Roy Harris says of the transformation of traditional grammar into modern linguistics that "[t]he situation in which an established descriptive format devised for one particular purpose is taken over and adapted to serve some new and quite different purpose is a situation fraught with potential errors and inconsistencies of all kinds" (1981: 54). That a similar situation obtains in the study of music is

clear from statements like "the existing body of music theory is essentially a non-formalised cognitive theory" (Marsden and Pople, 1989: 30), or "Rameau's *basse fondamentale* or Schenker's *Ursatz*, and more generally, 'music analysis' of almost any familiar kind, may be convincingly construed as attempted descriptions of underlying mental realities" (Agmon, 1990: 285). The attempt to transform music theory into a theory of mind accounts for some of the most basic characteristics of current music psychology: not just the emphasis on notational categories that I mentioned earlier, but the whole guiding principle that there are specialized psychological mechanisms which process different parameters of the music more or less independently of one another. As Eric Clarke notes (1989a: 4), this approach is derived from music theory; psychologists have taken theoretical constructs and attempted to give them a psychological interpretation. Tonal hierarchy theory is an example of just this process, and the acrimonious debate over it exemplifies the difficulties of which Harris speaks.

Nothing in the practice of Western tonal music suggests that unordered collections of notes, like the C major diatonic set, function in their own right as significant musical structures. It is *ordered* structures that are significant: harmonic progressions, melodic patterns. The diatonic set is simply a theoretical abstraction, a generalization from specific harmonic and melodic contexts. It is a pedagogical construct, like Schoenberg's chart of the regions. Tonal hierarchy theory, then, does not arise from the observable phenomena of music. It arises from the attempt to give a psychological interpretation to concepts drawn from music theory. In this sense, it is theory-driven rather than data-driven. Now in saying this I am going against Krumhansl's own claims regarding her topological representations of tonal structure: they are not theoretical models, she tells David Butler in reply to his criticisms, they are simply descriptions of data. Indeed, she appears to question whether there is such a thing as tonal hierarchy "theory" at all (1990b: 309–10). But there is something disingenuous about this argument. In the first place, what Krumhansl presents as (say) a major-key profile is an extrapolation from test materials in which certain notes of the C major scale appeared in a certain order; the extrapolation is made on the assumption that unordered pitch sets constitute meaningful contexts. This is a theoretical assumption. In the second place, as Eric Clarke says, "there is a strong sense in much of this work that these descriptions or formalisms are regarded as being very close to truly mental structures—not least because they are presented as contributions to the cognitive psychology of music" (1989a: 6). The title of Krumhansl's recent book-length exposition of her work is *Cognitive Foundations of Musical Pitch*.

Why did the debate between Krumhansl and her critics become so acrimonious? The basic reason seems to be that the protagonists could not agree what they were talking about. They could not agree what tonal hierarchy theory was a theory of. They could not agree whether it was a theory at all. The story of tonal hierarchy theory is the story of a description in search of a meaning.

Should Theory Reflect or Challenge Musical Perceptions?

Jay Dowling writes that "psychologists like myself often assume that cognitive processing (whether consciously explicit or not) proceeds in an analytic mode—that like Schumann's 'ideal listener' the brain reconstructs the score as it goes along" (1989: 250). And he adds: "This assumption feeds a theoretic position built on the experimental analysis of the brain's feature analysis." When he says "theoretic," Dowling is referring to psychological theory. But the same assumption feeds—and is fed by—music theory, which has always had a basically scriptist orientation. The result of the psychologization of music theory (I am tempted to write, the music theorization of psychology) is that it has come to seem natural for both theorists and psychologists to explain music in terms of formal principles or rules—if not actually the rules offered by current music theory, then future rules, better rules, that will be shown to be psychologically valid. Lerdahl and Jackendoff's work obviously represents a giant step in this direction and holds out the promise of a single theory that will be at the same time musical and psychological. What I want to suggest in this final section is that such total convergence between music theory and psychology may not be desirable, or even feasible, because the two disciplines have essentially different and mutually incompatible aims.

Lerdahl and Jackendoff's theory of music is both music theory and psychology because it assumes, not just that there are rules governing both composing and listening to music, but that they are essentially the same rules. Or rather, it assumes that they *ought* to be essentially the same rules, and that to the extent that they are not, there is a failure in the communicative process. Earlier I mentioned how, in his "Cognitive Constraints on Compositional Systems," Lerdahl attacks *Le Marteau sans Maître* on the grounds that there was a mismatch between its "compositional grammar" and its "listening grammar." He goes on to prescribe a number of conditions that must be fulfilled if this kind of mismatch is to be avoided. And he puts forward two general aesthetic laws: "The best music arises from an alliance of a compositional grammar with the listening grammar," and "[t]he best music utilizes the full potential of our cognitive resources" (1988a: 255–56). If the first of these laws excludes *Le Marteau* and serial music in general, the second has still more drastic effects: Ligeti's *Atmosphères* drops out because it blurs distinction between events (p. 239), Balinese gamelan music "falls short with respect to its primitive pitch space" (p. 256), and "[r]ock music fails on grounds of insufficient complexity." (Rock music attracts massive audiences, plays a major role in the personal and social development of young people, and makes fortunes, but it fails all the same.) Such conclusions will strike many people as astonishing; however, this doesn't invalidate Lerdahl's starting point, which is that a composer can't just stuff structure into a piece of music and expect listeners to be able to reconstruct it

simply because it is there. There are constraints on the kind of structures that listeners can reconstruct.

But this brings us back to the question that Dowling raised: how far *are* people engaged in reconstructing structure when they listen to music? Dowling continues, "We should not forget that the brain and mind is not always so precise and analytic, and that cognitive processing can operate effectively on a more global level." In other words: even if it is possible for people to listen analytically, they may choose to listen holistically instead. There is plenty of evidence that they do just this. If Lerdahl's account of listening grammar is correct, then the subjects in Clarke and Krumhansl's experiments could have listened to the Mozart Fantasie grammatically—that is, could have reconstructed the structure—in a manner impossible in the case of *Klavierstück IX;* but they apparently listened to both pieces in much the same way. (Similar, though less formal, experiments of my own produced comparable results.)[14] Again, Alan Smith played incomplete movements from Haydn symphonies to a group of music students, and asked them to say at what point in the form the music had stopped; in the first test "[t]he results were not better than might have been expected had the subjects all guessed. However, during two sequent selections the subjects, who now knew what was expected of them, performed well" (1973: 212–13). In other words, the students could perfectly well have listened grammatically the first time, but they *chose* not to. Introspective and anecdotal evidence suggests that this is how most people listen most of the time.[15]

The idea that music is a process of communication in which listeners decode structures that composers have encoded—the idea we saw at its most basic in Wolpert's article—is, then, based on several disputable assumptions: that people choose to listen grammatically; that there is, or ought to be, an equivalence between compositional and listening grammars; and, most fundamentally, that there is such a thing as musical grammar. It seems to me that a strong argument can be made that, if music is like language at all, then it is most like everything in language *except* grammar. In a book entitled *The Violence of Language*, Jean-Jacques Lecercle writes, "Words speak. They alliterate . . . , they proliferate in the inventories of subjects and passions, . . . they quibble . . . , and of course they endlessly pun. Homophony is the law of the remainder" (1990: 98). By "the remainder," Lecercle means the power of words to create signification of their own, to subvert intended meanings, to do violence to their users. He means the "parts of language that no grammar can ever reach" (p. 18). Lecercle, like Harris, does not believe in formal grammars. In fact, he does not believe in grammars at all. Or rather, he believes that they consist of "largely arbitrary and negative frontiers" (p. 52); he sees them as interventions in the world, historical institutions, part of the politics of language. Now Lecercle's analysis is at least equally applicable to music; what is music but the speaking, alliteration, proliferation, quibbling, and endless punning of sounds? What is its basic law, if not homophony? And it seems clear enough that the rules of music theory serve to codify,

legitimize, and institutionalize musical styles. They explain music, to be sure, but not in the sense that formal grammars explain language; more in the sense that books of etiquette explain how to behave in public.

I can clarify this by going back to the issue of tonal closure. As I said, theorists explain forms like sonata in terms of tonal excursions creating and resolving tension. But we have seen that listeners do not, in practice, respond to large-scale tonal structure. The theory of tonal closure, then, fails to predict listener responses. It is bad psychology. But then, it was never meant to be psychology. It was meant to be a way of thinking about large-scale musical structure. For the tonal plan of a sonata movement governs the disposition of themes and textures, the patterning of loud and soft and high and low, the pacing of climax and relaxation—all aspects of music that *do* directly bear on the listener's experience (Rosner & Meyer, 1986). The idea of tonal closure allows us to recapture something of the way in which composers of the eighteenth and nineteenth centuries conceived their music. Schenker's reductive graphs, or Lerdahl and Jackendoff's, show how these composers adopted the same principles in shaping the small-scale and the large-scale structure of their music. They built sections and even entire movements on the model of a single phrase, articulating each through the motion of tonic to dominant and back to tonic. They created a hierarchy of closures ranging from the perceptible to the imperceptible. And because of this, it does not really make sense to look upon hierarchical theories of music as theories of perception. At their higher levels, at least, theories such as Schenker's or Lerdahl and Jackendoff's tell us far more about what composers of tonal music did than about what listeners to their music do.

A psychological theory of music is successful to the extent that it reflects perception. Musical perception is pluralistic and fluid; listeners make use of multiple cognitive frameworks (Marsden & Pople, 1989) and shift their strategies from one moment to the next (Hantz, 1984: 255). A psychological model of perception needs to embody these characteristics. But there is no reason why music theory should be like this. When a theorist analyzes a piece of music, she is taking up an interpretive stance in relation to it. She is following through the implications of a particular way of thinking about it. She is aiming, perhaps, to change the way people experience the music. From this point of view, the psychologist's perceptual model is totally inappropriate because, as David Osmond-Smith puts it, "the resultant theoretical construct will be devoid of critical content: it cannot challenge our pre-formed responses because it sets out to reproduce them" (1989: 92). The aim of music theory, then, is to go beyond perception. In fact, you might put the point polemically and say that, from the music-theoretical point of view, an analysis can have value only to the extent that it *deviates* from perception. As an illustration of this, consider Schenker's analysis of the opening theme from Beethoven's Sonata, op. 90 (Figures 3.4, 3.5) Schenker suppresses the most perceptually salient feature of Beethoven's music—the pause on the dominant and registral displacement at bar 16. He

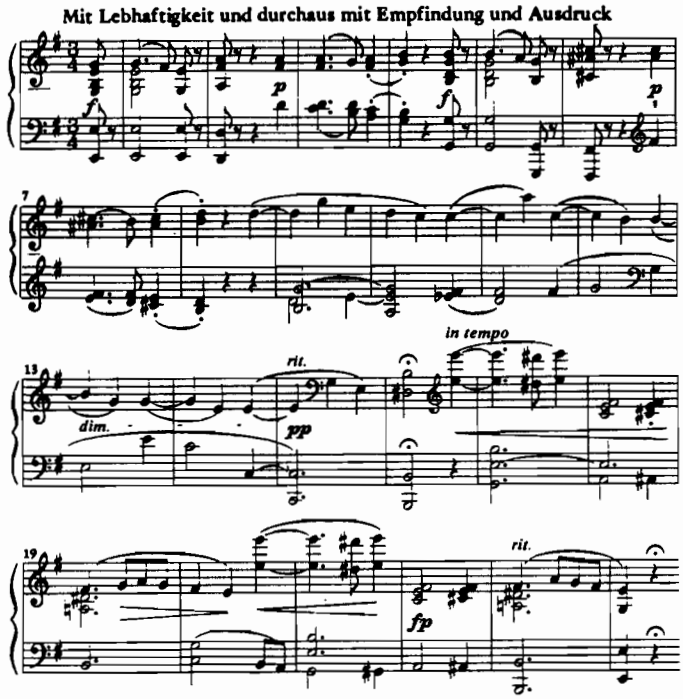

FIGURE 3.4. Beethoven, Sonata, op. 90, first movement, bars 1–24.

reads a tonic prolongation right across this passage. Critics who accuse Schenker of reducing the classics to abstract formulae could have a field day here! But such accusations are the result of looking *at* the analytical graph, instead of looking *through* it to the music. Schenker's graph expresses a stylistic norm, against which Beethoven's music stands out in all its singularity. It casts an oblique light on the music, thus throwing its characteristic features into relief. The content of the analysis, then, lies in the divergence between the graph and the music listeners hear.[16]

Another illustration of this is Charles Rosen's analysis of Haydn's String Quartet in B minor, op. 33, no. 1. This is focused round the interaction of B minor and D major. The tonal ambiguities of the opening (Figure 3.6), leading to the trenchant A-natural/A-sharp clashes of bars 3–4, create a tension that Rosen sees as generating much of the work's large-scale structure. The rest of the movement resolves the dissonant D major, he says, "first by treating it as the dominant or secondary key . . . , and then by expanding this in the 'development' and resolving everything in a recapitulation which—except for two measures at the opening—insists dramatically on the tonic" (1976: 120). But do listeners hear all this? Well, maybe they *do* after they have read Rosen's analysis, which succeeds wonderfully in sharpening perceptions. (It's an obvious fact,

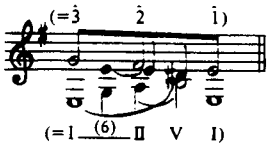

FIGURE 3.5. Schenker's reduction of Beethoven's Sonata, op. 90, first movement, bars 1–24.

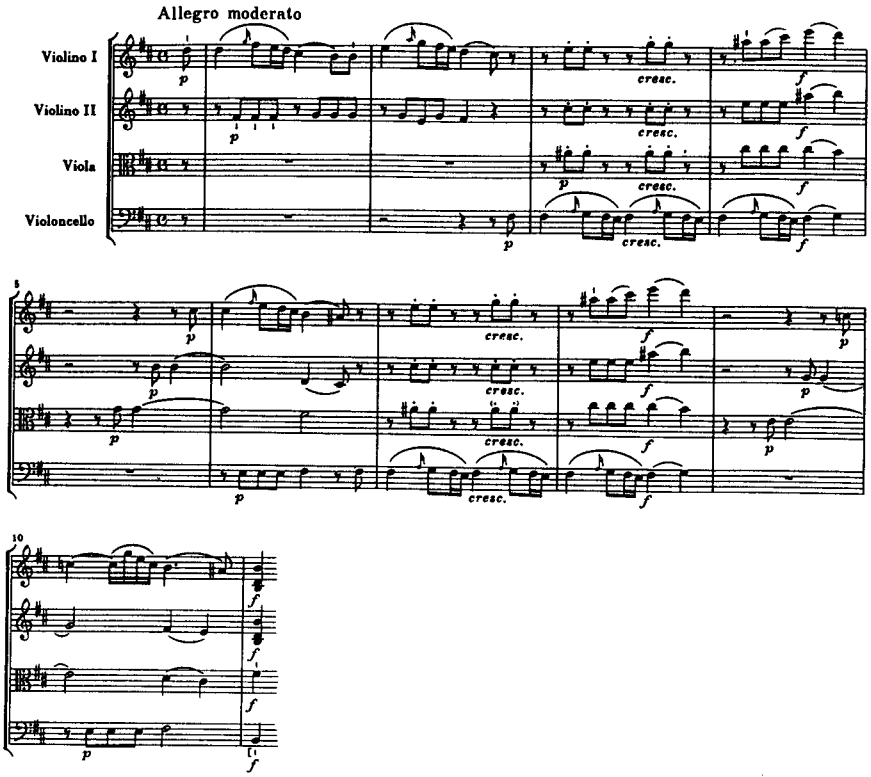

FIGURE 3.6. Haydn, Quartet, op. 33, no. 1, movement 1, bars 1–10.

though not often mentioned in the psychological literature, that people hear music differently after they have studied the score.) And maybe Rosen's analysis recaptures something of the refined sensibility of the aristocratic connoisseurs and dilettanti for whom Haydn wrote his quartets. Or maybe it doesn't; there is no way of knowing for sure. But that does not really matter. If we accept Rosen's analysis, we do not do so because we believe it to be in some absolute sense correct. We do so because we find it persuasive. We do so because it contributes to our experience of the music. The value of the analysis, to repeat what I said earlier, is that it enables us to respond to the excess of music over sound.

Only a few years ago, music theorists with an interest in psychology were inclined to complain that psychologists ought to stop reinventing the wheel and learn some theory.[17] Things have changed; psychologists know a lot of music theory nowadays. The problem, as I have argued, is that they have tended to assimilate theory, treating it as a kind of incompletely formed psychology, rather than seeing it as a related but distinct discipline with its own aims and its own methods. Of course we do not want to go back to the bad old days, when psychologists knew little or nothing about theory and theorists knew little or nothing about psychology. But what Clarke (1989a: 2) calls the "rather unstructured 'leakage' between the disciplines" is potentially damaging to both of them. Music psychology risks losing the ability to pose fundamental questions through too ready an acceptance of music-theoretical concepts and categories; it becomes unduly influenced by music theorists' preoccupation with issues of formal structure. And conversely, music theory risks losing its identity in a welter of incompatible claims regarding both procedures and objectives. What is needed is the careful translation—or maybe it would be more accurate to say the careful *mistranslation*—of concepts from one discipline to the other.

NOTES

1. Clap your hands regularly once a second, record the sound, play it back 440 times faster, and you have the pitch A = 440.

2. See, for example, Sloboda 1985: 151–54.

3. The instruments were, in fact, synthesized.

4. This is rather like the musicians in an experiment conducted by Lucy Pollard-Gott; they judged the similarity of different excerpts from Liszt's B minor Sonata purely in thematic terms, because theme is an essential component in the language game of traditional formal analysis. "One expert commented that after the similarity task was over, he realized that there might have been other criteria for judging similarity such as relative loudness. Yet when he heard the passages, their thematic relations were compelling and seemed to be the only natural basis for comparing them" (1983: 81).

5. Often abbreviated *GTTM*. The first comprehensive statement of the theory was in the book of that name (1983); subsequent extensions to it have appeared in Lerdahl's articles on timbral hierarchies (1987), tonal pitch space (1988b), and atonal prolongational structure (1989). An outline of *GTTM* will be found in Chapter 2.

6. Also published, minus one piece, as *Vier kleine Klavierstücke*. Examples 1 and 2 are taken from Cook, 1990, where a more detailed discussion of these issues may be found.

7. The tests are fully reported in Cook, 1987. Subjects evaluated the test pieces along four dimensions: coherence, completion, pleasure, and expressiveness. There was, in general, a high level of redundancy between these measures. Bengt Edlund, of the University of Lund, reports similar results from a series of tests carried out in 1991 (unpublished paper, "Tonics and Returns").

8. This was in fact only a fragment: the theme from Brahms's *Haydn Variations*. All other pieces in the tests were complete movements.

9. This is an adaptation of G. Lakoff and H. Thompson's description of language, cited in Hantz, 1984: 247.

10. Short for pitch class set theory, a music-analytical system first described in Forte, 1973.

11. See Figures 2.8 and 7.4 in Krumhansl, 1990.

12. At least the subjects in Krumhansl's experiments probably knew what they were doing, which seems unlikely to have been the case in a cross-cultural study of tone hierarchies carried out by Kessler, Hansen, and Shepard (1984). In what must rank as one of the most farcical episodes in the history of music psychology, the team from Stanford jumped on their motorbikes and set out to find the remotest village in Bali. Eventually they discovered a village whose inhabitants had never heard the Indonesian national anthem, and who regarded the Americans as "Javanese" on the grounds that they obviously were not from Bali. The probe tone tests presented some difficulties, and the rating scale had to be reduced from 7 to 5 so that the villages could respond by holding up their fingers. When processed back at Stanford, the results indicated that the villagers were equally unfamiliar with the tonal hierarchies of Western and Balinese music. Another interpretation might be that the villagers were completely baffled by the whole undertaking and simply gave the first answers that came into their heads in order not to disappoint their visitors. What Kippen (1987: 175) refers to as the "cultural insensitivity" of the whole episode underscores the difficulty of adapting the procedures of experimental psychology to non-Western or non-Westernized cultures.

13. The chart now appears in yet another form: see Lerdahl's Figure 17.

14. See Cook, 1990: 44–45, 56–58.

15. For a particularly telling introspective account of musical listening, see Osmond-Smith, 1989: 95. An extended treatment of this whole topic may be found in Cook, 1990.

16. A fuller version of this argument may be found in Cook, 1989: 131–34. The graph is taken from Schenker, trans. 1979, Example 109a (1).

17. This is the general tenor of, for instance, Walsh, 1984.

Developmental Perspectives

4

Songsinging by Young and Old: A Developmental Approach to Music

LYLE DAVIDSON

Introduction

There have been many investigations of the musical development and the musical abilities of children in recent years (see overviews by Hargreaves, 1986a; Shuter-Dyson & Gabriel, 1981). Research ought to benefit educational practice, but there have been difficulties in establishing an effective dialogue between the scientific and educational communities (Hargreaves, 1986b; M.E.N.C., 1981; Sloboda, 1986). In Chapter 4 and 5, Lyle Davidson and Jeanne Bamberger discuss issues related to musical development and education. Both writers stress the importance of integrating experimental results in pedagogical practice.

Scientific research in music development has examined the abilities of children from a very young age. Chang and Trehub (1977) found that five-month-old infants are already sensitive to the sequential structure of a melody. The investigations presented a series of short melodies to the babies and, by monitoring their heart rate, noticed that when a new melody was presented some of the infants showed changes in their heart rate, a reliable indicator of perceived novelty. Studies in the perception of tonality have also investigated the young child's sensitivity to tonality. Zenatti (1969) asked five-, six-, and seven-year-old children to listen to a series of three-note tonal or atonal melodies. Each melody was followed by a repetition in which one of the notes had been altered in pitch. While five-year-olds performed equally poorly on both types of melodies, children six and seven years of age performed better on the tonal melodies than on the atonal ones, thus showing that they had extracted some structural information that helped them in comparing the melodies.

The psychologist Jean Piaget (1960, 1967) believed that to study the

intellectual growth of the child we must look at growth over a period of years, and his work has led to a developmental model for researching musical growth longitudinally (Serafine, 1980). The research headed by Howard Gardner at Harvard University's Project Zero, has investigated the musical development of children, providing a naturalistic and detailed record of the development of their song output over several years. Gardner (1973) has proposed that the artistic development of children can be traced to their acquisition of symbols and their sensitivity to artistic styles.

Lyle Davidson, a senior investigator on the Project Zero research team, has extensively researched musical development, focusing on songs (Davidson, 1985; Davidson & Scripp, 1988a, 1988b). In Chapter 4 Davidson discusses the development of tonal knowledge, looking at the preschoolers' earliest songs, the singing of musically untrained adults, and the perceptual changes in tonal relationships that a student undergoes in music school. Davidson notes that we do not have a comprehensive view of the goal of musical development and instruction because we fail to learn from the uncoordinated and loosely connected chunks of knowledge that we have. He encourages educators and professional musicians to consider the psychological nature of musical knowledge. Davidson describes the musical growth of the child by showing how the child's early approximations of a song later acquire a definite melodic shape and a stable contour, and he illustrates this process with drawings of the child's musical notation (see also Chapter 7 by Jay Dowling in this volume, and Dowling, 1984, for additional research on the development of children's songs).

In this chapter, I argue that taking a developmental perspective reveals a great deal about the nature of musical ability and the nature of effective music instruction. Based on methods of developmental psychology, the development of tonal knowledge is traced by considering preschoolers' earliest songs, the songsinging of musically untrained adults, and finally, the transformation in a student's grasp of tonal relationships in performance, which result from the intensive training that takes place in music schools. Contour schemes—the organizing mental structures of tonal materials in music typical of young children—continue to function beyond the years of childhood, unless there is considerable broad musical training like that typically found in music schools.

Musical Talent: A Determined Ability or a Propensity for Development?

A deep-seated assumption about the nature of musical ability is the belief that musical ability is largely (if not wholly) innate and fixed. From this point of view (I will call it the "talent model"), development is assumed to occur very nearly all by itself—in the person endowed with talent. Environment, training, education, hard work: these are assumed to play little role in musical ability and knowledge. At least two difficulties follow from this assumption: only the gifted and talented are seen as worth the teacher's investment of time and energy, and the scope of

the teacher's and the student's activity is reduced. Let's consider each of these issues in turn.

First, the talent model suggests that fine teachers, good instruments, and time devoted to mastering even elementary musical skills are wasted on those not obviously talented. This line of thinking is reinforced by the assumption that an individual's natural gifts should be allowed to develop freely. Unfortunately, a model of education based on the romantic concept of the flowering of talent ultimately fails to recognize and develop the capacities for musical expression and thought in those students who are not identified as gifted.

Research suggests that *the musically untrained have surprisingly sophisticated abilities.* For example, the average child and adult, although unable to read music notation and without any performance training, can represent the musical dimensions of phrase structure, melodic contour, pitch, and rhythmic elements surprisingly well (Davidson & Scripp, 1988a; Davidson, Scripp, & Welsh, 1988) (Figure 4.1). Furthermore, research suggests that the average adult, although unable to read music notation and without any performance training, can solve musical problems *at least* at the level of undergraduate music students who have years of performance experience in their background (Scripp, Meyaard, & Davidson, 1988). *By investigating the development of musical ability,* it is possible to see degrees of difference and similarity among various groups, children and adults. From this more articulated perspective, it is possible to make better arguments in support of teaching music to the general student, and better strategies for teaching students at all levels of education (Davidson & Scripp, 1988a).

Another difficulty is the assumption that the talented student basically learns by herself. This reduces the scope of the teacher's and the student's interaction. There is little incentive to probe deeply into the nature of musical knowledge and understanding. The narrow version of the talent model assumes that instrumental proficiency alone accounts for careers and alone is powerful enough to override the need for strong interpersonal skills. It reduces the opportunity, as well as the motivation, to consider other aspects of musical life and musical thinking. For the student, *the talent model isolates later development from early experience.* The continuity of growth is cut off. Early forms of musical knowing are ignored in favor of the formal, articulated knowledge of the expert. Talent is necessary but not sufficient.

The oversimplification typical of the talent model greatly misrepresents the reality of the engaging and dynamic exchange in music, just as learning in the classroom misrepresents the knowledge required beyond school (Resnick, 1981).

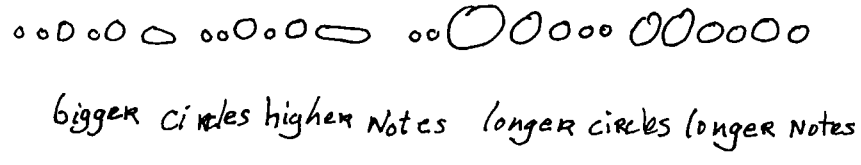

FIGURE 4.1a. Child's invented notation of "Happy Birthday to You."

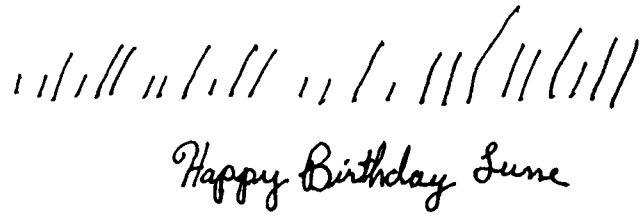

FIGURE 4.1b. Adult's invented notation of "Happy Birthday to You."

It presents a lean concept of what is involved in the development of a rich form of expression. *It results, in part, because educators and professional musicians do not consider the psychological nature of musical knowledge.*

Development: Knowledge Under Construction

It is axiomatic in developmental psychology that our knowledge changes as it develops and matures (Wohlwill, 1973). As we acquire new degrees of mastery in a skill, our relationship to our former level of skill, knowledge, and understanding changes significantly as well. But, as musicians know if they think about it for a moment, this change is more than a simple addition to an already formed base. Its impact is deeper than adding one more element to what is already known. For example, when I learn second position on the violoncello, I do more than add another finger position to my repertoire of skills. Knowledge of the new position forces me to reinvestigate the notes I mastered in first position. My relationship to the fingerboard changes. My physical connection to the instrument is different. The implications of these changes continue to spiral beyond the moment. The change in my physical position changes my sense of what the issues are when I play a line. My choice of string on which I play a given note now reflects my understanding of the role timbre plays in my interpretation. As my options expand, the choices I make become increasingly significant, their impact increasingly wide ranging.

This dramatically transforms my perspective of the musical experience as well as the nature of performance. For example, as my ability to differentiate among possible physical movements and choices increases, my awareness of the elements of a piece also increases. When second position has become integrated into and extends the knowing represented by first position, I can begin to construct multiple views of a note, a passage, or a section. For instance, I can imagine the note A below middle C on one of two strings, and choose which one to play on the basis of the nature of the passage I am trying to play and on the basis of the musical shape I am trying to project. Finally, in this manner, my ability to consider simultaneously multiple aspects of an event, or concept, reflects considerable transformation in my mental representations of that event or concept. All of this reflects considerable developmental change.

The understanding at various points along the way to mastery is usually not noticed, except when deficient. This is not surprising, because when considering musical knowing, we normally take the most complete knowledge (the expert's) as the point of reference. When we adopt such a perspective from which to develop the musical knowledge of novices, we fail to take into account the knowledge the student brings to the task. The knowledge of an expert is very different from that of the less developed student in at least three ways: the degree of its articulateness, its stability, and the extent of its internalization (Trotter, 1986). Indeed, research shows that, contrary to what we might expect, novices and beginning musicians often confuse distinctions easily made by mature musicians (e.g., pulse and duration, contour and interval) when they make representations of each (Bamberger, 1991; Davidson & Scripp, 1988a).

We have a view of the goal of development and instruction without a corresponding view of the path that leads to the goal, because we fail to learn from the uncoordinated and loosely connected chunks of knowledge. If we don't consider the nature of the diffuse, unstable, and relatively unregulated knowledge of the musically naïve, we have little opportunity for reflecting on the knowing typical of the average nonmusician and the beginning musician as well. The study of development reveals changes in what we know, as well as in how we know it. The process of bridging the gap between the musically sophisticated and the musical novice leads to a transformation of our understanding of issues and origins, and ultimately produces new forms of knowing.

Stages of Musical Development: The Expert's Perspective

> Domains were (previously) broken down into their principles and theories, but not studied in terms of the ways in which individuals move from encounter to engagement, from engagement to mastery of early levels, from apprentice to journeyman, and so on. Feldman, 1980: 168

Musical experts provide the models of pedagogy and set the standards for mastery. Yet unlikely as it may seem, these experts may not be the best sources of information about how knowledge of a domain develops and matures. Developmental psychologist David Feldman argues for a way to bridge the gap that separates the expert and the novice. He makes a strong case for the need to redefine a domain in terms of its psychological reality, not its logical analysis. He advocates looking at how the individual knowledge changes with experience and training, instead of defining what a person needs to know on the basis of expert *a priori* assumptions. Traditionally, developmental psychologists have been concerned with building and refining models of intellectual growth within various domains (Furth, 1969; Fischer, 1980). They seek to describe convincingly, whenever possible, invariant *and* universal stages representing changes in cogni-

tive processes and skills as they develop from novice to expert. Consider children's understanding of how to draw a person.

When children begin to develop a concept of space, what do they use as the reference point around which to organize their picture? Unlike adults, children do not always honor the horizontal baseline as an element in the organization of pictures. Instead, children first work from unit to unit, figure to figure, without an overarching reference system (Piaget & Inhelder, 1967). Thus, they first attend to and create the topological features of a drawing without reference to the whole picture. The integrating structure occurs later. Children work with the contour and more general aspects of depiction in the absence of the physical coordinates that involve the horizontal and vertical relationships which adults and experts assume to form the foundation of spatial perception and formation. So, in children's early drawing of human figures, one sees that the proximities are generally correct: arms and legs are appropriately attached to the body, the eyes are placed on the head, and they may even be placed beside one another. But the overall design is uncoordinated, proportions are unrelated to the subject as they work only from one unit to the next (Goodnow, 1977).

However, as children become able to make reference to multiple dimensions of relationships they can begin to show coordinated and geometrical relations. Thus, only when they are able to consider and honor the relationship of the horizon, the house, the angle of the roof, and the chimney in reference to one another are they able to represent the three-dimensional features necessary to make what would be an acceptable adult-style picture (Piaget & Inhelder, 1967). In music, the ability to relate individual pitches to a highly structured order (the musical scale) and the ability to coordinate the regular pulse and the varied pattern of the rhythmic surface demonstrate levels of integration necessary for an advanced knowledge of music and suggest an advanced stage of musical development which I call operational (Davidson & Scripp, 1989).

Operational Thinking: Performance Accompanied by Awareness and Coordination

> . . . as a result of their internalized and integrated nature, concrete operations are actions accompanied by an awareness on the part of the subject of the techniques and coordinations of his own behavior. Piaget & Inhelder, 1969

Piaget's statement about the quality of actions taken in a context of awareness of techniques and coordination is a useful reference point when considering the further development of musical skills. His concept of operationality is important when considering the evolving mastery of tonal knowledge by children and adults, because it describes what takes place in the training of professional musicians. In Piaget's terms, the difference between the different grasps of tonal relationships involves contrasting aspects of thought: *figurative* and *operational*

thinking (Piaget, 1970). The figurative aspect is manifest in the initially passive aspect of knowledge as it relates to perception, imitation, and mental imagery. Mental imagery at this level is internalized imitation. For example, the finger movements that so often accompany the piano student's sightsinging, the arm movements of the trombone player, or the physical feeling of the vocal placement for the singer are examples of representation linked to an auditory image at the figurative level.

