tumors are more common in adults. Unlike pleural mesotheliomas, there is no association with asbestosis. Although solitary pericardial mesotheliomas occur, more frequently, they cover most of the parietal and visceral surface of the pericardium, encasing the heart. In contrast to sarcomas,

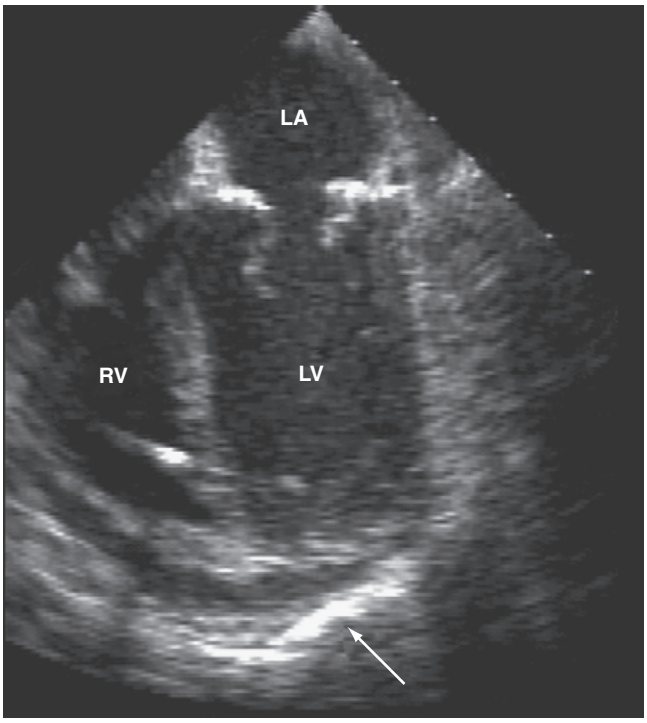

**Figure 46-20 Pericardial mesothelioma.** A TEE, four-chamber view, in a 47-year-old man with Hodgkin disease treated with radiation and chemotherapy presenting with a clinical diagnosis of constrictive pericarditis is shown. The pericardium is thickened (*arrow*), and there is a small associated pericardial effusion. The visceral pericardium also appears thick. At surgery, the pericardium was thick and friable. Histology confirmed pericardial mesothelioma.

invasion into the myocardium is only superficial. CT scan and MRI define tumor extent and degree of myocardial invasion.

## Secondary or Metastatic Malignant Tumors of the Heart

Whereas primary tumors of the heart are rare, secondary tumors are common. Among unselected autopsies, the incidence rate is about 4% and may be as high as 20% in patients dying of malignant disease.[138,139] Malignant tumors spread to the heart by direct extension, usually from mediastinal tumors, hematogenous spread, lymphatic spread, or intraluminal extension from the inferior vena cava.[140] Metastatic involvement can be either localized or diffuse. The nodules may be found in discreet locations or encase the epicardial surface. Pericardial effusion or cardiac tamponade may often be the initial presentation of secondary cardiac involvement. The noninvasive imaging appearance of metastatic deposits seldom distinguishes the tumor type. Rather, a careful evaluation for the primary tumor or a detailed history of malignancy disease provides the strongest clue.[126]

### DIRECT EXTENSION

Most secondary tumors of the heart arise contiguously from tumors in the chest cavity, most commonly breast, lung, or esophageal carcinoma. The initial clinical manifestation of these tumors is usually from pericardial involvement, and consequently, the most common echocardiographic finding in these patients is a pericardial effusion with or without cardiac tamponade.[15]

### HEMATOGENOUS SPREAD

Metastatic spread to the heart is usually hematogenous, with right-sided and left-sided metastases equally reported.[15] Ninety percent of metastases are clinically silent.[31]

Malignant melanoma, although a less common tumor than lung or breast carcinoma, is well recognized as having the highest rate of cardiac metastasis of any tumor,[141] with as many as 50% of all autopsy cases having cardiac involvement.[141] Moreover, more cases of cardiac involvement are being diagnosed as a result of rising melanoma incidence and increasing survival. Melanoma can involve any cardiac chamber and any cardiac structure, but most metastases are located in the myocardium, and valvular involvement is rare (Fig. 46-21). Glancy and Roberts[142] found cardiac involvement in 45 of 70 cases of metastatic melanoma. Most had multiple small metastases throughout the heart, with the right atrium most commonly involved. Intracavitary metastases from malignant melanoma make up most published cases and are usually discovered incidentally.[141] In patients with a history of melanoma who have cardiac symptoms, cardiac involvement can be ascertained with either transthoracic echocardiography or TEE, although TEE is better suited in identification of smaller lesions and definition of mobility and attachment.[16,143,144] MRI also shows site of mural attachment but defines extension of tumor into adjacent mediastinal structures better than TEE.[141] It also produces a characteristic hyperintense signal on T1-weighted images because of paramagnetic scavenging by melanin.[141]

Malignant carcinoid heart disease usually manifesting with characteristic valvular abnormalities may rarely present with metastatic cardiac disease typified by intramyocardial masses. These usually occur in the setting of known carcinoid syndrome (Fig. 46-22).[145]

### LYMPHATIC SPREAD

Most patients with cardiac metastases from lymphomas or leukemias have concomitant involvement of the mediastinal lymph nodes. Stagnated lymph flow allows for retrograde extension of the tumor. Lymphomas form discreet endomyocardial masses, which are usually clinical silent.

### INTRALUMINAL VENOUS EXTENSION

Tumors may propagate within blood vessels returning to the heart, most commonly originating from abdominal tumors via the inferior vena cava to the right heart. Renal cell carcinoma, adrenal carcinoma, hepatocellular carcinoma, and uterine leiomyosarcoma are the most common tumors that reach the heart in this manner.[15] Of these, renal cell carcinoma is the most common. These tumors usually appear as large elongated masses inside and emanating from the inferior vena cava and entering the right atrium, sometimes extending into the RV (Fig. 46-23).[4,146] These intraluminal tumors may be distinguished from simple thrombi because they have a rather more "mass-like" appearance, unlike thrombi, which usually appear as thin, elongated venous casts.[147]

Diagnostically, TEE is useful because it provides excellent visualization of venous inflow to the heart. It can also guide complete en bloc resection of the abdominal and intraluminal tumor and enable real-time monitoring of tumor embolization (see Figure 46-23).[4,148-150] On occasion, these tumors may also cross a patent foramen ovale, appearing as a thrombus in transit.

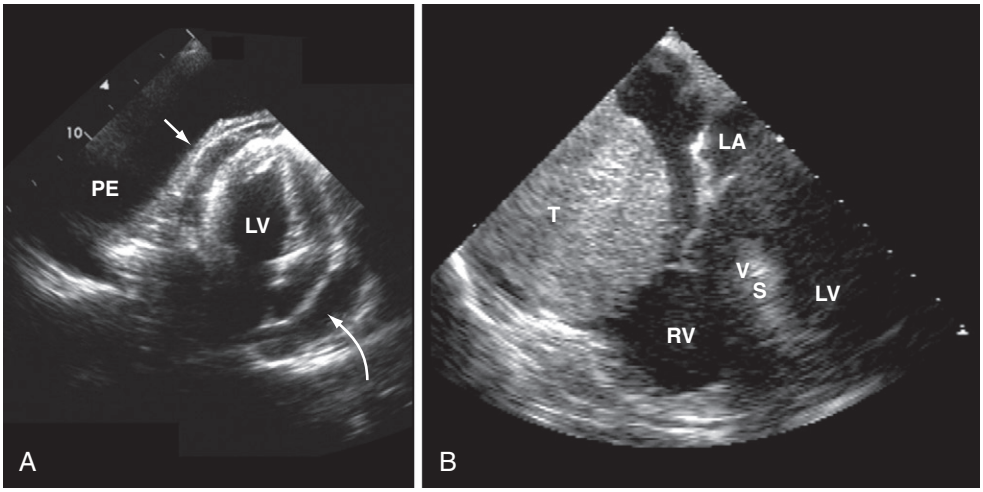

**Figure 46-21 Metastatic melanoma to the pericardium. A,** In the TTE four-chamber apical view, the pericardium around the LV is thickened with an irregular surface and texture (*arrow*). There is a moderate to large pericardial effusion around the RV and right atrium (*curved arrow*) and large pleural effusion (*PE*). **B,** A TEE in a 72-year-old man with a history of melanoma presenting with fatigue shows a 4 × 6 cm polypoid tumor (*T*) arising from the right atrium and prolapsing into the RV. Importantly, the tumor does not arise from the atrial septum, a factor potentially distinguishing it from a myxoma. It did not arise from the inferior vena cava (*not shown*). At surgery, the tumor was black in color, and pathology confirmed metastatic melanoma. *VS,* Ventricular septum.

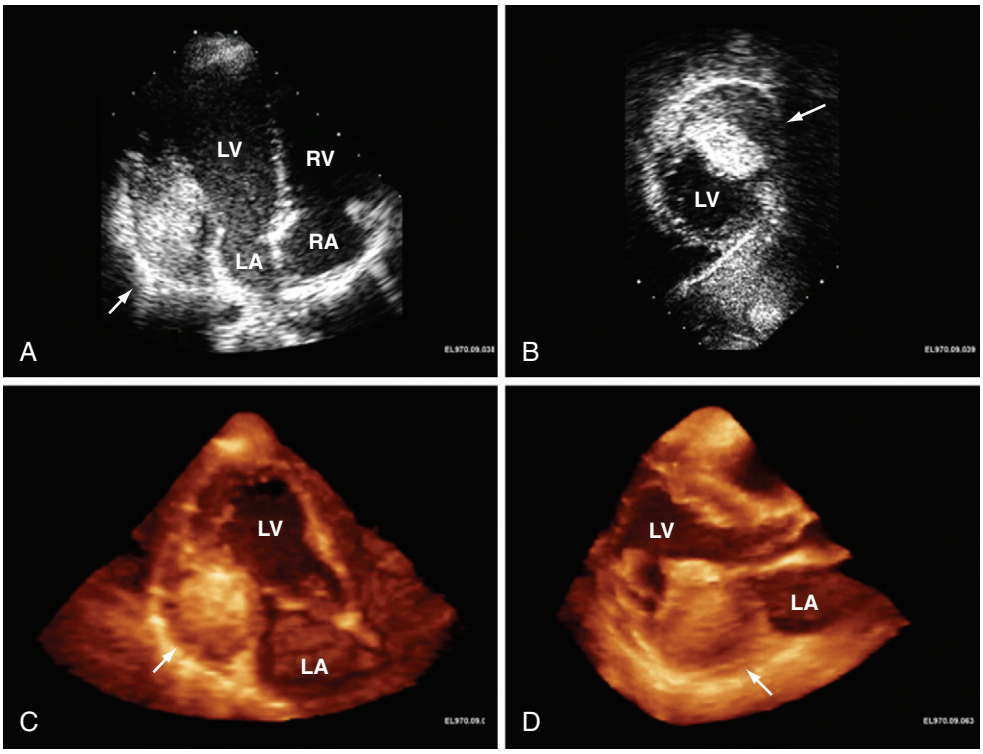

**Figure 46-22 Metastatic carcinoid tumor with atypical cardiac involvement. A,** Apical four-chamber view shows the relationship of the tumor to the atrioventricular groove, distorting the mitral annulus and mitral leaflet (*arrow*). **B,** Parasternal short-axis image at the basal LV level shows the large metastatic tumor located in the lateral wall (*arrow*). **C** and **D,** 3D images show the relationship of the tumor to the mitral valve apparatus.