Musical training, and not only instrumental training, provides the structure for transforming the more "figurative" thinking represented by contour scheme knowledge and knowledge of tonal relationships as "tunes" into progressively operationalized thinking. This is often achieved by mixing images from different modes of representation. For example, by asking the pianist to "play" the notes while singing them with syllables or note names, the teacher is deliberately combining kinesthetic and symbolic modalities. In solfège classes, the student must initially "call up" and confirm the sounds of notes by naming them while singing melodies. Gradually, more of the sound can be imagined directly from the page, until eventually, the imagined sounds can be transformed mentally with relative ease (without externalized vocal expression). During this process, the student's knowledge of tonal space becomes increasingly articulated and internalized (Davidson & Scripp, 1988c; Scripp & Davidson, 1988; Davidson, Scripp, & Meyaard, 1988).

This provides some indication of the symptoms of what operational thinking in music might sound like. Operational thinking in music is evident in the degree to which one can make transformations and reversals of actions from one state to another (e.g., singing "Happy Birthday" in a major mode and then in a minor mode). Children and adults without musical training cannot do this simple task (except when supported by a great deal of rote imitation) because they lack the stable, yet articulated and internalized, structure on which the transformation is based. Musically untrained adults, who use either contour schemes or their memory of the specific and unique melodic shapes as whole units, can perform their songs in one way, but not both.

Tonal Knowledge: Contour Schemes, Standard Songs, and Scales

The process of making tonal knowledge operational is as long and complex as the developmental profiles of other intelligences (Piaget, 1976). Piaget describes three distinct stages leading to the development of operational and internalized knowledge: sensorimotor, concrete operational, and formal operational (Piaget & Inhelder, 1969). In relation to tonal development, we might think of tonal knowledge as being constructed first through contour schemes, then as phrases of melodies in which the individual relationships of the pitches are not articulated,

and finally, as scales which reflect the hierarchical knowledge typical of operational thought.

Examples of the first phase clearly show the process of constructing the schemes or mental tools that precede higher levels of musical knowledge. The sound of the singing is often diffuse and unfocused. Contours of songs are typically reduced. Even if learned correctly, the range of the song usually shrinks with time to match the level of the child's current contour scheme. There is no evidence of key structure.

The second, or concrete operational, phase is different in various ways. The diffuse singing of the beginning years is replaced by discrete pitches. At this level, a singer can usually make transformations on an entire melodic set, but not on elements of the set. For example, a singer may be able to make stylistic shifts, imitate the sound of a specific performer, or sing the entire melody at a different tempo or with a different dynamic. However, other changes will be more difficult, especially changes that affect individual pitches of the melody. Singers during this stage depend on their externalized vocal production to maintain relative intonation of notes of a melody. When they imagine notes without singing them, their tonal reference slips. Their knowledge of music appears to be partitioned as performance, perceptual, or reflective ways of knowing, each one relatively independent and isolated from the other (Davidson & Torff, 1991).

We most often see the final phase of the developmental process (making tonal knowledge operational) in the context of formal music education. In music schools the instrumental lessons are linked to learning and development in several ways: through performing without the aid of one's own instrument (e.g., in the solfège class, the study of a second instrument, or chorus); through specifying one's perception (e.g., when transcribing solos, taking dictation, or making an analysis by ear), and when discussing and critiquing the music and performances of one's peers and mentors. Singers with third-stage operational knowledge do not require explicit vocal monitoring to maintain their tonal orientation or to check their notation when learning by imitation, sightsinging, or taking dictation. They can imagine the notes of a melody, transform or modify them on demand, and sing specific notes with intonation that reflects understanding of the tonal context.

To be useful, a developmental view takes into account the entire range of procedural and discursive knowledge, in a context of productions, perceptions, and reflections. These reflect the intellectual skills necessary for musical expression (Davidson & Scripp, 1992). Mapping how individuals change as they move from the "initial engagement" of their youthful years to the "early mastery" of middle teens, to become mature artists, is the business of developmental psychology. Therefore, we want to place the musical knowledge and skills of children, adolescents, and adults side by side and see what the trajectories of change really are. We ask about the antecedents of adults' musical knowledge by approaching it from a psychological as well as a musical perspective, in the hope

that with this experience we will be better able to understand and assess the skill, talent, and artistry that support mature musical expression.

Before we continue, it will be useful to review some of the arguments. First, I will argue that a logical analysis of the elements of music will not reveal the psychological knowledge on which naïve understanding is based. The psychological nature of understanding is not revealed by a logical analysis of features. It can, however, become evident by close comparison of different levels of ability. Second, a psychological analysis of musical development reveals there are plateaus of musical development. Each of the preceding levels prepares the way for the next level, but does not necessarily lead immediately to it.

Showing What We Know: The "Felt Path" or the Formal System

The pioneering work of Jeanne Bamberger (Bamberger, 1986) provides an indication of the differences between the musically untrained and the musically trained mind. It reveals an unexpected difference between the two groups' use of the tonal reference system. Bamberger reports that untrained children and adults play melodies on Montessori bells by arranging the bells in the order of the notes of the melody as performed (a "felt path" of pitch relationships). For example, the untrained novices require one bell for each of the notes of the melody, *including the repeated tones*. Thus, for them, the first two notes of the opening of "Happy Birthday" require two different bells, one for each note (even though both pitches are the same), and the first phase, therefore, requires six bells. In the novices' understanding of melody, the notes of the tune and the order of the action of bell playing are fused together, making it unthinkable to restrike a bell in order to sound the repetition of a note.

The approach favored by the musically trained is very different. They first construct a scale of eight notes (making a formal system of pitch relationships). They then play the notes of the song, extracting them from an operational scheme of tonality. Only two notes are needed to play the first four notes of "Happy Birthday," and only four bells are required to play the first phrase. The musically sophisticated people begin the task of representing the melody with the bells by constructing an abstract scheme with which they can more efficiently represent all the notes of the melody.

The difference between these two approaches to tonal structure reflects a qualitatively different orientation to musical elements. At one level of development, the functional units of tonal space stand in such fragile relation to one another that issues like key establishment are moot. At the other level of development, the construction of the hierarchical structure of scales makes several issues relevant for consideration: the identity and stability of pitches on the one hand, and the capacity to establish and maintain keys on the other hand.

From this perspective, one index of musical sophistication is the ability to

integrate localized pitch knowledge into increasingly less contextualized tonal structures as represented by scales and keys. That is, the untrained subjects can be expected to work only within the context of the sequence of the notes of the tune, whereas the trained subjects can be expected to infer a higher-order structure: a tool with which to integrate the various notes of the tune.

Bamberger's work reveals some of the power that can be attained by comparing the performance of the same task by individuals possessing very different levels of expertise. In the next section, we will consider the songsinging abilities of young children and adults.

Songsinging in Preschoolers: Constructing a Basic Vocabulary

Let's consider the very beginnings of performance ability, the first songs a child sings. By viewing the prototypes of musical practice as a moment on the path that leads to sophisticated musical thought, it is possible to learn a great deal about music if we watch children's first years of songsinging. Even in the beginning songs, the earliest efforts to participate in musical thinking and practice, musical elements common to all songs emerge. However, during the development of musical knowledge, the significance of various dimensions may change. For example, rhythmic structures appear to be relatively robust at first hearing, especially and when compared with children's grasp of pitch. However, careful analysis of the quality of early rhythmic structures which children use in songs appears to be first closely linked to words (Davidson & Colley, 1987). Later, independence of rhythmic development from words begins to emerge as children become able to hold a note across a beat or pulse (as with a dotted quarter note in common time). Similarly, dimensions that fail to appear early may require considerable support at later stages of development, as in the case of key stability (Davidson & Scripp, 1988c) or music students' knowledge of key use (Davidson & Welsh, 1988).

The following three songs illustrate the kinds of changes that are at issue. Despite their differences, each of these songs is a version of "Twinkle, Twinkle, Little Star," sung by the same child at three different ages (Figure 4.2).

At age three, Jeannie already knows several important things about the way songs combine words and pitches. She knows that in singing, more than in speaking, the voice is consistently modulated in a way that produces a complex contour of ups and downs, and she also knows that the pitches in the melody should be distinct from one another (i.e., not continuous slides). In addition to understanding these general characteristics of music, Jeannie has some more precise knowledge. She duplicates some of the rhythms of the standard version of the song and can divide the song into smaller units or phrases, yet she makes no attempt to measure the interval between the phrases. Where pitch relations are concerned, the contours the child sings do not match the model and her song

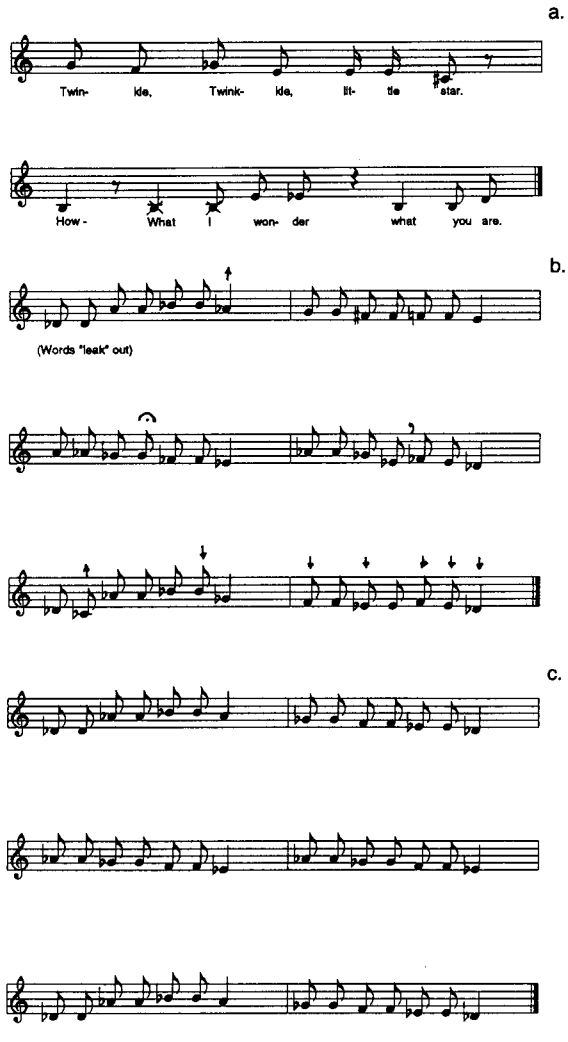

FIGURE 4.2(a,b,c). Jeannie's three versions of "Twinkle, Twinkle, Little Star."

lacks the tonal coherence that a stable scale would provide. The song structure is difficult to recognize: Jeannie sings only two of the song's four phrases, and the ends of the phrases are not marked by notes of longer duration.

In the second version of the song, when Jeannie is four, she carries the melodic contour by humming. At the same time, she forms the words with her lips closed, thus sounding all the changing vowel sounds in the text. This suggests that at four, she is still dependent on the text to keep her place in the melody. While the contour of each phrase is closer to the model, some of the notes and intervals remain inaccurate. The way these phrases approximate the model suggests a greater pitch stability. However, the fluctuating intonation and the lack of

a note-to-note match across phrases make it difficult to give her credit for having a firm sense of tonality or scale. However, the rhythmic shapes are much sharper in this version. At the end of the phrases, there is a longer note, but the interval of time between phrases is not yet measured by an underlying pulse (i.e., the steady beat of the music).

By six years of age, Jeannie's version of the song matches the model. The contours of the phrases are accurate, and the pitches and intervals suggest regulation by a sense of tonality and scale. She lends a steady pulse to each phrase and this pulse controls the duration of time between the phrases. While the words are in place, the completeness of the music suggests that the text no longer dominates the musical aspects of the performance. It is equally significant that the child now uses the constituent phrases of the song (the first and second phrases) to make a simple three-part form, which can be represented by ABA. The repetition of the melodic material of the A section at the end of the song is exact. Every aspect of the song is related to a structure that governs the whole: a single scale, a regulating pulse and surface pattern, and a specific form that binds the individual phrases into a coherent musical whole.

These three songs provide a sense of the nature of the essential questions in musical development. The streams of pitch and rhythm emerge as primary, for two reasons. First, studying these aspects of musical understanding provides explicit connections between children's songs and those of adult singers. Moreover, as the examples illustrate, each of these, pitch and rhythm, exhibits considerable development in the years between one and six.

With respect to each of these streams, there are critical questions to consider. First, we want to explore how development occurs in pitch: Is it a process of gradual approximation of adult models? Or, do children organize their songs using qualitatively different principles? If the latter is the case, can we describe these principles in terms of rules or stable structures? Is development steady or are there marked shifts in musical abilities?

The three versions of "Twinkle, Twinkle, Little Star" that Jeannie sang suggest that learning to sing songs is a more complex task than it appears at first. Learning to sing songs involves: (1) singing articulate pitches that reflect an underlying scale or tonal structure; (2) performing both surface and underlying rhythmic patterns regulated by a common pulse; (3) mastering the canons of song form that guide standard songs so they can be applied to invented compositions; (4) forming structures that make possible the use of internal reference (repetition, variation, and development).

Development of Pitch Relationships

Three components are basic to the control and understanding of pitch relationships: (1) the capacity to grasp the figurative shape or contour of a phrase; (2) the ability to match individual pitches; and (3) sufficient memory or organizing

structure to maintain key stability across the phrases of a song. There has been considerable discussion about the manner in which these various aspects of pitch relations develop. Some earlier research suggests that knowledge of pitch relations may develop through a series of broad levels or phases in which children grasp first the contour, then the specific pitches, then intonation, and finally, key stability. For example, Moorhead and Pond (1941) and Shuter-Dyson (1968) report that contour is perhaps the first aspect of melody to be grasped by the child. Teplov (1966) finds that children sing the contours of the melody first and are only later able to match the specific intervals contained in a model melody. Still other research suggests that tonal knowledge may develop out of the ability to match specific pitches. Specifically, Wing (1963) reports that children's ability to match pitches and intervals precedes their ability to produce the general shape of the melody. However, Sargeant and Roche (1973) report that children's ability to match pitches even declines as their ability to match contours improves.

There is more widespread agreement that the ability to sing in key appears late. Michel (1973) reports that by the end of the preschool years, children are able to perform music in major and minor scales, and even to appreciate harmony. However, this rich description of young children's tonal understanding is questioned by other researchers who report that children even four or five years of age are not able to sing scales at more than chance levels (Bridges, 1965).

Beneath these descriptions lie two difficult, but highly significant, problems in analyzing children's tonal knowledge. First, many analyses have been too narrow in focus insofar as they have examined either the development of interval matching or the growth of the ability to seize the figural shape of a melody. If one studies tonal development by breaking up musical performances into their smallest units or intervals, one loses an important aspect of pitch relationships—the ongoing motion of the melodic impulse. On the other hand, if one focuses only on the motion of unfolding melodies as contours, one misses a close look at the precision, accuracy, and stability of individual intervals.

The second difficulty arises because studies of children's songsinging are often based on an inappropriate unit of analysis (Wertsch, 1985). It is evident that the tonal knowledge of musicians reflects the control of individual contours, pitches, intervals, and keys. However, and this is critically important, these musical organizers are the by-products of considerable and protracted activity constructing pitch relations. Children's early songsinging simply does not depend on linking of fixed pitches or key structures. Because of this, there is little reason to analyze their productions in those terms. Indeed, to analyze the songs of a three-year-old in these terms is akin to applying the rules of point perspective to early drawings or the rules of transformational grammar to one-word utterances. In effect, the key to understanding the development of musical ability lies in discovering a unit which captures the melodic aspect of children's songs but which does not presume that children organize their songs in terms of notes, contours, or keys from the outset. Thus, an early and major focus of our work was

to develop a way of describing children's growing understanding of pitches, intervals, and contours which did not assume that the child used fixed pitches, measured intervals in diatonic terms, or organized performances based on knowledge of keys.

So how do children, in fact, learn to control pitches of their songs? Although researchers confirm that musical pitch development follows neither course associated with the adult predictions suggested (Dowling, 1982; Ries, 1982), a systematic and empirical model of pitch development has been offered. Systematic observation of 78 children over a six-year period at Harvard Project Zero suggests that *contour schemes* rather than gradual refinements in the overall contour or interval matching account for the route of emerging tonal knowledge (Davidson, 1985). The term *contour* conveys the importance played by the figurative shape of melody—its contour; while *scheme* conveys the importance of recognizing levels of mental organization. This model, which emerged out of the Project Zero research, suggested five specific levels of pitch development in young children's singing between the ages of one and six years. These levels characterize children's knowledge of tonal relationships as expressed through their performances of songs.

When singing invented and conventional songs, preschool children first use these melodic schemes with a descending direction. Except for the first contour scheme, the phrases children sing are longer than individual notes or intervals, yet, at the same time, smaller than the individual melodic phrases of model songs. With development, the vocabulary of schemes grows from those that span roughly a third to those that span roughly a sixth. It would simplify the story if, as one might assume, development occurred by filling in the initial space with stepwise movement, and then expanding the tonal space by adding more steps. This would be efficient (on the surface of it) and would reflect some models of ear training and sightsinging currently proposed (Adler, 1979). But the path of development is not so neat and tidy. Contour schemes do not develop in ways one might logically predict from interval learning—that is, proceeding from smaller to larger fixed intervals. Although they begin as small, descending motions and expand through a fourth, fifth, and sixth, this simple line of development does not immediately account for the occurrence of stepwise motion within each tonal frame.

Expand the boundaries of the tonal space first, then go back and fill in the gaps in previously acquired schemes with steps—that appears to be the rule. For example, only after developing the next larger contour scheme does the child fill in the gap between the top and bottom of the previous contour scheme with stepwise motion. For example, not until a child has acquired the ability to reliably sing a fourth (as a leap) does she fill in the earlier leap (the third) with stepwise motion. This "backing and filling" process continues until finally the contour scheme of a sixth has been achieved. At this point the accretive process of development stops. Contour schemes do not continue to develop in the same

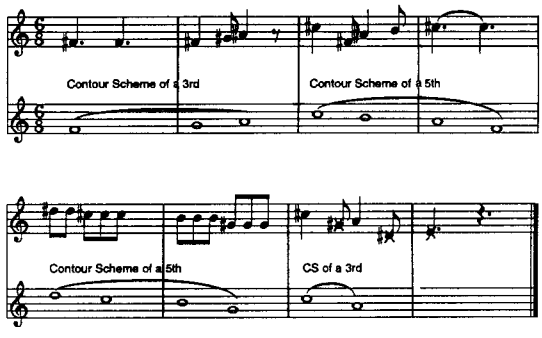

FIGURE 4.3. Transcription of a typical preschooler's performance of "Row, Row, Row Your Boat" with contour scheme analysis below.

way beyond the span of the sixth. The octave, which emerges only later, appears to arise from fundamentally different processes (perhaps having a great deal to do with memory for register, for example).

Figure 4.3 shows how these schemes function only in very local contexts (i.e., within an individual phrase) when preschool children sing "Row, Row, Row Your Boat." Substantially more developmental change is required to construct a level of tonal stability that can be sustained from phrase to phrase and in a variety of contexts.

The increasing differentiation and stability of pitches are two characteristics of pitch-singing development in the early years. At first, preschool children fail to return to established pitches or reference points in their songs as they generate only the individual contours which form the child's repertory of melodic schemes. As the repertory of contour schemes grows, the number of different reference pitches used when singing a song decreases until there is a relatively stable one-to-one correspondence between the pitches of a model song and the pitches the child sings. However, during the preschool years, the locus of this stability is restricted to pitches within the unit of the phrase. It does not yet extend across all the phrases of songs.

Collecting Songs and Forming a Database

The setting in which musical behavior occurs is very important. Much research is conducted in laboratories in which designated variables can be controlled. However, what is learned from laboratory and clinical settings cannot easily be generalized to everyday experience. By taking a more ecologically sensitive approach to the study of music and how our musical knowledge develops, we can trace the connections between the productions of children, adults, and professional musicians. The songs on which this study is based were collected in the homes as part of a larger study of children's symbolic development. Seeing the children every other week for six years made the researchers "part of the family."

The songs collected during the study include the traditional songs American

children learn during the preschool years, as well as some songs that were composed for experimental purposes. In addition, many novel songs were invented by the children under a wide variety of circumstances—sometimes requested as a part of warm-ups to experimental tasks in other domains, sometimes as spontaneous responses to looking at "wordless books." The more than 500 songs that form the corpus were collected under a wide variety of contexts: inventing a song at the request of an observer, singing while playing with the materials of another domain (most often drawing or playing with blocks), singing favorite songs on request, and singing on private occasions when parents thoughtfully made home recordings of their children's performances.

A word about the methods. While the data from this study are rich, the corpus of songs scored includes only those songs which consisted of two or more phrases. The songs were transcribed by experienced musicians and checked by outside experts. Because every attempt was made to reflect the characteristics of the children's performances faithfully, the notations include special symbols. For pitch, in addition to conventional notation, there are symbols for speech, contour, and notes which are half spoken and half sung. The rhythm symbols used reflect free groupings, proportional durations, and more measured and regular rhythmic patterns. Analysis of each song was done from both the notation and a tape of the child's performance.

The transcription and the analysis of the songs were separate processes. Before scoring a song, we determined the number of phrases it contained and, when possible, the tempo at which it was sung. We also classified the song as either invented or standard, and the manner in which it was performed as either spoken, sung with diffuse pitches, or sung with articulated pitches. We then rated each phrase of the song for the way in which the boundaries of the phrases were marked, the type of tonal motion it contained, and finally, the type of song structure that the song exemplified.

What conditions must be present in order to determine that a musical response or behavior is stable? In short, when does a child acquire a behavior as opposed to simply showing an isolated instance of its occurrence? A conservative rule was developed. In order for a musical shape to be counted as a stable part of a child's repertoire of pitch relationships, it had to appear twice in different songs and in different sessions. Separate analysis was carried out on each group, invented and standard songs. This made it possible to distinguish between development within the two different repertoires of songs the children made up and the songs of the culture they were taught. (For more detailed description of the scoring process the reader is referred to Davidson, 1985.)

The following composite picture is based on the findings of a longitudinal study of nine firstborn children who were followed for five years. The first visits—which took place two times each month—were made shortly after the children's first birthdays. The findings of this longitudinal sample were replicated in a cross-sectional study that was made up of 69 children who were grouped by age across the same age range (from a matching socioeconomic class). Among

other tasks, the children in the cross-sectional sample were asked to sing their favorite songs and a song was taught to them during three separate visits. These songs were tape-recorded and later scored on the same measures as the songs from the longitudinal study.

Constructing the First Boundaries of Tonal Space

Contour Scheme: The Interval of a Third

There are many ways to tell the story of what is happening in Heather's song, or to put it another way, to determine the units of meaning in this song (Figure 4.4). Here, the danger is that the observer attributes an irrelevant meaning to the child's production. For example, from one perspective, one could argue the child is attempting to use many adult-like goals. One could say that Heather "decided" to invent a new version of the song "A, B, C, D" by beginning on what are "intuitively" more stable notes (the notes of a tonic, G-sharp-E), and closing on less stable notes (notes of its dominant chord, F-sharp-D-sharp). But once stated, this version seems somehow inadequate. For one thing, it at least implies that, since these tonal concepts are already visible in the songs of toddlers, appreciation and understanding of these tonal concepts (tonic and dominant functions) may be genetic givens, independent of culture, and thus musical universals. This story suggests that the child is already considering and using the materials of music in ways which music students find difficult even 17 years later (Davidson & Welsh, 1988). Thus, the unlikeliness of this precocious grasp of the harmonic structure of Western music by any but a very few makes it difficult to argue that the units of meaning for children in their songsinging are derived from the expert's formulations of musical theory and practice.

From another point of view, of the units of meaning a child uses when songsinging can be redirected to address the issue of the musical units of pitch, interval, contour, and phrase. A story based on this perspective might be about how children learn the rudiments of tonal structures by long experience, attempting to match the correct intervals or engaging in "trial and error" approximations of melodic contours, without regard for intervals. In any case, the stability and regularity of contour schemes, revealed by analysis of hundreds of children's songs, argues against such a successive approximation model of learning that controls the tonal materials of music.

The children's songs themselves suggest another possibility for units, the phrases. It is characteristic of young children's songs to *not* reflect a concern for melodic continuity beyond the level of the individual phrase. For example, at

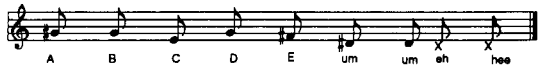

FIGURE 4.4. Heather's "A, B, C, D."

first they do not heed the importance of "reading" or acknowledging the rests and silences between phrases. Instead, they treat the space between phrases as "free" areas which do not need to be measured or regulated, quite unlike adults' performances. Children may develop the ability to control and regulate musical silences most naturally under the focused circumstances of a specific repertoire. The child distinctively segments the musical line into units, taking a breath between the units in order to begin speaking. Thus, phrases are the initial musical units of song.

There is more to say about Heather's version of "A, B, C, D." The reduced range of this song illustrates an important feature of psychological analysis: psychological boundaries in music are different from the physiological boundaries. When children first draw, they work from feature to feature—for example, from head to body to arms, and so on. They work without an overall scheme or design with which to regulate the individual units. They move from one unit to the next and the drawing is the result of a series of localized moves (Goodnow, 1977). When singing, children operate in much the same way. Early songs suggest that children operate on a principle of nearness similar to that found in drawing research: the notes of early songs and melodies are not extremely disjunct, but surprisingly contained within a small register. Regardless of the melodic model, and they appear to be used as repetitive chunks, the notes of individual phrases are relatively close together.

The constrained range children use when singing is not physiological. Children can vocalize across a wide range (Fox, 1990; Jersild & Bienstock, 1931). Yet Heather fails to imitate the melody of the song as she has heard it. This is consistent with the performances of the other children of this study. Unless excited or pushed to do so by an adult, children don't use their full vocal range when singing songs. Instead, they use a psychological unit or scheme as a means of coordinating the tonal aspects of their singing.

There is no evidence of the highly distinctive contour of the song's melodic line. The ascending perfect fifth leap of the first phrase is nowhere to be seen. Typical of children's first songs, the contour of this earliest of melodies is a small descending motion. Greatly reduced in length, in number of words, using a compressed register with a descending contour, Heather's song is representative of the first songs children sing.

There are several more things to notice about Heather's early performance of "A, B, C, D," however. The song is not only reduced in register, it is also severely reduced in length. Only two phrases of the song are sung. The words of the song are very simple, yet only a small portion of them is rendered. Nevertheless, the singer's ability to render the song appears to draw more heavily on the text than on the melody—that is, the song is more fully represented by its text than by its melody. Also typical of the first songs children sing, the text consists of single words. However, the order and sequence of phrases of early songs are not always that of the model. The salience of the text plays an important role in what phrases of the song are going to be produced.

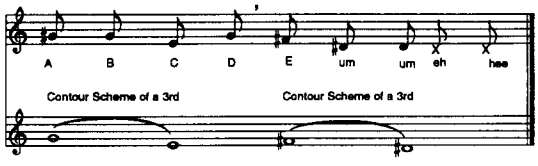

FIGURE 4.5. Heather's "A, B, C, D," showing the construction of contour schemes.

Throughout the development of songsinging there is a consistent pattern in children's grasp of pitch relationships: once a set of boundary pitches has been established and integrated as a stable mental structure, that scheme is used in conjunction with others to reflect more accurately the contour of a given standard song. Contour schemes have several characteristics. First, each contour scheme is identified by a single framing interval: a third, a fourth, a fifth, and a sixth. These "framing intervals" mark the boundaries of the contour of a phrase of song as the child sings it. Thus, the initial contour scheme delineates the interval of a third, and there is a leap between the two notes that form this interval. Later, this leap is filled in, and a more mature form of contour scheme is revealed through stepwise motion. This stepwise motion appears first in the descending form, and with the development and an increasingly operational grasp of the contour scheme, it appears in the ascending form as well. In the initial stages, the pitches of a contour scheme are relatively unstable. Often sounding like a portamento (a special manner of singing with the voice gliding gradually from one tone to the next through all the intermediate pitches; *Harvard Dictionary of Music*), these diffuse pitches become increasingly stable and articulated with development.

Contour schemes appear to represent the tonal structures for the musically untrained child as scales represent the tonal structure of the more musically trained. Children use their repertoire of contour schemes, either singularly or in tandem, to form and control the tonal materials of their songs. Children who are using contour schemes as their mental representation of the pitches of a song will reduce the range of the contour of a song that goes between the range of the most recent contour scheme acquired. In many instances, they will even inappropriately expand the range of a phrase in order to match the size of the framing interval of a new contour scheme under construction. In "A, B, C, D," Heather is using two juxtaposed contour schemes of a third. As Figure 4.5 shows, Heather is using two intervals of a third.

Contour Scheme: The Interval of a Fourth

Kori's version of "Itsy Bitsy Spider" illustrates the contour scheme of a fourth. Throughout the melody the chunks of phrases are bounded by the intervals of a third or fourth. Like "A, B, C, D," the text appears to be driving the content of this song, in that the pitches of the song are not nearly as well represented as the words.

This contour scheme is characterized by a tonal frame of a fourth—that is, the

interval of a fourth forms the top and bottom of the unit of measure at this level of development. As with the previous level, the child may imitate larger intervals when they are modeled, but the child will revert to the fourth as the largest stable interval within a phrase when left alone. Leaps larger than the fourth, when they occur in standard songs, are typically compressed to the smaller size (Figure 4.6).

Children appear to construct the contour scheme of a fourth by adding an outside step to the tone of the boundary notes of the already stable contour scheme of a third. The first step of this level is characterized by either descending step-leap, or leap-step, motion, which more or less outlines an interval of a fourth (approximately in perfect or augmented form). As with the contour scheme of a third, this motion still does not reveal an underlying scale structure. The high-low dichotomy functions as it did in the contour scheme of the third, only now expanded to the slightly wider interval. There is still little stability of individual pitches at this stage. During this period of development, the framework of a third and fourth provides the stable structures for songsinging.

The average range of songs sung during this phase of development expands. It includes the notes of an octave, specifically from c′ to c″, or from middle c to c one octave higher. Each song does not use the entire range. Because the contours of standard songs are compressed to fit the framing interval of the contour scheme, however, individual songs can start higher. The contours of the melodies of this level are still sometimes diffuse and unmarked by articulated pitches, and now, both rising and falling contours are sometimes found. However, more of the pitches are clear.

An important milestone of development occurs during this level: individual pitches of songs can now be matched when they are sung in the appropriate range. Even intervals larger than a fourth can be matched if they are sufficiently supported, prompted, or modeled. These larger intervals are not used in songs, however, suggesting that songsinging uses different skills than interval matching; that representations of melody are based on contour scheme rather than intervals. Additional evidence supports this perspective. When the child is learning a

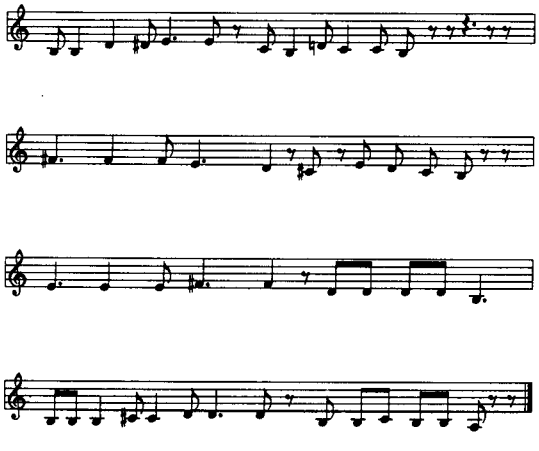

FIGURE 4.6. Kori's "Itsy Bitsy Spider."

new song, or singing a song while performing some other task (such as playing a set of bells, drawing a picture, or moving about the room), the contour scheme currently under development, when it occurs in a song, may itself be replaced by a more stable and smaller scheme—in this case, that of a third.

As noted earlier, the child at this level does not have a reliable way of representing leaps larger than a fourth, so larger leaps in standard songs are compressed. Also typical of this level, there is little evidence of key and pitch stability. Indeed, the tonal structures used at this stage are still extremely local in nature, which means the child does not always match the high or low note within the contour scheme being used.

As with the contour scheme of a third, the second step of this level involves a filling in of the framing interval. This stepwise descending fourth pattern occurs only after the boundary interval of a fourth is stable and after the contour scheme of the fifth is acquired.

Contour Scheme: The Interval of a Fifth

Max's rendition of "Happy Birthday" illustrates the use of the contour scheme of a fifth (Figure 4.7). The range of the first two phrases (d′–a′) establishes the framing interval. The notes he uses in the first two phrases (a′, g′, f-sharp and d′) are typical of the first, unfilled form of the contour scheme. They represent the linking of the two forms of the contour scheme of a third (see Figure 4.8).

Like the others, this is another two-step contour scheme—the first unfilled, the second filled. In both, as in the earlier contour schemes, the descending contour initially predominates. Later, the contour can be rendered flexibly (as in Figure 4.7). The shapes that result in this contour scheme are few in number and can be derived from the two previous contour schemes. The framing interval of the fifth coordinates the notes within this register.

When children sing a song using the previous contour schemes, they appear to not return to specific pitches, but only move up or down reflecting the contour of the phrases. Thus, often there are relatively few shared pitches within a song. By contrast, when children use the contour scheme of a fifth to sing a song, they tend to return to specific pitches as they sing the contour of the piece. Thus, now there are more shared pitches across the phrases of the song. This produces songs that begin to sound as though there were a superordinate structure like a scale in place. However, while the effect of this is to create songs that may use as few as five pitches, this should probably not be taken as evidence for a scale or key structure. For one thing, as in the earlier levels, the child may imitate intervals

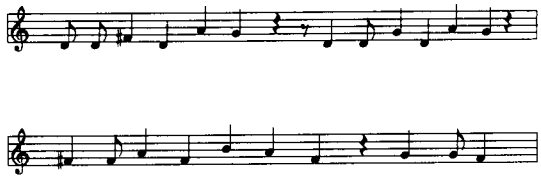

FIGURE 4.7. Max's "Happy Birthday to You."