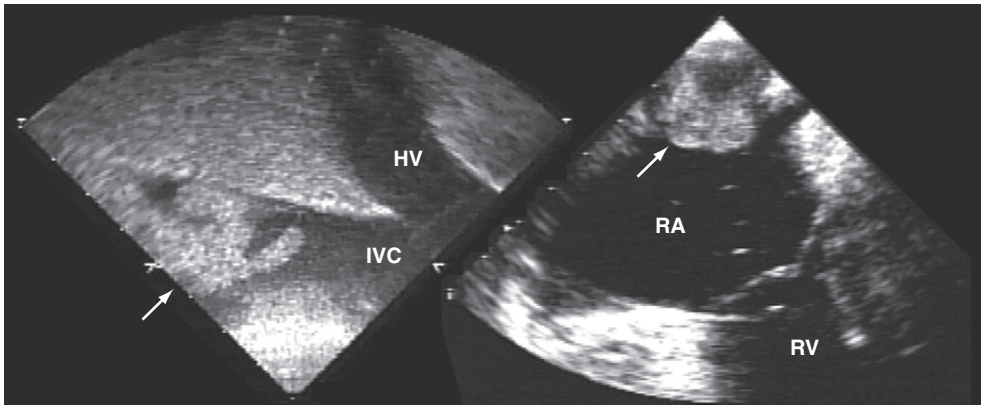

**Figure 46-23 Examples of classic venous extension of tumor thrombus from the kidney into the inferior vena cava characteristic for hypernephroma (renal cell carcinoma).** A complex tumor thrombus is seen within the lumen of the inferior vena cava (*arrow, left image*). The most distal extent of the tumor is 2 cm proximal to the origin of the hepatic vein. No intracardiac tumor was present in this patient. The *right image* shows tumor extension from the inferior vena cava into the right atrium (*arrow*). Both these tumors were successfully removed via a cavotomy with intraoperative TEE guidance. Transesophageal imaging confirmed complete removal of the tumor thrombus without embolization. *HV,* Hepatic vein; *IVC,* inferior vena cava.

In cases of intraluminal leiomyosarcoma, multiple points of attachment in the inferior vena cava may help distinguish these tumors from renal cell carcinoma or hepatoma. Thyroid carcinoma has been described growing along the superior vena cava into the right atrium,[151] and carcinoma of the lung may also extend into the LA intraluminally directly from the pulmonary veins.[15,147,152]

## Differential Diagnosis

When confronted with a suspected "mass," as always, it is important to integrate all the clinical information (e.g., age and history of malignancy disease) with all the echocardiographic information. The most likely etiology of an intracardiac mass is a thrombus, followed by vegetation. Primary cardiac tumors are rare, with metastatic involvement of the heart more frequent and usually occurring in the setting of previously diagnosed malignancy disease. Often, a cardiac mass is diagnosed when in fact the "mass" really represents an unusual tomographic plane of a normal cardiac structure or normal variant of cardiac anatomy. It is important to distinguish these findings from cardiac tumors. Box 46-2 includes the most common normal or variants of normal cardiac anatomy that are often confused with abnormal masses or tumors. Apart from the clinical history, associated echocardiographic findings also provide important clues as to the etiology of the "mass." For example, thrombi and vegetations have characteristic echocardiographic features, but in addition, they can often be distinguished from one another and from other cardiac masses by their particular intracardiac location (e.g., LA appendage or ventricular apex versus valve leaflets) and the "company they keep" (e.g., atrial fibrillation, LA enlargement, mitral valve disease, valvular destruction, and bacteremia). Thrombi seldom occur as an isolated finding. Ventricular thrombi usually occur in the setting of coronary artery disease with associated akinetic or dyskinetic myocardial segments, most commonly an aneurysmal LV apex with concomitant LV dysfunction. Atrial thrombi usually occur within the LA appendage in patients with atrial fibrillation, mitral valve disease, and LA enlargement. Ancillary features of sluggish blood flow, such as spontaneous echo contrast and reduced LA appendage emptying velocities, may be present. Another useful clinical strategy for determination of whether a mass is a thrombus or a tumor is to perform a serial echocardiographic evaluation after a period of systemic anticoagulation therapy. Thrombi usually resolve after 4 weeks of anticoagulation therapy, whereas tumors either increase in size or remain unchanged despite anticoagulation therapy (Fig. 46-24).

Vegetations may be confused with cardiac tumors (Fig. 46-25). However, apart from papillary fibroelastomas, primary tumors of the cardiac valves are exceedingly rare. Vegetations appear as mobile echogenic masses attached to valves and are usually diagnosed in the setting of known or suspected valve disease and bacteremia. Occasionally, when vegetations are seen in the absence of a bacteremia, other clinical features such as rheumatologic disease or underlying malignant disease may signify Libman-Sacks endocarditis. Valvular vegetations in the setting of infective endocarditis are also usually accompanied by features of valvular destruction and consequent regurgitation. Nonvalvular vegetations occur at sites of turbulence and may be attached to the ventricular endocardial surface in patients with hypertrophic obstructive cardiomyopathy and in patients with septal defects.

**Box 46-2**

### ECHOCARDIOGRAPHIC FINDINGS THAT MAY BE CONFUSED WITH CARDIAC TUMORS

**Normal or Normal-Variant Cardiac Structures**
- Right atrium
- Crista terminalis
- Eustachian valve
- Chiari network
- Left atrium
- Floor of left upper pulmonary vein adjacent to the LA appendage ("Q-tip")
- Right ventricle
- Moderator band
- Left ventricle
- Papillary muscles

**Nontumor Cardiac Pathology**
- Intracardiac
  - Thrombi
  - Valves
  - Vegetations (infective and marantic)
  - Lambl excrescence
  - Flail or prolapsing leaflet
  - Severed mitral valve apparatus after mitral valve replacement
  - Fatty tricuspid valve annulus
  - Mitral annular calcification
- Myocardium
  - Asymmetric ventricular hypertrophy
  - Noncompaction of the left ventricle
  - Hypereosinophilic syndrome
- Atrial septum
  - Lipomatous hypertrophy
  - Atrial septum aneurysm
- Extracardiac
  - Compression of LA by aorta
  - Coronary aneurysm or fistula
  - Potential space of the transverse sinus
  - Left lower lobe atelectasis
  - Hematoma
  - Hiatal hernia
  - Pericardial fat infiltration
  - Mediastinal tumor

**Intracardiac Hardware**
- Pacing leads
- Pulmonary artery catheter
- Central line catheter

Infiltrative disorders that involve the heart may mimic cardiac tumors. These include cardiac involvement by sarcoidosis,[153] Wegener granulomatosis,[154] hypereosinophilic syndrome,[155] and tuberculosis. Also, specific pathologic cardiac disorders reported to have been confused with cardiac tumors[156] include cardiac varices,[157] coronary artery fistula,[158] coronary artery aneurysm,[158,159] atrial septal aneurysm,[160,161] intramyocardial hematoma[162] after percutaneous intervention, blood cysts,[163] and pericardial cysts.[164]

Normal cardiac structures potentially confused with tumors include the crista terminalis (Fig. 46-26), Eustachian valve, Chiari network, lipomatous hypertrophy of the atrial septum, and the ridge of tissue seen between the left superior pulmonary

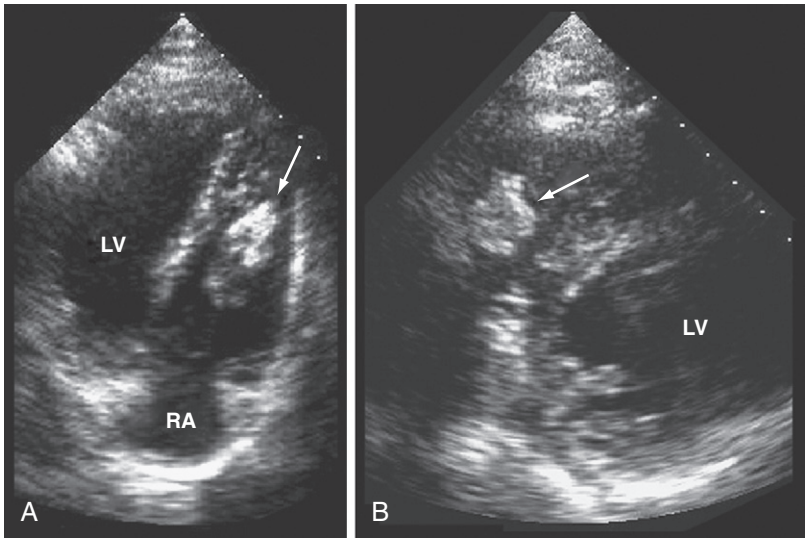

**Figure 46-24 Intracardiac thrombus.** A transthoracic echocardiogram (**A,** apical four-chamber view; **B,** parasternal short-axis view) in a 20-year-old with pulmonary embolism shows a calcified thrombus in the RV apex (*arrow*). The etiology of the mass was indeterminate and did not resolve after a month of systemic anticoagulation therapy. Surgical excision was advised. Histology showed a calcified amorphous tumor or thrombus with a mixed inflammatory infiltrate and associated calcification.

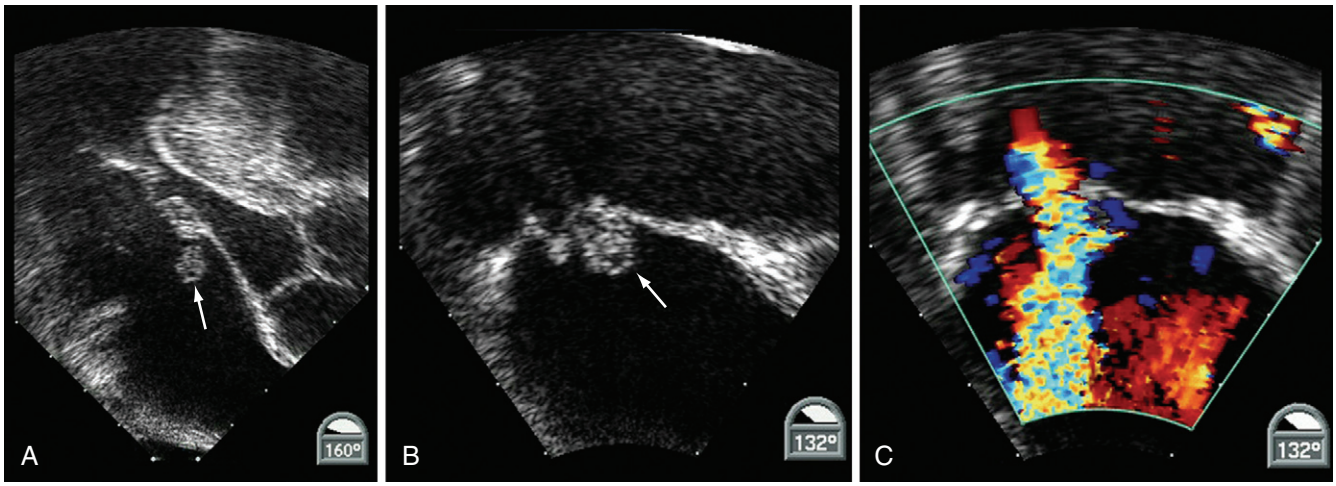

**Figure 46-25 Vegetations may be confused with papillary fibroelastomas.** These TEE images show distinguishing characteristics of endocarditis. A mobile 6 × 7 mm globular vegetation (*arrow*) is attached to the atrial aspect of the anterior mitral valve leaflet tip, seen in diastole (**A**) and systole (**B**). Color flow imaging of the mitral valve (**C**) shows severe mitral regurgitation from destruction of the mitral valve as the result of a perforation of the anterior leaflet. This characteristic mass lesion, associated with valvular destruction and positive blood cultures, is consistent with a diagnosis of a vegetation and thus infective endocarditis.

vein and LA appendage on TEE commonly referred to as the "Q-tip." Even a diaphragmatic hernia may be confused with a cardiac tumor. This can be readily identified by having the patient drink a carbonated beverage while being imaged and confirming the presence of gas bubbles in the stomach. Knowledge of these normal cardiac structures and normal variants of cardiac anatomy is important to avoid unnecessary additional evaluation, biopsy, or operation (see Box 46-2).

## Newer Echocardiographic Techniques

Although transthoracic echocardiography is an excellent screening tool, because of the limited image frequency of the transducer, detection of small tumors is insensitive. Transthoracic imaging has improved with the advent of tissue harmonic imaging, particularly in obese patients or those with chronic lung disease, and this has probably contributed to the increasing diagnosis of cardiac tumors ante mortem. Nevertheless, TEE is more sensitive than transthoracic echocardiography in diagnosis of small tumors, particularly papillary fibroelastomas. The reported diagnostic sensitivity for detection of mass lesions with transthoracic echocardiography and TEE is 93% and 97%, respectively.[165] TEE is also more sensitive in detection of abnormalities that involve the posterior cardiac structures, particularly the atria, interatrial septum, and pulmonary veins. Intracardiac ultrasound scan, with a variable frequency (5 to 10 MHz) phased array transducer affixed to the end of a deflectable catheter, provides very high-resolution images of intracardiac structures. These imaging catheters have been used to guide intracardiac tumor biopsy (see Fig. 46-18). However,

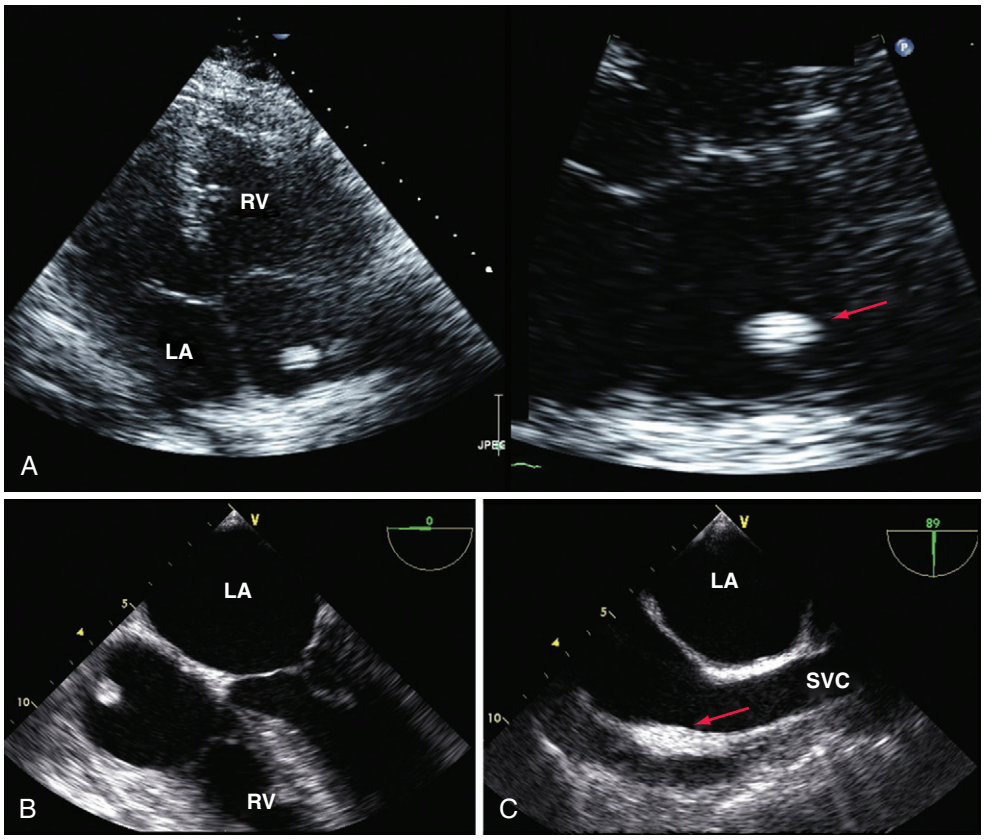

**Figure 46-26 Prominent crista terminalis. A,** An apical four-chamber view shows an echogenic circular "mass" in the right atrium. Zoomed view depicts the "mass" (*red arrow*). **B,** TEE, 0-degree mid-esophageal view, shows the same structure. **C,** Rotating the transducer to 90 degrees provides an orthogonal view of the circular structure demonstrating its longitudinal extent (*red arrow*), typical for a prominent crista terminalis.
*SVC,* Superior vena cava.

because this is an invasive tool, more widespread application for cardiac tumor diagnosis is limited.[166,167]

From both a diagnostic and therapeutic standpoint, echocardiography not only has an important and established role in invasive procedures related to diagnostic biopsy of cardiac masses but also has a role in the therapeutic and diagnostic drainage of suspected malignant pericardial effusions. Open thoracotomy, cardiopulmonary bypass and resection, or open biopsy remains the diagnostic standard.[167-172] However, in patients with right-sided lesions (most commonly malignant) who may be too ill, have unresectable disease, or only need a diagnostic tissue biopsy before chemotherapy, TEE or intracardiac echocardiography can be especially useful to guide percutaneous biopsy. Real-time visualization of the procedure enhances safety, minimizing risk of inadvertent damage to delicate surrounding structures and increasing diagnostic yield by directing the bioptome to the tumor tissue directly, as compared with use of fluoroscopy alone. For pericardial effusions, concomitant transthoracic echocardiography complements percutaneous pericardiocentesis. This approach has been well described and not only enhances safety of the procedure but also permits immediate hemodynamic assessment after pericardiocentesis and serial assessment after ongoing pericardial drainage.

Intraoperative TEE is also an important tool in guiding surgical intervention. In a report from the Mayo Clinic on patients undergoing cardiac surgery primarily for resection of mass lesions, intraoperative TEE added diagnostic information that resulted in modification of the surgical procedure, both before and after cardiopulmonary bypass in 16% of cases. In fact, this study and others have documented the importance of confirming that the mass is indeed present immediately before the skin incision to avoid unnecessary surgery for tumors that may have embolized in the period between initial detection and surgery.[173,174]

In recent years, 3D transthoracic echocardiography and TEE have evolved into a new clinical diagnostic tool in cardiac imaging.[175-178] With use of this technique, anatomy and pathology can be appreciated without having to perform "mental reconstruction" of the problem, permitting morphologic, volume, and spatial assessment of masses and tumors in vivo (Fig. 46-27).[179] It also permits noninvasive "sectioning" of the mass to better evaluate its morphologic and spatial characteristics, thereby reportedly helping guide preoperative decision making.[175,179] Unlike CT scan and MRI, a hemodynamic assessment can be performed at the same time.

Although 3D reconstruction can be derived from both transthoracic and transesophageal studies, transthoracic imaging yields poor quality images if poor acoustic windows are encountered. This can be overcome with TEE provided the probe is stabilized during held respiration and the study is gated to heart rate.[180] 3D TEE also permits volume quantification of intracardiac mass lesions. These volume assessments have been shown to correlate well with in vitro measured volumes of surgical specimens.[181] Currently, transthoracic 3D image resolution and quality is suboptimal for detection of small tumors. Therefore, standard 2D imaging techniques should still be used to identify cardiac tumors.

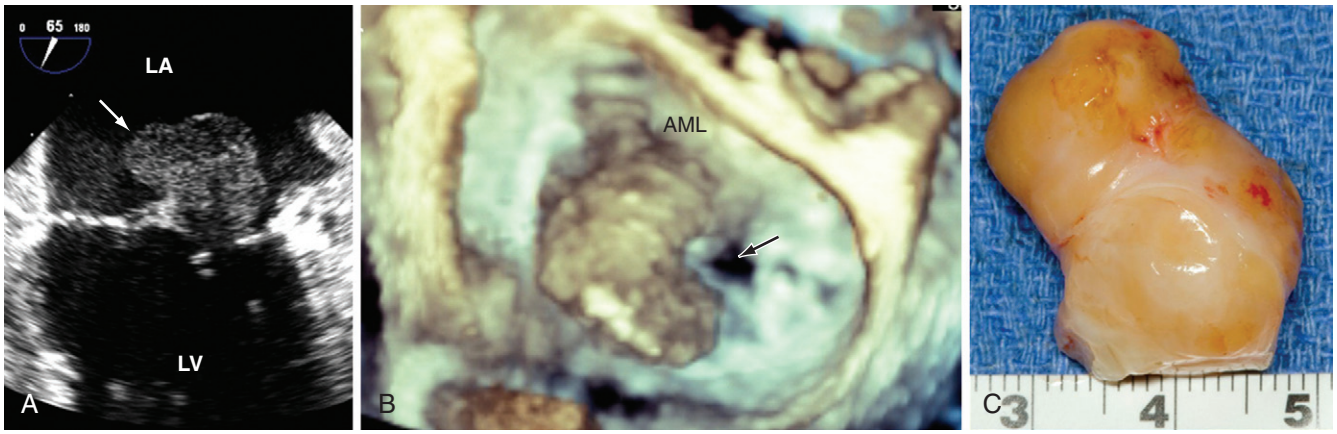

**Figure 46-27 Comparison of 2D and 3D imaging of a cardiac tumor with corresponding excised gross pathology.** This 57-year-old man with history of non-Hodgkin lymphoma presented with recently diagnosed Hodgkin lymphoma. A transthoracic echocardiogram before chemotherapy (**A**) documented an intracardiac mass; thus, a TEE was performed. Although the mass is appreciated well on 2D TEE (*arrow*), its volume and geometry, and broad base of attachment to the base of the anterior mitral leaflet (*AML*), are readily appreciated with 3D TEE. **B,** In the 3D image, the mitral valve is viewed from above (surgeon's view) and the *arrow* points to the mitral orifice. Histology of the tumor (**C**) confirmed nodular sclerosing Hodgkin lymphoma.