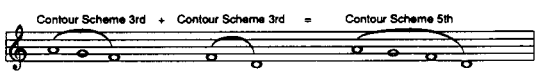

FIGURE 4.8. Constructing the contour scheme of a fifth.

larger than those of a fifth when they are modeled, but the fifth is still the largest stable interval. That is, intervals exceeding a fifth are typically compressed to a fifth. Furthermore, although the child may give an appropriate tonic (or ending note) in a completion task (especially if prepared by a stepwise descending motion), as in the last phrase of "Row, Row, Row Your Boat," the use of contour schemes in his invented songs does not show the coordination among pitches or the constraints which go with knowledge represented by scales. The child's use of the contour schemes is the same as in the earlier levels, as a high-low boundary.

When a song contains leaps larger than the interval of a fifth, they are compressed to a fifth. Not only does compression of larger intervals occur, but also smaller intervals are sometimes expanded. In these cases a smaller interval (which we know a child has acquired) may be pulled in the direction of a fifth (or whatever contour scheme is being constructed) and thus distorted in a new way. This illustrates the powerful influence that a mental structure can have on memory, perception, and production.

During this level, the average range of the singing expands very little, up a step from c″ to d″. As in the earlier levels, an individual song probably will not use the entire range. Also during this level, the nature of diffuse singing changes markedly. Diffuse singing does not occur as part of a rising and falling contour, but may sometimes occur as a sliding between two discrete pitches. This may reflect an unstable contour scheme, but the individual pitches are much clearer and more distinct than during the previous contour schemes.

There is another development. The child is now able to differentiate between the starting and ending pitches of phrases by often making the ending pitches lower. There is also evidence that during this level a child begins to use an internal model when singing. The following example shows that the child was able to correct the intervals of the first phrase during the musical repetition in the second phrase.

When learning a new song, the child characteristically reduces the contour of the melody to earlier acquired levels (e.g., contour scheme of a third). Later versions of the song show that the child has replaced those smaller intervals with the appropriate one of a fifth. There are a variety of ways of ordering the internal space of this contour scheme. All of these ways can be related to the previous two levels. For example, one way of constructing this level is to repeat the process of adding on to an already stable contour scheme. This often occurs after the contour scheme of a filled-in third has been acquired. Another way of constructing this contour scheme involves interlocking thirds, which can also be derived from the contour scheme of the third.

As with the contour scheme of a fourth, the second step of this level involves filling in the framing interval. This stepwise descending fifth pattern occurs only

after the boundary interval of a fifth is stable. Also, this level occurs relatively late, as anyone who listens carefully to a five-year-old's version of the last phrase of "Row, Row, Row Your Boat" can testify.

Contour Scheme: The Interval of a Sixth

Maja's version of "Jack and Jill" provides a good example of contour schemes at this level (Figure 4.9). She is the only one to acquire the filled-in version of the contour scheme of a sixth. As in the previous levels, the many routes to this contour scheme may be derived from a limited number of strategies, based on previous contour schemes. Phrases of melody that employ a range of tonal frames of more than a fifth, but less than an octave, are characteristic of this level. Some of the ingredients of this level are the result of linking the contour schemes already mastered. Thus, the contents of this contour scheme are less narrowly defined than the earlier ones. Because there is not much evidence of a stable octave, the organization is still based on the local knowledge that contour schemes represent.

The average range of the songs at this level extends a little on both ends, spanning the notes between b and e″. Songs end on pitches that are lower than those on which they begin. As before, individual songs do not use the entire range, but only a portion of the tonal register available. The child sings pitches that are well formed and clear during this level. Diffuse singing is sometimes found around the outer limits of the register, and there may be an occasional sliding between two distinct pitches.

There is a major change in the stability of individual pitches within a phrase and across phrases. At this level, a child can remember a specific pitch and, having left it, can return to it. This makes it possible for the child to sing and resing notes and pitches consistently throughout an entire song. The result is that the songs are much less chromatic than during earlier levels, because the phrases of songs at this level tend to share the same pitches—rather than to use different pitches. Since the child still lacks a scheme for the octave, intervals larger than a sixth are usually reduced to the interval of a sixth. "Somewhere over the Rainbow" shows how this reduction occurs (Figure 4.10).

Another interesting strategy begins to emerge. It shows the role memory can now play in melodic construction. The greater memory capacity that the child now has is used to fix a specific register as a reference point. For example, when

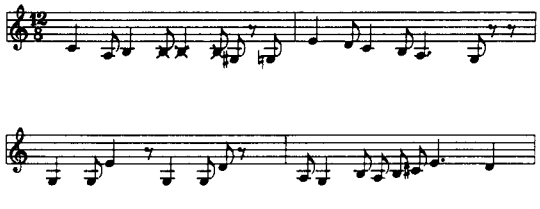

FIGURE 4.9. Maja's "Jack and Jill."

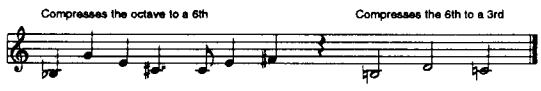

FIGURE 4.10. Jeannie (4:6) "Somewhere Over the Rainbow."

Jeannie now sings "Old MacDonald Had a Farm," she places the melody of the phrase "EIEIO" in a higher register and returns to the same register and same notes whenever the phrase is needed. She does this without regard for the appropriate tonal relationships across phrases. The song appears to exist in two distinct registers, one distinctively low and the other distinctively high. The song is sung maintaining these two registers throughout.

Contour Scheme: The Interval of an Octave

While none of the children sing the interval of an octave before the age of six, there are some single instances that indicate what can be expected. As with earlier levels, the unfilled space appears first. Also, like the earlier levels, this level is constructed by combining earlier contour schemes. The song in Figure 4.11 exemplifies songs that count as instances of this level.

This song is very different from earlier ones in several ways. First, the only notes present in the song are those of an appropriate scale (i.e., they meet a musician's expectation). For example, Maja's song uses only the notes of the F major scale (or, if you prefer, a pentatonic on F since there is no B-flat in the melody). Second, these songs differ from those of earlier levels in that they tend to begin and end on the tonic of the scale, even though the range is now bound by the vast space of the octave. Another way this level differs from earlier ones is that notes on either side of leaps are discrete—there is rarely any glissandi or diffuse singing. Finally, some completions of target pitch patterns (the child is asked to finish fragments of a descending scale) show that the appropriate tonic can be inferred from the context of a given pattern of notes. It appears that these traits are characteristic of both invented and standard songs.

This ends the story of how young children construct the tonal space of their songs. It has been argued that children's grasp of tonal relationships undergoes systematic development as they expand their repertory of contour schemes and, correspondingly, as they more often return to individual referent notes of the model song. Additionally, it appears that development does not proceed neatly from steps to leaps, nor does it follow a direct sequence from simple to more complex intervals. Finally, a significant first phase leading to mastery of tonal space appears to be completed by the age of six or seven. What happens next?

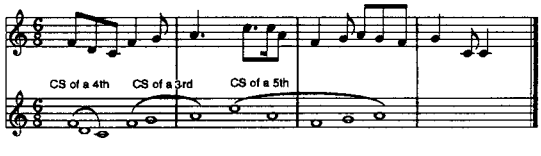

FIGURE 4.11. Maja invented song.

Meeting the Culture: Middle Childhood and Beyond

After this phase, development appears to take another direction; knowledge of tonal relationships is linked to the individual's song repertory. In many ways this progression parallels that found in the visual arts, where, after a burst of creative brilliance, young children refocus their drawing efforts toward mastering the somewhat mundane and canonical forms of objects. The resulting flatness of their efforts is dull when compared with their earlier products.

A similar closing down and focusing on cultural forms may also occur in music. Young children, after a long period of eagerly engaging in musical tasks like inventing a song about a rabbit, become shy about singing. Now, after being asked to invent a song, they are likely to respond by throwing back a challenge, "You sing one." One may lament the loss of invention, but there is another interpretation of this phenomenon. This seeming reduction of creativity is perhaps the next important step toward mastery of the materials of the domain. Children have, by now, a rudimentary grasp of the materials of music, pitch, and rhythm. During this new phase, children are becoming aware that there is a cultural bank of standard songs, and they learn that their knowledge of those songs is limited. From this perspective, their response, "You sing one," is social in nature. It reflects a desire to take part in the culture which lies beyond that of their own making. Thus, during the years of middle childhood, the focus of activity shifts away from the materials of music toward practicing the canonic forms, thereby learning the artistic language of culture. There are, doubtless, other interpretations. Yet the parallel in visual arts strongly suggests that in music there may also be something like the "retreat" from free invention into prolonged study of cultural forms.

During the years of early adolescence music becomes extremely important to children. Children now spend an enormous amount of time listening to and learning songs that reflect the repertoire of the culture, usually the favorites of their peer group. During the middle childhood years the focus of musical activity shifts, perhaps beyond the canonical forms of the music of the culture to using music as a means of negotiating and establishing social relationships. What is the effect of so much listening and the singing it generates? Such intensive exposure should have a powerful effect on their understanding of tonal space, but does it? Does this amount of singing result in the construction of a hierarchical tonal structure to be used when performing songs? If contour schemes are characteristic of young children's song performances, at what point in development and under what conditions does a singer's command of tonal space reflect the hierarchical thinking evident in the construction and use of scales?

Song of the Culture: Way Points to Operational Knowledge

Ongoing work at Project Zero is taking up the issue of the continued development of tonal knowledge into adulthood: How do musically untrained adults use tonal relationships in singing songs? Do adults use scales to integrate pitches when they sing songs, or do they continue to use the looser tonal structure typical of the contour schemes we observed in children (Davidson & Torff, 1991)? Put another way, how do musically untrained adults differ from or resemble the seven- or eight-year-old child's performance of children's songs? Are their performances similar to those of children in spite of years of experience listening to the music of culture?

There are some clues that indicate what we might expect. There is a strong resemblance between the invented notations of seven-year-olds and untrained adults (Davidson, Scripp, & Welsh, 1988), as Bamberger noted in her comparison of musically untrained children and adults (Bamberger, 1986). Surprisingly, there is little difference between the notations made by the two groups, in spite of the fact that adults have had nearly 15 years more experience hearing music than the children.

Turning from children's performance of songs to that of adults, we found that the study of musically untrained adults' songsinging ability has three conditions (Davidson & Torff, 1991). The first one is simple: Sing "Happy Birthday" once, then resing it. Since the second performance might be much better than or different from the first, this controls for the effect of warming up. In the second condition, subjects are asked to sing the song and then listen to a tape of someone else singing the song—this version contains the most frequent errors made by adults. After identifying the location of the errors, they sing the song again. This allows us to look at the relationship of their singing to their perception of errors. The final condition is like the second, except that the tape is of their own singing (not someone else's version). They are asked to reflect on their performance, imagine how the song goes, and compare that with the version they just performed. At the end of the discussion, they are asked to sing the song again.

Although the study is in progress, some of the results already noted have a bearing on the topic of this chapter. In the case of tonal knowledge, it is clear that a significant number of musically untrained adults sing "Happy Birthday" without employing the integrating structure of the scale. As with young children, adults typically compress the range of the third phrase (an octave) and surprisingly end the song in a different key from the opening phrases. These two errors strongly suggest the use of contour schemes, as we saw in our study of children, for these reasons: first, the octave is usually performed as a smaller

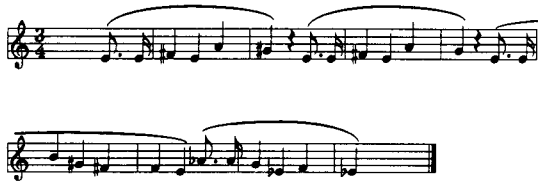

FIGURE 4.12. Typical errors in an adult's version of "Happy Birthday to You."

interval, typically compressed to a fifth or sixth, just as young children do; second, the last phrase is lower than it should be, ending in the register of the starting notes, suggesting that closure depends more on register than on hierarchical tonal relationships (Figure 4.12).

In our ongoing work with adults we are finding that musical performance knowledge is remarkably stable. And there is no significant warm-up effect; repeated singing does not change the quality or accuracy of the first version. Furthermore, even after hearing their flawed version of the song, many subjects report that it represents their "best" version of the song. Others will describe their errors as "not high enough" (for the third phrase) and "got off" (for the ending) and then resing the song without correcting the problems they have clearly identified.

The questions this work raises extend beyond the scope of this chapter, but one question is worth pursuing. What is the nature of the tonal understanding that results from the songsinging of middle childhood?

Musical Study: Continuing the Path of Development

The course of development enters a new phase when music instruction begins around the age of 10 or 11 (for those students who take lessons on an instrument). Contour schemes begin to be integrated into the hierarchical structure provided by the scales of the culture. However, as tonal memory and the use of scalar structures expand, sensitivity to tonal functions increases and the contour schemes are gradually, yet still only somewhat, coordinated with the tonal vocabulary of the culture. Clues about the limitations of this path of development lie in the performance of major scales under a variety of conditions by students entering professional music schools. Their performances suggest they know scales as whole chunks, as melodies. These structures are difficult to pull apart and are unstable if not performed in a manner or speed which allows the student to perform, perceive, or monitor the entire shape as a single unit.

By the time music students enroll in a college-level sightsinging class, they bring with them a vocabulary of contour schemes, a repertoire of standard songs that they share with nonmusicians, the perceptual knowledge of tonal functions, a first-draft knowledge of the scale, and years of instrumental training and exposure to music literature. Given this background, it is odd that when they enter professional schools to begin formal music study, their knowledge of scale sys-

tems and tonal melodies is so incomplete and their grasp of tonal structure is so superficial.

Yet this superficial stage of tonal knowledge is easy to demonstrate. Just a few moments with a beginning solfège (sightsinging) class in the United States reveals students' relatively figurative grasp of scales. Although able to sing scales and melodies, many will be unable to easily sing specific notes of a scale on demand, for example, scale degrees four or six. Additionally, if individuals are asked to sing a one-octave span on a neutral syllable starting on scale degree two of a major mode (singing the notes of the C major scale starting on the note D), one of three things happens. Some students will sing the octave but transform the second scale degree into a tonic and sing a major scale. Many more students stop singing when they reach the tonic instead of completing the octave by continuing up one more note. In each case the students often are not aware of what they've done. Still other students use knowledge extrinsic to music—that eight steps make an octave—to determine when to stop. They solve the task by counting up eight notes as they sing.

These responses are evidence that students have not yet learned to partition musical space on demand, nor do they have an articulated and internalized representation of tonal space. They know the scale as a whole performance act, a string of notes linked into specific relationships. Singing the scale as if it were a "melody," they stop where it "feels right," not where they are asked to stop. In other words, they are unable to monitor and control their performance of the scale to show musical understanding of the parts in the context of the whole; merely counting the number of steps is not enough to engage intrinsic musical sensibilities.

Their knowledge of pitches within a scale is initially very much like the nonmusician's grasp of the notes of a song. The nonmusician's understanding of a melody is static, a rote performance without reflection, a recitation without comprehension. The song becomes a sign for music, formulaic and canonical. It is understood as a whole, not as a collection of independent units yoked into special connections. It is as if the smaller units of contour schemes are replaced by the relatively larger, yet completely context dependent, phrases of melodies.

Development and Talent

This chapter looked at the abilities of children and adults to sing tonal songs, but our findings carry implications for the relationship of development to talent. The context for investigation has not been the laboratory, but the natural settings in which nonmusicians first begin songsinging and young musicians first begin training. Given the point of view advanced here, one can begin to appreciate the effect of musical training on the relatively naïve musical knowledge of the novice in unsuspected ways. For one thing, it suggests that, to a remarkable degree, nonmusicians and beginning musicians share the same reference system when

they are singing unaccompanied songs. Surprisingly, when deprived of the advantage of their instruments, these young talented musicians look like the nonmusicians. This, in turn, strongly suggests that instrumental training by itself does not guarantee a grasp of musical relationships, and that musical thinking in these cases is constrained to the use of the instrument.

This finding has broad implications for the study of musical talent. A developmental picture of musical knowledge suggests that natural gifts may not develop very far when allowed to grow freely or when students are not encouraged to use their knowledge and skills in ways that promote integration. Instruction focused exclusively on playing an instrument or passing on the masterpiece of the culture fails to carry the mind of the individual far enough beyond the instrument and into musical thought to make integration and operational understanding likely. A far broader program is suggested. A developmental perspective suggests that a range of musical instruments and contexts be explored rather than a restrictive focus of musical study and instruction on an instrument of choice. The differences between younger and more mature musicians suggest that integration does occur, but that it may be dependent on the extent to which knowledge and skills are used in diverse and increasingly complex relationships to one another. Studies designed from this perspective will ensure that young musicians will be able to coordinate their use of musical knowledge and skills across a range of situations.

Finally, for all of us, knowledge of the developmental path that leads to a moving musical performance can help us better understand the remarkableness of the achievement. In addition, it can help us appreciate more fully the meaning and richness of the musical knowledge that supports such a performance.

Coming to Hear in a New Way

JEANNE BAMBERGER

Introduction

In the second developmental chapter "Coming to Hear in a New Way," Jeanne Bamberger focuses on the relationship between the description of music and the perception of music. She describes in detail how the students' descriptions of the music represent their perception of it. Bamberger illustrates how differently students may perceive a rhythm by setting up an imaginary dialogue between two students: one who stresses the metric features of the rhythm, the other who emphasizes the functional aspects of the rhythmic structure. Through their exchange of ideas, both students gain a new dimension in the ways in which music may be heard. Bamberger urges teachers to utilize the differences in the students' descriptions as a tool for broadening the students' understanding of music.

Moreover, Bamberger encourages teachers to see *behind* what, at first, may seem wrong in the students' descriptions, and to seek instead "the logic" reflected in their descriptions. For Bamberger, hearing music is a process of instant perceptual problem solving, and hearing in a new way is learning to enrich one's own understanding of music, to perceive in a new way (see Bamberger, 1978, 1981, 1990, 1991, and Bamberger and Schön, 1991, for a description of these theories and their pedagogical applications, and Bamberger, 1986, for a discussion on the development of musically gifted children).

Knowing How and Knowing About

I begin with a conversation that will most likely sound familiar to many readers and yet its very familiarity continues to puzzle me. It starts with an observation by the speaker that she enjoys listening to music and can make sense of most of what she hears. Upon questioning, she agrees that she can clap simple rhythms, recognize tunes she has heard before, even sing or whistle at least some of them. But she then hastens to add: "But of course, I don't know anything about music."

These remarks are so familiar that, like much that is commonplace, the puzzlements in them pass by unnoticed. But if, for some reason, they catch our attention and we turn back to reflect on them, we may be surprised by what we have heard. Wittgenstein puts it like this:

> The aspects of things that are most important for us are hidden because of their simplicity and familiarity. (One is unable to notice something—because it is always before one's eyes.) The real foundations of his enquiry do not strike a man at all. Unless THAT fact has at some time struck him.—And this means: we fail to be struck by what, once seen, is most striking and most powerful. (Wittgenstein, 1953: 50)

The puzzlement that catches my attention in the conversation is this: How can a person say that she can remember, enjoy, sing, and understand the music she hears everyday and still say that she "doesn't know anything about music"? Is it the difference between knowing how to do something in contrast to knowing about it? Or perhaps the distinction isn't in the "knowing" at all, but in the "it"—the music, itself. Could "music" stand for two different kinds of things—one kind that you sing, dance to, recognize, and enjoy; and another kind that you

"know about"? Or could it be both: when you "know about music," the music itself changes?

The conversation raises, in a quite natural way, questions such as the following: What do we mean by "knowledge," or more specifically, what does it mean to know, to have, or to use musical knowledge? And even if we could come to some agreement about that, we are quickly led on to other questions: How does musical knowledge develop? What, for instance, is the difference between what you or I hear in listening to the same piece of music? Why do even professional musicians so often disagree in their "interpretations" of the same piece of music? And how do we ever come to hear in new ways?

Musicians are more likely to talk to one another about their "hearings" of a piece rather than about knowledge. In rehearsing a string quartet, for instance, the violist might say to the cellist, "How do you hear that last passage?" And the cellist might answer, "Well, the second phrase begins on the downbeat of bar 19." To which the violist might answer, "No wonder we aren't together, I hear the phrase beginning with an upbeat starting in the middle of the previous bar." Or among music theorists you might hear one saying of another's analysis of a piece, "Your hearing just doesn't make sense to me." What, then, is meant by a "hearing" and how can we characterize the differences among them; or, even better, try to elicit and account for the usually tacit underlying assumptions that give rise to these differences?

But what is the evidence for another's hearing? My evidence for such hearings are usually subjects' descriptions of them, albeit in several media of which verbal descriptions is one, drawings and the spatial ordering of pitch-playing objects another. While each of these modes of description has its special qualities and constraints giving each a differing potential for what it might be trying to "say," still they all raise a very knotty problem for the observer: since a hearing is by its nature a necessarily private, internal experience, an external description in whatever mode can provide only impoverished clues to a subject's momentary organizing of a melody or rhythm—that is, to his or her hearing. Further, descriptions are influenced in interesting and often very specific ways by the terms—the "units of description"—that the hearer has available. We need to ask, then, what are the relations, often reciprocal relations since terms also influence hearings, between these units of description and what I will call the hearer's "units of perception"? And since a hearing is, perhaps paradoxically, a silent affair, how can anyone know?

I have addressed some of these questions elsewhere[1] but here I want to focus attention on an argument that must necessarily precede them. My argument is that *a hearing is a performance*; what the hearer seems simply to find in the music is actually a process of instant perceptual problem solving—an active process of sense making something like that evoked by the comments of the painter Ben Shahn: "So one must say that painting is both creative and responsive. It is an intimately communicative affair between the painter and his painting, a conversation back and forth, the painting telling the painter even as it

receives its shape and form" (Shahn, 1957: 49). Like a painting, a hearing, too, is both creative and responsive, a conversation back and forth between the music, as material, and the hearer as he or she shapes its meaning and form in some particular way.

Making Meaning

In arguing that a hearing is a process of instant perceptual problem solving, I obviously intend to suggest that what we casually call "the mind" is actively engaged in making meaning—that is, in organizing incoming sensory material. And I also want to suggest that this is an ongoing generative process—that we are actively doing this organizing in real time as the sound/time phenomena are occurring "out there." But I do not want to suggest that by "organizing" I mean some kind of "decoding" process, as if the incoming material has already been segmented, and these entities labeled or otherwise symbolically "encoded." Rather, it is exactly because sound/time phenomena do not come already structured, but rather *hold the potential for being structured* that different hearings are possible. As Israel Rosenfield has said, "we perceive the world without labels, and we can label it only when we have decided how its features should be organized" (Rosenfield, 1988: 187).

However, I find Rosenfield's word, "decided," somewhat problematic here, since even that suggests more of an overtly intentional action than I mean to imply with the notion of instant perceptual problem solving. In fact, I suspect, and have some evidence to show, that the processes through which we actively organize incoming pitch/time phenomena are closely linked with the very basic, sentient organizing of our bodies as we move through space and time. For example, it is the *sequence of actions* that we practice and internalize in the process of carrying out familiar activities—most particularly action-paths that we internalize in learning to perform a piece on an instrument—that become our most intimate ways of knowing that piece. I call these internalized action-paths "felt paths."[2]

Research Methodology and an Example

In searching for research questions that might effectively address some of these larger issues, I have found that the most compelling and also most productive questions emerge from puzzling events that occur in the course of my everyday work with students in the classroom, or in working on a composition in preparation for teaching or performing it. Once I recognize an issue, and when I find it impossible to turn a question or puzzle aside, I am led to the design of more formal experimental situations.

For instance, initial evidence that there are specific differences in the hear-

ings of familiar rhythms emerged first in children's drawings of rhythms, drawings that "happened" quite spontaneously in response to a practical necessity: As part of a composition project, the children in a fourth-grade music class had invented a rhythm they called their "Class Piece." The Class Piece was created during a regular class period and was to be played by all the children as a central part of their composition. But with much work still to be done on the composition, the children noticed that the class period was coming to an end. In response, one child suggested, "We had better put our rhythm on paper so we can remember it tomorrow." In the next 10 minutes, each of the children invented a way of "notating" the piece so he or she could remember it the next day. And, as is often the case with invention, there was an unexpected spin-off: While the drawings were indeed there the next day to help the children remember their Class Piece, subsequent analysis of the drawings suggested surprising but very specific differences among them.

The drawings fell into two types, which I tentatively labeled "figural" and "metric." The differences between the two types rested on the kinds of features and relations the children chose or were able to attend to: Those who made metric drawings, as the term suggests, focused their attention on *measuring* the relative duration of events. Thus, clapped events were classified with respect to "same relative duration"—for instance, all "longs" were drawn with one size shape (large) and all "shorts" were drawn with another size shape (small). Metric drawings, then, were based on a notational strategy that is similar to standard rhythm notation and thus could easily be mapped onto it. In contrast, figural drawings exposed for scrutiny functional aspects of musical structure that are not captured by standard music notation. These children focused their attention on the *grouping of performed events into phrases or figures.* The Class Piece, notated in standard rhythm notation along with prototypical examples of each type, is shown in Figure 5.1.

It was only after the distinction between figural and metric drawings had emerged from the spontaneous drawings of the fourth graders that I was able to design an experiment to test the robustness of that distinction. To do so, I asked 186 children between the ages of 4 and 12 to clap and draw five different rhythms, including the children's Class Piece. The data from this larger experiment confirmed the robustness of the initial distinction. In addition, it was possible to organize the wider range of drawings into a typology that included

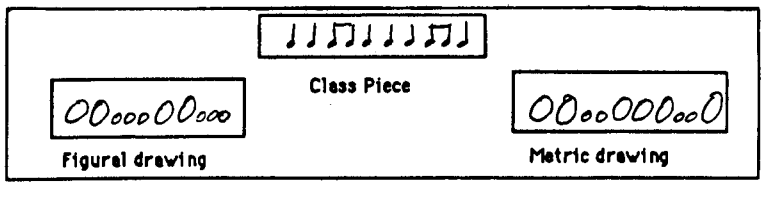

FIGURE 5.1. The Class Piece.

developmental tendencies within the figural/metric distinction (see Bamberger, 1980, 1981, 1988, 1991).

But the robustness of the distinction produced another unanticipated result: In discussing the drawings with the children and later with musically untrained adults who were asked to perform a similar task, it turned out that when subjects were asked to play back a rhythm from another's drawing, each type of drawer found it difficult to make sense of the other's. Figural drawers usually found a metric drawing to be inscrutable or they would suggest that "it must be a different rhythm"; metric drawers typically found a figural drawing simply wrong. (See Hildebrandt & Bamberger, 1979.)

Puzzling over this consistent and somewhat troubling response, it was important to remember that differences in subjects' drawings were reflecting, or were at least clues to, differences in their spontaneous hearings. It was not so surprising, then, that if a description of a hearing ran counter to one's own hearing, it was quite natural to find it difficult to grasp and more difficult to believe.

A Paradox and a Proposal

Considering that metric drawings give priority to the same kinds of entities as standard rhythm notation (SRN), while figural drawings give priority to entities that are not represented at all by SRN, it was also not surprising that regular users of standard notation (including some, but not all, professional musicians) had difficulty making sense of these figural drawings. At the same time, it is paradoxical that figural drawings express the ability to hear just those structures that professional musicians put great value on in their actual practice, namely, the grouping together of melodic events to form meaningful gestures, motives, or what I have called figures. To do so is often associated with what we call a "musical hearing," specifically with the performer's ability to "shape a phrase." In short, figural drawings show evidence of a musical intelligence we value—the mind behind a "musical ear."

It should now be clear that while figural and metric drawings point to different *kinds* of entities, both figural and metric relations are inherent in and contribute to the structure and coherence of rhythms; indeed, it is the particular intersection of metric and figural groupings that gives a rhythm its unique coherence. (See Cooper & Meyer, 1960; Lerdahl & Jackendoff, 1983.) And yet, the evidence suggests that musicians give a different status to the two aspects of musical structure—the one, metric relations, are considered "objective," the ability to recognize and encode them being associated with what can be taught and with knowledge in the domain; the other, figural relations, are considered "subjective," associated with intuition and musicality, even with the magic of musical "talent," but not easily notated and more difficult to teach and learn.

But in the interest of coming to hear in new ways, it would seem that rather than pitting one kind of structure against the other, or giving each a specially

favored status, what is required is to help individuals learn selectively, knowingly, and at will to shift focus among the possible features and relations that give a composition its unique coherence, and to coordinate these features in new ways. In short, we need to help individuals learn to make *multiple hearings* of even simple rhythms or melodies.

But the difficulty in doing so lies in the nature of the spontaneous hearings we make: a hearing, particularly of an apparent simple rhythm, is usually experienced all at once, and at the moment it is made, it seems immutable—how could it be heard otherwise? And assuming that these ineluctable hearings, like drawings of them, differ with respect to the features one chooses or is able to attend to, then to make a hearing other than one's own, may require a shift, perhaps even a fundamental restructuring of one's focus of attention—giving priority to different features, regrouping, making new boundaries that carve out new entities, and liberating from the meld features that were previously unnoticed, even inaccessible.

Making Multiple Hearings

How, then, can we help individuals to make multiple hearings? As a first step we need to ask: How can we help individuals *to become aware of their own hearings* of even a simple rhythm so as to recognize which of the possible aspects they are giving priority to in their instant perceptual problem solving? We can then go on to ask: How can we help them to shift their focus of attention so as to participate in and to experience a hearing that differs from their own?

In working with students in my MIT classes, I have found one way that seems to be effective in achieving these goals. These classes usually include students with varied music backgrounds and thus it is predictable that, when asked to notate a rhythm, some will make figural notations and others will make metric notations. It is also predictable that each type of student will defend his or her notation as "right," rejecting others as "wrong." My ploy is to bring the two types of students into direct confrontation with one another, the challenge being that each should try to "put on another's head"—that is, each should try to make sense of and to hear the rhythm in the way his or her counterpart does.

To illustrate this process and to help readers actually live through the sometimes confusing experience of coming to hear in a new way, I have created a dialogue between myself and two college students modeled after those that have actually taken place in these classes. I think of the two students as prototypical figural and metric types: One, whom I have called Met, hears rhythms *met*rically; the other, whom I have called Mot, hears rhythms *mot*ivically (or what I have been more generally calling a figural hearing). While the students initially hold firmly to their respective hearings, I encourage their confrontations and also try to mediate between them. Through this process, the two students eventually succeed in making sense of one another's hearings but only after struggling with

and revealing some of the fundamental assumptions that each of them holds. And since my experience strongly suggests that one or the other of these hearings is that of the reader, it is my hope that in following these conversations, the reader, too, will come to hear in a new way. However, I am also quite aware that to do so may require just as much work on the part of the reader as it does for Met and Mot.

In Which Met and Mot Come to Understand One Another's Hearings

The dialogue begins after I have asked each of the students to clap and draw the children's Class Piece. They have already looked at one another's drawings and are now in the midst of arguing about them. As shown in Figure 5.2, Mot makes a prototypical figural drawing, while Met makes a prototypical formal drawing. Met is a computer science major who is very forthright in his opinions. Met took clarinet lessons in elementary school and currently plays the guitar. Mot is a humanities major who has had no formal music training and is rather easily intimidated by Met.

MOT (*to Met*): I don't see how you can say that my third little circle should be a big one or a long. With a big circle there, it doesn't look the way it feels when you clap it.

MET: It just seems obvious to me that your third little circle has to be a big one—at least if the circles are supposed to stand for longs and shorts.

MOT: Of course they are. . . .

MET: O.K. But then it's very difficult for me to understand the rhythm the way you've drawn it.

JEANNE: Let me try to help. What I think Mot is paying attention to, and what I see in her drawing, are the little motives or groups of claps inside each of the larger repeated rhythms.

MOT: Yes, that's right. Inside of each larger repeated pattern there are two groups of claps—you can see them quite clearly with my two big circles and then three little ones. And in between the two larger patterns I sort of take a breath and start again. I could make the grouping even more clear with a drawing (Figure 5.3).

JEANNE: That's good. Now could you clap the rhythm again and while

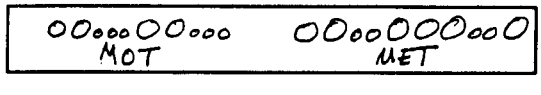

FIGURE 5.2. Mot's figural drawing and Met's metric drawing.

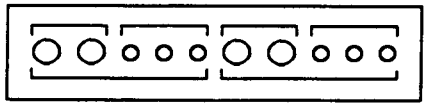

FIGURE 5.3. Mot's grouping structure for the Class Piece.

you are clapping say some numbers that seem to go along with your clapping?

MOT: Sure. It would be (*clapping the class piece*): 1 2 1-2-3, 1 2 1-2-3.

MET: But that's wrong again!

JEANNE: Please try to be a little patient, Met. Now, Mot, would you put the numbers you just said under the circles in your drawing so that we can see just what you mean? (*Mot adds numbers to her drawing; see Figure 5.4*).

JEANNE: O.K. Now try something else. Can you clap just the rhythm for the tune "Twinkle, twinkle, little star; How I wonder what you are" and, while you're clapping, say some numbers that seem to go along with your clapping?

MOT: (*clapping and counting*):

1 2 3 4 5 6 7 1 2 3 4 5 6 7
(Twin-kle twin-kle lit-tle star, How I won-der what you are.)

MET: Oh my!

JEANNE: All right, Met, so how would you count it?

MET: It's obvious. (*Met claps and counts*):

1 2 3 4 1 2 3 4 1 2 3 4 1 2 3 4
(Twin-kle twin-kle lit-tle star, How I won-der what you are.)