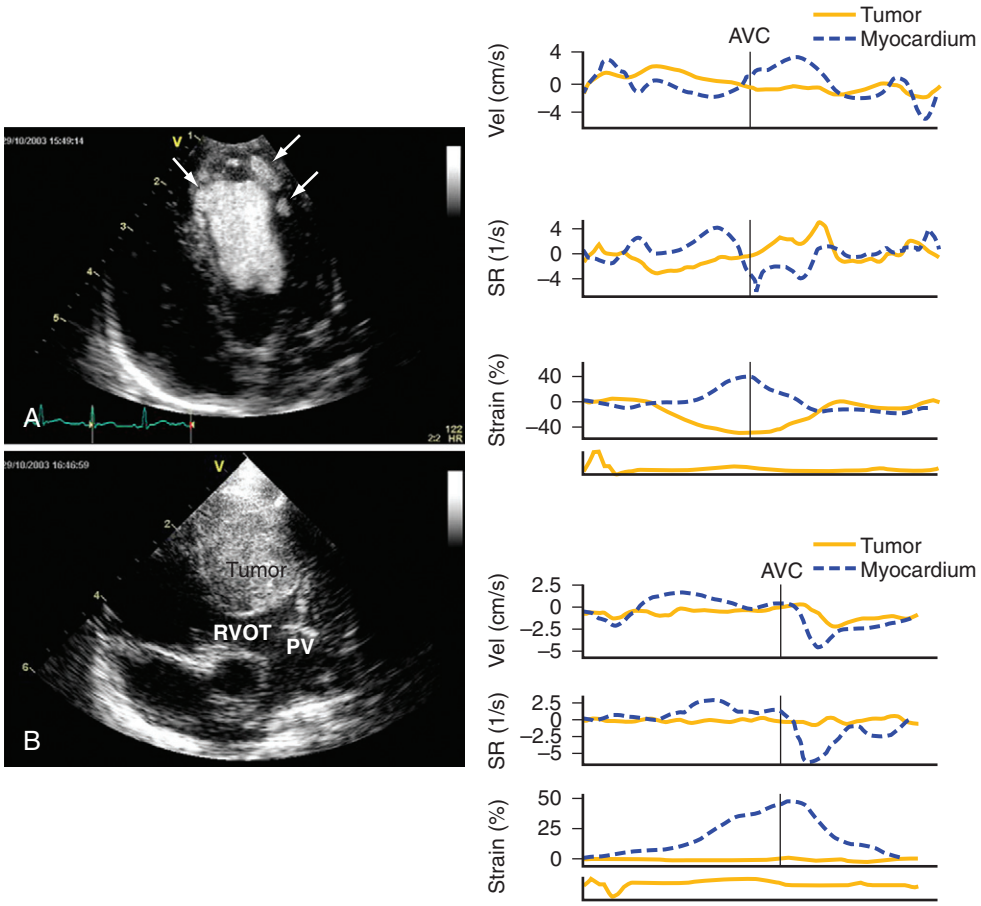

**Figure 46-28 Newer echocardiographic-based strain analysis applied to cardiac tumor diagnosis. A,** An apical four-chamber view shows three cardiac tumors in the LV (*arrows*) consistent with rhabdomyomas. Corresponding longitudinal color Doppler myocardial imaging curves are shown recorded from the tumor and adjacent interventricular septum. The *upper, mid,* and *lower curves* show myocardial velocity, strain rate, and strain, respectively. In early systole, the tumor moves and deforms in the same direction as the surrounding myocardium. Later in systole, the myocardium squeezes the soft mass in the opposite direction. **B,** Parasternal short-axis view shows a fibroma attached to the RV free wall extending toward the right ventricular outflow tract (*RVOT*). In this case, the fibroma neither moves nor deforms. These tissue Doppler characteristics may potentially be used to differentiate the rhabdomyoma from fibroma. *PV,* Pulmonic valve. *(With permission Ganame J, D'Hooge J, Mertens L: Different deformation patterns in intracardiac tumors.* Eur J Echocardiogr *6:461-464, 2005.)*

Analysis of myocardial motion with tissue Doppler imaging has also been used to characterize differences in tissue velocity of tumors versus normal myocardial tissue. Strain imaging, derived from either tissue velocity data or speckle tracking algorithms, is less susceptible to translational motion. It identifies contracting from noncontracting tissue and thus may be potentially helpful in distinguishing noncontractile tumors and thrombi from normal contracting myocardium. This concept has already been explored to identify and distinguish fibromas and rhabdomyomas.[182,183] Fibromas are composed of fibroblasts and collagen, and rhabdomyomas are composed of altered myocytes. Consequently, the fibroma has less deformability than the rhabdomyoma or the surrounding normal myocardium. Echocardiographic derived strain data can identify this deformation or lack thereof, providing additional diagnostic information to identify and distinguish these tumors (Fig. 46-28). This technique can also be used with tagged MRI, but it is labor intensive.[184]

Although the concept that unique ultrasound-tissue interaction holds potential in identification of abnormal from normal cardiac tissue, and despite being extensively explored in carefully controlled experiments, ultrasound-based tissue characterization has not proved practical or robust enough to be useful clinically.[185-187]

Echocardiographic contrast imaging may be useful in evaluation of cardiac tumors by enhancing border definition, better outlining tumor location and site of attachment, and also distinguishing vascular from avascular structures (e.g., thrombi) with assessment of myocardial perfusion.[188] Perfusion imaging has improved significantly with advances in second generation contrast agents and new imaging techniques, such as power modulation.[189-191] Both qualitative and quantitative differences in gray scale have been reported in various cardiac masses with this technique.[190] Malignant and highly vascular tumors showed greater enhancement than adjacent myocardium, whereas myxomas showed partial perfusion and quantitatively less enhancement than surrounding myocardium. Thrombi showed no perfusion. In this study, perfusion imaging also identified pericardial malignant disease, an area less well appreciated with standard noncontrast imaging. Although promising, a limitation of this method in clinical practice is that it is time consuming, requiring off-line analysis of time intensity curves. Also, the technique requires skill and experience in contrast administration and image acquisition.

Targeted microbubble delivery represents an exciting frontier. Echocardiographic contrast bubbles are being engineered to target tumors to "unmask" them, making them easier to identify and characterize and also potentially to serve as vehicles for targeted therapy delivery. A study in a tumor-bearing mouse model has evaluated the use of contrast microbubbles targeted to tumor vasculature via conjugation with the tumor-binding peptide arginine-arginine-leucine. With this technique, the investigators were able to distinguish normal tissue and tumor tissue in vivo. This pioneering work may open the possibility of ultrasonic molecular imaging of tumor angiogenesis in the clinical setting, thereby permitting improved noninvasive identification of tumors, assessment of malignant potential, and monitoring of tumor response.[192]

## ACKNOWLEDGMENTS

*The author thanks Bridgette A. Wagner for her assistance with this chapter.*

## KEY POINTS

- Cardiac tumors are rare. Incidental cardiac masses usually represent thrombi or vegetations. Three quarters of primary cardiac tumors are benign.
- Myxomas are the most common benign primary cardiac tumor and occur sporadically as an isolated tumor in the LA, usually attached to the fossa ovalis by a thin stalk. Multiple tumors or atypical locations suggest familial myxoma.
- Papillary fibroelastomas, characterized by a small mobile pedunculated "anemone"-like mass with a stippled edge, are the most common valvular tumors.
- Lipomatous hypertrophy of the atrial septum may be confused with an intracardiac tumor. It results in a dumbbell-shaped intraatrial septum with characteristic sparing of the fossa ovalis membrane. The diagnosis can be confirmed with MRI or CT scan.
- Rhabdomyomas are the most frequent cardiac neoplasm in childhood. They are almost always multiple, occurring in both the LV and the RV, and can be expected to spontaneously regress in size in most patients less than 4 years of age. They are seen in 50% of infants with tuberous sclerosis.
- Cardiac fibromas are the most common resected cardiac tumor in childhood. These characteristically solitary circumscribed tumors are usually located in the ventricles.
- Only 15% of primary cardiac tumors are malignant, the vast majority of which (95%) are sarcomas. Sarcomas do not have a characteristic echocardiographic appearance. They are most commonly found in the right atrium. Widespread local infiltration is usually present, and the clinical course is dismal.
- Secondary cardiac malignant disease or metastatic disease is 30 times more common than primary cardiac tumors. Malignant tumors spread to the heart by direct extension and hematogenous, lymphatic, and intraluminal spread. Malignant melanoma has the highest rate of cardiac metastasis of any tumor. Renal cell carcinoma is the most common tumor to spread to the heart by the inferior vena cava.
- Multiple tumors may be missed, particularly if the imager is distracted by finding the index tumor. Careful evaluation of all cardiac chambers is necessary to exclude multiple tumors.
- When confronted with a suspected "mass," it is important to integrate all the clinical information to make the most accurate noninvasive diagnosis.