JEANNE: Does that make any sense to you, Mot?

MOT: Not really. I especially don't understand why Met keeps counting up to 4 and then starting over again with 1.

JEANNE: Well, let's leave that problem for the moment. Could you draw a picture of the rhythm of Twinkle like you did for the Class Piece, Mot, and then put in numbers just like you said them when you were clapping?

MOT: I think so. (*She draws and numbers her graphics; Figure 5.5*).

MET: Now you're getting some place! Did you notice that you left a space between the two phrases, I mean between the words "star" and "How I"?

MOT: Of course. That's where you sort of inhale, take a breath. Like I

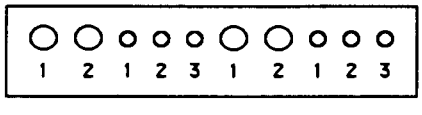

FIGURE 5.4. Mot adds numbers to her drawing of the Class Piece.

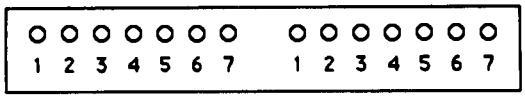

FIGURE 5.5. Mot adds numbers to her drawing of "Twinkle, Twinkle, Little Star."

said about the Class Piece, you take a breath and then start again.

MET: Exactly. But you have to *count that breath*, too—that stop before you start again.

MOT: What do you mean?

MET: Well if I count up the way you were counting up, then it would be like this: (*Met writes his numbers above Mot's drawing; Figure 5.6*).

MOT: That's interesting! You mean it's like there's a ghost beat there (*she points to the space where Met has written an* "8"). You don't actually sing or clap the ghost beat, but it's there anyhow.

MET: A ghost beat; I really like that. You see, time never stops, and the beats keep right on going, too, so you have to keep right on counting, right through the breath, even though you're not making any clap there.

MOT: Why don't we actually put the ghost beat in—the one you call "8." (*Mot draws her ghost beat; Figure 5.7*).

MET: You got it.

MOT: And now I see how you got your "8." Where I counted up to 7 and stopped, you counted up to 8 because you counted the ghost beat, too. So the ghost beat is the stop which sort of isn't a stop after all. But still, it is a stop, you know. I'm getting confused again.

JEANNE: But confusions need to be nurtured, too; they are often the necessary first step to learning anything new. Mot, would you mind clapping the Class Piece, again? And this time pay attention especially to the breath you talked about between the two larger figures.

MOT (*clapping the class piece again*): Hmm. Yes, it seems like there's a space there, too; I mean between the two larger figures. Or I guess you could call it a space-of-time. How come I didn't notice that space before?

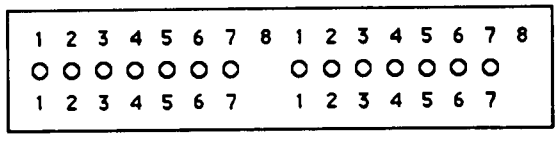

FIGURE 5.6. Met's numbering for "Twinkle, Twinkle, Little Star."

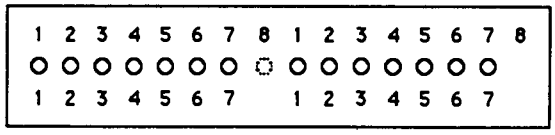

FIGURE 5.7. Mot's "ghost beat" in "Twinkle, Twinkle, Little Star."

JEANNE: Well, what do you think?

MOT: I seem to come to a boundary. I mean, when I clap the rhythm it's like I'm going along heading for a goal. For instance, I'm going along the path inside the inner fast figure till I come to the goal; and then I'm just inside the next figure, going along that one. I never paid attention to what was going on in between the two larger figures. In fact, there really wasn't any in between; I was simply in one figure and then I was in the other. The rhythm of Twinkle made me realize there is an in between. I sort of get it, but I don't.

JEANNE: That's quite understandable; it's hard to pay attention to all the different things that are going on: the claps you're making as you move along anticipating the goal or boundary; then arriving but also going across the boundary crossing. I think the way you talked about being inside one figure, moving along the path to the goal and then inside the next one, really captures what it feels like when you're actually clapping a rhythm.

MET: Sounds pretty strange to me. The rhythm is just there. . . .

MOT: Wait, I just realized something else.

MET: What's that?

MOT: I could put a ghost beat into my picture of our rhythm, too. (*Draws the Class Piece adding a "ghost beat" between the two larger figures; Figure* 5.8).

MET: That's great!

JEANNE: Do you think you could clap the Class Piece and actually clap the ghost beat, too, Mot?

MOT: I can try. (*Claps the Class Piece and includes the "ghost beat" as in Figure* 5.8) It seems like you almost expect that ghost beat to be there, but instead there's nothing.

MET: There isn't nothing. If there were nothing, you would clap it wrong. In fact, that's interesting—you clap it right, but you draw it wrong. Think about it this way: The *breath* you were talking about exactly takes up the space, I mean time, of your ghost beat.

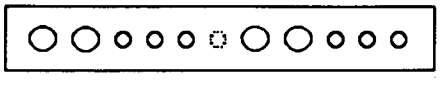

FIGURE 5.8. Mot's "ghost beat" in the Class Piece.

JEANNE: Good point, Met. And that suggests another question: Mot, how many faster claps would you say there are for each slower one?

MOT: Well, I think the little ones go twice as fast as the big ones. So I guess there are two for one. In fact, you could say there is a ghost beat inside of every big circle, too.

JEANNE: Could you explain that a little more?

MOT: It's hard to explain. . . . It seems like there's always a silence, a space, between every clap sound and I think the time of the actual clap sounds is always the same. So it must be the space-of-time between clap sounds that makes the difference between longs and shorts. Gosh this is getting so detailed!

JEANNE: But getting down into the details is useful, provided you can integrate what you've learned down there into the larger design when you climb back up again.

MET: Anyhow, what we are calling the length of a clap is really the clap sound and the gap before the next clap sound.

MOT: Yes, the length of the clap is really a package that includes both the clap and the gap. But when you're actually clapping, you don't think about that at all. With the first two claps you set a natural pace, and then you double it . . . or halve it. . . . Which is it, anyhow?

MET: When you start the faster claps, you double the speed but halve the time from one clap to the next.

MOT: This is beginning to sound like physics, not music.

MET: Not really. But now it should be obvious that if there is a clap and a ghost beat inside of every big circle like you said, then your fifth short clap, together with your ghost beat, will make up one longer clap. So the fifth clap that you've drawn as a little circle together with the gap is a slow clap so it should be a big circle—it's just the same as the slow sixth clap. (*He draws*; *Figure* 5.9).

MOT: But now that just doesn't look right. I can't see the larger repeated patterns any more. And besides, the fifth clap isn't just like the sixth clap. The fifth clap is an *ending*, the sixth clap is a *beginning*, it starts the repetition, and that's not the same at all!

MET: Well, that's all beside the point.

JEANNE: No, Met, that is the point! You see, Mot is saying something very important. It's true that both the fifth clap and the sixth clap are the same if what you're paying attention to is simply measuring the time from one clap to the next. But that's not all there is to rhythms. Did you notice, for instance, that Mot talked about "beginnings" and "endings"?

MET: I did, but . . .

JEANNE: What do you make of that?

MET: Well, I guess you can't have a beginning and an ending without

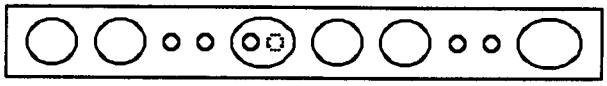

FIGURE 5.9. The fifth clap together with the "ghost beat."

something happening that makes a start and stop. So Mot's first little circle or faster clap *starts off a new thing*—what you would call a new figure; and the last of her little circles (that fifth clap, again) ends the figure, or more like stops it.

MOT: Yes, and that's exactly why your big circle for the fifth clap gets me so upset. If you draw the fifth clap as a big circle, it makes the fifth clap look like the beginning of a three-clap slower figure when really the fifth clap is the ending of the previous faster figure.

MET: But we're not talking about how things *look*. I think we're getting off the track; we're supposed to be talking about time and motion, not about how things look standing still in space. Now I'm getting confused.

JEANNE: That's a beginning, too, Met. In fact, what you just said is the beginning of a real philosophical insight, so just hang onto your confusion for a bit. What do you think makes an event function as the beginning or the ending of a figure?

MOT: I've been wondering that, too. It seems like the function of a clap—whether you hear it as beginning or ending a motive—depends on where it happens—what comes before and after it. For instance, when I start clapping the rhythm, I sort of set the normal pace with the first two claps. So when I start going faster with the third clap, or really when I go from the third to the fourth clap, it feels like the beginning of something new. That new pace sets off the new figure.

MET: And I suppose the next one, the fifth clap that we keep arguing about, stops that run of claps. You get going at this new faster pace and when you get to the fifth clap it's longer than what you expect.

MOT: Well, I'd say it's because what you expect doesn't happen.

MET: I don't get it.

MOT: I mean, you're going along faster, and then you're stopped short because nothing happens. All right, I know, Met, we've been through this before; it's the gap, the ghost beat that's there but you don't actually play it. But that silent ghost beat is more like a comma at the end of a clause. So I guess another reason I made a small circle for the fifth clap is because I was drawing the claps I actually made and not the silent punctuation mark. After all, when we're reading out loud, we don't say commas either; we

just make a little pause and that helps you to group the words so they make sense. Anyhow, just because the fifth clap has the same time as the sixth clap that comes next, they're still not the same.

JEANNE: Now, let's see if I've got it straight. What I hear you saying, Mot, is that even if two events have the same time value, they can still be different depending on where they happen. To use your example, if there's a change to a faster pace, that will set off a new little figure. Then you are moving along inside the new figure at that faster pace, expecting that pace to keep going. But when that pace changes because there is a silence where you might expect another event to occur if the faster pace continued, the new figure is brought to a halt. And that's what makes the boundary.

MOT: That's right.

JEANNE: But Met wants to make things simpler.

MET: Exactly. Since the fifth clap and the gap after it together make a long, it's a long event. What's the problem?

MOT: But if you only pay attention to how *long* an event lasts, never mind where or when, then you'll miss the boundaries altogether. And you will also miss the functional differences between beginning and ending events.

MET: That's funny. I never thought of it before: In a rhythm "where" and "when" mean the same thing.

MOT: That's true. Anyhow, a long after a run of shorts just isn't the same as a long after a long.

MET: Wait a minute, are you trying to tell me that the same two claps can be both the same and different at the same time?

MOT: Yes, depending on where they happen and what you're paying attention to.

JEANNE: Well put, Mot. And that turns out to be very important when you're performing a real piece of music. For instance, even though two notes have the same time value—let's say they both look like this in standard music notation (*she draws* ♩ ♩), you might very well play them differently exactly in order to express a beginning in contrast to an ending of a motive or a phrase. And the difference might involve, among other things, just how long you sustain a note. That is, inside the same sound-silence package, what we usually call the same notated duration, there can be a different relation between the sound and the silence. But when you're really playing a piece, you don't think about it at that level of detail; if you did, you'd feel paralyzed. It all becomes part of expressing the meaning of the piece, including its motives and phrases.

But the funny thing is, that while conventional music nota-

tion in its barest form is very good at showing you the time value of events in relation to one another, it really doesn't tell you anything about beginnings and endings of phrases or figures. That's why violinists, for instance, spend so much time and thought experimenting with bowings and fingerings, and clarinetists worry so much about where to take a breath—they're trying to find the best way to project these important differences between notes that look the same on the page. For instance, in some of Bach's suites for violin solo, practically all the note values are the same. Can you imagine what that would sound like if the violinist wasn't paying attention to the differences in the functions of events that otherwise look the same timewise? Composers, or sometimes editors in the case of Bach, try to help by adding various kinds of so-called expressive markings—slurs, or staccato marks like these (*she draws; Figure 5.10*).

But still, if you strictly follow the rule "what you see is what you get," you'll hear a pretty boring and very unmusical performance. I remember Louis Krasner, the violinist who commissioned the Berg Violin Concerto, saying to a student, "Just forget the score and play the music." But to get back to where we were, yes, two events can be both the same and different depending on the context and on what you're paying attention to.

MET: That reminds me of a picture I saw in a book on vision, once. When you look at it, you see this same shape in two different ways depending on what's next to it (Figure 5.11). At first it seems like you have no choice—you see two different shapes, a diamond and a square. But if you really pay attention to the geometric properties—just stare at the angles and the sides of one shape at a time—of course you can see that they're the same. So, yes, you could say they're both the same and different depending on what you're paying attention to.

MOT: That's a great example, Met.

MET: But you know, we keep shifting back and forth between time and space, and that makes me think of something else. Talking about performers and experimenting, let's try one. You, Mot, pull this piece of paper slowly across the table. While you're doing that, I'll move my pencil up and down in one place, tapping out the rhythm over your moving paper.

(*Mot and Met make the experiment. It leaves this trace; Figure 5.12*).

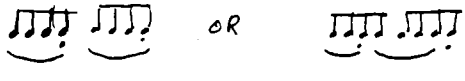

FIGURE 5.10. Slurs as expressive markings.

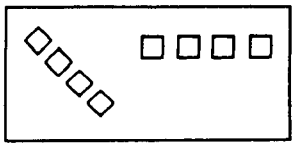

FIGURE 5.11. The same shape can look different.

MOT: That looks fine. You can see the repeated big patterns and the little inner figures, too. How come that works?

MET: Well, because we really made time become space. The trace left behind shows how continuous time or motion—the paper moving across the table—was marked off by my taps. That's the way the old piano rolls worked, and the first mechanized looms, too. First the paper was punched out as someone played—much like we just marked off the moving paper. Then, whenever the sensing mechanism moved across a hole in the paper piano roll, a piano key would be activated. So spatial relations turn into time relations or rhythms.

MOT: I guess I understand, but I keep getting confused between the dots and the spaces between the dots.

MET: Well, just reverse the process. Run your hand at a steady pace over the dots we made and every time you come to a dot make a click or something (*Mot tries it.*)

MOT: It works, all right. And I can really see the faster inner figures, too; the run of three faster claps stands out because there's a bigger space on either side of it—that's really a space-of-time, of course. In fact, what you see is the change of pace that actually generates the boundaries of figures.

MET: And putting it that way helps me to understand your drawing better, Mot, and to hear what you mean by figures, too.

MOT: Well, I'm glad of that. But what about the last clap—you could just go on forever.

MET: As a matter of fact, that's been bothering me all along. You can't know how long the last clap is because it always takes two to tango. I mean, seriously, you always need two claps to mark a time interval. It's your beginning and ending problem, in a way, but on a smaller scale: a beginning by itself, one mark or one clap, like you said, can go on forever; you need another one to stop it. But then, of course, you wouldn't know how long that one was.

JEANNE: This is getting pretty metaphysical. I really liked your experiment, Met, and I especially like the trace it left behind. It's a new notation that I think might have real possibilities.

FIGURE 5.12. The trace left by Met's experiment.

MET: By the way, you said I'd made some kind of philosophical insight back there. Aren't you going to tell me what it was?

JEANNE: Actually, the two of you sort of acted it all out just now. It was about the problems we make for ourselves when we try to describe actions moving through time. We make descriptions of moving things on paper in order to make them stand still, but then we end up with all these issues and confusions about time and space—like the ones that you've both noticed as we've been going along. When you learn how to make motion stand still like you've just been doing through your drawings of rhythms, you gain real power because then you can see, all at one time, what we necessarily experience as fleeting, evanescent, gone.

For instance, it was only after Mot had made her drawing of Twinkle that she was able to invent her ghost beat. Once the rhythm was held still in paper-space, then she could see the bigger space between the two phrases. And once seen, she could also recognize it as really a space-of-time. Only then could she catch on to what Met was saying, even if not totally agreeing with him. Making these static, spatial descriptions solves the problems of time and motion that Heraclitus might have put this way: "You can never put your foot in the same river once."

The trouble is, we are able to find ways of making actions and motion stand still on paper through the invention of a notation system, and that is very useful, even sometimes profound. But once it is made and deeply internalized through continuous use, we come to believe in the notation so thoroughly that we actually experience whatever it is—clapping, wheels turning, drummers drumming—through the lens of the notation, itself. So we go from Heraclitus's problem to taking literally what-you-see-is-what-you've-got.

MET: This has all been more interesting than I thought it was going to be at the beginning. And I think I do understand, now, what you were showing in your drawing, Mot.

MOT: Thank goodness. Things got better once you calmed down, Met. And I have to say I learned a lot, too. In spite of your unpleasantness at the beginning, and in spite of feeling like my head was swirling around some of the time, you helped me get at things I probably would never have gotten to by myself.

Comments on our Dialogue

While Met and Mot begin their conversation in what seems like irreconcilable conflict, by the end they have clearly come to a resolution of their sometimes

contentious disputes. But interestingly, they have done so without either of them giving up the hearings expressed in their initial drawings. Instead, by actively confronting one another, each helped the other to notice features and relations of the rhythm that had been essentially inaccessible at the outset. In short, each has succeeded in making the hearing of the other but without either of them giving up his or her own.

And in the course of this educational resolution of their figural/formal disputes, Mot also answers a question that has remained quietly waiting beneath all the discussion of figural grouping: What are the temporal relationships that *generate the boundaries* of figures that figural drawings describe? Through Met's experiment—Mot pulling the paper while Met taps out the rhythm with his pencil—Mot is able to see that "the run of three faster claps stands out because there's a bigger space on either side of it—that's really a space-of-time, of course." In other words, it is a *change of pace* that generates the boundaries of figures. And in summarizing her comments, I point out that if there is a change from a slower pace to a faster pace, it will set off a new little figure; and within that faster pace if there is an event of longer duration, that will bring the new figure to a halt, thus creating a boundary.

Such contrasts in the prevailing rate of events can suffice in accounting for figural boundary making within these musically minimal examples—in particular, where events differ only with respect to their time values. But an account that may suffice for brief rhythms played on a nonpitch instrument (claps) and where there is not even any change in loudness will hardly suffice at the moment we consider "real compositions" such as a Beethoven piano sonata movement or a movement from a Bach partita with their much richer network of intersecting, sometimes conflicting, dimensions. Indeed, the issue of what generates grouping boundaries, and how hearings may differ with respect to the groupings heard, is a vexing and fascinating topic to which a number of music theorists have given their attention in recent years. (See Cooper and Meyer, 1960; Lerdahl and Jackendoff, 1983; Bamberger, forthcoming.) And yet, musically impoverished examples such as the Class Piece are useful because they can help to make clear just what kinds of questions we need to ask, what kinds of clues we need to look for, and how seemingly irreconcilable conflicts among disparate hearings might be resolved.

Conclusions

In the dialogue between Met, Mot, and myself, I have shown an instance of just how such clues to hearings can emerge, and how, through recognizing them, hearings can develop and change as each participant brings into existence features and relations that were inaccessible at the outset. For example, Mot's initial drawing provides clues that her attention is focused on the grouping of adjacent events as these form figures. And despite Met's objections, she seems unable to

recognize, or is at least inattentive to, the shared proportional time values of some events. Met, recognizing these clues, helps Mot to hear that "time keeps on going" and that she needs to count the time "in between" clapped events, as well. This leads Mot to invent her "ghost beat," which, in turn, helps her to bring into existence, so to speak, an entity that had simply not existed for her before. And once seen, this new entity also helps Mot to understand why Met insists that the disputed fifth clap in the Class Piece should be a big circle instead of a small one—even though she doesn't like "the way it looks."

Met's initial drawing shows us clues to his singular focus on the measured time properties of events—all events that share the same event time are for him simply the same. Despite Mot's repeated attempts, she is at first unable to help Met shift his focus so as to hear her figures. But as she recognizes a critical aspect of her own hearing, Mot is able finally to help Met, too. Pointing out that even though two events may share the same time value, their *function* can change depending on the context in which they are embedded, Met is finally able to hear and appreciate the significance of the figural groupings within the rhythm. And in doing so, he too brings into existence an aspect of rhythms that had not existed for him before.

Through this process of reflective confrontation, then, new features emerge, making it possible for both students to include in their hearings new aspects of even these trivial rhythms. And it is this "liberation" of new features that eventually enables Met and Mot to resolve their disputes. With each having access to the preferred features of the other's hearing, they are able to agree that two events can be both the same and different *depending on what you are paying attention to:* Specifically, even though two events may be the same in that they *share the same event time* (e.g., claps 5 and 6), they can still be different with respect to their *figural function*—"where and when they happen" and what role they play as the rhythm unfolds in performance. Thus claps 5 and 6 are indeed the same with respect to their time values, but they still differ in their functions—one an ending, the other a beginning.

This, then, is an example of individuals coming to hear in new ways. Through the work of the two students, I have tried to illustrate that to make a new hearing we must confront those intimate, silent conversations back and forth through which we make and shape the meaning and form we seem simply and immutably to find in the musical phenomena "out there." I have also tried to show that one way to do that is to confront and perturb the hearings of others so as to become aware of *possible* aspects of a rhythm. For in that way we learn to recognize just those aspects to which we are currently giving privileged attention in making our own hearings. Experimenting with one another's hearings, then, we can learn to shift focus at will among the possible features and relations that give a rhythm, or even a moment in a complex composition, its unique coherence.

And through this process, knowing how and knowing about develop a new, *reciprocal* relation to one another in contrast to the adversary relationship I

proposed at the outset: Interrogating what it is you know how to *do* becomes the means for learning to know *about* the music you can sing, clap, or dance to. Thus, instead of knowing about being distanced in and through the privileged languages of others, knowing about becomes a useful way of informing what is most intimate and most familiar. Together, then, knowing how and knowing about, in reflective interaction with one another, help us to hear in new ways, at the same time giving us the power to choose selectively and knowingly among the multiple possible hearings that we are able to make—depending on where, when, and what we want to use them for.

Music Performance: Expression and the Development of Excellence

JOHN A. SLOBODA

Introduction

Music performance is a skill. As with any skill, there are two main psychological questions: What is the skilled performer like (the nature of skill) and how did the skilled performer get to be skilled (the acquisition of skill)? In the last two decades psychologists have given these questions intensive study (e.g., Anderson, 1981; Chi, Glaser, & Farr, 1988; Ericsson & Smith, 1991).

From studying a very wide range of skills (e.g., chess, sport, medical diagnosis, mathematics), a number of general conclusions have emerged. First, skill almost always depends on the ability of the performer to detect pattern and structure in the material, and to conceive the activity in terms of these patterns. Second, the level of skill is almost entirely dependent on the amount of relevant practice undertaken. In other words, learning to detect patterns and structures takes time, so the more time you have spent on a skill, the better you are at it. Third, as skills become practiced and fluent, they tend also to become "automatic"; that is, the details of how they are executed disappear from the conscious awareness of the performer. Fourth, because patterns and structures tend to be specific to a particular domain, there is little transfer between skills. A person can become very good at one skill (e.g., chess) while remaining very poor at another (piano performance). Partly because of this, some skills seem to be independent of general intelligence, and the psychological literature contains numerous examples of people with low general IQ who nonetheless excel at particular cognitive tasks (e.g., Ceci, 1990; Howe, 1989).

All these conclusions are true of music as well. The present chapter concentrates on the evidence for the first three of the above conclusions. For

discussion of the fourth conclusion, including some fascinating studies of musical skill in the absence of high general intellect, the reader is referred to Howe (1991) and Miller (1989).

The chapter concentrates on a key aspect of music performance, that is, the ability to play notated solo compositions expressively. For a discussion of wider aspects of performance, including improvisation, ensemble playing, sight-reading, and performance anxiety, the reader is referred to Sloboda (1982, 1985, 1988).

The final prefatory comment concerns the status of music performance research. Although such research has a long history, it has, in recent decades, been eclipsed by studies of musical perception. This partly reflects a fact of our culture, that many more people engage in music passively (through listening) than they do actively (through performance). But it may also reflect the fact that experimental science likes to control situations in a rather tight way. It is much easier to do this when constructing computer-generated musical sounds than when confronted with a free-performance situation. Nonetheless, in the past decade, performance studies have reestablished themselves as able to meet the rigors of experimental science while addressing questions of theoretical and practical importance in fairly realistic settings.

Expressive Performance

The Rationality of Expression

Technical mastery of a difficult composition is undoubtedly an impressive achievement. We can admire such qualities as rapidity of playing, evenness of touch and timing, and large-scale accurate memory. Yet these things, necessary as they are to musical performance, are insufficient to justify the huge effort that goes into producing top-class performers. If that was all there was to performance, we might as well program scores into a computer, have them performed on instruments via a digital interface, record "perfect" performances once and for all, and close our conservatories!

It is well known, however, that computer renditions of familiar compositions sound dull and lifeless, no matter how fast or accurate they are. Human performances gain their lasting interest and appeal from the fact that they go beyond the information contained in the printed score. It was one of the earliest discoveries of the scientific studies of music performance (see Seashore, 1938) that musicians rarely play two apparently identical notes (from the point of view of the notated score) in the same way. Timing, loudness, tone quality, and intonation can be substantially varied, even within the same measure. Such variations together constitute what we usually call "expression." Variations in expression are what make one note-perfect performance different from another note-perfect performance. They explain why we bother to hear different people play the same piece. They explain why it is worth training successive generations of performers to repeat the same classical repertoire over and over. New and insightful interpretations are always possible.

Most musicians would agree that assigning expressive features to a performance (i.e., deciding on an interpretation of a composition) is a rational enterprise. That is to say, we agree that it matters which notes we vary and how. We can compare different interpretations and offer reasons why we feel one interpretation to be more appropriate or pleasing than another. This is not to say that there is only one acceptable interpretation of a piece of music. There may be an indefinite number. Rather, it is saying that there are criteria by means of which most musicians could come to a judgment that certain possible interpretations are not appropriate to the composition. Expression is not some kind of random or arbitrary variation that we apply to a performance. The structures in the music constrain the expression. Performance and pedagogical traditions constrain the expression. Dialogues between performers, teachers, judges, and critics formulate and make explicit these constraints and apply them to particular pieces and particular performances.

There is, however, a difference between saying, on the one hand, that an activity is rational and, on the other hand, that it is a matter of explicit conscious

awareness to the performer during performance. On any particular occasion, a performer may be unaware of the exact nature of all the expressive variations that are being used, or may be aware only of some rather high-level description of the nature of the expression (e.g., "jerky") rather than the precise means by which this expressive quality is being produced. This has been demonstrated in several experimental studies. For example, Gabrielsson (1974, 1988) asked performers to produce absolutely strict rhythms, as notated, yet they produced performances that consistently deviated from strictness by making some notes shorter than their notated values, other notes longer. It appears that some types of expressive variations have become so automatic for some performers that they are not usually aware of them. Psychological investigations of performance expression cannot, therefore, proceed purely from verbal accounts given by performers of what they do. We actually have to measure performance parameters with a high degree of accuracy. The development of sophisticated computer-instrument links (e.g., the MIDI interface) has made such studies relatively easy, and the last 15 years has seen a steady growth in performance studies.

Quite a lot of the experimental research on performance has been devoted to showing that expressive variations are, indeed, rational, related to musical structure, and have a clear effect on perception. Such research is, however, nowhere near providing a complete explanation for, or prediction of, every expressive parameter of a performance. Musicians who are afraid that this kind of study will rob them of their art have really grossly overestimated the power of contemporary scientific investigations. Attempts to synthesize expressive performance by the computer application of expressive rules (e.g., Sundberg, 1988) are still rather primitive and pose no strong threat to real performers!

Experimental Studies of Expression in Performance

The first step in establishing the rationality of expressive performance is to demonstrate that expressive variations are *intentional*. There are two kinds of variation present in performance which we would not consider as intentional. The first we could call "noise." Every human performer has variations that reflect such limiting factors as muscular control or time estimation. These limits will create small random fluctuations. Hopefully, practice and experience will reduce the magnitude of these variations, but there will always be a residual "jitter." Because of the random nature of noise we would not expect it to show itself in identical ways in two performances. Therefore, the way to find out what is noise and what is not is to ask a person to repeat the same passage of music with exactly the same interpretation, several times over. Only those expressive variations which show up each time can be counted as intentional.

A number of studies of musical performances by professionals have shown a remarkable consistency in successive performances of the same piece (Seashore, 1938; Shaffer, 1981, 1984; Shaffer, Clarke, & Todd, 1985). For instance, Shaffer (1984) compared three performances by the pianist Penelope Blackie of a

Chopin étude, two of which were given a year after the first. Beat duration is plotted in Figure 6.1, which shows a remarkable consistency, not only in the location of major slowings (measures 20, 28, 53, and 57), but also in the distribution of beat durations within a measure (for instance, in measure 30 the first beat is always longer than the second).

The second kind of "unintentional" performance variation comes about be-

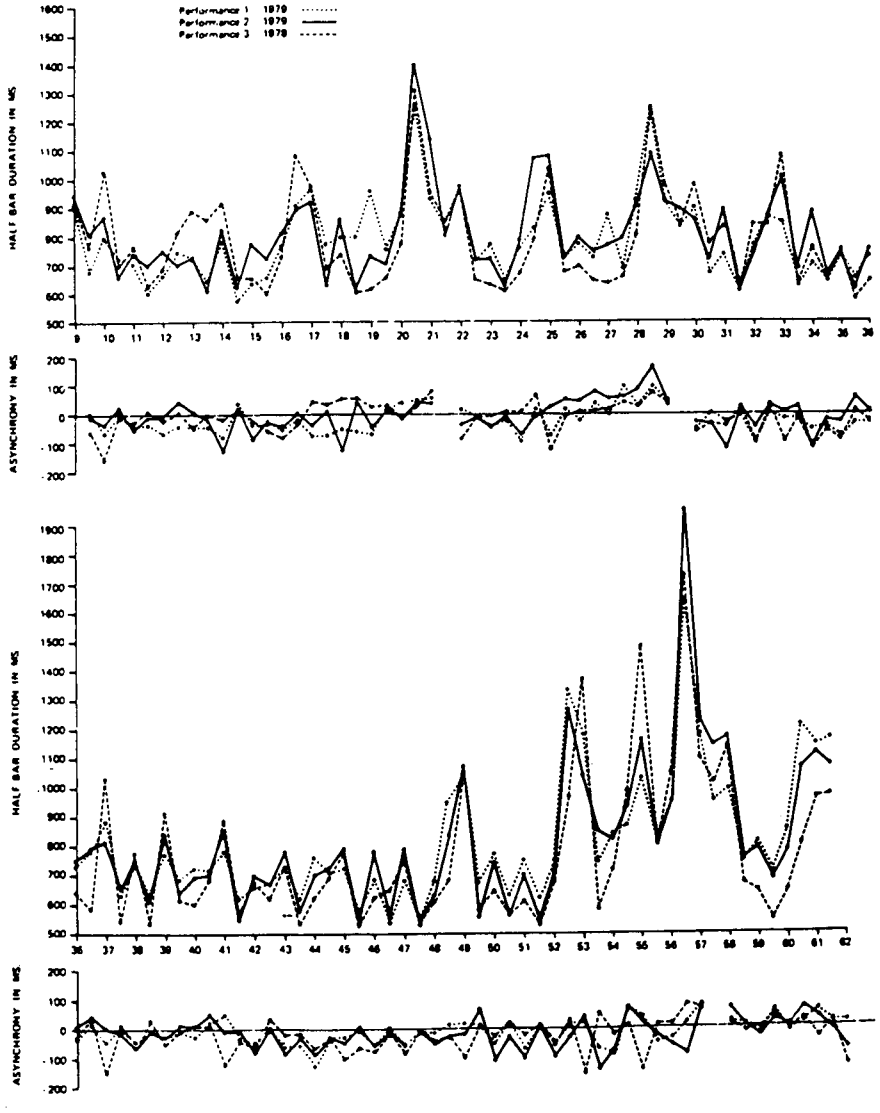

FIGURE 6.1. Beat duration in three performances of a Chopin Etude by the same pianist (Shaffer, 1984).

cause of some technical difficulty. Suppose, for example, that a pianist slowed the performance prior to every large intervallic leap. We would soon suspect that the sheer distance between two notes was the unintended cause of the delay, and would advise the pianist to go away and do some more practice. The most convincing way of showing that this kind of problem is absent is to find instances where exactly the same set of notes is played in two quite different expressive ways. If we can find such instances, then neither expressive pattern can be due to a technical difficulty. Sloboda (1983, 1985) used this method in a study where pianists were asked to provide five consecutive performances at sight of a set of simple melodies. Unknown to the performers, each melody was paired with a "twin" produced by shifting the bar-lines one note along the original melody, leaving the actual notes, their speed, and the fingers with which they were to be played exactly the same. An example of such a pair is shown in Figure 6.2.

Because the members of a pair were always separated by other melodies, no performer realized that the notes were identical. Despite being identical in all respects other than metrical location, the two melodies were played quite differently by all performers. Furthermore, these differences related very closely to the metrical structure. For instance, performers tended to make the first note of a measure significantly louder, longer, and more legato than the notes on either side. These differences were, therefore, truly intentional, even though the details of them may not have been fully available to the conscious awareness of each performer.

The results of this research help to elucidate the reason why a shared language of expressive "rules" does not lead to uniformity in performance. Each pianist's performance of a given melody in this study was quite different from every other pianist's performance although all used the same basic expressive strategies. This is because each pianist varied the extent, degree, and precise location of the variations available. Some pianists made more use of duration parameters, others of loudness. Some made large variations, others made more subtle ones. Some marked every measure, others marked only selected measures, and so on. Even within a fairly tightly defined "rational" expressive system, the potential for individual variation is still immense. There are many "free" parameters, even within a constrained system. We may suppose that the way which different performers "fill in" these free parameters is what is responsible for their unmistakable individual style that permeates all their performances (Sloboda, 1985). Connoisseurs of particular genres can often tell within a few measures of a recording who the performer is.

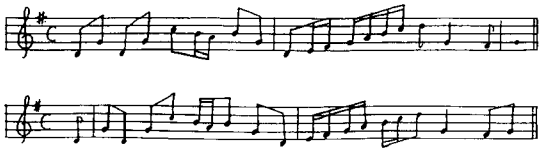

FIGURE 6.2. A sample pair of same-note melodies used in Sloboda's (1983) study.

The Effectiveness of Expressive Performance

It is one thing to show that measurable and intentional expressive variations are present. It is quite another to show that these variations are *effective*. What, in the context of music performance, do we mean by effective? First, differences in expression must be *detectable* by listeners; second, they must be *interpretable*. The first condition is there to ensure that expressive variations are large enough to make a difference to listeners; the second, to ensure that the variations mean something to the listener, at either an intellectual, aesthetic, or affective level.

Psychological studies of expressive musical communication have tended to remain at the level of intellectual judgment. So, for instance, Sloboda (1983) showed that listeners had some ability to correctly judge which member of a twinned pair of melodies a particular performance was representing. Different performers, however, had differing levels of success in conveying meter. This seemed to relate to performance experience. The most experienced pianist in the sample had 40 years of professional playing, and he was the most effective in conveying meter to a panel of listeners. The least experienced player had only (!) been playing for 12 years, and was the least effective communicator of meter. The most effective communicator was both more consistent and more exaggerated in the use of expressive devices. The least effective communicator showed some inconsistencies, with some expressive variations going against the "rules" extracted from the majority of the performances.

Meter is only one small part of what an expressive performance might communicate. Palmer (1988, 1989) in an extended series of studies showed that pianists asked to exaggerate or accentuate a melody tended to make the melody notes precede other notes which were notated as simultaneous. When asked to exaggerate or highlight a particular phrasing, they tended to increase rubato at intended phrase boundaries (similar results have been obtained by Todd, 1985) and increase legato playing within the phrase. In one experiment, pianists were asked to play the same piece in three different ways—as they normally do and then two exaggerated performances which accentuated different melodies or phrasings. Listeners tended to be able to accurately judge which performance was intended. Palmer also showed that it was, indeed, the timing variations that communicated the intended interpretation to the listeners. She resynthesized the performances by computer in such a way that all timing variations were eliminated while the loudness variations of the original were retained. Listeners were poor at identifying expressive intention from these resynthesized performances.

Davidson (1991, 1993) has recently shown that not all of the expressive intent of a performance is necessarily contained within the sound parameters. Her studies demonstrated that the body movements made by performers while playing contribute to the expressivity of the performance as judged by observers.

Movements of wrist, torso, and head tend to be systematic and related to specific structural features of the music. It is as if such body movements draw the observer's attention to particular parts of the music, enhancing their salience. Even when performers are asked to play the music "deadpan" (i.e., without expression), small but detectable body movements still occur. These are of exactly the same type as the movements observed when the performer is asked to play expressively and occur at the same points in the music. Just as in the Gabrielsson (1974) study discussed earlier, these movements seem to have become automatic. Davidson's results raise some interesting questions about the context of musical performance. Do they help explain why live performances are often so much more engaging than recorded ones? Does our society's increasing dependence on audio recordings of music mean that a whole dimension of musical expressivity is being downplayed or abandoned?

Summary

It has become increasingly clear from performance studies of the type described here that expressive variations in music are not simply a matter of arbitrary convention. They actually help listeners assign a structural interpretation to a passage of music that is the one intended by the performer. Many theorists (notably Lerdahl & Jackendoff, 1983; see Chapter 3) believe that an important part of what it is to have understood a piece of music is to have assigned to it a structural description in which related notes are grouped together, and in which different events are assigned different importance or prominence. Lerdahl and Jackendoff propose that this description is arrived at by assessing various cues in the music and then trying to achieve an interpretation that is consistent with them. In some musical passages, all the different cues (rhythm, harmony, articulation) are consistent, and so strongly suggest one structural description. In other cases, there are several possible descriptions, and the performer's role may well be to add expressive cues that will incline the listener toward one or another interpretation. These cues follow from general principles of musical perception. For instance, all other things being equal, notes that are longer than their neighbors will be heard as more prominent. Therefore, if a performer wishes to disambiguate a metrically ambiguous passage, he or she will tend to lengthen the first note of a metrical unit.

The Development of Excellence in Performance

Talent Versus Learning

There can be few questions which are of more intrinsic interest and pressing practical concern than the question of how music performers acquire high levels of expressive skill. Why is it that musicians differ in their level of expressivity? It

has been common to discuss differences between musicians as differences in "talent" or "musicality." Yet, on their own, these words are simply redescriptions of the phenomenon to be explained. How *is* it that one person is more "musical" than another? The implicit assumption behind such language is that these differences are inborn or innate. Yet there is remarkably little evidence to support such an assumption. Studies by behavior geneticists (see Coon & Carey, 1989) suggest that the impact of environmental variables on musical achievement is unusually high when normal methods of estimating heritability (i.e., twin studies) are used. The validity of such twin studies has, of course, been widely questioned in any case (Ceci, 1990; Rose, Lewontin, & Kamin, 1984).

An alternative perspective, and one which follows rather naturally from the view that expressive performance is a rational activity closely related to the performer's understanding of the musical structure, is that such performance is a cognitive skill that is learned. If this latter perspective is correct, then to call someone exceptionally talented is to assert no more than the fact that such a person has had a certain sort of exceptional life, in which crucial and statistically unusual experiences occurred, allowing the development of skill beyond the norm. As I have argued elsewhere (Sloboda, 1990), exceptionality cannot be observed by its inherent qualities, as it were from within the person. A person is only exceptional in a certain cultural or historical context by virtue of doing better than most other people. For instance, the normal reading ability of a contemporary high-school graduate would have been considered totally exceptional 500 years ago.

Few people would consider it plausible to explain the general increase in reading efficiency by a massive increase in innate ability for reading over the last 500 years. Rather, we would look to broad social changes which turned exceptional experiences into common ones. As intensive exposure to the products of literacy and literacy education became more and more normal, it became possible for increasing numbers of people to undergo the set of experiences that resulted in the level of attainment we consider normal today.

What are the general characteristics of the lives of those people who have attained exceptional levels of musical skill by today's standards? To answer this question, researchers have recently begun to examine elite groups of musicians at various stages of their careers: students at special music schools, conservatory students, successful professionals, and competition winners.

The Role of Practice

Ericsson, Krampe, and Tesch-Romer (1991) recently conducted an extensive study of the practicing history of 40 violinists. Thirty of these were students at the Music Academy of West Berlin; 10 "best" students nominated by their professors as having the potential for careers as international soloists; 10 "good" violinists from the same department; and 10 "teachers" studying the violin in a department (education) with lower performance admission standards. All these groups were

matched for age and sex. The fourth group ("professionals") comprised 10 middle-aged violinists from two symphony orchestras in West Berlin with international reputation.

Each participant undertook extensive interviews, was asked to keep a daily diary of activities for a week, and was asked to estimate the number of hours of practice on the violin each week for each year since he or she had started to play the violin. Figure 6.3 shows the accumulated hours of practice for each group at each age up to 20. The "best" and "professional" violinists show a very similar curve, which suggests that the professors' classification was accurate. By age 20, they had accumulated an average of over 10,000 hours of practicing, compared to some 8,000 for the "good" students, and some 5,000 for the "teachers." Indeed, the "best" violinists had accumulated by the age of 15 the same amount of practice as the "teachers" had by age 20. Even as young as 10, there is a distinct difference between the "best" players and the others.

The reliability of the estimated figures was checked by comparing estimated figures for the current year to the actual figures recorded in the diaries. The concordance was quite high. At the time of the study the "best" students were averaging 30 hours per week of practice, the "good" students 25, and the "teachers" only 10.

Ericsson, Tesch-Romer, and Krampe (1990) point out that accumulated skill through practice has "many of the properties associated often attributed to inherent characteristics such as talent. If, for example, two individuals of the same age differ dramatically in accumulated practice time . . . there is no way for the less trained individual to catch up with the more experienced person, if both maintain the same weekly schedule."

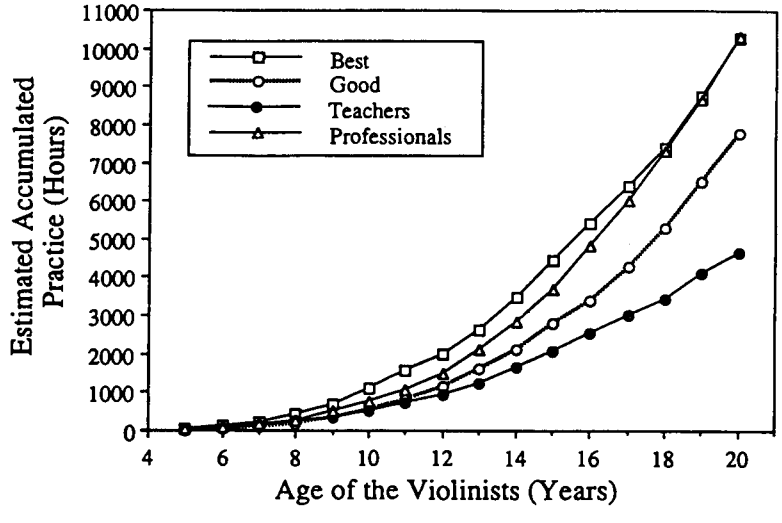

FIGURE 6.3. Accumulated hours of practice in four groups of violinists (Ericsson, Krampe, & Tesch-Romer, 1991).

Where, as in the case of music, access to the highest levels of teaching and coaching is based on competitive hurdles to be overcome in a narrow age window (typically 18 to 20), then clearly the successful musicians will be those who managed to accumulate as much practice as possible by this age. There is now considerable evidence that the highest levels of musical achievement are normally attained by individuals who began systematic study of an instrument before the age of 10 and maintained regular and increasing amounts of practice through the years of adolescence. In Ericsson et al.'s (1991) study, the mean age of the first violin lesson was 7 years. In a study of 21 international pianists in the United States, Sosniak (1985, 1990) found that the mean age of the first lesson was 6. A study by Sloboda and Howe (1991) on 42 adolescent students of a specialist English music school also revealed a mean starting age of 6 (range 3 to 10).

Of course, sheer amount of practice is a rather crude measure from a psychological point of view. The nature of learning will depend on what is done during practice as well as how much of it is done. Surprisingly, there is almost no reliable scientific information on how musicians practice. Gruson (1988) is the only researcher to date who has compared the practicing strategies of expert and novice instrumentalists. She found that experienced musicians showed much more sensitivity to structural units in the music (by, for instance, taking such units in isolation for repeated practice). Novices tended to indulge in more playing through of a whole piece, and repeating individual wrong notes, rather than repeating the sections in which they were embedded. A detailed case study of an individual professional pianist (Miklaszewski, 1989) confirms the importance of identifying structural "fragments" for detailed work. Clearly, since expressive performance is closely related to the detailed structure of a composition, practice that shows awareness of structural factors is more likely to lead to the development of an appropriate expressive repertoire.

Although amount of practice may be a conveniently simple predictor of "talent," it is far from simple to explain how large amounts of practice are initiated and sustained over a long period of a person's life. Ericsson et al. (1990: 113) expresses the problem succinctly:

> Practice activities, which involve careful analysis of one's performance, deliberate fine-tuning and acquisition of new procedures through massive repetition, are of a very different nature from spontaneously enjoyable activities within the domain. Examples of such spontaneously enjoyable activities are the play of children and the "flow state" which is defined by Csikszentmihalyi (1975) as the optimal match between the individual's skill level and the demands of the chosen field, with the individual feeling fully consumed by the activity. In contrast, practice requires deliberate control and effort, which most people, especially children, find unpleasant, particularly as it is extended over longer periods of time.

The issues here are basically ones of motivation and reward. Why do some children start music lessons and then continue effortful involvement through many years, when the "typical" child abandons effort after a few months or years?

Early Biographical Precursors of Excellence

One prevalent "myth" concerning exceptional musicians is that they typically demonstrated very early signs of their exceptionality by, for instance, early accurate singing, early reproduction of melodies on an instrument, exceptional concentration on music, or spontaneous early requests to begin lessons. Evidence from neither Sosniak (1985, 1990) nor Sloboda and Howe (1991) unequivocally confirms this view. Although parents of some children reported such things, the majority of children showed no special or outstanding ability or interest in music significantly before the start of lessons. In Sloboda and Howe's study, most children began instrumental lessons for reasons other than their own choice. In some cases it was a normal part of the school routine; in others the parents had decided it was a good thing for all their children to do, regardless of "ability." Sosniak discovered that it was sometimes not until five or six years after the start of formal instruction that her top pianists began to show the signs that led teachers to believe that a professional career was possible. When they started lessons, all of her sample were perceived as normal and unexceptional.

Sloboda (1989) has provided evidence to suggest that where the motivation for beginning lessons comes from the child, it is more likely to arise from some intense and pleasurable experience of music listening rather than from performance accomplishment. Such experiences motivated their recipients to wish to be able to reproduce these experiences through performance. The study, which asked adults to recall music-related events from their childhoods, suggested that early performance-related activities were very often negatively, rather than positively, motivating, being perceived as sources of anxiety, humiliation, or even physical abuse. It is possible to account for many apparent cases of "unmusicality" through early negative reinforcement, usually administered by a schoolteacher, which inhibited further engagement or effort in music performance.

Even when instrumental learning is not inhibited by negative reinforcement, it is clear that many young people become unhelpfully focused on "playing the right notes," and are so anxious about their own performance that they cease to enjoy the music or become emotionally engaged in it for its own sake. In these contexts it may become rather difficult to learn to play expressively. The tuition in expressive performance given by a teacher will fail to generalize unless a student can experience *why* that expressive device is appropriate through his or her own listening responses. If a young person has never experienced the emotional delight of, say, an enharmonic change, then he or she won't grasp, from the inside, why a slight slowing before the change may heighten the aesthetic effect. The teacher's performance instruction will seem arbitrary, rather than something which is immediately understood and assimilated for use in analogous situations.

Recent data on emotional responses to music (Sloboda, 1991a, 1991b) demonstrate that intense physical concomitants of emotional responses to music (such as tears or shivers down the spine) are linked to specific structures in the music, such as appogiaturas or enharmonic changes. If a child rarely has the opportunity to experience music in the kind of relaxed settings that promote these intense responses, then he or she will never be able to apply appropriate performance expression to such events other than something learned mechanically. The amount of expressive detail in a single performance is so great that it would be very difficult and time consuming to learn it "from scratch" for each piece. Good performers must be able to apply general rules of expression which make intuitive sense to them. Intense, involved, and enjoyable listening experiences are the key to the acquisition of this intuitive "sensibility."

The Early Years of Instrumental Learning

The general conclusion that emerges from the various biographical studies mentioned is that, for those children who later achieve performance excellence, the earliest years of instrumental learning are characterized by an atmosphere of pleasure and enjoyment. In this respect, the first teacher seems to have been crucial. In both Sosniak's (1985) and Sloboda and Howe's (1991) studies, respondents tended to describe their first teachers with such adjectives as warm, friendly, fun, loving, and encouraging. Lessons were enjoyable events to be looked forward to, and it seemed to be the quality of the teacher-pupil relationship, rather than the technical excellence of the teacher, which counted for most. In Sosniak's study first teachers were very often characterized as the "nice old lady down the road."

Two findings from Sloboda and Howe's study extend this "pleasure principle" to the home environment. Their sample contained both outstanding and average students from a specialist music school. It was discovered that the outstanding students generally had parents who were not themselves performing musicians. Average students were more likely to have come from families where one or both parents earned their living as a musician. Second, the outstanding students had accumulated significantly less practice than the average students prior to entry at the specialist. Table 6.1 shows accumulated practice for each group by instrument. It is necessary to present the results by instrument, because an unexpected finding of the study was the fact that most students had studied at least two instruments. The first instrument learned was not necessarily the one on which the student currently excelled. Table 6.1 makes it clear that the differential practice effect shows most strongly for the first instrument studied.

A tentative interpretation of these findings, supported by the more qualitative aspects of the data (see Howe & Sloboda, 1991a, 1991b), is that children of nonmusicians are more likely to be praised for their early accomplishments so that they acquire an early sense of themselves as "musician" and "special." Parents tend to be supportive but nondirective, allowing their children freedom

TABLE 6.1 Accumulated Hours of Practice as a Function of Ability

	Ability	
Instrument	*Exceptional*	*Average*
First	454	1,095
Second	320	422
Third	217	62
All	1,012	1,580

to decide whether to do formal practice or more free improvisatory musical play. Musician parents, in contrast, tend to view their children's accomplishments in the light of known standards to be attained. They are less likely to praise early achievements and are more likely to impose a rather rigid or structured practice regime. Such children may become technically adept, but fail to find their own musical motivation and creativity. Staff at specialist music schools are only too aware of the possibility of "adolescent rebellion" among such children, who belatedly realize that they are fulfilling their parents' ambitions rather than their own.

The Transition to Commitment

Practice cannot always be enjoyable, and at some stage in an instrumental career, a young person must make the decision to invest in practice activities beyond what is immediately rewarding. Transitions to new teachers or schools appear to be a vital component of this process. Almost all respondents in the various studies discussed reported a progression through a series of teachers who imposed increasingly demanding requirements on their pupils. Terms like "stretching" or "challenging" tended to be used much more when describing later teachers. Many students at music school came to see their teachers as role models or "heroes." The desire to be like the teacher, or like another eminent performer, is apparent in the motivation of many young performers.

As adolescence approaches, the existence of a reference group for whom high musical achievement is the norm becomes more important. One clear reason why many children drop out of instrumental learning is that their efforts are not valued by their peers (Howe & Sloboda, 1991c). In many environments, including schools, musical achievement is met with indifference, or even mockery. This seems to be particularly so for boys, because other boys brand musical activities as "unmasculine." Specialist music schools can provide a haven for young musicians where, for the first time in their lives, their activities are accepted as normal by their peers (Sloboda & Howe, 1990). Those who do not go

to such schools typically find similar support in specialist music groups such as orchestras.

Because there are so many pressures on children to do other things than devote time to instrumental learning, parents play a crucial role. Despite misgivings about the "ambitious parent," the studies of Sosniak (1985), Manturszewska (1990), and Sloboda and Howe (1991) all confirm the vital importance of a high level of parental support and encouragement. Almost all parents of successful musicians devoted large amounts of time, effort, and money to their children's musical activities. In Sloboda and Howe's (1991) study, the vast majority of parents had regular meetings with instrumental teachers and provided specific incentives to undertake practice. In a large minority of cases this actually involved being present throughout a practice period, helping the child to structure the practice activity. Research currently underway intends to specify the precise differences in parental behavior between successful and unsuccessful musicians.

Conclusions

This part of the chapter has outlined a picture of exceptional achievement as resulting, not from some unique or rare characteristic of an individual, but from a series of events and experiences that stimulate a statistically rare learning trajectory. Following from, but extending, a framework devised by Ericsson et al. (1990), a three-stage developmental framework may be proposed. In the first stage musical engagement is sustained primarily through pleasure: aesthetic/sensual pleasure in the experience of musical sound; pleasure in rewarding relationships; pleasure in praised achievements. Many nonmusicians seem never to have experienced this stage at the appropriate point in childhood. Some average musicians may also have experienced this stage inadequately, leading to "proficiency without spark." In the studies examined here, this first stage typically encompasses the first three to four years of instrumental study.

In the second stage, musical learning is sustained primarily through a constructed environment in which practice levels may be increased and sustained. This involves some external regulation of activity by parents and teachers, often in the context of specialist environments with like-minded peers. Specific achievement targets (such as examinations) often become prominent motivators. This stage typically coincides with the period of secondary schooling and ends when the individual decides on his or her long-term goals for music, whether to give up serious effort, to remain at an amateur level of proficiency, or to progress to professional levels.

In the third stage, the impetus for musical learning becomes fully internalized to the maturing individual, who will sustain and direct his or her own practice activities independently. Typically, in the highest group of performers, practice activity now predominates over all other forms of life activity. The role of the teacher moves toward that of mentor and guide rather than director. This

stage typically begins in the late teens or early twenties and continues to the point where a professional career is established.

There are, of course, further stages in the life-span of a professional musician (see Manturszewska, 1990), but there is not space in this chapter to describe them. It is more important to point out that the stages described are relative to a particular culture, that of the Western classical music profession. Little serious study has been made of the development of the popular or jazz musician (although see Sloboda, 1991c, for a discussion of the untutored development of Louis Armstrong). What is clear from case studies of jazz musicians and idiots savants (see Miller, 1989; Sloboda, Hermelin, & O'Connor, 1985) is that high levels of intrinsic motivation can sustain learning in the absence of formal tuition provided certain environmental conditions appertain (Sloboda, 1991c).

Finally, it is necessary to point out that there exist many cultures, especially traditional non-Western cultures, where the spread of musical accomplishment in the population is much more even than it is in modern Western culture. In such cultures, participation in musical activity is often more rooted in the whole life and work of society, rather than being something separate (e.g., Blacking, 1976). In the long view, it may turn out to be modern Western society that is unusual in its capacity to inhibit musical development in all but a small minority. Rather than looking within a small number of individuals for signs of genetic superiority in "musicality," we may need to look more closely at the way our culture operates to inhibit the majority of people from becoming the fully expressive musical performers that they could be.

The Perception of Melody, Tonality, Rhythm and Timing

7

Melodic Contour in Hearing and Remembering Melodies

W. JAY DOWLING

Introduction

In recent years, research on the perception of melody has received much attention. Frequently, the melody is the musical element we most easily recognize, reproduce, and remember because it is perceptually the most salient. A melody is a sequence of single pitches organized as an aesthetic musical whole. In trying to explain how some sets of notes are heard as integrated melodic wholes, psychologists have invoked Gestalt principles (see discussions in Deutsch, 1982a; Dowling & Harwood, 1986; Sloboda, 1985). These are principles of perception that were originally formulated to investigate the perception of visual stimuli (Wertheimer, 1923; see Arnheim, 1969, for application of Gestalt principles to the perception of visual art). Some of the most important of these principles are based on laws that govern proximity, good continuation, and similarity, as illustrated in Figure 1.

If we consider a melody as a line, it is easy to see how principles of perception may be successfully applied in researching melodic patterns. Indeed, in music performance and music teaching there is an emphasis on the "direction," the "shape" of the melodic line. We often speak of a melody and its accompaniment as the "foreground" and the "background." All these are visual analogies that are very pertinent musically.

A melodic contour is a sequence of single pitches that resembles the original intervallic pattern of a melody. The importance of the melodic contour, or shape, is such that it is nearly impossible to recognize a familiar tune if its pitches are played in random octaves on the keyboard: that is, if the original melodic line is broken as illustrated in Figure 2.

The more the pitches of the melody are played randomly among several octaves, the more difficult it is to recognize the melody. Such randomness violates the Gestalt principles of good continuation and proximity. Our recognition of this familiar melody increases as more pitches are played within the

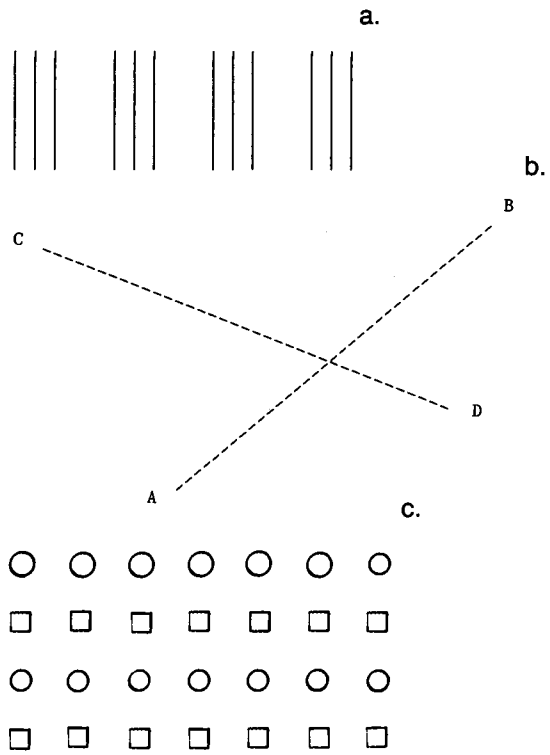

FIGURE 1. Gestalt principles. (A) *Proximity.* We tend to group nearer elements together rather than spacing them apart; therefore, we tend to perceive this diagram as four sets of three lines each rather than a set of 12 lines. (B) *Good continuation.* We tend to perceive that the set of dots starting from point A goes to point B rather than going to point C or D. (C) *Similarity.* We tend to perceive the above as rows of similar elements—namely, rows of squares or circles—rather than perceive columns combining both squares and circles.

same octave, or within an overall order of ascending or descending octaves—that is, as the distorted version begins to resemble more and more the original version. These findings, which are based on earlier studies by Diana Deutsch (1972, 1973), encouraged much research on the importance that pitch height (the location of a pitch on a piano keyboard) and pitch chroma (the position of a pitch within a scale) have in the perception of melodies.

To perceive a melody, we must perceive a coherence within the sequence of pitches that make up the melody. We group sounds according to various perceptual and cognitive organizational mechanisms. Some of the musical characteristics that may influence our perception of a melody are its contour, timbre, rhythm, intensity, and tempo (Deutsch, 1982a,b). Bregman (summarized in Bregman, 1990; see also Bregman & Campbell, 1971) has shown experimentally that when we hear rapid sequences of tones varying widely in frequency, we organize the sounds into perceptual streams of narrower range to create a psychological coherence. Musically speaking, in hearing the beginning of the Bourree from the Suite for Violoncello No. 3 in C major by J. S. Bach, although only one instrument is playing, we segregate the sounds perceptually as if we were hearing two lines: a higher and a lower one (Figure 3).

Polyphonic compositions are excellent examples of how perceptual principles are applied when listening to music. For instance, the practice of avoiding part-crossing in writing polyphonic compositions reflects the composer's sensitivity to avoiding potential perceptual confusion on the part of the listener (Huron, 1991).

We may not necessarily recognize, reproduce, or remember a melody exactly as we heard it. Instead, we may recognize, reproduce, or remember a melodic contour that approximates the original melody. In this chapter, W. Jay Dowling discusses the perception of the melodic contour and describes some of the features that make it perceptually relevant. He demonstrates how we perceive the difference between the overall contour of a melody and the specific intervals that make up the contour. He explains the interaction between contour and tonality and describes the results of several experiments that look at the contour of tonal and atonal melodies and transpositions to closely or remotely related keys.

What Is Melodic Contour?

Melodic contour—the overall pattern of intervals that make up a melody—is a feature of music that stands out distinctively for the listener on first hearing, and indeed composers use this feature in the construction of pieces of music, making use of the aesthetic tension that results by repeating a contour with altered intervals. A striking example is provided by the first movement of Beethoven's Fifth Symphony, which is built out of a brief melodic motif presented twice in succession at the outset (Figure 7.1). That motif and its sequences share contour (indicated under the score) but differ in the size of the interval between the two pitches: four semitones between G and E-flat in the first presentation and three semitones between F and D in the second. Throughout the movement,

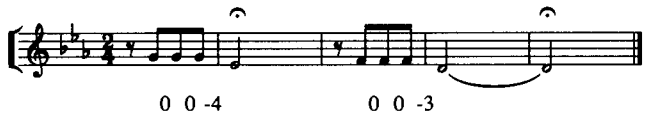

FIGURE 7.1. The opening measures of Beethoven's Fifth Symphony. Contour and interval sizes are indicated under the score by 0 for unison and – with the interval size in semitones (half steps) for a descending interval. Ascending intervals would be indicated by +.

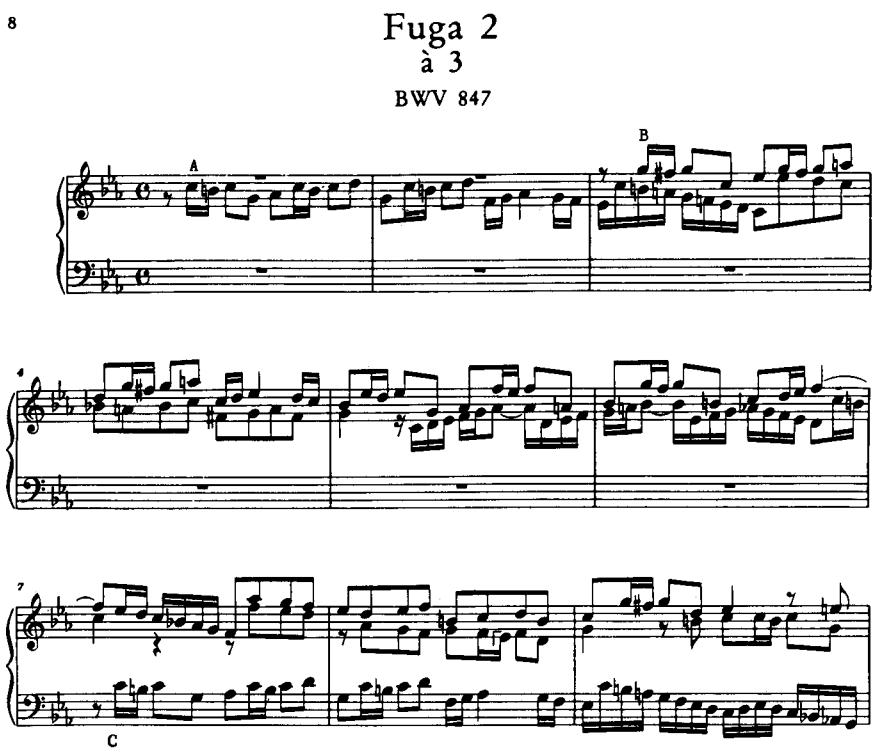

FIGURE 7.2. Bach's Fugue in C Minor from Book I of *The Well-Tempered Clavier.* Occurrences of the subject in the three voices. (Schott/Universal Edition, ed. Walther Dehnhard.)

TABLE 7.1 Interval Patterns in Semitones for Presentation of the Three Voices in Bach's Fugue in C Minor from *The Well-Tempered Clavier,* vol. 1, BWV 847

Occurrence/ measure		*Intervals*
1	1	−1 +1 −5 +1 +4 −1 +1 +2 −7 +5 −1 +1 +2 −9 +2 +1 −1 −2 −2
b	3	−1 +1 −7 +3 +4 −1 +1 +2 −7 +5 −1 +1 +2 −9 +2 +1 −1 −2 −2
c	7	like a

Beethoven repeats this motif over and over, using virtually all the possible intervals between the two pitches, in each case preserving the contour. The repeated contour provides unity to the piece, while the small intervallic changes with each repetition provide interest.

There are many examples of the use of a repeated contour with changes in intervallic detail. One can be found in Bach's Fugue in C minor from volume 1 of *The Well-Tempered Clavier* (Figure 7.2). The initial pitch contour [− + − +] at a in the subject is repeated not only in recurrences of the whole subject (at b and c) but also as a simple thematic kernel throughout the fugue. If we compare the recurrences of the initial melodic contour a, we see that while b preserves the contour pattern, it does not preserve the pattern of exact interval sizes in semitones. This is because of the difference between "tonal answers" and "real" answers in a fugue—tonal answers modify the interval pattern so that they can remain in the same key, while exact answers preserve the melodic pattern at another pitch level. Table 7.1 lists the pattern of intervals for the three appearances of the initial contour. Here Bach has treated contour as a feature of the melody that can be transported into other contexts and given different intervals while still preserving its identity. In fact, melodic contours recur in fugues with each return of the subject, but only sometimes does the subject repeat the initial melodic interval pattern exactly.

The Importance of Melodic Contour: Experimental Evidence

The importance of melodic contour in melodies we hear for the first time is borne out by experiments that test the recognition memory of subjects. In such experiments the listener hears a novel melody—never before encountered—on each trial, and then has the task of recognizing a transposition of that melody. Sample trials from a typical experiment are shown in Figure 7.3. On some trials the test melody will in fact be an exact transposition of the initial melody, in which case the listener's response should be, "Yes, that is the melody I just heard." (Figure 7.3B is a transposition of Figure 7.3A.) On other trials, however, the test melody will be different, and the listener should say, "No, that is not the

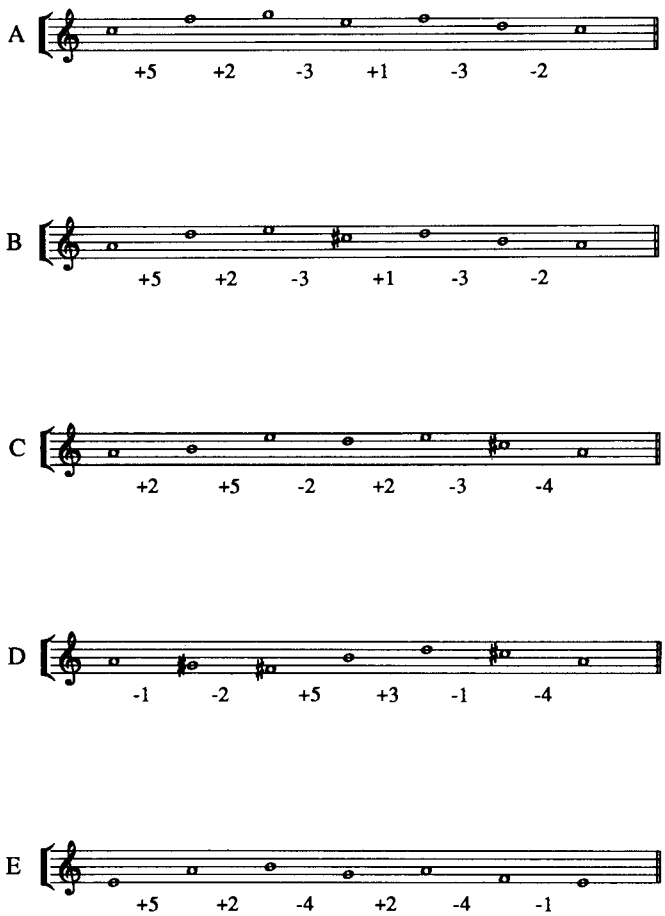

FIGURE 7.3. Typical melodies used in recognition memory experiments: (A) a novel melody in the key of C major presented on a trial; (B) an exact transposition of that melody to the key of A major; (C) a same-contour imitation of the initial melody, with different interval sizes; (D) a test melody with a different contour; (E) an imitation produced by moving the original melody along the C major scale, preserving diatonic but not semitone intervals. The contour and interval sizes are shown below each score.

same as the first melody." When the test melody is different, it might have a totally different contour (as in Figure 7.3D), in which case it will be easy for the listener to reject it. The most difficult type of melody recognition test will be an imitation of the original melody that shares its overall contour but differs in interval sizes (as in Figures 7.3C and 7.3E). Contour similarity will pull the listener in the direction of saying "Yes," while the intervallic differences, which are not always easy to notice on first hearing, prevent such a melody from being an exact transposition.