## A

Abscess, paravalvular, in infective endocarditis, 410t, 412-413, 412f
Acromegalic heart disease, 742-744, 743t, 744f
Acute chest pain in emergency department, 236-246
  coronary angiography in, urgent, assessment of need for, 242
  diagnostic challenge of, 236
  echocardiography in
    in chest pain cause evaluation, 243, 243f, 244t
    in chest pain units, clinical algorithms and, 240-241, 240b
    clinical applications of, 239-243
    cost effectiveness of, 241-242
    future developments in, 244, 244f
    goals of, 236, 237b
    image acquisition in, 237, 238f-239f
    image interpretation in, 238-239, 240f
    limitations of, 243
    in long-term clinical outcome analysis, 242-243, 242f
    myocardial contrast, 239, 241f
      clinical use of, 239-240, 241f
    personnel availability limiting, 243
    in risk stratification, 242-243, 242f
    stress, 237-238
    technical aspects of, 237-239
  triage of patients with, 239, 239t
Acute coronary syndrome (ACS)
  diagnostic challenge of, 236
  echocardiographic evaluation for, limitations of, 243
Acute ischemia, physiology of, echocardiography and, 236-237
Acute ischemia/risk area detection in emergency setting, 52-53
Acute myocardial infarction
  complications of, detecting, 251-260, 251b, 251t
    acute mitral regurgitation as, 252-253, 253f
    infarct expansion as, 257-259, 258f
    left ventricular thrombus as, 259-260, 260f-261f
    pericardial effusion as, 252
    pericarditis as, 252
    pseudoaneurysm as, 256-257, 257f-258f
    true aneurysm formation as, 257-259, 258f-259f
    ventricular free wall rupture as, 255-256, 256f
    ventricular septal rupture as, 253-255, 254f-256f
  diagnosis of, echocardiography in, 248, 248t
  hemodynamic classification of, using Doppler echocardiography, 251-252
  localization of, 248-250, 249f
  right ventricular, 250-251, 250b
  risk stratification after, 260-263
    coronary flow reserve in, 262-263
    left atrial volume in, 262
    left ventricular diastolic function in, 261-262, 261t
    left ventricular remodeling in, 262
    left ventricular systolic function in, 260-261
    mitral regurgitation in, 263, 263f
    regional wall motion score in, 261
    stress echocardiography in, 262
Adenosine stress echocardiography, in coronary artery disease diagnosis, 301
Afterload
  definition of, 160-161
  right ventricular, pulmonary artery pressure and, 629-630
Aging, 774-790. *See also* Elderly.
  aortic root diameter changes in, 775, 775f
  aortic valve sclerosis in, 778-779
Aging *(Continued)*
  cardiac amyloidosis in, 786
  cardiac chamber dimensions in, 775, 776t
  cardiac function changes in, 777-778, 778t, 779f
  cardiac response to exercise stress in, 778
  cardiac response to pressor stress in, 778
  cardiac structural changes in, normal, 774-777
  cardiogenic thromboembolism in, 786, 786f
  clinical outcome data in, 778-786
  coronary artery disease in, stress testing and, 784-786, 785f, 785t-786t
  heart failure in, 782-784, 783b, 783f-784f
  left atrial size changes in, 775, 775f, 776t
    outcomes and, 782, 782t, 783f
  left ventricular changes in
    in chamber dimensions, 774
    in diastolic function, 778, 778t, 779f
    in dimensions, 775, 776t
    hypertrophy as, 781-782
    in mass, 774-775
    in systolic function, 777
    in wall thickness, 774, 775f
  mitral annular calcification in, 779-781, 780f
  valvular heart disease in, 778-781, 780f-782f, 782t
Alcohol septal ablation, for hypertrophic cardiomyopathy, 109-110, 110f
Alferi edge-to-edge mitral repair, 106, 107f-108f
Alveolar hypoventilation, pulmonary hypertension from, 637
Amyloidosis
  cardiac, in aging, 786
  diastolic function assessment in, 211, 212f
  restrictive cardiomyopathy in, 548-551, 550f
Aneurysm(s)
  atrial septal, echocardiography in, 800-801
  sinus of Valsalva, 854-855, 855f
  thoracic aortic, familial, 762
  true, formation of, complicating acute myocardial infarction, 257-259, 258f-259f
Angiography
  coronary, with intravascular ultrasound in cardiac allograft vasculopathy diagnosis, 592-593, 593f
  intravascular ultrasound versus, 133-134
Ankylosing spondylitis, 722-723, 723f-724f, 727t-728t
Annuloplasty, coronary sinus, for mitral regurgitation, 106-107
Annulus paradoxus, 213
Annulus reversus, 213
Anorexigen use in obesity, 751-752
Anthracycline, restrictive cardiomyopathy induced by, 555-556
Antiphospholipid syndrome, primary, 718-719, 719f
Aorta
  acute syndromes involving
    diagnosis of, imaging approaches to, 698-702
    spectrum of, 696-698, 696b
    transesophageal echocardiography in, 702-705, 702f
  ascending, perioperative and periinterventional imaging of, intracardiac echocardiography in, 125, 126f
  coarctation of, 855-857, 856f, 857b
  congenital disorders of, determination of, 840
  descending, measurements of, 767, 768f
  dilation of, in connective tissue disorders, 763-764, 763f-765f
  dissection of, 692-711. *See also* Aortic dissection.

    implantation of, transcatheter. *See* Transcatheter aortic valve implantation (TAVI).
    regurgitation
      evaluation of, integrative, multiparametric approach for, 481f-482f, 483
      imaging considerations in, 480, 481f-482f
      recognition and quantitation of, 480-483
      severity of, parameters of, 481f-482f, 482-483, 483t
    stentless, Doppler evaluation of, 485
    3D echocardiography of, 82, 82f
  repair or replacement of, for heart failure, 508
  sclerosis of, in aging, 778-779, 781, 781f-782f, 782t
  transcatheter implantation of, echocardiography in, 445
  transesophageal echocardiography of, 13
Aortic views, in transesophageal echocardiography, 4t, 10-11, 10f
Aortitis, in ankylosing spondylitis, 722-723, 724f
Aortopulmonary shunts, palliative, issues resulting from, 880-881, 880t, 881f
AR. *See* Aortic regurgitation (AR).
Arrhythmias, in pregnancy, 685
Arterial switch surgery, issues resulting from, 887t, 888-889
Artery(ies). *See also specific artery, e.g.* Pulmonary artery (PA).
  great. *See* Great arteries.
Arthritis, rheumatoid, 719-722, 721f-722f. *See also* Rheumatoid arthritis.
Artificial hart, 598t, 599, 600f
AS. *See* Aortic stenosis (AS).
ASD. *See* Atrial septal defect (ASD).
Asymmetric apical hypertrophic cardiomyopathy, 527, 528f-529f
Atherosclerosis
  aortic dissection risk and, 694
  carotid artery, contrast-enhanced ultrasound in detection of, 60
  in systemic lupus erythematosus, 715-717, 717f
Atherosclerotic plaque
  intravascular ultrasound assessment of, 138, 139f
  in proximal aorta, systemic embolic events and, 802-804, 803f, 803t
Athlete's heart, hypertrophic cardiomyopathy differentiated from, 520-521, 521f, 521t
Atrial fibrillation
  atrial size and, 815-816
  atrial thrombi detection in, 816-820, 816f-820f, 816t
  cardioversion of
    electrical injury to atria from, 822
    guidance of, 817-820, 817f-818f, 818b
    thromboembolism mechanism after, 820-821
  catheter-based therapy of, 3D echocardiography guiding, 84-85
  mitral annular calcification and, in aging, 780
  prevalence of, 814-815
  symptoms and clinical impact of, 815
  therapeutic interventions in, guidance of, echocardiography and, 822-823, 823f
  thromboembolism predictors and, 817
  transesophageal echocardiography in, 15-16
Atrial flutter, 822
Atrial septal defect (ASD)
  closure of
    intracardiac echocardiography guiding, 120-122, 121b, 121f
    3D echocardiography guiding, 84
  congenital, 857-861, 858f
    echocardiographic evaluation of, 858-860, 858t, 859f-860f
    management of, 860-861, 861f
  corrective procedures for, issues resulting from, 882-883, 882t, 883f
  echocardiographic guided interventions for, 99-101, 103f
  transesophageal echocardiography in, 15, 798f, 799-802, 800f
  transthoracic echocardiography in, 799-802, 800f
Atrial septum
  aneurysms of, echocardiography in, 800-801
  defect of. *See* Atrial septal defect (ASD).
  imaging of, in transesophageal echocardiography, 4t, 5f-6f, 8
Atrial situs, congenital disorders of, determination of, 836-838
Atrial switch surgery, issues resulting from, 887-888, 887t, 888f-889f
Atrial systole, 197
Atrial volume, 3D echocardiography of, 76-77
Atrioventricular septal defects (AVSDs), corrective procedures for, issues resulting from, 887t, 892-893
Atrioventricular valves
  congenital disorders of, determination of, 838-840, 839f
  morphology of, 834, 834f
Atrium(ia)
  congenital defects of, corrected, issues with, 877, 877t
  electrical injury to, from cardioversion, 822
  left. *See* Left atrial *entries; Left atrium.*
  mechanical function of, 814, 814f
    return of, after cardioversion, assessment of, 821
  morphology of, 833, 833f
  right. *See* Right atrium.
  size of, atrial fibrillation and, 815-816
Automated border detection (ABD)
  active-appearance models of, 228-230, 230f
  classification and, 230, 231f
  in digital images. *See also* Digital images.

    detection technique choice for, 223
    image quality and, 222-223
    practical considerations for, 222-223, 223b
    problems and pitfalls of, 222
  future promise of, 230-231
  geometric modeling in, 225-226
  intelligent ultrasound systems in, 231
  methods of
    feature-driven, 223-224, 224f
    object-based, 225-226
    overview of, 223-230, 224t
    population-based, 228-230, 230f
    rules for, 222
    structure-based, 224-225, 225f
  pattern matching in, 226-227, 226f-227f
  3D active surface detection in, 227-228, 228f-229f
  tissue tracking in, 224-225, 225f

## B

Bacteremia, in infective endocarditis, evaluation of, 415-417
Ball and cage valves, 460f, 462, 465t
Balloon aortic valvuloplasty, echocardiographic guidance of, 104-105
Balloon mitral valvotomy (BMV), 389-407
  complications of, 396, 396t
  contraindications to, 400, 400b
  echocardiography in
    after procedure, early, 392-396, 394f-395f
    during follow-up, 396

Balloon mitral valvotomy (BMV) *(Continued)*
guiding procedure, 105, 106f
before procedure, 391-392, 392f, 393t-394t
during procedure, 392, 393f-394f
failure of, 396
imaging during, intracardiac echocardiography in, 127
results of, 396-400
in elderly, 399, 400f
immediate, 396-397, 397f, 397t
late, 397-398, 397f-398f, 398t
in pregnant women, 400
in restenosis after previous commissurotomy, 398-399, 399f
in young patients, 399
timing of, 401-402, 402t
Balloon tricuspid valvotomy, echocardiographic guidance of, 109
Beriberi heart disease, 752, 752t
Bicuspid aortic valve, 761-762, 761f-762f, 846-849
aortic dissection risk and, 696
conditions associated with, 847, 847b
corrective procedures for, issues resulting from, 882t, 884, 885f
echocardiographic evaluation of, 847-848, 848f
management of, 848-849
Bileaflet valves, 460f, 461t-462t, 462, 463f-465f, 465t
Bioprostheses, 460f, 461t-462t, 466, 466f, 466t
Biopsy, endomyocardial, after cardiac transplantation, 590-591, 590f-591f
Biventricular repairs, issues resulting from, 887t, 893, 893f
Blalock-Taussig shunt, palliative, issues resulting from, 880t, 881, 881f
Blood flow, coronary, 318-328
in acute coronary syndrome diagnosis, 325
assessment of, alternative approaches to, 325-326, 326t
clinical applications of, 321-325
coronary artery anatomy and, 318, 319f
coronary flow velocity reserve measurement of, 321-322, 322f
in coronary stenosis diagnosis, 322-323
Doppler evaluation of, 318-319
in detection of flow, 319, 320f-321f
technical aspects of, 318
no-reflow phenomenon in, 325, 325f
in noninvasive diagnosis of coronary stenosis, 322-324, 324f
profile of, assessment of, 319-321, 322f
retrograde, in total occlusion detection, 323, 324f
to right ventricle, 615, 616f
BMV. *See* Balloon mitral valvotomy (BMV).