The results of a number of experiments show that listeners usually find it easy to respond positively to all comparison melodies that share contour, and respond negatively to melodies with different contours. Listeners find it much more difficult to distinguish exact transpositions from same-contour imitations. Dowling and Fujitani (1971) found this to be true using nontonal melodies; Dowling (1978) found it true using tonal melodies.

The confusion of transpositions with same-contour imitations is especially strong when the two melodies are in the same or in closely related keys (Bartlett & Dowling, 1980). That is, two melodies that share both contour and scale are easily confused, even if they differ in pattern of intervals. This confusion diminishes as the scales are made less similar by increasing key distance around the circle of fifths.

What psychological principles underlie the importance of contour in human memory? We now proceed to a description of the psychological features of melodies. The evidence suggests that contour similarity is especially important for recently encountered novel melodic phrases that are about five notes long. Contour is less important as melodies are remembered for longer periods of time, as they become more familiar, and when they are longer than five notes. Contour is more important for younger children under the age of 5 than for older ones, since before the interval patterns of tonal scales in a culture's music must be learned and incorporated into the listener's pitch, analyzing procedures and contour represents the main organizing principle for pitches in melodies (Dowling & Harwood, 1986).

The Role of Tonality

Features of Melodies

In addition to contour and interval sizes, a set of pitches also serves as a set of features to describe a melody. With that set of pitches comes the feature of its "key," or "tonality" (at least for tonal melodies). Key or tonality is the organization of the tones and chords of a piece of music in relation to a tonic. Contour and intervals remain invariant when a melody is transposed but the key changes—now it is based on a different tonality (as between C major and A major going from Figure 7.3A to 7.3B). All these features are psychologically relevant. Listeners are often led to treat an imitation as a transposition when contour and key remain similar to the original (Bartlett & Dowling, 1980). This tendency to confuse imitations and transpositions is especially strong when the key remains the same, and the imitation has simply been moved along the original scale (as in Figure 7.3E), preserving only some of the intervals (Dowling, 1978).

Key is an important feature in other ways. Watkins (1985) has shown that listeners experienced in Western music find a melody easier to recognize when

its pitch set remains within a diatonic musical scheme. Furthermore, the key is not just a static set of notes; it is a framework that assigns tonal functions to the various pitches in hierarchical relations to one another (Krumhansl, 1990). The tonic pitch is the most important, and other pitches tend to gravitate toward the tonic as a center of stability. Melodies such as those in Figure 7.3A to 7.3D begin and end with the tonic, moving from a stable point out into the rest of the scale and then returning to the stable tonic. The seventh scale degree (or "leading tone") for example, tends to pull upward toward the tonic. Francès (1958/1988) showed that when the leading tone was mistuned downward, contrary to that tendency, the mistuning was much more noticeable than when it was mistuned the same amount in the direction of the tendency.

A key defines a set of more or less expected pitches within the range of possibilities. When a melody follows those expectations, it is easier to follow and to remember. Watkins (1985) contributed additional evidence for the importance of key and the tonal hierarchy by showing that melodies whose pitches are chosen from a relatively small region around the circle of fifths are easier to recognize than melodies that involve large leaps around the circle of fifths.

A feature of melodies that should be mentioned here because of its importance is rhythm. In all the examples mentioned so far, not only melodic contour but the rhythmic pattern of the melody has been preserved. Changing the rhythm would produce a markedly different melody (Monahan, 1984). However, consideration of rhythm is beyond the scope of this chapter.

A variety of features can be used to describe a melody. In addition to contour, there are the interval pattern, pitch set, and the key. All of these have been shown to have some importance to the way in which melodies are first perceived and then remembered. But which of those patterns is most fundamental in our memory for melodies? Since interval patterns most obviously remain constant through transposition, a good case can be made that they are the most fundamental. Nevertheless, I believe that melodies are remembered as ordered sets of pitches. The pitch framework provided by the scale temporarily fixes a set of pitches as landmarks in terms of which the pitches of the melody are organized and understood.

From a psychological point of view, the scale framework itself is best understood as a set of pitches, rather than as a set of intervals, as I have argued at greater length elsewhere (Dowling, 1991a). The dynamic tendencies of pitches to gravitate toward points of stability in a tonal context, as described above in the experiment by Francès (1958/1988), are characteristic of sets of pitches, not of intervals. Furthermore, intervals, far from being psychologically more fundamental than pitches, are themselves most easily grasped with reference to pitch patterns of familiar melodies. Imagine the case of a music student faced with the task of singing the interval "ascending minor seventh" (Figure 7.4A). Abstracted from a context of melody and key, this is a very difficult task. However, if the student should happen to recall that a familiar melody (such as "Somewhere" from Bernstein's *West Side Story*; Figure 7.4B) begins with an ascending minor

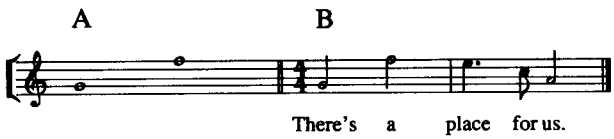

FIGURE 7.4. The interval of an ascending minor seventh (10 semitones); (B) the same interval embedded in the start of the song "Somewhere" from Leonard Bernstein's *West Side Story.*

seventh, the task is easily solved. Students learn to sing difficult intervals most easily with reference to the pitch patterns of familiar songs in which they occur.

Another line of evidence arises from multidimensional scaling studies which suggest that intervals in a melodic context are generally heard, not as intervals per se, but rather in terms of their position within the scale (Balzano & Liesch, 1982). Still more evidence comes from studies involving cued recognition, in which the listener hears a familiar tune and then is asked to discern it even when it is presented in a confusing way designed to preserve the pitch classes of its notes while destroying their interval relationships. Listeners are able to recognize tunes even when their intervals (but not their pitches) are obscured by scrambling their notes into different octaves (Dowling, 1984a) or interleaving distractor tones temporally among their notes (Dowling, 1973a). All of this strongly suggests that the psychological representation of the tonal framework is in terms of pitches, and not the logically equivalent representation in terms of intervals.

Memory for Melodic Contour

Several factors affect listeners' memory for melodic contour relative to memory for other features of melodies such as intervallic detail. Those factors include the delay between first hearing a melody and when it is tested, the familiarity of the melody to be remembered, its length, and the age and experience of the listeners. I will treat each of these factors in turn.

Short versus Long Delays in Recognition Memory

Contour is a strong determinant of transposition recognition when the comparison follows the introduction of a new melody by an unfilled delay of a few seconds. Contour becomes less important, however, after a delay of 30 or 40 seconds, while interval sizes become more important (Dowling & Bartlett, 1981; DeWitt & Crowder, 1986). One reason contour decreases in importance over time in relation to intervals is a decrease in the confusion due to scale relations, as already noted. After a short delay the scale of the initial melody is still fresh in memory, and perception of the comparison melody is affected by it. When the comparison is in a relatively close key (as in the experiments just cited), confu-

sion between exact transpositions and same-contour imitations results. Following a delay filled with other material the scale of the initial melody becomes less salient, and false recognitions of same-contour imitations decline. According to this explanation, the shift over time of the relative importance of contour and intervals should disappear with atonal melodies, since confusions due to key similarity should no longer operate. And that is exactly what happens (Dowling, 1991b). Atonal melodies are more difficult to recognize than tonal ones after both long and short delays, and (as with tonal melodies) discriminating contour differences is easier than discriminating interval differences. However, the relative difficulty of those two discriminations does not shift over time as it does for tonal melodies.

A second reason that has been put forward for the decline in importance of contour with longer delays is that contour can serve as a much better retrieval cue when the initial melody and its comparison are close together in time and there are fewer alternatives to choose from (Dowling & Bartlett, 1981). However, when the comparison comes after a delay filled with alternative possible choices lying between it and the initial melody, the relative importance of contour declines. (This would be like a series of trials with melodies such as in Figure 7.3, but with numerous items like 7.3D intervening between 7.3A and 7.3B.) We cannot rule out the possibility that more precise information than contour (namely, interval sizes) may be needed to differentiate among the numerous melodies we store in our memory. One could argue that such an effect ought to operate as well with atonal as with tonal melodies. Moreover, Dowling (1991b) failed to find any decline in the usefulness of contour information between short and long delays in that experiment.

Nevertheless, it is clear that with the passage of time the contours of tonal melodies become relatively less important to recognition and specific intervals become relatively more important. The end result of this shift can be seen in the great importance of intervals in memory for overlearned melodies in long-term memory storage.

Familiar versus Unfamiliar Melodies

Contour is highly salient in memory for novel melodies. In contrast, the exact interval patterns of familiar melodies are very well remembered. Dowling and Fujitani (1971) found that listeners rarely confused same-contour imitations with familiar versions of tunes such as "Twinkle, Twinkle, Little Star" and "Yankee Doodle." In fact, when asked to respond positively to the imitations, listeners succeeded about 60% of the time. Listeners' knowledge of the intervals of familiar tunes is so precise that Attneave and Olson (1971) were able to use memory for the intervals of the call signal of NBC, an American television network (G-E-C; intervals +9 semitones, −4 semitones) as the basis for a pitch-scaling task. This accuracy with familiar melodies is true of musically inexperienced as well as experienced listeners.

Melody Length

The familiar versus unfamiliar melody results were obtained with five-note-long melodies (Dowling & Fujitani, 1971; Dowling, 1978; Bartlett & Dowling, 1980) and seven-note-long melodies (Dowling & Bartlett, 1981; Dowling, 1991b). Edworthy (1985) has shown, however, that contour is not nearly so easy to remember with longer tonal melodies of 11 or 13 or 15 notes. Part of this result must be due to complexity, and Cuddy, Cohen, and Mewhort (1981) have shown that contour complexity affects memory. Part of the result may, as Edworthy suggests, also be due to the fact that a longer melody provides time for the listener to achieve a firmer grasp of the key. Edworthy's task was quite difficult, requiring the listener to notice particular details in the contour rather than make a global same-different judgment. However, it is plausible that contour should decline in importance with melody length, since inevitably the number of possible contours (hence the amount of contour information conveyed) increases with length.

The way longer melodies are remembered should be a fruitful area for research. Longer melodies must break down into phrases that should be to some extent remembered independently. We know that phrases are in fact remembered as units. Dowling (1973b) constructed melodies using four five-note phrases to form the rhythmic pattern [. . . ._ . . . ._ . . . ._ . . . ._]. Each phrase had a different pitch contour. After hearing such a melody, listeners were given test patterns that replicated whole phrases from the longer melody [. . . ._] or that cut across phrase boundaries [. ._ . .]. Memory performance was much better with the whole phrases (about 70% correct) than with the ends of one phrase and the beginnings of another (about 60% correct). We also know something of the way melodies are parsed into phrases on the basis of rhythmic grouping, changes in melodic contour, melodic leaps, patterns of repetition, and so forth (Jones, 1987). The relationship between memory for phrases and memory for whole melodies poses a particularly interesting question for future research.

The Role of Development

Infants are sensitive to changes in melodic contour long before they begin to speak or sing (Trehub, Bull, & Thorpe, 1984). As soon as children begin to speak they also begin to sing. That singing generally takes two forms: vocal play exploring the limits in pitch and loudness and rapidity of what their voice can do, and the creation of spontaneous songs (McKernon, 1979; Dowling, 1982, 1984b, 1988; Dowling & Harwood, 1986). Spontaneous songs at the age of one or two years are characterized by a more or less regular beat on which the speech

rhythms of the words of the song and the use of discrete levels of pitch are overlaid. The pitches are not those of the adult scale and the pitch levels are continually in flux. Nevertheless the steadiness of the metrical pattern (the beat) and the use of discrete, sustained pitch levels for vowels distinguishes singing from speech at this age. What the child controls at this age in terms of pitch is not the exact frequency or pitch of the tone, but the pattern of ups and downs—the contour.

Children sing spontaneously created songs beginning around the age of one. Such songs divide naturally into phrases that are characterized by melodic-rhythmic contours. The melodic contour patterns recur within the structure of the song. Sometimes contour patterns are copied from nursery tunes the child has heard, but typically they are made up by the child. Sometimes a contour will repeat over and over with the same words, whether nonsense ("Sippah, suppah. Sippah, suppah. . . .") or relatively meaningful ("Come a duck on my house. Come a duck on my house. . . ."). Sometimes one contour shape will alternate with another in a regular pattern throughout the song. Often the song ends with a "coda" constructed from new contour material. As the child gets older, some of the songs come to approximate nursery tune models more and more closely, but even then those songs are not literal reproductions of adult models, but are versions that have been regularized according to the child's own musical syntax (Dowling, 1984b). Children's spontaneous singing through the preschool years involves principally a manipulation of musical materials encoded as rhythmic and melodic contours.

By the age of five children's pitch levels are beginning to approximate adult categories, and some children younger than that can distinguish between tonal versions of familiar melodies that conform to adult pitch categories for the diatonic scale and atonal versions that do not (Trehub, Morongiello, & Thorpe, 1985), especially if they are rated by adult judges as being able to sing "in tune" (Dowling, 1988). Also, by five, children are able to stay within the scale of a single key in singing a familiar tune (Davidson, McKernon, & Gardner, 1981). By the age of eight, children notice changes of mode from major to minor (Imberty, 1969), are better at noticing pitch alterations in tonal (vs. atonal) melodies (Zenatti, 1969), and are beginning to acquire a sophisticated scheme for the hierarchical organization of pitches in a tonality (Krumhansl & Keil, 1982).

These shifts in relative importance of the various melodic features with changes in age and experience can be seen in the results of Andrews and Dowling (1991). Their listeners across a variety of ages were asked to identify familiar melodies in versions that either exactly reproduced their familiar pitch intervals or were changed in pitch while preserving contour. The changed versions either remained within the same key ("tonal") or did not remain within any key ("atonal"). Andrews and Dowling found a regular developmental progression of reliance on different melodic features. Five- and six-year-olds identified the melodies equally well in all forms, changed as well as original versions. Seven- and

eight-year-olds tended to identify principally tonal melodies, original and changed. Nine- and 10-year-olds performed much better with original version of the melodies than with either tonal or atonal changed melodies. With these highly familiar melodies, adults performed about equally well on all versions.

Contour and Gestalt Principles

One result that has gradually emerged from experiments in which listeners have judged melodic contour in a variety of contexts is that a melody is very much an integrated whole, a Gestalt. Contour is not an entirely separable feature of a melody in Garner's (1974) sense. Contour interacts with both tonality and rhythmic pattern in perception and memory. This is not what I initially thought when I began to investigate this area. In 1978 (Dowling, 1978) I suggested that contour and scale (the embodiment of the features of tonality) might be processed and remembered independently of one another. Thus a melody could be created by generating a contour and hanging it on a scale. Scale similarity might cause confusions in short-term recognition tasks, but only with interval, not contour, recognition. That is, changes in the scale should not affect recognition of the pattern of ups and downs.

Recent studies have shown, however, that tonal context affects memory for contour. Bartlett and Dowling (1988) had listeners judge sameness of contour in pairs of seven-note melodies in which one member of the pair was tonal and the other atonal. The contour change was produced by making the lowest pitch in the melody the highest, or vice versa. There were always the same number of specific pitch differences between members of a pair. Listeners were better at discriminating contour changes when the pairs were presented in atonal-tonal order than the reverse. And in a study already cited (Dowling, 1991b), I had listeners attempt to discriminate transpositions from same-contour imitations and different-contour test melodies (like those in Figure 7.3) either immediately or after a delay of about 40 seconds filled with other melodies. The melodies were strongly tonal, weakly tonal, or atonal. Strongly tonal melodies began and ended on the tonic (like Figure 7.3A to 7.3D), and weakly tonal melodies began and ended on pitches other than the tonic (like Figure 7.3E). Listeners' performance is shown in Figure 7.5. At short delays discriminating transpositions from different-contour lures was uniformly easier than discriminating them from same-contour lures for both tonal and atonal melodies (Figure 7.5). With increasing delay this difference tended to disappear for the tonal melodies, but not for the atonal. Furthermore, the tendency to falsely recognize different-contour lures was markedly affected by tonality, being lowest for strongly tonal melodies. Thus listeners' ability to reject a different-contour test item depended on tonal context, and not just on its difference of contour.

Contours are interrelated in memory with tonal and rhythmic context. The parsing of a contour into phrases and the assignment of melodic accents depend

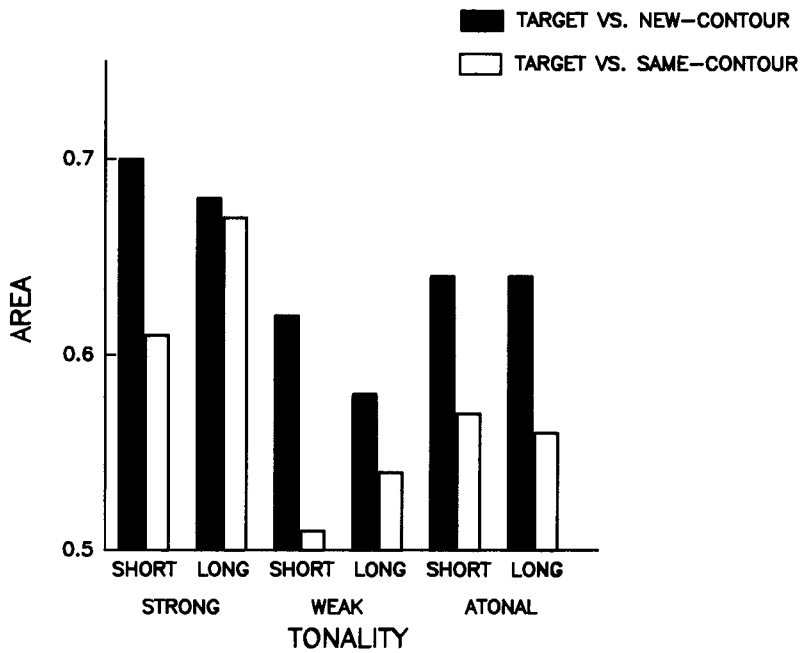

FIGURE 7.5. The interaction of tonality (Strongly Tonal, Weakly Tonal, Atonal) by delay (Short and Long) by test comparison (Targets vs. Different—or Same-Contour Lures). Performance distinguishing between exactly transposed targets and different-contour lures is shown by solid bars; that for targets versus same-contour lures is shown by open bars (after Dowling, 1991b).

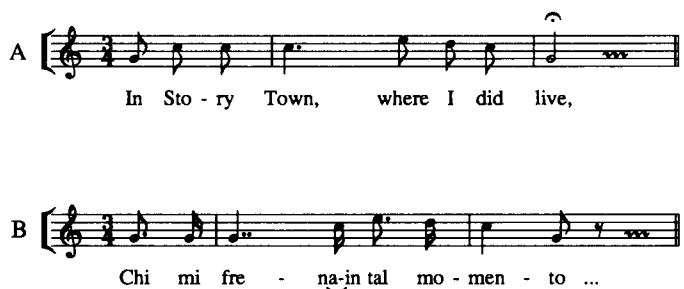

FIGURE 7.6. The opening phrases of a version of the folksong "Barbara Allen" and the sextet from Donizetti's *Lucia di Lamermoor* (after Kolinski, 1969, Fig. 17). Note the identical pattern of pitches with different rhythm, which in effect makes it a different melody.

not only on note durations, but also on accents arising from contour inflections (Jones, 1987; Drake, Dowling, & Palmer, 1991). Kolinski (1969) vividly demonstrated the interrelatedness of pitch and rhythmic patterns by showing that, if the rhythm and the number of a repeated pitch were altered, a variant of "Barbara Allen" would become the tune from the Sextet from Donizetti's *Lucia di Lammermoor* (see Figure 7.6). The very same pitch pattern (and contour) can become an entirely different tune with a change of rhythm.

It would have been simpler for psychology if melodies had divided neatly into contours, rhythms, and pitch sets, but it would probably have been a loss to music. The ways in which musical material is transformed by shifts of context provide an important source of complexity which contributes to its richness as art.

Summary

In this chapter I discussed melodic contour in relation to other features of melodies in the pitch and time domains. An important feature of melodic contour is the distinction between pitches as interval patterns and pitches as patterns within a tonality. Evidence was cited suggesting that both representations are necessary in music cognition. Along with evidence showing the importance of contour in melody recognition and production, I presented evidence showing the limits of that importance. Contour is most important in memory for novel melodies tested after brief delays, and less so after longer delays and with familiar melodies. While contour dominates much of the preschool child's music behavior, adults are able to use contour more flexibly when the task demands it. Finally, I noted that melodic contour does not function entirely independently of the other features of melodies, but rather is part of the integrated melodic Gestalt.

Describing the Mental Representation of Tonality in Music

DAVID BUTLER AND HELEN BROWN

Introduction

The research of Hermann von Helmholtz (1885/1954) on the combinations of musical sounds and the qualities of musical tones has influenced most subsequent investigations of the perception of consonance and tonality. Helmholtz believed that to study auditory events carefully they should be broken down into their most elementary units, and that certain pitch relationships are musically significant because of the physical properties of the tones themselves.

During the last decade, research in the perception of tonality has figured prominently in the psychology of music. The scholarly work of Carol Krumhansl described in *Cognitive Foundations of Musical Pitch* (1990) has been very significant (see also Krumhansl, 1991; for summaries of her earlier work see Krumhansl, 1983, 1985). Krumhansl's research has offered empirical validity to aspects of music theory such as the prominence that specific tones assume within a scale, and the relationships between the keys in the circle of fifths. Often she utilized geometric models to describe her results. Most of Krumhansl's experiments investigated tonality using what she called "the probe-tone technique." This technique required subjects to listen to a musical context that could be an ascending or descending diatonic scale, a chord, a chord progression, or a brief excerpt from a musical composition. The musical context was followed by the presentation of a tone (called "the probe tone") which was randomly chosen from among the 12 pitches. Subjects are asked to rate on a scale from 1 to 7 (1 = very bad to 7 = very good) how well the probe tone fit in the previously heard musical context.

In one of her early experiments (Krumhansl & Shepard, 1979) Krumhansl investigated how subjects perceived tonality using as the musical context an

incomplete ascending or descending C major scale played without the final tonic and followed by the probe tone. She found that the results of subjects with a formal musical background conformed to the qualitative predictions of music theory: these subjects perceived the tonic, the dominant, and the mediant tone of the scale as the tones best fitting the given musical context.

Krumhansl's probe-tone ratings have also been applied in investigating the perception of North Indian (Castellano, Bharucha, & Krumhansl, 1984) and Balinese music (Kessler, Hansen, & Shepard, 1984), demonstrating that the probe-tone technique could also be successfully used to investigate the tonal hierarchies of these non-Western musical styles.

The research conducted by Butler, Brown, and Bharucha has provided valuable information that emphasizes other aspects of the perception of tonality. In this chapter, Butler and Brown describe the importance of the temporal element in perceiving tonality. They look at how single pitches and combinations of pitches are organized over time and show that it is the order in which pitches are played, not just the pitches themselves, that influences which key the listener perceives a piece to be in (see Brown, 1988; Brown & Butler, 1981; Butler, 1989, 1991). Butler and Brown believe that the scale per se does not adequately describe the relationships that listeners actually hear in the music; instead, they propose that the intervals of the scale indicate the tonality to the listeners.

Specifically, Butler and Brown demonstrate that within a major scale, the minor second and the tritone provide distinctive cues in perceiving tonality. Butler and Brown call the minor second and the tritone "rare" intervals because within a major scale the interval of a minor second occurs only twice (between the third and fourth scale degrees, and between the seventh scale degree and the tonic) and the tritone occurs only once (between the fourth and seventh scale degrees); thus they are heard less frequently than the other intervals. Butler and Brown propose that the infrequency with which these intervals occur within the major scale gives the listener distinctive cues for perceiving which tonality a piece is in.

During the past three centuries, listeners in our Western musical culture have learned to expect certain underlying conventions in ways tones are combined to form meaningful patterns. A few of these conventional combinations are related to acoustical and sensory characteristics of tones, but most tonal patterns can change from one musical culture to another and from one style to another within a culture. Our purpose in this chapter is to examine these tonal patterns as perceptual objects and as cognitive processes. A goal of this discussion is to impress on the reader the importance of temporal relations in the comprehension of pitch relationships in tonal music—the importance of the manner in which pitches provide context for one another as the music unfolds before the listener.

Nature presents us with choices of smoother- or rougher-sounding combinations of tones and these combinations might have important connotations within one musical style, or throughout an entire musical culture; yet, musical cultures are sometimes very different. Our own musical culture includes highly varied approaches to combining pitches and even to contriving pitch-sets from which pitches may be combined; as the same concert, for example, you can hear a minimalistic work that might contain only five or six pitch classes, followed immediately by a microtonal work containing two dozen or more tones within the octave. Within these extremes, several well-worn, well-understood stylistic norms have been tremendously important in shaping Western music for the past

three centuries or so. Another way of saying this is that composers and listeners have formed an unspoken pact, a fairly sophisticated set of ground rules, regarding how pitches are to be organized to form normal-sounding patterns. This set of conventions is known as *tonality*, which undergirds the learned system of "keyness" that to some extent governs how melodies and chords are organized throughout the duration of a tonal musical composition. In this chapter, we describe these conventions of organization and then review experimental studies that have described listeners' recognition of these conventions.

Pitch Relationships

It is necessary to make a few distinctions about the ways that the term "pitch" might be used.[1] Pitch may refer to nothing more than a loose registral differentiation, the difference between "high" and "low." Sounds with little or no discernible pitch—clicks, thumps—can nonetheless be described as having a higher or lower pitch. The definitions of pitch relating more directly to this discussion are two levels more specific than this, however. The first level of specificity refers to the pitch material from which tonality is built. There are 12 equal logarithmic divisions of the octave; these equal divisions produce the equal-tempered 12-tone set, variously called the *chromatic set*, the *chromatic scale* (if the tones are arranged in scalar order), or the *equal-tempered twelfth-octave collection*. Distances among tones in this 12-tone set can be described neutrally using modulo-12 (clockface) numbers: 0 stands for C, B-sharp, D double-flat, and its other enharmonic spellings in all possible octave registers; 1 stands for the next-higher semitone, and so on through 11, which stands for B and its enharmonics. The system therefore refers not to single, specific pitches, but rather to 12 *pitch classes*. The neutrality of these pitch-class numbers is appropriate for discussions of pitch relations beyond the scope of the Western tonal tradition, but discussions of tonal pitch relations cannot remain neutral. The second level of specificity pertains to tonal context. Intervals can sometimes be considered nothing more than gaps between pitches. The term "interval class" is conventionally applied to these neutral spans of pitch space: the intervals E–F and D-double-sharp–G-double-flat both belong to interval-class (ic) 1, for example, because each spans one semitone. Interval-class labels, however, are not precise enough to describe pitch relationships in tonal music. For example, the three-semitone gap between pitch classes 0 and 3 has no distinctive tonal meaning, but when 0 becomes the specific pitch middle C, and 3 becomes the E-flat a minor third above it, that particular three-semitone gap will be found in different harmonic and tonal contexts than it would if 0 were C and 3 were the D-sharp an augmented second above it. When discussions involve pitch sets derived from specific tonal contexts, spelling definitely counts.

This discussion implies that the pitch set comes close to describing a pitch pattern found in a piece of music already composed. This is not just academic

fussiness; rather, it is one of the more important musical observations in this chapter. Although some accounts describe scales as the basis of music, historically the music comes first, and the scales come later. Scales are theorists' attempts to describe the pitch materials in music that already exists.[2] The scale is a handy index of the pitch contents of some piece or pieces of music, but the scale's simplicity comes at a hefty price. The scale is a highly simplistic construction that fails to describe much of what is most important about pitch relationships in tonal music. First, there is no guarantee that all notes in the scale may be used in a composition, and there is definitely no guarantee whatever that the scale fully represents all notes that may be encountered within the music. Second, the scale says nothing at all about how the notes within the piece of music are to be arranged throughout the composition—how they are to unfold as the composition is heard.

A listener who has become familiar with the tonal idiom tacitly gains an underlying sense of *key level*, and within that a sense of *harmonic level*, in a piece of tonal music as it unfolds across time. This is one of the strongest perceptual binding forces—that is, features through which we perceive coherence—in tonal music (see, for example, Krumhansl, 1979; Brown & Butler, 1981; Deutsch, 1982; Krumhansl & Kessler, 1982; Brown, 1988; Butler, 1989). Although we may never have been formally trained to do it (see, for example, Moog, 1976; Shuter-Dyson & Gabriel, 1981; Hargreaves, 1986; Serafine, 1988), most of us seem to pick up some skill—some of us have a little, others a lot—at hearing tonal music as arranged around the context of a perceptually central pitch (e.g., Brown & Butler, 1981; Butler, 1983, 1989; Butler & Brown, 1984; Brown, 1988).

Harmonic Context

The term "harmony" has acquired several meanings. One colloquial definition is roughly equivalent to "good-sounding accompaniment" as, for example, when two people might sing in two-part harmony. Harmony also is often equated with *chord*. On a more abstract musical level, harmony is often used to mean harmonic level, something bigger than a single chord. Music analysts may speak, for example, of a lengthy segment of a composition existing on a single harmonic level, even though it may be represented in some compositions by a sequence of several (or several dozen) chords. Although this chapter does not contain a discourse on harmony on this level of abstraction, it is important to recognize that harmony can carry any or all of these connotations. At both the simplest and the most abstract levels, we can refer to harmony without dealing directly with chords.

Chords, however, are what first come to mind when we speak of harmony. To some extent, chords are similar to the harmonic partials of a complex tone. In fact, many music theorists have argued that chords in Western harmonic practice

are (or ought always be) patterned after the harmonic series; some theorists have gone so far as to call the harmonic series the "chord of nature" (e.g., Catel, 1801). Although it has become a mainstay in some theories of tonal music, this resemblance between *harmonic* partials of complex tones and musical *harmony* is restricted in three important ways. First, the harmonic partials of complex tones are ideally positioned at exact integer relations (1:2:3: . . . :*n*) to one another, but this isn't always true in real musical sound; the partials of some "harmonic" complex tones (such as tones produced by the piano) are actually slightly inharmonic. Second, virtually all fixed-pitch instruments are tuned so that the octave is divided into 12 equal logarithmic increments, and this equal-tempered tuning system produces no intervals other than the octave that match exactly with the intervals between the partials of a complex tone. Third, chords can be built of intervals other than thirds, although chords built in thirds and containing perfect fifths are considered inherently consonant in many accounts of tonal relationships. But tastes change. Only a brief millennium ago, for example, a major triad was considered a clashing discord by many writers: the two outer tones (the fifth) would have been thought acceptable, but the middle tone (the third) was considered a clangorous dissonance. Twentieth-century composers such as Debussy and Hindemith have made consonant sonorities of chords built in fourths and seconds.

There is another aspect of consonance and dissonance beyond the sensory response that two tones may sound either smooth or rough in the presence of one another. In most accounts, dissonance (a "rough-sounding" combination such as a second, a seventh, a tritone, or any chord containing one or more of these intervals) is regarded as a point of musical instability, of musical tension: the listener is expected to respond to dissonant combinations of tones with the feeling that they do not project the sense that the music has "arrived" at a convincing point of repose, a good stopping point. Alternatively, consonant combinations of tones ("smooth-sounding" intervals such as thirds, perfect fourths, fifths, and octaves, or chords limited to them) are presented in these accounts of music as points of stability, good stopping points. Historical and speculative music theory, as well as empirical evidence (e.g., Cazden, 1980; Brown, 1988), offer convincing counterexamples to this point of view. To illustrate, you might try playing a chord containing the pitches C_3-B_3-E_4-A_4-D_5 (Figure 8.1a); although it contains sensory dissonances in the form of several minor and major seconds (or their octave complements or compounds), the chord forms a perfectly acceptable ending chord in some tonal styles, particularly the big-band and jazz styles of the 1940s and later. Conversely, a major triad built on the dominant scale degree may sound perfectly smooth and agreeable (Cazden used the term "euphonous"), and yet be interpreted by a listener as an unstable, unfinished point within a tonal composition. Because sensory consonance and dissonance are not necessarily equivalent to perceived stability and instability, there is growing acceptance of the use of such terms as "systemic" or "musical" consonance and dissonance to refer to perceived instability (nonfinality) and stability (finality), and "sensory" consonance or dissonance when referring to the smoothness or roughness of the

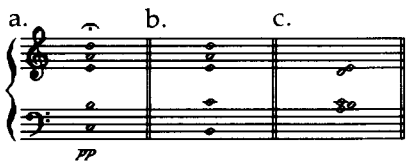

FIGURE 8.1. (a): Simultaneity containing several sensory dissonances forming a stable harmony in some styles. (b) and (c): Simultaneities discussed in note 3, p. 210 containing the same pitch classes but in varied registral arrangements.

combination's sound.[3] Moreover, dissonance means something more than tension and consonance means more than release. Meyer (1956; see esp. pp. 35–42), for example, has argued persuasively that musical events—which may be single tones, chords, entire phrases, or even entire sections of compositions—have "embodied meanings": they point to, or make us expect, other musical events. For example, an expert musical listener, upon interpreting a chord as a dominant harmony, will likely be able to know more than simply that the chord is unstable or tension-arousing; in addition, the listener will quite firmly anticipate that the dominant seventh chord will lead directly (or seldom with more than a perfunctory delay) to a tonic harmony. The essential two points in all of this are that there is a resemblance between acoustical and musical harmony, and that there is a relationship between sensory and musical consonance and dissonance, but the relationships are neither as rigid nor as extensive as they are sometimes portrayed.

Key Context

Earlier, the term "tonality" was characterized as "keyness": a system of pitch relationships governing how we interpret music to be situated "in" a key, and how we interpret what that key is. Tonality can actually be considered a bigger and more abstract concept than key, however, and in fact even bigger and more abstract than a single *style* of music (Brody, 1985). Tonality is perhaps best considered as an idiom—similar to a dialect, or similar perhaps even to an entire grammatical system. Within the tonal idiom, one can point to a number of different Western musical styles including late Baroque, Classical, Romantic, and some twentieth-century art-music styles, and also including most of the Western popular and folk styles of the last three centuries.

One perceptual feature shared by all these styles is that music written in any of them will give the enculturated listener some sense that the music has a home base, a central and most-important pitch. This pitch stands for the *key* (sometimes called *key level*) of the piece. It is common to speak of the key as the more-general scheme of pitch relationships within a piece of music, and of the mode—major or minor—as the more specialized set of relationships within that key level. For example, Mozart's Symphony No. 40 is in the key of G minor, which is a brief way of saying that its most-important focal pitch is G and the pitch relationships in the minor scale come closer to describing the music than

do the pitch relationships in the major scale. Even though the symphony is said to be in the key of G minor, at various points the listener hears a fair amount of music in B-flat major, one movement in E-flat major (in which the key migrates to B-flat major and then returns), and other sections in even other keys (such as G major and F-sharp minor). In trying simply to describe the perceptual object, then, we must recognize that tonal music is complex enough that the concept of key exists on more than a single level. Returning to the Mozart example, G minor is a global description of the primary key level of the entire four-movement composition, but the listener hears a succession of keys within different parts of each movement of the composition. As complicated as this sort of listening activity seems, both musical and psychological theorists concur (e.g., Brown & Butler, 1981; Browne, 1981; Deutsch & Feroe, 1981; Deutsch, 1982; Boltz, 1989) that musical listeners do interpret tones according to the context of the single key governing the music.

Depending on the experience of the listener and on the specific piece, the perceptual clarity of this central pitch class will vary. Yet (as stated earlier) listeners who can successfully hear musical pitch patterns within the mental context of a key do not necessarily have to have gone through a great deal of formal training in music. Nor do they necessarily have to be able to read musical notation, or have a working knowledge of scales or chords or key relationships. It is not customary to distribute scores to audience members at concerts, nor is it common for the performer(s) to play a tone, a scale, or a chord, as a point of reference with which to prime the audience before each composition is performed. How, then, do we get a mental grip on the music—that is, how do listeners recognize that the music is tonal, and simultaneously recognize the key in that piece of tonal music, given nothing more than an aural presentation of the music itself? Obviously, the code must be located within and among the pitch patterns in the music, rather than inside some abstract construct such as a chord, a scale, or some other set of pitches.

Most accounts of this code have to do with the traditional notion that the *tonic* or keynote is the reference point in any key, it is somehow invested with the most stability of any of the tones in any key, and that all other tones in the set relate to the tonic in varying ways, and to varying degrees. Until recently there has been comparatively little experimental research conducted to explore how we recognize these tonal relationships. So how do we recognize tonic as tonic, dominant as dominant, and so on? In the next section, we examine studies undertaken in the attempt to answer these questions.

Research on Key Identification

Major Mode

One testable model of this recognition was proposed by Richmond Browne (1981). Browne began with a well-known property of the major pitch set (Bab-

bitt, 1960), which is that each interval class occurs at least once in the set and each class occurs a unique number of times. This is shown in Figure 8.2, represented by the C major set. Although the intervals in Figure 8.2 are notated specifically out of necessity, they are merely a single representation of all possible enharmonic spellings, octave complements, and octave compounds of those intervals.

It should be emphasized that there is an important difference between *scale* and *pitch set:* while pitch sets are not necessarily ordered or grouped in any certain way, scales are conventionally ordered within an octave span, and also ordered so that they form a ladder-like arrangement. The order of tones in any scale is a matter of convention and convenience, but it does not impose any necessary order on the pitches as they may be used in a piece of music.

Although the tones in Figure 8.2 are arranged as scales, the intervallic properties of the major pitch set go beyond the obvious pattern of whole steps and semitones that we see in the scale. For example, consider the intervals formed by tones not adjacent in the scale. Some intervals span three semitones, some span four, and so on. Browne (1981) recognized that the major diatonic set stands out from other pitch-class sets because every interval class is present somewhere in the set—none is omitted. Each occurs a unique number of times. There are two semitones in the set (see Figure 8.2a); no other interval is present that exact number of times. Each interval class is pointed out in each succeeding line within Figure 8.2: two members of interval class (ic) 1 (i.e., semitones, Figure 8.2a) and five members of ic2 (Figure 8.2b); four members of ic3 (Figure 8.2c) and three members of ic4 (Figure 8.2d); six members of ic5 (Figure 8.2e) and

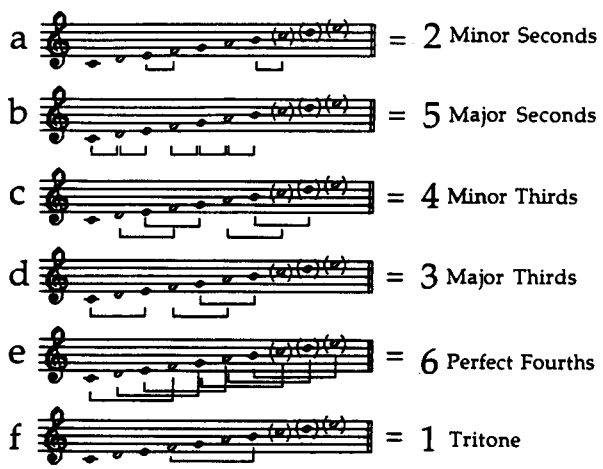

FIGURE 8.2. The various intervals comprising in the C major set (shown in scalar order in this figure). Beginning with the smallest interval other than the unison, there are (a) two intervals of one semitone (interval class or ic1); (b) five intervals comprising a two-semitone span (ic2); (c) four three-semitone spans (ic3); (d) three four-semitone spans (ic4); (e) six five-semitone spans (ic5); and (f) one six-semitone span (ic6).

only one member of ic6 (Figure 8.1f). Octave complements and compounds are assumed within interval classes.

Browne pointed out that while some intervals are abundant, others such as the semitones and the tritone occur infrequently within the major diatonic set. These rarer intervals (a term indicating relative rarity in the set, but not necessarily rare in actual tonal music), Browne reasoned, ought to serve better as perceptual cues that listeners can use to gain a sense of key in music they hear. A series of experiments has produced evidence bearing out Browne's prediction.

In the first study (Brown & Butler, 1981) listeners heard a minimal amount of pitch information, in melodic trichords, from which they made determinations of key center. Choices were limited to the major mode and excluded chromatic interpretations (these will be discussed later). After hearing only three tones in each pattern, listeners were asked to hum, whistle, sing, or otherwise produce a direct judgment of key center. Examples of these three-tone stimulus patterns are shown in Figure 8.3.

Although the pattern in Figure 8.3a looks quite similar to that in Figure 8.3e, the small change of pitch (one semitone) in the third note of the pattern produces a very different intervallic configuration, as can be verified by reviewing Figure 8.2. The rarest interval to be found among the three tones F-G-C in Figure 8.3e is the two-semitone span between F and G. The tones G and C fall within interval class 5, as shown in Figure 8.3e. This means that the intervals between the notes in Figure 8.3 are quite common in the diatonic set. One way of demonstrating this is that we can find that same pattern of ic2 combined with ic5 at five different starting points in the C major scale, as may be seen in Figure 8.4a. Another demonstration (Figure 8.4b–f) is that we can find the specific notes F, G, and C at various points in five different major scales. But the tritone (Fig. 8.3a) occurs just once in the major set; thus there is only one correct major-mode key interpretation for the pitches shown in Figure 8.3a.

When a listener is required to identify appropriate key centers for sequential combinations of tones such as those illustrated in Figure 8.3a and 8.3e, the listener may reasonably expect two things to be true. First, since a rare-interval pattern such as that in Figure 8.3a could fit into only one major pitch set, it

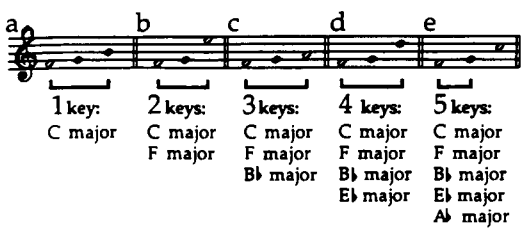

FIGURE 8.3. Transcribed examples of trichordal patterns representative of stimuli used by Brown and Butler (1981). The rarest intervals in each trichordal pattern narrowed its tonal field such that pattern (a) could fit into one major pitch set, pattern (b) into two, and so on.

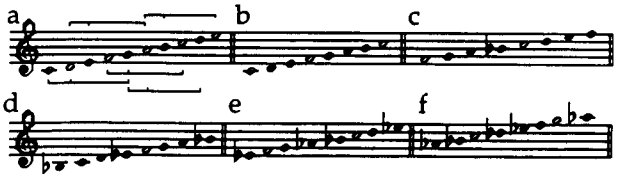

FIGURE 8.4. (a) Five places within the C Major scale where one can find the intervallic combination of ic2 and ic5. (b–f) Conversely, the five scales containing ic2 and ic5 represented by the tones F, G, and C.

ought to be much easier to identify an appropriate tonal center for a pattern such as that in Figure 8.3e, to which one could respond with five different and equally appropriate key centers. Second, although there would be more potential right answers to a pattern such as Figure 8.3e illustrates, listeners' responses might well be spread out among the several appropriate alternatives. Both expectations were borne out in the results reported by Brown and Butler (1981), who asked musicians to sing, whistle, or hum the most appropriate tonal centers for three-tone patterns such as those illustrated in Figure 8.3. Although overall accuracy in key identifications for the common-interval combinations (as represented by Figure 8.3e) were a few percentage points higher than for the rare-interval combinations (as represented by Figure 8.3a), listeners were fully twice as likely to agree on a key center for the rare-interval combinations as for the combinations containing only common intervals.

Another result of this test was that variations in the order of presentation of tones made a difference in the accuracy levels of responses to the patterns containing rare intervals. For instance, listeners concurred more on the choice of tonal center when they heard the pattern shown in Figure 8.3a than when they heard its reverse. The clearest sense of key center seemed to arise when scale step 7 was heard after scale step 4; whenever the temporal order of these two steps was reversed (regardless of the placement of the third tone in the pattern), response accuracy and confidence levels both dropped.

The stimulus patterns drawing the strongest responses (in both accuracy and confidence levels) were not necessarily the patterns adhering to any scalar order, so it was suspected that the patterns carried implied harmonic messages—in other words, that listeners mentally supplied something like a chordal accompaniment as a perceptual framework for these tiny melodic patterns. If this were true, the impact of the varying of time orders of tones on listeners' responses could be explained in terms of common harmonic practices in Western tonal music: it is much more common in typical harmonic successions for the subdominant harmony to precede the dominant than to follow it. If the fourth scale degree were interpreted as representative of the subdominant harmony, and the seventh scale degree (the leading tone) as representative of the dominant, listeners could be expected to feel that they were on firmer tonal harmonic ground hearing the four-to-seven order of presentation.

The second study (Butler, 1983) dealt directly with chordal successions. The test explored this question of temporal order by presenting, as paired dyads, four members of the major diatonic set: scale members 3, 4, 7, and 8(1). The critical variable was the time order in which the tones were presented. In the first of two stimulus categories, set members 4 and 7 were always heard simultaneously, as were scale members 8(1) and 3; these combinations are shown in Figure 8.5a. The 4-7 combination comprises the tritone, the rarest interval in the set; it also is the clearest, most unequivocal presentation of dominant harmony that can be made with a dyad. (Scale members 4 and 7 were combined to imply the dominant harmony in this test, in contrast to the earlier study in which scale degrees 4 and 7 were presented separately, perhaps implying different chords.) The 8(1)-3 combination is the clearest representation of tonic harmony that can be produced with two tones, and—as Figure 8.5a shows—the 4-7 combination can proceed to these two tones by semitone succession. Patterns such as these were presented both to expert musicians and to musical novices, and it was found that as long as the simultaneities clearly represented the dominant and tonic harmonies, as they do in Figure 8.5a, both experts and novices concurred strongly in their choices of the key that each of these patterns represented. On the other hand, both experts and novices were much less accurate in their identification of the key that patterns such as those in Figure 8.5b represented—this even though exactly the same set members were heard, and even though the intervals separating the simultaneities were still semitones. The critical difference apparently was that the simultaneities no longer clearly represented an unequivocal dominant-tonic or tonic-dominant harmonic succession. It seemed clear from this result that pitch relations alone were not sufficient to convey a sense of key to musical listeners; the clarity came when those pitch relations were presented in a temporal order that allowed listeners to interpret those tones within a meaningful harmonic context that the listener tacitly provided.

Subsequent experimental studies have added interesting detail to what we know about the effects of temporality on the perception of pitch relations in tonal (and posttonal) music. Brown (1985, 1987, 1988) demonstrated that when well-known musical excerpts are distilled by deleting repeated pitches, the source pitch set can be ordered so that listeners identify the melody's original key as the key of the new pattern, but when those same pitches are ordered another way, listeners are just as convinced that the pitches belong to a second key. When the pitches are reordered in a third way to induce tonal confusion in listeners, listeners are indeed much less likely to agree on the key for that pattern.

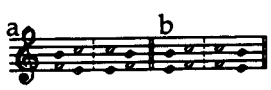

FIGURE 8.5. Transcribed examples of three-tone patterns representative of stimuli used by Butler (1983). Tones were arranged temporally either so that (a) the tritone was presented as a simultaneity, or so that (b) the tritone was presented asynchronously, within different vertical dyads.

Figure 8.6 is an example from Brown's (1988) study. Listeners were 86% accurate in identifying D as the tonal center of an excerpt (see Figure 8.6a) from the third movement of Schubert's Sonata in D Major, D.664, in which tonic and dominant seventh chords are arpeggiated over a tonic pedal. The remaining 14% mistook F-sharp, the last tone heard in the melody, as tonic. When the excerpt (which comprises the diatonic set of D major, missing only the submediant) was reduced to one instance of each within an octave of its component pitches and was ordered to promote identification of the original key (shown in Figure 8.6b), agreement on D as tonic increased to 95%. The pitches were also ordered and presented with the intent of eliciting the choice of G major as the key (Figure 8.6c). While 41% responded to the diatonic set, identifying D as the tonal center, 45% chose G, a key that no listener thought was implied by the musical excerpt or by the ordering of pitches shown in Figure 8.6b. When the sequence was arranged so that rare intervals did not imply clear harmonic progressions in any key (Figure 8.6d), choices of key were indeed more diffuse: Forty-five percent of the listeners chose D, but tonic identifications were scattered among seven other pitches, three of which were not in the tonal pattern (as indicated by whole notes). Responses to the pitch set as ordered in Figure 8.6c and 8.6d indicate that reversal of the single tritone from its optimal 4-7 ordering (the ordering that clearly suggested its major tonic in the pattern shown in Figure 8.6b) greatly diminishes the power of even the rarest interval to suggest a key.

This effect can also be observed in melodic patterns comprising the tones found in a single major triad. In a recent study by Brown, Butler, and Jones (in progress), listeners heard short contextual patterns such as those shown in Figure 8.7, and then rated all members of the chromatic set (which followed the

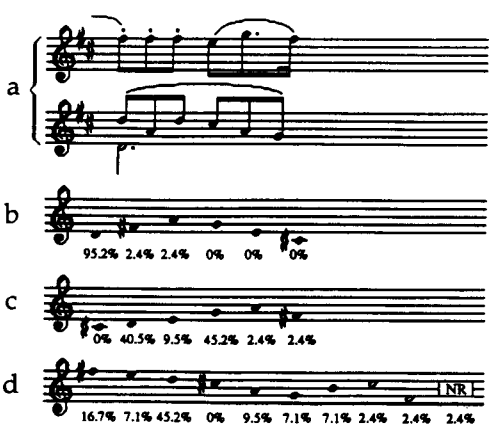

FIGURE 8.6. (a) Excerpt from Schubert, Sonata D. 664, movement III, containing at least one of each interval in the diatonic set and containing no conflicting rare intervals; (b) pitches extracted from the Schubert excerpt and ordered serially to promote identification of D as tonal center; (c) the same pitches reordered to promote G as tonic; (d) the same pitches reordered to be tonally ambiguous. Levels of identification as tonal center for each pattern are given in percentages; whole notes in (d) show out-of-pattern pitches identified as tonic. (NR means no response.) (After Brown, 1988.)

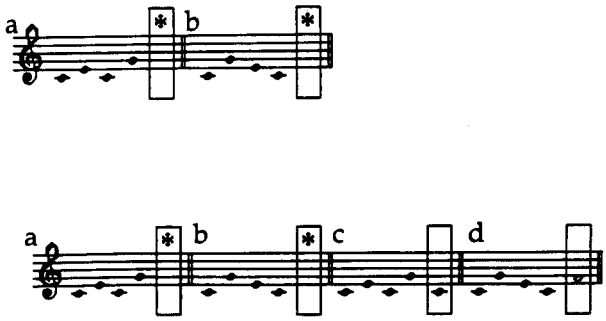

FIGURE 8.7. Tones of a C major triad arranged in two temporal orders (a,b) that preceded all members of the chromatic set (presented at the points indicated by the asterisks). (c) The tone with the highest rating for well-fittedness for the first pattern; (d) the tone rated as best-fitting for the second pattern.

patterns at the point indicated at the asterisk in Figure 8.7a,b); ratings were based on the listeners' estimates of how well each tone fit with the pattern preceding it. Listeners rated the root of the triad as the most appropriate completion when the triad was arranged to reinforce that choice (see Figure 8.7c). When the same contextual tones were rearranged (as is shown in Figure 8.7b,d) to undo the rhythmic regularity of C4 within the contextual pattern, the highest rating indicated an interpretation of the contextual pattern as a dominant chord, with the test tone implying resolution to tonic (Figure 8.7d).

Minor Mode

Our discussion until this point has been limited to tonal harmony in the major mode. This is an important limitation. The perceptibility of other important aspects of tonal harmony has received relatively little experimental investigation thus far. We next consider the topics of minor mode and chromaticism and their relationships with tonality.

One likely reason that most research in tonal harmony has concentrated on the major mode is that it is so much simpler to discuss than the minor mode is. The harmonic form of the minor scale is most relevant to the topic of harmony and tonality because this form has both a leading tone below the tonic and an "upper leading tone" above the dominant. There are three semitones and one augmented second among the adjacent scale members in harmonic minor; this is shown in Figure 8.8.

As Figure 8.8 illustrates, the minor diatonic set has very different intervallic properties from the major set. There are two of the rarest interval class in this set, and only five of the most common. The tritone in major mode is likely to sound unique because it is; the two tritones in minor, however, are obviously not unique. They are inherently more ambiguous in regard to placement in the

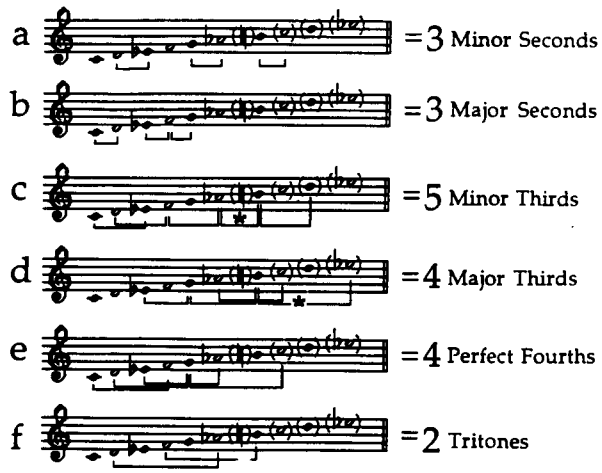

FIGURE 8.8. The various intervals found among tones in the C minor diatonic set (shown in scalar order in this figure). Beginning with the smallest interval other than the unison, there are (a) three members of ic1; (b) three also from ic2; (c) five members of ic3; (d) four members of ic4; (e) four members of ic5; and (f) two tritones (ic6).

pitch set, because any tritone we hear in a piece of music in the minor mode has two potential diatonic points of reference.

There are unique intervals within the six categories shown in Figure 8.8, however. Notice that in Figure 8.8c there are five intervals within interval class 3. Four of these are notated as minor thirds, while one, marked with an asterisk, is notated as an augmented second. Similarly in Figure 8.8d, there are four intervals within ic4: three are notated as major thirds, while the fourth interval is notated as a diminished fourth. Within a musical context (see Figure 8.9) sufficient to clarify the identities of the augmented second and the diminished fourth, it is logical that these rare intervals both assist listeners as they ascertain their tonal whereabouts in music in minor mode. Butler's (1992) data show that this is the case; listeners who heard brief melodic patterns resembling those in Figure 8.9 exhibited almost the level of agreement on minor-mode tonal center as they did for analogous patterns made up of the rarer intervals in the major diatonic set.

Chromaticism

Chromaticism has been equated with randomness or atonality in some perceptual studies (e.g., Taylor, 1976; Krumhansl, 1990). Notice, however, in the second melodic sequence derived from the Schubert excerpt above (Figure 8.6c), in which pitches were arranged to elicit tonic responses of G major, that listeners who did interpret it in that key understood C-sharp to be the leading tone of D,

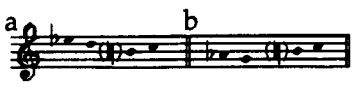

FIGURE 8.9. (a) A melodic pattern that includes a diminished fourth between notes 1 and 3; (b) a melodic pattern that includes an augmented second between notes 1 and 3.

the dominant pitch, which follows it here. Listeners in Brown's (1988) study were able to interpret this C-sharp as a raised fourth scale step that harmonically intensifies the approach to the dominant. This melodic emphasis on a note other than tonic, achieved by chromatically raising the note below it, is known as *microtonicization*.[4] Listeners' responses indicate that, in direct judgments of tonal center, chromaticism is not an element of the tonal fabric that necessarily suggests randomness or atonality. Temporal arrangements and harmonic implications in experimental stimuli can be evaluated as reflective of cognitive processes that enable listeners to incorporate chromaticism into their interpretations of tonality in music. The discussion below draws from both analytic interpretations and experimental data to support this position.

Figure 8.10 contains an example of a set of stimuli (Brown, 1985) manipulated in a way similar to the Schubert excerpt discussed above, but the pitch set of this musical excerpt from Ives's *Concord Sonata* can be reduced neither to a diatonic set nor to any familiar scale. Its interval-class content includes one more minor second than the major diatonic set and one fewer tritone (that is, none). The musical excerpt (Figure 8.10a) consists of an arpeggiated E-flat major triad, in addition to these nonchord tones: F functioning as an appoggiatura on the downbeat, and D and F-sharp functioning as lower neighbors to the root and third of the triad. F-sharp, the chromatic tone that adds two minor seconds to the set, acts as a microtonicization of G both in the excerpt and in Figure 8.10b, the melodic sequence arranged to suggest the key of E-flat to listeners. In the latter context, an arpeggiation of the dominant triad (F–B-flat–D) resolving to the tonic note by the best rare interval available for E-flat, this chromatic pattern elicited unanimous agreement among listeners. In Figure 8.10c, although there is no A-flat and no rare interval for the key of A-flat major in this set, arpeggiation of its dominant triad (B-flat–E-flat–G) ends with its leading tone to suggest resolution to A-flat to listeners. This resulted in 60% agreement on that key while choices of E-flat as tonic dropped to 12%. Responses to the last ordering, shown in Figure 8.10d, clearly illustrate the features of a tonally ambiguous melodic pattern: Responses were scattered among 10 of the 12 possible tonics, with listeners exhibiting the most reliance on the first and last pitches.

With musical excerpts and their reduced melodic sequences that included from as few as three to as many as 10 of the 12 pitches of the chromatic set, results in these studies indicated consistently that virtually any set of pitches could be manipulated temporally either to suggest various tonal centers or to be tonally confusing. Even subsets of a single diatonic pitch set could not be assumed to suggest that key on the basis of nontemporal considerations. In other words, the results indicated that critical relationships among pitches in tonal

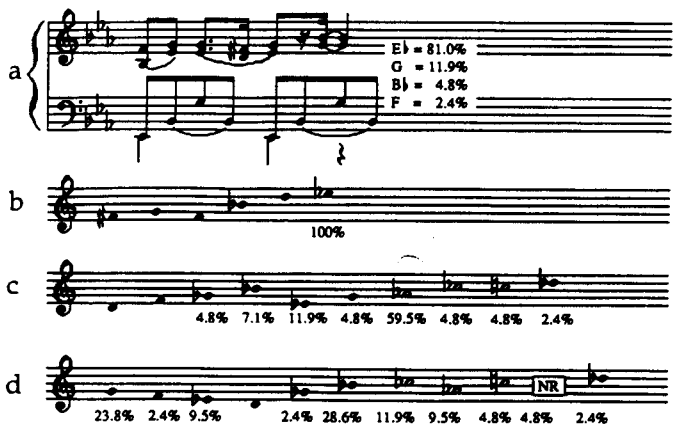

FIGURE 8.10. (a) Excerpt from Ives, Sonata No. 2 (Concord), "The Alcotts"; (b) pitches extracted from the Ives excerpt and ordered serially to promote the identification of E-flat as tonal center; (c) the same pitches reordered to promote A-flat as tonic; (d) same pitches reordered to be tonally ambiguous. Levels of identification as tonal center for each pattern are given in percentages; whole notes show out-of-pattern pitches identified as tonic. (NR means no response.) (After Brown, 1985.)

music do not arise solely from the pitch-set properties of those tones, but arise also to a great extent from their temporal context in the specific pattern being heard.

It is possible, though, for each pitch in a chromatic set to carry a unique meaning that suggests relationships to a tonal center. It takes more than the usual chromatic scale to illustrate this, because tonal music may have only 12 tones per octave, but it has more than 12 functional pitches per octave. In Mitchell's words:

> The ordering force of diatonicism becomes a dispersing force of the chromatic scale. Where each degree of the diatonic major scale is imbued with a single meaning, due to its characterizing interval set and its distance from a tonic degree, the tones of the chromatic scale have multiple meanings. (Mitchell, 1962: 8)

A representation of pitch classes called the "tonal chromatic collection," developed by Brown (1987, 1992), illustrates a distinction among the multiple meanings resulting from mixture and tonicization. According to Proctor (1977), these two processes are the sole sources of chromaticism in diatonic tonality. Although there can be abundant chromaticism in diatonic tonality, the asymmetry of the diatonic basis, with its unique pitch relationships, is preserved. This is distinguished from symmetrical structures in chromatic tonality (Proctor, 1977), where an equal-tempered 12-pitch-class collection is appropriate and where enharmonicism is a tonal, as well as a notational, phenomenon. An example of

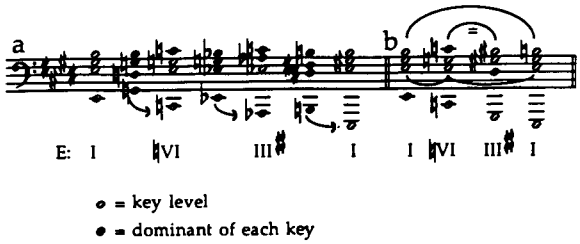

FIGURE 8.11. Synopsis of key areas in Chopin's Prelude in E Major, op. 28, no. 9. (a) Each key level in the prelude is prefaced by its dominant; (b) ties indicate pitches in common among the tonic harmonies.

this symmetrical construction is found in Chopin's E major Prelude, op. 28, no. 9, where key relationships represent a symmetrical division of the octave into major thirds: E, C, A-flat/G-sharp, E. These relationships are shown schematically in Figure 8.11.

The process of chromaticism has also received experimental attention (see, e.g., Brown, 1988, 1992; Butler, 1980, 1988), and these studies indicate that the process involves much more than simply adding nondiatonic pitches to somehow dilute the strength of the prevailing tonality. Chromatic chords can lead skilled listeners to expect that some chords will form more appropriate resolutions than others and can thus be clear signals both of the key level and of unfolding harmonic events at the local level. Until much more experimental research has been carried out, however, it is impossible to say just how unequivocal these signals are, or to say just how many listeners can reliably pick them up.

Summary

Theoretical discussions of tonal harmony tend to begin with abstractions such as scales, idealized chords, and key signatures. It is important to remember, however, that listeners are forced to pick up information about tonal harmony from one or several tones at a time as the music unfolds perceptually across time. Leading theories of tonal harmony have been only partly successful in explaining how this information is picked up, however. There are two leading reasons for this limited success. First, some of the most influential theories assert (or imply) that musical harmony is intrinsically related to the harmonic frequency relations among partials of periodic tones (e.g., Helmholtz, 1863; Schenker, 1906; Schoenberg, 1911). One hazard of this assertion is that harmony could then be considered solely as a relationship of simultaneous sounds; musical harmony, on the other hand, comprises relationships among sounds that may be successive, or even sounds that may be temporally far removed from one another. Second, theories have emphasized abstractions such as scales and chordal prototypes (e.g., Forte, 1979; Piston, 1987), devoting comparatively little attention to the temporal aspects of harmony and tonality.

The discussion in this chapter, on the other hand, has proceeded on the assumption that the perception of tonal music is inherently temporal—that listeners discover harmonic relations within a key, and track harmonic successions hinting at or actually moving to other keys, as tonal music unfolds in time. This discussion has concentrated on the perception of two facets of musical harmony: first, how listeners recognize the key in which the harmonies reside, and second, how listeners recognize harmonic successions that may or may not be limited to the notes within a single diatonic system. These harmonic successions may be conveyed explicitly by chains of chords, or they may be implicit in a single line—in as few as a handful of tones. Riemann's theory of harmonic function includes this central assertion:

> There are only three kinds of tonal functions (significance within the key), namely, tonic, dominant, and subdominant. In the change of these functions lies the essence of modulation. (Riemann, 1895: 9)

If we are to learn how a listener can recognize any of these three fundamental harmonic functions, we must begin by asking how the listener recognizes the key forming the context for these functions. A number of studies reviewed in this chapter (e.g., Brown & Butler, 1981; Butler & Brown, 1984; Brown, 1988; Butler, 1989) have gathered evidence that listeners get their tonal bearings from the critical intervallic relationships, arranged in conventional patterns across time, that convey the harmonic message of dominant harmony progressing to tonic. If we then ask how a listener is to recognize the change of these functions wherein the essence of modulation lies, we find that the functions change when critical intervallic relationships are taken away from the primary dominant-tonic progression and transposed to some alternate progression. Riemann, in fact, stated that modulation—the change of harmonic functions—resulted from "leading-tone exchange" (*leittonwechsel*). A number of studies cited in this chapter have presented evidence that this leading-tone exchange is recognized when the rare intervals of the diatonic set are encountered in conventional temporal patterns: when one rare interval—the tritone—can indicate a dominant harmonic condition (either on the original dominant, or elsewhere in chromatic harmony), and when other rare intervals—the semitones—lead to the dominant's objective harmony (either the original tonic, or elsewhere in chromatic harmony, or in modulation). These leading-tone relations carry the essence of dominant-to-tonic harmonic progression. They can be fragmented and transposed to produce chromatic harmonic successions that are clearly tonal, or they can be subverted to deny tonality.

NOTES

1. While we assume that the reader has a solid working acquaintance with traditional musical terminology, some of this nomenclature is problematic because some of the most basic terms have been encumbered with too many meanings. Thus, we will give narrow operational definitions to the terms "pitch," "harmony," and "key," and will discuss their relationships to traditional Western tonality.

2. It is obviously true that most instruments in our musical culture are designed such that they will most readily produce tones separated by twelfth-octave pitch increments. This certainly does not mean that composers are limited to those choices of pitch materials, as compositions by Harry Partch, Easley Blackwood, and numerous others will attest. More germane to this discussion, scales possess no intrinsic properties that force—or even necessarily guide—composers' choices on how the members of the scale are to be arranged across the time-span of the composition.

3. What if the voicing of the chord C_3-B_3-E_4-A_4-D_5 were changed to B_3-C_4-E_4-A_4-D_5 (Figure 8.1b)? —or to A_3-B_3-C_4-D_4-E_4 (see Figure 8.1c)? It might well be that fewer listeners would accept the second voicing as pleasant, and fewer still the third. Although some readers might argue that this undermines Cazden's distinction between sensory and systemic dissonance, other readers could argue that it strengthens Cazden's argument: if the same pitch-classes (and thus the same interval classes) can give rise to different reactions of sensory dissonance, how can sensory consonance and dissonance be a sufficient basis for a rigorous and useful musical theory of consonance and dissonance?