## C

CAD. *See* Coronary artery disease (CAD).
Calcific aortic stenosis, imaging of, 425-426, 427f
Calcification
aortic valve, assessment of, 426, 427f
cardiac, in primary hyperparathyroidism, 744
mitral annular, in aging, 779-781, 780f-782f, 782t
valvular, in aging, 776-777, 777f, 778t
Cardiac amyloidosis, in aging, 786
Cardiac assist devices, 597-612
artificial hearts as, 598t, 599, 600f
ventricular assist devices as. *See* Ventricular assist device (VAD).
Cardiac chamber dimensions in aging, 775, 776t
Cardiac embolism, 791
Cardiac output (CO)
increased
in pregnancy, 664-665, 665f-666f, 665t
pulmonary hypertension related to, 638-639
in intraoperative ventricular function monitoring, 26-28
measurement of, in pregnancy, Doppler, technical aspects of, 667t, 668-669
in monitoring separation from cardiopulmonary bypass, 32-33, 33t
Cardiac resynchronization therapy, in heart failure, 508-511, 511f
Cardiac synchrony, 190-192
disorders of. *See* Dyssynchrony.
Cardiac tamponade, transesophageal echocardiography in, 16
Cardiac transplantation, 585-596
acute rejection in, structure and function of cardiac allograft during, 589-591
changes in left ventricular mass or wall thickness in, 590
changes in systolic and diastolic function in, 589-590
endomyocardial biopsy in, 590-591, 590f-591f
cardiac allograft in
in acute rejection, 589-591
physiology of, 588
structure and function of, 587-589
vasculopathy in, posttransplant, diagnosis of, 592-594, 593f, 593t
complications of, early postoperative, 591
donor heart evaluation before, 586
evaluation before, 585-586, 586b, 586f
exercise echocardiography applications in, 281-282
for heart failure, 512-513
monitoring after, 591-594, 591b, 592f
pericardial effusion after, 591
pregnancy after, 683
right ventricular structure and function after, 589
risk assessment before, 585-586, 586b, 586f
technique of, 587, 587f
tricuspid regurgitation after, 589, 589f
ventricular function monitoring during, 37, 38f
ventricular systolic and diastolic function after, 588-589, 588f
Cardiac tumors, 902-928
background on, 902-904
benign
cardiac myxomas as, 904-908. *See also* Myxomas, cardiac.
features of, 907t
fibroma as, 907t, 915, 915f
hemangioma as, 907t, 912-914, 913f
lipoma as, 907t, 912, 912f-913f
papillary fibroelastoma as, 908-912. *See also* Papillary fibroelastoma.
paraganglioma as, 907t, 915, 916f
rhabdomyoma as, 907t, 914-915, 914f
classification of, 903-904, 904t, 905f
diagnostic approach to, 903t, 904, 906f, 906t-907t
differential diagnosis of, 920-921, 920b, 921f-922f
direct extension of, 918
hematogenous spread of, 918, 919f
intraluminal venous extension of, 918-920, 919f
lymphatic spread of, 918
malignant
metastatic (secondary), 918-920, 919f
primary, 915-918
lymphoma as, 917
mesotheliomas as, 917-918, 918f
sarcoma as, 915-917, 916f-917f
newer echocardiographic techniques for, 921-924, 923f
transesophageal echocardiography in, 15, 795-797, 796f-797f
transthoracic echocardiography in, 795-797, 796f
Cardioembolic event, transesophageal echocardiography in, 14-15
Cardioembolic stroke, 791
Cardiogenic thromboembolism, in aging, 786, 786f
Cardiology, handheld echocardiography in, 152-153, 152f
Cardiomyopathy
dilated
diastolic function assessment in, 210-211
exercise echocardiography applications in, 281
hypertrophic, 517-541. *See also* Hypertrophic cardiomyopathy (HCM).
LV function quantitation in, 156, 158f
peripartum, 682-683
in pregnancy, 682-683, 682f
restrictive, 542-564. *See also* Restrictive cardiomyopathy.
uremic, 747, 747f
Cardiopulmonary bypass, separation from, monitoring of, 32-33
cardiac output in, 32-33, 33t
intracardiac air in, 32, 33f
CARDIOsphere, in ultrasound contrast imaging, 46
Cardioversion, of atrial fibrillation
atrial mechanical function after, assessment of return of, 821
electrical injury to atria from, 822
guidance of, 817-820, 817f, 818b
thromboembolism mechanism after, 820-821
Carotid artery atherosclerosis, contrast-enhanced ultrasound in detection of, 60
Catheter-based interventions, intracardiac, 3D echocardiography guidance of, 83-85
Catheterization
laboratory of future for, 113-114
transapical, echocardiographic guidance of, 98
transseptal, echocardiographic guidance of, 98, 99f
Central venous pressure air aspiration catheter positioning, intraoperative transesophageal echocardiography in, 29, 34
CHD. *See* Congenital heart disease (CHD).
Chest pain, acute, in emergency department, 236-246. *See also* Acute chest pain in emergency department.
Chest pain syndrome, coronary flow reserve in, 325
Chest pain units, echocardiography in, 240-241, 240b
Children, balloon mitral valvotomy in, 399-400
Chloroquine, restrictive cardiomyopathy induced by, 555-556
Chronic obstructive pulmonary disease (COPD), pulmonary hypertension in, 637-638
Cineangiography, in structural heart disease interventions, 97
Circumferential stress, calculation of, 159
CO. *See* Cardiac output (CO).
Coarctation of aorta, 855-857, 856f, 857b
corrective procedures for, issues resulting from, 882t, 884-885, 886f
Cocaine use, aortic dissection risk and, 695
Color Doppler echocardiography
in congenital heart disease evaluation, 842-843, 843f
M-mode
clinical use of, 207
in diastolic function evaluation, 206-207
in filling pressures estimation, 207
flow propagation velocity and hemodynamics in, 206-207
image acquisition in, 206, 206f
prognosis and, 207
in restrictive cardiomyopathy, 547, 548f
in mitral regurgitation quantification, 336-341, 337f, 338t
in myocardial velocity imaging, 177-178, 178f-180f
Commissurotomy, mitral valve repair involving, 362
Computed tomography (CT)
in aortic dissection diagnosis, 699, 701f
in guidance of structural heart disease interventions, 111-113
Conduction abnormalities, in ankylosing spondylitis, 723
Conduit, in congenital heart disease repair, issues from, 878
Congenital aortic stenosis, imaging of, 426, 427f
Congenital heart disease (CHD)
"complex" malformations in, corrective procedures for, 887-897, 887t, 888f-896f
palliative procedures for, issues resulting from, 878-882, 880f-881f, 880t
postoperative, 876-901
evaluation and management of, knowledge required for, 876
general issues in, 877-878, 877t
in pregnant patient
in acyanotic patients
with no prior surgical procedures, 673-674, 673f-674f
with prior surgical procedures, 674-677
coarctation of aorta as, 675, 676f
cyanotic heart disease as, 677-678, 678f
Fontan repair of, 675-676

Congenital heart disease (CHD) *(Continued)*
tetralogy of Fallot as, 675, 675f
transposition of great arteries as, 676-677, 677f
simple lesions in, corrective procedures for, 882-887, 882t, 883f, 885f-886f
suspected, echocardiographic approach to, 830-845
basic principles of, 830-831
cardiac anatomy and, 835-840, 835t-836t, 836f-839f
cardiac morphology and, 833-835, 833f-835f, 833t
cardiac position and, 831-833, 831f-833f
color and spectral Doppler imaging and, 842-843, 842f-843f
univentricular heart in, 840-842, 841f-842f
3D echocardiography of, 82-83, 83f
transesophageal echocardiography in, 16
unoperated, 846-875
complex, 867-871
by complexity, 847b
congenitally corrected transposition of great arteries as, 869-870, 869f, 870b
of left ventricular outflow tract and aorta, 852-857
septal defects and shunt lesions as, 857-867
tetralogy of Fallot as, 867-869, 868f
valvular, 846-852
Connective tissue disorders, 758-773
alternate diagnostic approaches to, 770-771, 771f
aortic dilation in, 763-764, 763f-765f
aortic dissection in, 765
assessment limitations in, 769
assessment methods in, 767-769, 767f-768f
bicuspid aortic valve as, 761-762, 761f-762f
diastolic function in, 766
echocardiographic findings in, 763-766, 763f-765f
Ehlers-Danlos syndrome as, 759
familial thoracic aortic aneurysm and dissection as, 762
fibrillinopathies as, 760
forms of, 758-762, 759b
histopathology of, 763
homocystinuria as, 760
left ventricle in, 766
Loeys-Dietz syndrome as, 760-761, 760b
Marfan syndrome as, 758-759, 759b
mitral valve prolapse in, 765-766, 765f
natural history of, 766-769, 767t
pharmacologic strategies for, 769-770, 769t
pulmonary artery in, 766
surgical strategies for, 770, 770f-771f
systolic function in, 766
therapeutic strategies for, 769-770, 769t
Turner syndrome as, 762
Conservation of mass, in fluid dynamics, 450-451, 451f-452f
Constrictive pericarditis, 568-571
causes of, 568b
Doppler flow abnormalities in, 569-570
echocardiographic diagnosis of, 568-571
effusive, 579-580
M-mode abnormalities in, 568-569, 569f
pathophysiology of, 568
restrictive cardiomyopathy compared with, 557t, 571
restrictive cardiomyopathy differentiated from, 556-559, 557f-558f
strain imaging in, 570-571
tissue-Doppler imaging in, 570-571, 570f
2D abnormalities in, 568-569, 569f
Continuity equation method, for aortic valve area calculation, 429-430, 430f-431f, 431t
Gorlin formula compared with, 431-432, 432f
Continuous infusion imaging, 50
Continuous wave Doppler
in mitral regurgitation quantification, 343
in restrictive cardiomyopathy, 547, 547f
Contractile function, definition of, 157-159
Contractility
definition of, 159, 161
in intraoperative ventricular function monitoring, 29
Control volume, in fluid dynamics, 450-451, 451f-452f
in energy analysis, 452-453
Cor pulmonale, in scleroderma, 725
Coronary artery(ies)
anatomy of, 318, 319f
anomalies of, corrective procedures for, issues resulting from, 882t, 886-887
in aortic dissection, transesophageal echocardiography in visualization of, 704-705, 705f
blood flow in, 318-328. *See also* Blood flow, coronary.
fistulas of, 867, 867f
left circumflex, blood flow detection in, 319, 321f
left main
blood flow detection in, 319, 320f
disease of, assessment of, intravascular ultrasound in, 135, 135f
stenosis of, diagnosis of, noninvasive, 322-324, 324f
Coronary artery disease (CAD)
in aging, stress testing and, 784-786, 785f, 785t-786t
diagnosis of
nonexercise stress echocardiography in, accuracy of, 301-303, 302f, 302t
pharmacologic stress echocardiography versus perfusion scintigraphy in, 312, 312t
diagnostic challenge of, 236
exercise echocardiography in, applications of
in initial diagnosis, 279
in known coronary artery disease, 279-280
prognostic, 280, 280f
in women, 280-281, 281t
LV function quantitation in, 156, 157f
in mixed connective tissue disease, 723-725, 727t
in polymyositis and dermatomyositis, 726, 727t
preinterventional assessment of, in aortic stenosis, 444-445
in primary antiphospholipid syndrome, 719, 727t
in rheumatoid arthritis, 719-720, 727t
in scleroderma, 724-725, 727t
stable, nonexercise stress echocardiography in prognostic evaluation in, 304-305, 305t
transesophageal echocardiography in, 16
ultrasonic contrast detection of, 53-58, 55f, 55t
during dobutamine or exercise stress echocardiography, 54-56, 56f-57f, 57t
vasodilator stress perfusion imaging in, 53-54, 55f, 55t
Coronary blood flow, 318-328. *See also* Blood flow, coronary.
Coronary care unit, echocardiography in, 247-267
in acute myocardial infarction, 248-251
in complication detection, 251-260, 251b, 251t
diagnostic role of, 248, 248t
in localization of infarction, 248-250, 249f
right ventricular, 250-251, 250b
applicable modes of, 247-248
Coronary flow reserve, in risk stratification after acute myocardial infarction, 262-263
Coronary sinus, in transesophageal echocardiography, transgastric view of, 4t, 10, 10f
Coronary sinus annuloplasty, for mitral regurgitation, 106-107
Coronary sinus cannulation positioning, intraoperative transesophageal echocardiography in, 36, 37f
Critically ill ICU patient, transesophageal echocardiography in, 16
Cryptogenic cerebral ischemia, transesophageal echocardiography versus transthoracic echocardiography in, 792, 792t
Cryptogenic stroke, 791
patent foramen ovale and, 800-801, 800f, 801t
Cushing syndrome, heart disease in, 745, 746f
Cysts, pericardial, 581

intracardiac, 118-129. *See also* Intracardiac echocardiography (ICE).
3D, 67-94. *See also* 3D echocardiography.
Effusion, pericardial, 571-572. *See also* Pericardial effusion.
Effusive constrictive pericarditis, 579-580
Ehlers-Danlos syndrome, 759
Ejection, in left ventricular physiology, 183t, 187
Ejection fraction
hemodynamic determinants of, 167
in intraoperative ventricular function monitoring, 28-29, 29f
in left ventricular systolic function assessment, 166-167
Elderly. *See also* Aging.
balloon mitral valvotomy in, 399-401, 400f-401f
diabetic heart disease in, 736
hypertrophic cardiomyopathy of, 530
septal hypertrophy in, hypertrophic cardiomyopathy differentiated form, 521
Electronic device, cardiac implantable
evaluation of patient with, 417, 418f
infected, imaging of, 410t, 413-414, 414f
Embolic events, systemic, 791-810. *See also* Systemic embolic events.
Embolism
cardiac, 791
cardiogenic, transesophageal echocardiography in, 14-15
Emergency department
acute chest pain in, 236-246. *See also* Acute chest pain in emergency department.
handheld echocardiography in, 151, 151b
End-diastolic area, in intraoperative ventricular function monitoring, 25-26, 26f
End-systolic area, in intraoperative ventricular function monitoring, 25-26
Endocarditis
infective, 408-424. *See also* Infective endocarditis (IE).
mitral annular calcification and, in aging, 781
3D echocardiography in, 86-87, 87f
Endocrinopathies, heart disease in, 733-746
in acromegaly, 742-744, 743t, 744f
in adrenal diseases, 745-746
in Cushing syndrome, 745, 746f
in diabetes mellitus, 733-738. *See also* Diabetic heart disease.
in hyperaldosteronism, 745-746
in hyperthyroidism, 740-742, 741t
in hypothyroidism, 739-740, 740t, 741f
in metabolic syndrome, 738-739, 750f
in primary hyperparathyroidism, 744-745, 745t
Endomyocardial biopsy, after cardiac transplantation, 590-591, 590f-591f
Endomyocardial fibrosis, restrictive cardiomyopathy in, 551-553
Esophageal intubation, for transesophageal echocardiography, 3-4
Exercise
hemodynamic changes in, pregnancy changes similar to, 669
physiology of, in pregnant women, 670
Exercise echocardiography, 268-291
appropriate use of, 278-279
in cardiac transplantation, applications of, 281-282
comparison of, with other stress modalities, 277-279, 277t, 278f
coronary artery disease applications of
for initial diagnosis, 279
in known coronary artery disease, 279-280
prognostic, 280, 280f
in women, 280-281, 281t
cost effectiveness of, 278
diagnostic accuracy of, 276-277, 276f, 277t
in dilated cardiomyopathy, applications of, 281-282
Doppler, 274
equipment for, 272
exercise stressors used in, 270-272, 271b, 272t
future directions for, 283-286, 284f-285f
in hypertrophic cardiomyopathy, applications of, 281, 282f
imaging in, 273-274
interpretation of, 275-276, 275t
methodology for, 272-276
personnel for, 274-275, 275b
physiologic principles of, 268-270, 269f-271f
procedure for, 272-273, 273b, 273f
in pulmonary hypertension, 642-643
quality assurance for, 278-279
Exercise echocardiography *(Continued)*
in risk stratification prior to noncardiac surgery, 281
room layout for, 274, 274f
safety of, 278, 279b
3D, 285-286
in valvular heart disease, applications of, 282-283, 283f
Exercise-stimulating agents, in nonexercise stress echocardiography, 293-294
technical aspects of, 299-300
Exercise stress, cardiac response to, in aging, 778
Exercise stress echocardiography
as alternative to nonexercise stress echocardiography, 311, 311f
in coronary artery disease detection, 54-56, 57t

## F

Fabry disease
hypertrophic cardiomyopathy differentiated from, 519
restrictive cardiomyopathy, 554-555, 555f
Familial aortic dissection, 696
Familial thoracic aortic aneurysm and dissection, 762
Femoral venous cannula positioning, intraoperative transesophageal echocardiography in, 37, 37f
Fibrillinopathies, 760
Fibroelastoma, papillary, 908-912. *See also* Papillary fibroelastoma.
Fibroma, cardiac, 907t, 915, 915f
Fistula(s)
coronary artery, 867, 867f
formation of, in infective endocarditis, 410t, 413, 413f
management of, 420
Fluid dynamics, of prosthetic valves, 450-469. *See also* Prosthetic valve fluid dynamics.
Fluoroscopy, in structural heart disease interventions, 97, 97t
Fontan atrial surgery, issues resulting from, 887t, 889-892, 889f-892f
Foramen ovale, patent. *See* Patent foramen ovale (PFO).
Four-chamber views, in transesophageal echocardiography, 4t, 5f-6f, 8-9, 8f
Fractional shortening, in left ventricular systolic function assessment, 167-168, 167f
Frank-Starling mechanism, 160

## G

Gaucher disease, restrictive cardiomyopathy, 553-554
Gender
diabetic heart disease and, 736
left ventricular response to aortic stenosis and, 436-437
Gene delivery, microbubbles in, 56f, 60-61
Genetic diseases, aortic dissection risk and, 695-696
Genetics, molecular, of hypertrophic cardiomyopathy, 518
Glenn shunts, palliative, issues resulting from, 880t, 881-882
Global systolic function, in intraoperative ventricular function monitoring, 26-30
Glycogen storage disorder
hypertrophic cardiomyopathy differentiated from, 519-520
restrictive cardiomyopathy, 554
Gorlin formula, in aortic valve area calculation, continuity equation method compared with, 431-432, 432f
Great arteries
color and spectral Doppler evaluation of, 843, 843f
congenital disorders of, determination of, 840
morphology of, 834-835, 835f
transposition of
congenitally corrected, 869-870, 869f, 870b
corrective procedures for, issues resulting from, 887-888, 887t

## H

Hand-carried ultrasound (HCU) devices, 146. *See also* Handheld echocardiography.
Handheld echocardiography, 146-154
  accuracy of, 147-148, 149f
  background on, 146-148
  in cardiology, 152-153, 152f
  clinical applications of, 151-153
  education and training guidelines and requirements for, 150-151
    for emergency physicians, 151
    for intensivists, 151
    for medical residents, 150-151
    for medical students, 150
    recommendations on, 151
  in emergency department, 151, 151b
  future directions for, 153
  in intensive care unit, 151
  in internal medicine, 150f, 152
  reliability of, 147-148
  ultrasound "stethoscope" in, 148-150, 149f-150f, 150b
HCM. *See* Hypertrophic cardiomyopathy (HCM).
Heart
  anatomy of, 835-840
    atrial situs in, 836-838
    atrioventricular valves in, 838-840, 839f
    concordant and discordant arrangements in, 836, 836f-837f, 836t
    great arteries in, 840
    nonsegmental abnormalities in, 836
    segmental approach to, 835-836, 835t
    semilunar valves in, 840
    venous connections in, 836-838, 837f-838f
    ventricles in, 838-840
  artificial, 598t, 599, 600f
  athlete's hypertrophic cardiomyopathy differentiated from, 520-521, 521f, 521t
  calcification of, in primary hyperparathyroidism, 744
  donor, evaluation of, 586
  function of, changes in aging, 777-778, 778t, 779f
  left-sided, 831
  morphology of, 833-835, 833f-835f, 833t
  position of, 831-833, 831f
  response of
    to exercise stress in aging, 778
    to pressor stress in aging, 778
  right, Doppler evaluation of, 203
  right-sided, 831-833, 832f-833f
  transplantation of, 585-596. *See also* Cardiac transplantation.
  tumors of, 902-928. *See also* Cardiac tumors.
  univentricular, 840-842, 841f-842f
    functional, 871, 871b
  valves of. *See also* Valve *entries*.
    calcification of, in aging, 776-777, 777f, 778t
    changes in, in aging, 775-776, 777t
Heart disease
  congenital. *See* Congenital heart disease (CHD).
  hypertensive, diastolic function assessment in, 211-212
  ischemic, diastolic function assessment in, 212
  nutritional deficiencies and, 752-753, 752t
  in pregnancy, 664-689. *See also* Pregnancy; Pregnancy, heart disease in.
  structural, 95-97. *See also* Structural heart disease (SHD).
Heart failure (HF), 496-516
  in aging, 782-784, 783b, 783f-784f
  cardiac resynchronization therapy for, 508-511, 511f
  definition of, 496, 497f
  diastolic, 198-200, 199f, 199t
  end-stage, cardiac transplantation for, 585. *See also* Cardiac transplantation.
  etiology of, 498, 498f
  heart transplantation for, 512-513
  intraaortic counterpulsation for, 508
  left
    acute, 498-499, 500f
    chronic, 499-505, 500f-503f
Heart failure (HF) *(Continued)*
    echocardiographic diagnosis of, 498-505
    systolic versus diastolic, 503-505, 505f
  left ventricular dyssynchrony in, detection techniques for, 511-512, 512f-514f
  left ventricular remodeling to, 502-503, 504f
  mechanical therapies in, echocardiography for, 507-513, 509f
  pharmacologic therapy for, 507, 508f
    echocardiography in, 507
  in pregnancy, 684
  prevalence of, 496-498
  right
    chronic, 506
    echocardiographic diagnosis of, 505-507
  right ventricular, acute, 505-506, 506f-507f
  right ventricular remodeling to, 506-507
  surgical valve repair or replacement for, 508
  ventricular assist devices for, 508, 510f. *See also* Ventricular assist devices.
Heart murmur, in pregnancy, 684-685
Heart rate, diastolic function and, 198
Hemangioma, cardiac, 907t, 912-914, 913f
Hematoma, of aorta, intramural, 697
  diagnosis of, transesophageal echocardiography in, 703
Hemochromatosis, restrictive cardiomyopathy in, 551
Homocystinuria, 760
Hyperaldosteronism, primary, heart disease in, 745-746
Hypereosinophilic syndrome, restrictive cardiomyopathy in, 551-553, 552f
Hyperparathyroidism, primary, heart disease in, 744-745, 745t
Hypertension
  in diabetic heart disease, 736, 738f
  diastolic function assessment in, 211-212
  pregnancy-induced, 670-671, 671t
  pulmonary, 629-645. *See also* Pulmonary hypertension (PH).
Hypertensive heart disease, diastolic function assessment in, 211-212
Hyperthyroidism, heart disease in, 737f, 740-742
Hypertrophic cardiomyopathy (HCM), 517-541
  alcohol septal ablation for, 109-110, 110f
  asymmetric apical, 527, 528f-529f
  athlete's heart differentiated from, 520-521, 521f, 521t
  condition mimicking, 519, 519b
  diagnosis of, 518-519, 518f
  diastolic function assessment in, 211
  diastolic function evaluation in, 530-531, 530b
  differential diagnosis of, 519-521, 519b, 520f-521f, 521t
  Doppler evaluation in, technical aspects of, 525-526, 526f
  dual-chamber pacing in, 532
  echocardiographic evaluation of, 521-523
  of elderly, 530
  epidemiology of, 517-518
  exercise echocardiography applications in, 281, 282f
  family screening for, 519, 519t
  impaired coronary circulation in, 325
  latent obstructive, 525
  medical therapy in, 532
  midventricular obstructive, 527-530, 529f
  mitral regurgitation in, 526, 526b, 527f
  molecular genetics of, 518
  obstructive, treatment strategies for, compared, 537, 537t
  outflow tract obstruction in, Doppler assessment of, 523-525, 525f
  in pregnancy, 682, 682f
  prognostication in, by echocardiography, 531-532
  septal ethanol ablation in, 532-534, 533f-534f
  septal hypertrophy in elderly differentiated from, 521
  storage diseases differentiated from, 519-520
  strain imaging in, 531, 531f
  subtypes of, 527-530
  surgical myectomy in, 534-537, 535f-536f
  3D echocardiography in, 86
Hypertrophy, septal, in elderly, hypertrophic cardiomyopathy differentiated from, 521
Hypothyroidism, heart disease in, 739-740, 740t, 741f

## I

ICE. *See* Intracardiac echocardiography (ICE).
ICU patients, critically ill, transesophageal echocardiography in, 16
IE. *See* Infective endocarditis (IE).

idiopathic, 555
imaging of, 542
postradiation, 556
in sarcoidosis, 553
speckle tracking echocardiography in, 543-544
in storage disorders, 553-555
Resynchronization therapy, in heart failure, 508-511, 511f
Rhabdomyoma, 907t, 914-915, 914f
Rheumatic aortic stenosis, imaging of, 426, 427f
Rheumatoid arthritis, 719-722
coronary artery disease in, 719-720, 727t
myocardial disease in, 721-722
pericarditis in, 720
pulmonary hypertension in, 722
valve disease in, 720-721, 721f-722f, 728t

Rheumatologic diseases, 712-732
ankylosing spondylitis as, 722-723, 723f-724f
cardiovascular involvement in, 727t
dermatomyositis as, 725-726
mixed connective tissue disease as, 726
polymyositis as, 725-726
primary antiphospholipid syndrome as, 718-719, 719f
rheumatoid arthritis as, 719-722, 721f-722f. *See also* Rheumatoid arthritis.
scleroderma as, 723-725
systemic lupus erythematosus as, 712-718. *See also* Systemic lupus erythematosus (SLE).
Right atrial pressure, estimation of, 618, 618t
Right atrium
anatomy of, 614, 791-792, 796f
compression, inversion, or collapse of, 573, 573f, 574t
physiology of, 614
size of, atrial fibrillation and, 815-816
Right heart. *See also* Right atrium; Right ventricle.
echocardiographic assessment of
basic approach to, 615-616
pressures in, estimation of, 618-619, 618f, 618t
Right-sided valve disease, 646-662. *See also* Pulmonic valve; Tricuspid valve.
Right ventricle, 614-628
anatomy and physiology of, 614-615, 615f-616f
compression, inversion, or collapse of, 572-573, 573f, 574t
diastolic function of, evaluation of, 625, 625t
double-outlet, corrective procedures for, issues resulting from, 897
dysfunction of
in diabetic heart disease, 735
in preimplant assessment for ventricular assist device, 601, 601b
echocardiographic evaluation of
alternate approaches to, 625-626, 626f
basic approach to, 615-616
clinical application of, 623
future directions for, 625
outcome data for, 622-623, 623t
potential limitations of, 625
reference ranges, quantitation and data analysis for, 617f, 621, 621t
research applications of, 623-625, 624f, 625t
technical details of, 619-621
transesophageal imaging in, 619, 619f
transthoracic imaging in, 616-618, 617f
function of
in intraoperative ventricular function monitoring, 30, 31f
measures of, 619-621, 619f-620f
pericardial interaction with, 566-567, 567f
pulmonary vascular interaction with, 630-632, 631f-633f
remodeling of, to heart failure, 506-507
size of, measures of, 619-621, 619f-620f
systolic function of, alternate measures of, 623-625
volume of, 3D echocardiography of, 75-76
Right ventricular assist device positioning, intraoperative transesophageal echocardiography in, 36
Right ventricular infarction, echocardiographic diagnosis of, 250-251, 250b
Right ventricular outflow tract, in intraoperative ventricular function monitoring, 27-28
Right ventricular overload, pulmonary artery pressure and, 629-630
Right ventricular-type univentricular heart, 841

## S

Sarcoid, pulmonary, pulmonary hypertension in, 638
Sarcoidosis, restrictive cardiomyopathy, 553
Sarcoma, 915-917, 916f-917f
Scintigraphy, perfusion, pharmacologic stress echocardiography versus, 311-312, 312t-313t
Scleroderma, 723-725, 727t-728t
Semilunar valves
congenital disorders of, determination of, 840
morphology of, 834-835
Senile amyloidosis of heart, 786
Septal defects, congenital, 857-867
Septal ethanol ablation, in hypertrophic cardiomyopathy, 532-534, 533f-534f
Septal hypertrophy in elderly, hypertrophic cardiomyopathy differentiated from, 521
SHD. *See* Structural heart disease (SHD).
Shunt lesions, congenital, 857-867
Shunting, intracardiac, color and spectral Doppler imaging of, 842-843, 842f-843f
Shunts, aortopulmonary, palliative, issues resulting from, 880-881, 880t, 881f
Sinus of Valsalva aneurysms, 854-855, 855f
SLE. *See* Systemic lupus erythematosus (SLE).
Speckle tracking, in exercise echocardiography, 284-285, 285f
Speckle tracking echocardiography (STE)
in diastolic function assessment, 209
of left ventricular rotation and twist, 185-186, 186f-187f
physical principles of, 183-186, 183f-184f
in regional function analysis, 244
in restrictive cardiomyopathy, 543-544
of strain, 183-185, 184f, 185t
limitations of, 185
Spectral Doppler imaging, in congenital heart disease evaluation, 842-843, 843f
Spondylitis, ankylosing, 722-723, 723f-724f
Starling law of the heart, 160
STE. *See* Speckle tracking echocardiography (STE).
Stenosis
coronary, diagnosis of, noninvasive, 322-324, 324f
recurrence of. *See* Restenosis.
severity of, assessment of, intravascular ultrasound in, 134-135
valvular. *See specific valve, e.g.* Mitral stenosis (MS).
Stent(s)
bioabsorbable
implantation guidance by intravascular ultrasound, evaluation of results of, 140-142
intravascular ultrasound evaluation of, 140
drug-eluding, in restenosis reduction, 139, 140f
malapposition of, late-acquired, intravascular ultrasound assessment of, 139-140
restenosis in, treatment of, intravascular ultrasound evaluation of, 140, 141f-142f
size selection for, intravascular ultrasound in, 135-136, 135f
Stent fracture, very late stent thrombosis and, 140, 141f
Stent thrombosis
after intravascular ultrasound-guided bioabsorbable stent implantation, 140-142
late malapposition and, 139-140
very late, stent fracture and, 140, 141f
Stented bioprosthetic valves, 460f, 461t-462t, 466, 466f, 466t
Stentless bioprosthetic valves, 460f, 461t-462t, 466, 466t
Strain
definition of, 181, 181f
imaging of, 181-182, 181f
in diastolic function evaluation, 207-209, 208f
in hypertrophic cardiomyopathy, 531, 531f
in myocardial ischemia, 189, 190f
in right ventricular systolic function evaluation, 624-625
speckle tracking echocardiography in, 183-185, 184f, 185t, 284-285
tissue Doppler imaging in, 182-183
Strain echocardiography
diastolic function assessment by, 207-208, 208f
in regional function analysis, 244, 244f
Strain rate
calculation of, 181
definition of, 284-285
in right ventricular systolic function evaluation, 624-625
Stress
cardiac response to, in aging, 778
definition of, 159
mechanical, in aortic dissection, 693-694
shear, in aortic dissection, 693-694, 693f
Stress echocardiography
in acute chest pain evaluation in ED, 237-238
coronary artery disease in aging and, 784-786, 785f, 785t-786t
exercise stressors used in, 270-272, 271b, 272t
in mitral stenosis, research applications of, 402
nonexercise, 292-317
alternatives to, 311-312
basic principles of, 293-298
combined approaches to, 294
contrast
in left ventricular opacification, 308

contractility in, 29
in coronary sinus cannulation positioning, 36, 37f
dP/dt in, 29-30, 30f
ejection fraction in, 28-29, 29f
end-diastolic area in, 25-26, 26f
end-systolic area in, 25-26
in femoral venous cannula positioning, 37, 37f
global systolic function in, 26-30
in heart transplantation, 37, 38f
in intraaortic balloon pump positioning, 34-35, 35f
in intravascular device positioning, 34-37
left atrial pressure in, 23-25, 25f
Ventricular function *(Continued)*
in left ventricular assist device positioning, 35-36, 36f
left ventricular diastolic function in, 25, 25f
left ventricular filling in, 23-26
left ventricular outflow tract in, 26-27, 27f
in left ventricular vent positioning, 37
left ventricular volumes in, 26
mitral valve in, 28
in noncardiac surgery, 33, 34t
in off-pump coronary bypass surgery, 33, 34f
practical considerations for, 28
in pulmonary artery catheter positioning, 34, 35f
pulmonary artery in, 27, 28f
regional wall motion in, 30-31, 32f
in right ventricular assist device positioning, 36
right ventricular function in, 30, 31f
right ventricular outflow tract in, 27-28
stroke volume in, 28-29, 29f
tissue Doppler imaging in, 29, 30f
transesophageal Doppler technology in, 26
transesophageal echocardiography in Doppler, 26
impact on postoperative outcomes and cost-effectiveness, 26f-29f, 34t, 37-42, 40t
in probe placement, problems in, 23, 24f
in specific clinical entities, 32-37
in postoperative congenital heart disease, 878
Ventricular septal defect (VSD), 861-865, 862t, 863f-864f
corrective procedures for, issues resulting from, 882t, 883-884
echocardiographic evaluation of, 864-865, 864f-865f
echocardiographic guided interventions for, 102-104
management of, 865
Ventricular septal rupture, complicating acute myocardial infarction, 253-255, 254f-256f
Viscous losses, in fluid dynamics, 453, 453f
Vitamin deficiencies, heart disease and, 752, 752t
Volumetric methods, of mitral regurgitation quantification, with pulsed Doppler imaging, 341, 341f-342f
Volumetric techniques, using 3D echocardiography, 67-69, 68f-71f
VSD. *See* Ventricular septal defect (VSD).

## W

Waterson shunt, palliative, issues resulting from, 880-881, 880t