4. The reader is invited to compare the process of microtonicization with Bharucha's (1984) perceptual study of melodic anchoring.

Tonality and Expectation

JAMSHED J. BHARUCHA

Introduction

Jamshed Bharucha's research has been highly influential in proposing that tonality gives rise to both expectations and aesthetic experiences (Bharucha, 1984). In this chapter Bharucha discusses how musical expectations are generated experimentally. He describes the relationship between tonal expectations, consonance, stability, and memory, and questions whether musical expectations are learned, innate, or based on the structure of the sounds themselves. His interest is in understanding the cognitive processes that underline tonal expectations and their acquisition. Bharucha points out that when listening to music listeners rejoice at what they already know; therefore, he asks, are they giving up the element of surprise or the element of familiarity? For Bharucha, tonal expectations are a compelling aspect of the aesthetic experience of listening to music. He divides expectations into two kinds: schematic expectations, which are culturally generic, automatic, and related to a general schema, and veridical expectations, which are related to the actual piece of music, to a specific memory.

Bharucha explains how he has used neural networks to account for certain findings about music perception. Neural networks are computer models that simulate brain-like systems based on fundamental principles of neural organization: they have been used to model human behavior. The application of neural networks to the perception of music is a promising and fast-growing area of research (see Bharucha, 1987 and 1991; Gjerdingen, 1989; Todd & Loy, 1991).

Why does a segment of music ending in a dominant chord generate strong expectations for the tonic to follow? What is the relationship between tonal expectations, consonance, stability, and memory? Are expectations of this kind learned, innate, or based on the structure of sound? If they are learned, how?

Some of these and related questions about tonality and expectation have been pondered through the ages by music theorists,[1] and today we benefit from a wealth of work on which to build. In this chapter I shall sketch an approach to these questions based on psychological experiments and computational modeling designed to explore the cognitive processes underlying tonal expectations,[2] their relationship to consonance, stability, and memory, and their acquisition.[3]

Tonal expectations are important to study for several reasons, including their role in the aesthetic experience of music, their role in the mental organization of music, their influence on consonance and dissonance, and their role in learning. The advantage of viewing these disparate phenomena in terms of expectation is that there is the promise that the processes that underlie expectations underlie aspects of these other phenomena as well.

The interested reader is directed to a substantial body of important work that will not be reviewed in this chapter, particularly work on the specific musical determinants of expectation (Meyer, 1956; Carlsen, Divenyi, & Taylor, 1970; Narmour, 1977, 1990; Carlsen, 1981; Schmuckler, 1989). The focus in this chapter will be on trying to understand the perceptual processes that underlie

expectation. Toward this end, only a small set of specific musical expectations will be addressed—tonal harmonic expectations—by way of illustrating the potential of certain experimental and computational approaches. The reader is also directed to the work of Jones (1981a, 1981b) for a more overarching theoretical approach to understanding musical expectation.

Tonal Expectation and Aesthetics

Tonal expectations are a compelling aspect of our aesthetic experience of music. The deception of a deceptive cadence, the irresolution of a half cadence, and the finality of a final cadence are only the most obvious examples of tonal expectations at work in Western tonal music. Delayed resolution of tonal expectations is often a central distinguishing characteristic ascribed to late romantic composers such as Wagner. Tonal expectations can be found in other cultures as well. Some of the most dramatic moments of a performance of Indian classical music involve an eventual resolution to the tonal center after a prolonged yearning for it.

The most influential modern exponent of the role of expectation in musical aesthetics is Leonard Meyer (1956). According to a widely accepted view based largely on the work of Meyer, a piece of music in a familiar genre generates expectations, the subtle violation of which is emotionally important. There is considerable support in psychology for the relationship between expectancy violation and emotion (e.g., Mandler, 1984).[4]

Little, if any, work has been done by cognitive psychologists on the affective aspect of experiences associated with expectation. In contrast, a fair amount of research has been done on the processing of sound that leads up to (and is a prerequisite to) this affective experience. This chapter thus focuses exclusively on trying to understand these prerequisite processes, without taking a position on the nature or interpretation of the affective experience induced thereby.

The Puzzle of Expectations

There is a puzzle concerning the role of expectations in music that Dowling and Harwood (1986) call "Wittgenstein's paradox": The puzzle is that when we are familiar with a piece of music, there can be no more surprises. Hence if expectancy violation is aesthetically important, a piece would lose this quality as it becomes familiar.

Attempts to resolve this apparent paradox often postulate a mental structure, called a schema (Dowling & Harwood, 1986), that has assimilated the music of a genre over a lifetime of experience. The expectations produced by this system are generic in that they represent the most likely transitions in one's musical culture.[5] They are also automatic, in the sense that they cannot easily be suppressed. Even when a given piece has been heard often enough to be familiar, it

cannot completely override the generic, automatic expectations. Surprises in a new piece thus continue to have a surprising quality because they are heard as surprises relative to these irrepressible expectations.

This line of reasoning seems necessary but cannot be sufficient. If the surprises in a new piece continue to be surprises even after repeated hearing, the piece would never sound familiar. Furthermore, a performer playing from a schematic representation would be unable to predict the next event, but would instead drift into the most generic progression; the performer would, for example, always follow a dominant chord with a tonic. Using this explanation, you either give up surprise or you give up familiarity.

Yet it clearly must be the case that an atypical transition in a familiar piece is both familiar and surprising. It is familiar in a sense and surprising in another. It is thus necessary to postulate two kinds of expectations, which may be called *schematic* and *veridical* (Bharucha, 1987a). Schematic expectations are the automatic, culturally generic expectations mentioned above. They must be generated by a system that has learned to expect the events that are the most likely. Veridical expectations are for the actual next event in a familiar piece, even though this next event may be schematically unexpected. They must be generated by a system that has learned that particular piece. Since schematic expectancies are acquired from hearing many individual pieces, the two kinds of expectancies will converge more often than not for pieces typical of one's musical culture. Sometimes they will diverge, however, creating the sense of violation of which Meyer wrote.

Expectation and Mental Representation

The existence of two kinds of expectations suggests (but doesn't require) the existence of two systems that generate them. These may be called a *schema* and a *memory*, which generate schematic and veridical expectancies, respectively. A schema is a term used by cognitive psychologists to refer to a mental representation of generic relationships. The memory, in contrast, would represent specific sequences of music in a way that enables them to be retrieved (recognized or recalled) individually. A schema enables one to recognize the style of a new piece; a memory enables one to recognize a particular piece.[6]

A schema generates expectations for events (such as chords) that *typically* follow. A schema thus embodies the information that would generate *typical* hierarchies of stability. These hierarchies, called *tonal hierarchies*, reflect the relative stability of tones or chords in given key-inducing contexts.

A memory, in contrast, generates expectations for events that *actually* follow in a particular familiar piece of music. A memory thus embodies the information that would enable a listener to recognize an error in a familiar piece, and that would enable a performer to play the correct note, however schematically unexpected.

Expected events are heard as more consonant and more stable than unex-

pected events, as will be seen below. Thus expectation, consonance, and stability covary with the musical context. If this is true, these terms refer to slightly different experiential aspects of the same underlying process.

The activation of a schema while listening means that, in addition to hearing the sounded pitch events (along with their temporal, timbral, and other qualities), schematic expectations are generated and are fulfilled or violated to varying degrees, with concomitant effects on stability. The schema thus imposes a cultural elaboration on the sounded events. Elaboration is widespread in perception and cognition (see Anderson, 1990). While reading a story, for example, inferences are drawn and familiar themes are triggered. These happen automatically, unavoidably, and constitute a mental elaboration of the text.

The representations postulated by Lerdahl and Jackendoff (1983) and by Deutsch and Feroe (1981) are essentially representations of mentally elaborated pieces of music. According to Lerdahl and Jackendoff, a piece of tonal music is represented as an inverted tree, of which the pitch-time events of the piece are at the terminal branches (see Figure 9.1). An inverted tree diagram shows levels of abstraction from the piece of music (eighth-note level, quarter-note level, etc.).

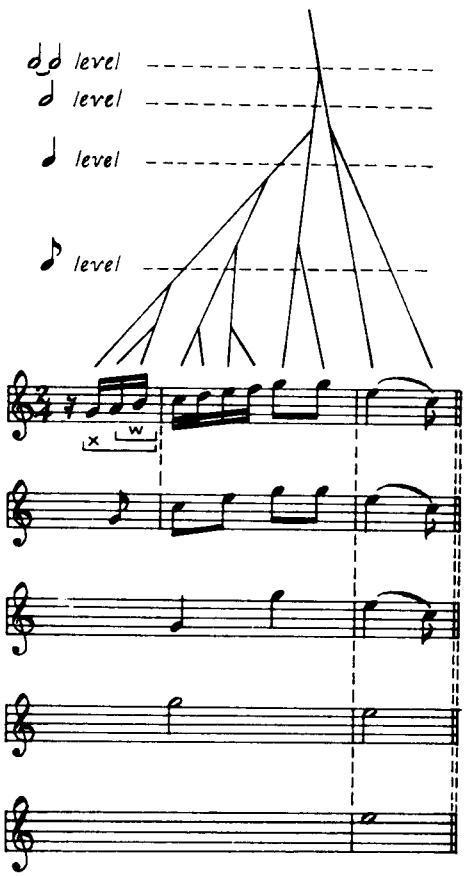

FIGURE 9.1. An inverted tree diagram shows levels of abstraction from the piece of music (eighth-note level, quarter-note level, etc.). A branch that terminates at a longer branch represents the subordination of an event to a more stable event. The most stable event (E in the last measure) is represented by the uninterrupted trunk of the tree. The increasing levels of abstraction are written out in musical notation below the score of the piece. (Reprinted from Lerdahl & Jackendoff, 1983. Copyright © 1983 by M.I.T. Press.)

to maximize the percent of trials they get correct (which is displayed at the end of the experiment).

Another reason for employing an intonation judgment is that it enables us to study how the perceived consonance of a chord is influenced on the basis of whether or not it was expected. To summarize, the priming task using an intonation judgment has two goals: (1) to measure expectation using reaction time, and (2) to study the effect of expectation on consonance. The task is designed so as to pursue these goals for musically untrained as well as trained listeners.

From trial to trial, the experimenter varies the degree to which the target chord is expected[8] given the prime. In the simplest such experiment (Bharucha & Stoeckig, 1986, experiments 2 and 3), the prime was a single chord, and the target was either most highly expected or most highly unexpected given the prime. Thus if the prime was C major, the target was either G major or F-sharp major, as shown in Figure 9.2 (all keys were used in the experiment).[9]

This yielded four types of trials: in-tune expected, out-of-tune expected, in-tune unexpected, and out-of-tune unexpected. The listeners only needed to concern themselves explicitly with whether or not the target was in-tune or out-of-tune.

The results were as follows. First, listeners were faster and more accurate, on average, to make intonation judgments for the expected chords than for the unexpected chords (see table). This demonstrates that the process underlying expectation is one of preparation or facilitation. It is as if a representation of the expected chord had been mentally activated even before the chord occurred, based on its being highly probable in the familiar tonal style.

The second central result was that listeners were faster and more likely to respond "in-tune" when the chord was expected than when it was unexpected, or, equivalently, they were faster and more likely to respond "out-of-tune" when the chord was unexpected than when it was expected. This indicates that expected chords sounded more consonant, or, equivalently, unexpected chords sounded more dissonant. This result shows starkly that there are at least two determinants of consonance. One is the relationship between simultaneous sounds. This in turn is based on the way sound interacts with the inner ear (see below) as well as learning. The second determinant is the relationship between

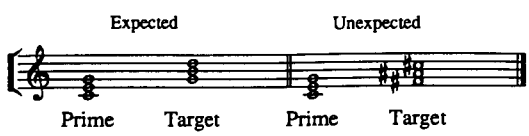

FIGURE 9.2. The design of the priming experiment (Bharucha & Stoeckig, 1986). The figure shows root position triads in close position only to illustrate the difference between expected and unexpected. The actual chords heard by the subjects were considerably more complex (see note 9).

In-tune	788	982
Out-of-tune	864	803
Average	826	893

two sequential sounds. This, it is claimed here, is primarily learned and is mediated by expectations.

Both effects described above were observed for rank novices and professionals alike. The novices were novices only insofar as they had no formal training and no experience playing an instrument. But by virtue of having grown up in a particular culture (in this case, the United States), they have presumably learned what to expect from extended passive exposure.

It is important to note that expected events aren't necessarily preferred over unexpected events. This caution about expectation holds true of consonance and stability as well. If there is any relationship between expectation and its associated concepts, on the one hand, and preference, on the other, it takes the form of an inverted-U function (see Dowling & Harwood, 1986, for a discussion): A moderate amount of violation of expectations is generally preferred over always fulfilling expectations or always violating them.

Even this trend should be viewed with some caution. People who are immersed in experimenting with new musical forms may develop preferences based on phenomena other than expectation, consonance, and stability. Although a composer may have exposure to several genres, including some that are very different from tonal-harmonic music, and would thus develop a rather diverse set of schemata, it is almost impossible to escape exposure to tonal-harmonic music if one grows up in a Western society. Tonal-harmonic music pervades television, radio, supermarkets, and the dominant popular forms of music. Some of the subjects in the above priming experiment were composers who viewed the experiment with grave suspicion, seriously doubted they would show any evidence of schematic tonal expectations, and asserted their lack of preference for expected tonal events. Nevertheless, they showed the same pattern of results as novices. A person is in a sense a prisoner of the schematic expectations driven by the inadvertent learning of musical patterns that pervade the environment.

This means that it is difficult to suppress schematic expectations. Can this be demonstrated empirically? In one experiment, 80% of the trials contained highly unexpected chords and only 20% contained highly expected chords. Even over a session of 100 trials, the chords that were processed more quickly were those that were traditionally expected even though they were in the clear minority during the session (Bharucha & Stoeckig, 1989). Distorting the musical environment in this way was not sufficient to wipe out a lifetime of exposure.

In another experiment, each prime-target pair was played twice in succession. For example, in an "unexpected" trial, the subject would hear C-F-sharp-pause-C-F-sharp. The last chord was mistuned on half the trials, and subjects had to decide whether it was in-tune or out-of-tune. The last chord, F-sharp, is schematically unexpected (since it rarely follows C) but veridically expected (since it actually follows C and the subject knows the same pair will be repeated). Nevertheless, schematically expected chords are still processed more quickly than schematically unexpected chords (Bharucha & Stoeckig, 1989). These experiments thus provide some preliminary evidence that schematic expectations are very difficult to suppress.

Expectation and Tonal Hierarchies

There has been a more extensive study to date of tonal hierarchies than of expectations. Since one of the claims in this chapter is that the processes that underlie schematic expectations may also be responsible for tonal hierarchies, a summary of research on tonal hierarchies is relevant.

Tonal hierarchies have been studied most exhaustively by Krumhansl (1979, 1990; Krumhansl & Shepard, 1979). The term "tonal hierarchy" signifies the relative differences in stability of tonal elements. For example, when the key of C major has been strongly established during a piece of music, the diatonic tones (C, D, E, F, G, A, B) are more stable than the nondiatonic tones. If a different key is established, a different set of tones will be the stable diatonic set. Among the diatonic set in any given key, the tonic is the most stable, and the major third and perfect fifth are generally more stable than the remaining four.

Although this tonal hierarchy for tones in the context of an established key is well known from elementary music theory of the common practice period, Krumhansl sought to quantify this hierarchy. Among the many advantages of quantifying a tonal hierarchy are the following. First, although the tonal hierarchy is quite clear when a key is strongly and unambiguously established, it is less clear when a key is weakly established or when there is more than one established key (as in polytonality). A quantification of tonal hierarchies makes it possible to track the development of keys even in the latter case. For example, there has been considerable debate as to whether the opening passage of Stravinsky's *Petroushka* is simultaneously in C major and F-sharp major or, alternatively, in no key at all. By quantifying the tonal hierarchy in this passage, Krumhansl and Schmuckler (1986) were able to determine that indeed both keys, C major and F-sharp major, were established.

A second advantage (perhaps the more significant psychologically) of quantifying the tonal hierarchies is that it makes it possible to depict tonal relationships spatially. For example, the circle of fifths is a spatial depiction of the relationships between major keys (see Figure 9.3). A single spatial representation such as a circle captures, all at once, the many pairwise relationships between

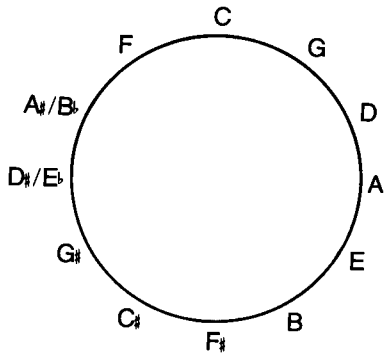

FIGURE 9.3. The circle of fifths.

the 12 possible major keys. Thus, instead of individually enumerating the relationship between all the keys (e.g., C is most closely related to G and F, less closely related to D and B-flat and so on, G is most closely related to D and C, less closely related to A and F, and so on, and so forth), a single diagram with the 12 keys labeled shows all the relationships simultaneously. The advantage is even more striking if minor keys are included. A single spatial representation that captures all these pairwise relationships at once provides a vivid insight into the psychological representation of tonality. That is not to say that the same spatial representation necessarily exists physically in the brain.[10] Rather, it means that the physical representation in the brain encodes the information that is contained in the spatial representation.[11]

At this point one might be inclined to ask why quantification of tonal hierarchies is an advance, since music theorists have a long tradition of tracking keys and employing spatial representations (the circle of fifths, in particular). The answer is that methods of quantification permit us to investigate tonal hierarchies in the minds of listeners other than theorists, who, after all, have extensive formal training and who, by the very nature of the enterprise, adopt a highly analytical stance toward listening.

The method Krumhansl has used most extensively to investigate tonal hierarchies is called the *probe tone technique*, originally developed with Roger Shepard (Krumhansl & Shepard, 1979). In this technique subjects hear a musical context followed by a probe tone. The musical context could be either a musical scale, a chord, a chord progression, or an actual sample of music. The *probe tone* is picked at random from the 12 chromatic pitch classes. The listener's task is to rate how well the probe tone fits within the musical context by rating it on a scale from 1 to 7. The context is then repeated and a different probe tone is presented. The context has been fully probed when all 12 chromatic pitch classes have been presented. This process may be repeated for the same listener and also repeated for many listeners, yielding several replications of each of the 12 probe tones. The ratings for each probe tone are averaged across the replications, yielding 12 numbers, one for each probe tone. This set of 12 numbers is called a *profile* (see Figure 9.4).

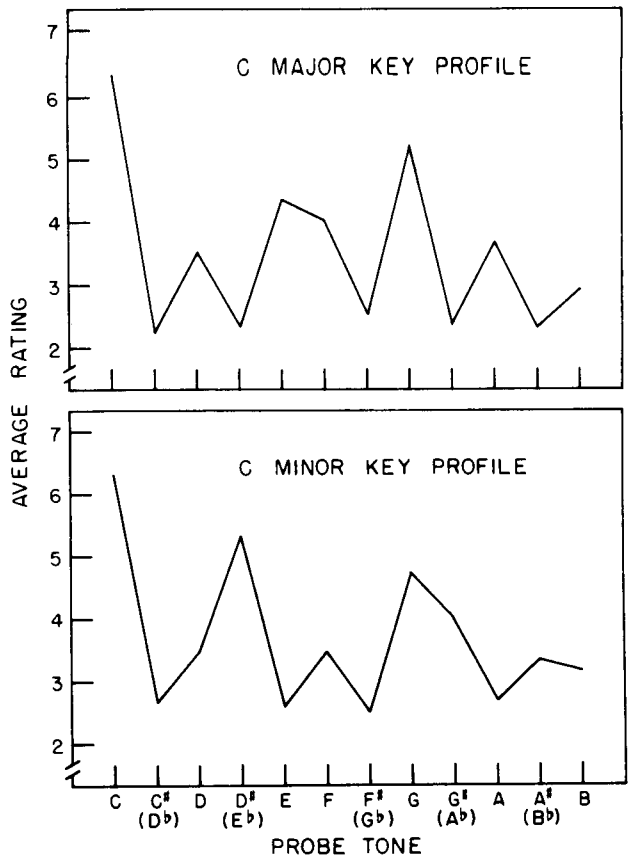

FIGURE 9.4. Profiles for major and minor keys. The rating for any given probe tone depicts the perceived stability of that tone in that key. The profiles are shown with respect to C major and minor for convenience only. (Reprinted from Krumhansl & Kessler, 1982. Copyright © 1982 by the American Psychological Association. Reprinted by permission.)

When the musical sample establishes a key strongly and unambiguously (e.g., a IV-V-I cadence), the profile shows the tonic being the most highly rated, followed by the other two tones of the tonic triad, followed by the remaining diatonic tones (Krumhansl, 1979, 1990). The profiles from samples with a strong and unambiguous key are averaged and the resulting profile is used as a standard profile for that key. The standard profiles for the 24 major and minor keys constitute the standards against which the profiles of samples with weaker or more ambiguous keys are assessed.

Krumhansl and Kessler (1982) showed how one can track the development of keys in a musical sample of interest. To do this, the profile obtained for that sample is correlated with each of the 24 standard profiles. The strength of the

sample's correlation[12] with a key standard indicates the strength of that key in the sample as of the moment at which the probe was presented. By probing a piece of music at different points in time, the development and change of keys over time can be tracked.

To represent the relationships between keys spatially, the standard profiles for the 12 major and minor keys are themselves correlated with each other. The higher the correlation between two keys, the closer they are in the spatial representation. Thus C major is highly correlated with G major and F major, as well as with A minor and C minor, and therefore needs to be located close to them. In addition, it has a range of correlations with the other keys, which must therefore be located at corresponding distances. Simultaneously satisfying all these constraints is very difficult. This is accomplished by a computerized method called multidimensional scaling, developed by Shepard (1964). Krumhansl and Kessler (1982) found that the spatial representation that best satisfies these multiple constraints is a torus. A torus requires four dimensions, but for convenience can be imagined in three dimensions as a doughnut, with the proviso that the inner and outer perimeters of the doughnut be equal (which is why three dimensions don't suffice). This solution captures the circle of fifths for major keys and for minor keys, and puts the two together in such as way as to preserve the relative and parallel major-minor relationships. The relative positions of keys on the torus can be examined by cutting it and unfolding it into a flat sheet, as shown in Figure 9.5. A torus results from joining the top and bottom edges

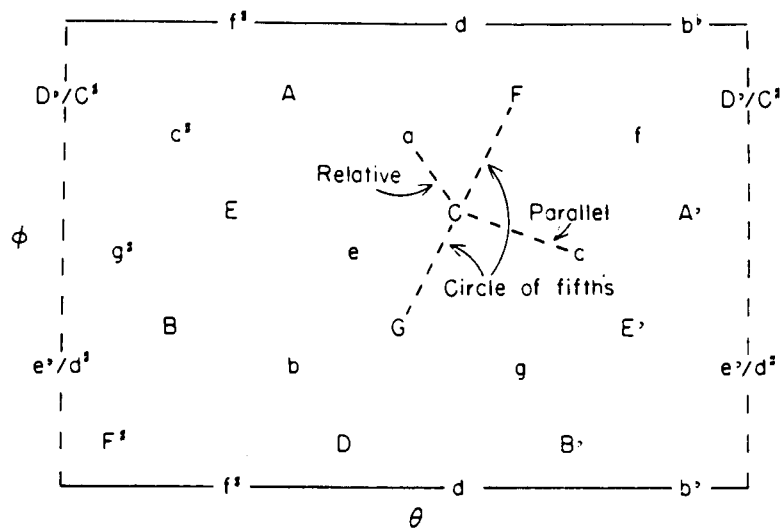

FIGURE 9.5. An equivalent two-dimensional map of the multidimensional scaling solution of the 24 major and minor keys. (Reprinted from Krumhansl & Kessler, 1982. Copyright © 1982 by the American Psychological Association. Reprinted by permission.)

together and joining the left and right edges together. If you actually try this with a piece of paper, it will either wrinkle or rip, which is why an additional dimension is needed.[13]

Tonal hierarchies usually, but not always, reflect the frequency of occurrence of tones just heard: tones heard more often are judged to be more stable. When American college students were tested with samples of North Indian music, for example, their profiles were very similar to those of Indian students (Castellano, Bharucha, & Krumhansl, 1984). The profiles of both groups of listeners matched the hierarchies described by theorists of Indian music (Jairazbhoy, 1971), but they also reflected the frequency of occurrence of tones in the samples. This should not be surprising: Tones that are heard as stable have typically occurred more often in the preceding sample. Numerous studies of note counts (summarized extensively by Krumhansl, 1990) show this to be true. In tonal music of the common practice period, tonics tend to occur most often, followed by the other tones of the tonic triad, and then the remaining diatonic tones. Tonal pieces tend to reveal their tonality in the selection of pitch classes and their relative priority. Tonal hierarchies obtained in these experiments thus show, at the very least, that listeners have a memory system that can integrate the pitch classes heard in the immediately preceding sample (called the *proximal context*). This integrated representation then leads them to hear pitch classes that immediately follow as being differentiated on the basis of stability.

The distribution of pitch classes in the proximal context is not the sole determinant of the tonal hierarchy. The profiles of the Indian students in the study by Castellano, Bharucha, and Krumhansl (1984) were found to be influenced by an additional factor: past exposure (called the *distal context*) to these musical forms. This determination was made by a regression analysis. A regression analysis enables one to determine the extent to which different factors contribute individually to an outcome. After determining that frequency of occurrence of pitch classes in the proximal context was the strongest determinant of the profiles for both American and Indian listeners, frequency of occurrence was factored out, and the residual portions of the profiles were analyzed for the influence of additional factors. The residuals of the Indian listeners correlated with profiles based on music theory (Jairazbhoy), whereas the residuals of the American listeners did not. Since the essential difference between the two groups of listeners was their background, it can be concluded that the ratings given by the Indian listeners were based in part on their familiarity with that genre and not just on the information contained in the proximal context.

It is this residual effect of the distal context—that is, prior exposure—that justifies the postulation of a schema, a mental structure that encodes the regularities of a genre as opposed to the specifics of individual pieces. There must nevertheless be enough information in the proximal context to engage the appropriate schema; after all, we have schemas for many things, possibly even many different musical genres. The information in the proximal context (such as

relative occurrence of different pitch classes) serves to activate the appropriate schema, which then generates expectancies that may compensate for the absence of tones that typically occur in those contexts.

There may be other determinants of tonality besides the distribution of pitch classes in either the proximal or distal context. Among them are the rareness of the intervals (see Chapter 8 by Butler and Brown in this volume).

Can Schematic Expectation Be Explained by the Structure of Sound and the Physiology of the Ear?

Consider two tones an octave apart, each containing eight harmonics. Every harmonic of the higher tone is present in the lower tone, and every second harmonic of the lower tone is present in the higher tone. This can be represented by the ratio 1:2, which, for convenience, we shall call the *overlap ratio*. Now consider two tones a perfect fifth apart. Every second harmonic of the higher tone is present in the lower tone, and every third harmonic of the lower tone is present in the higher tone. This interval has an overlap ratio of 2:3. For two tones a perfect fourth apart, every third harmonic in the higher tone is present in the lower tone, and every fourth harmonic in the lower tone is present in the higher tone. This interval has an overlap ratio of 3:4. If you are familiar with how these intervals sound, you know that an octave is the most consonant interval, followed by the perfect fifth, followed by the perfect fourth. As the overlap ratio gets more complex, the intervals sound more dissonant.

Pythagoras, the ancient Greek mathematician and philosopher, arrived at the same ratios more than 2,000 years ago on the basis of the lengths of stretched strings. A string player produces an octave above an open string by stopping the string at half its length, and produces a perfect fifth by stopping the string at two-thirds of its length, and so on. Since Pythagoras couldn't have known much about harmonics, and even less about the workings of the ear, he concluded that there was something inherently special about simple ratios. Today the most compelling account of why consonance is related to ratio simplicity is in terms of how the harmonics affect the inner ear.

The inner ear serves as a prism for sound: it separates sound into its various frequency (pure tone) components. For example, a tone with eight harmonics will cause the basilar membrane in the inner ear to vibrate at eight different places along its length. The vibration of the basilar membrane causes hair cells that are lined up against it to respond. The response of these hair cells thus constitutes a (spatial) representation of the sound spectrum.

Two frequencies that are very close together cause the basilar membrane to vibrate at two points that are close together. Under these circumstances, the membrane's response to one interferes with its response to the other. This produces a sensation of roughness that is typically heard as dissonant. Thus the more

complex the overlap ratio between two tones, the greater is the extent to which the vibrations of the basilar membrane caused by one will interfere with those caused by the other, and the more dissonant the tones will sound together.

If the consonance of intervals can be explained by spectral overlap, can other relationships in musical harmony be explained in a similar way? At first glance, this approach might seem promising. Chords that are considered most closely related tend to have tones in common—e.g., tonic-dominant, parallel major and minor, and relative major and minor relationships. In contrast, chords that are considered most unrelated have no tones in common, C and F-sharp major. Could it be that schematic expectations are simply driven by common tones?

To answer this question, the priming paradigm mentioned earlier was employed. In the original priming experiments, the expected target chord was one step away from the prime chord along the circle of fifths; for example, if the prime was C major, the target was G major. Notice that these two chords share a component tone (as well as all the harmonics of this shared tone). In contrast, the unexpected target was diametrically opposite the prime chord on the circle, and these two chords share no component tones. Thus the faster and more accurate responses to the expected chord could possibly be due simply to the fact that some of its tone components had just been heard. To eliminate this problem, it was necessary for the expected target to have no shared tones with the prime. This condition is easily met by selecting a target two steps away from the prime along the circle of fifths. For example, a C major prime leads to a greater expectation for D major than for F-sharp major, yet shares tones with neither. To strengthen the case, all harmonics that were common to the prime and target were removed, thereby ensuring that the expected target wasn't favored because of its physical similarity to the prime. In spite of this, the expected chord was processed faster and more accurately and was more likely to be judged in-tune than the unexpected chord (Bharucha & Stoeckig, 1987).

There are purely theoretical reasons to reject spectral overlap as the sole determinant of schematic expectations. Consider the following pairs of major triads: C-D versus C-A. C and D do not share any tones, whereas C and A share one tone (E). Thus C and D have less spectral overlap than do C and A. Yet C and D are considered to be more closely related to each other than are C and A, because they are closer along the circle of fifths of chords (see Figure 9.3).

Before rejecting spectral overlap as the basis for harmony, however, perhaps we should question the validity of the circle of fifths for chords. The circle of fifths is typically used to describe the relationship between keys (of the same mode). The (shortest) number of steps from one key to another along the perimeter of the circle represents exactly the number of tones present in the diatonic set of one key but not in the diatonic set of the other. For keys (of the same mode), then, spectral overlap (i.e., the intersection of the diatonic sets of different keys) exactly mirrors the circle of fifths. For chords, however, it does not. Yet the circle of fifths accurately describes the harmonic distances between chords, because

chords closer on the circle are more likely to occur in the same tonal piece (they have more parent keys in common).

Since we cannot rest our case on the mere use of the circle of chords as a descriptive device, a test is needed. The appropriate test is to see whether a chord generates stronger expectations for a chord that is closer on the circle of fifths but doesn't share a tone than for a chord that is further but does share a tone. This experimental design pits convention against acoustics in determining expectations. If schematic expectations are acoustically driven, C major would generate stronger expectations for E major (with which it shares a tone) than for D major (with which it shares no tones).[14] If, on the other hand, schematic expectations are driven by a schema that has encoded the chord relationships on the basis of their conventional typicality, C major should generate stronger expectations for D major than for E major. Recent results support the latter outcome (Tekman & Bharucha, 1991).

If schematic expectations are driven by spectral overlap, then any impairment of one's ability to process auditory spectra ought to be accompanied by a corresponding diminution of schematic expectations while listening to music. A man suffered a stroke that destroyed much of the auditory cortex of his brain. Although he could detect the presence of sounds at almost normal levels, he simply could not tell the difference between the in-tune and out-of-tune chords used in the priming experiments. He was unable to detect a mistuning so severe that people with normal hearing cringe almost without exception. In the priming task, his performance was never much above 50%, which would be expected from sheer guessing. What is remarkable is that he tended to judge expected targets to be in-tune and unexpected targets to be out-of-tune (Tramo, Bharucha, & Musiek, 1990). In other words, his sense of schematic expectation was intact even though his ability to process fine-grained spectral information was severely impaired. It seems that as long as some auditory information get through, the relevant schema can be activated, thereby generating schematic expectations. This is good news for people who experience a diminished ability to process the full range of the audible spectrum, as is typical with age.[15]

Even the relative consonance of simultaneously sounded tones cannot entirely be explained by the structure of sound and the mechanical characteristics of the ear. For otherwise one should be able to synthesize artificial sounds that have very different spectra, as Pierce (1969, 1983) has done, and predict the relative consonance of intervals formed with these tones. Although there is evidence for this using tones with nonharmonic partials that are so discrepant from harmonics that the tone has no clear pitch (Geary, 1980), cases in which the tones have clear pitch reveal an overwhelming tendency to hear the intervals as we are accustomed to.

Consider a clarinet tone, which has very little energy at the even-numbered harmonics. If the fundamental frequency is 440 Hz, the next harmonic would be $440 \times 3 = 1320$ Hz. The tone that should sound most consonant with the 440-

Hz tone is one whose fundamental frequency is 1320. All the harmonics present in the higher tone would also be present in the lower tone, and every third harmonic in the lower tone would also be present in the higher tone, yielding a 1:3 ratio of spectral overlap. This yields an interval of an octave and a fifth. Two clarinet tones an octave apart have no spectral overlap at all. If spectral overlap is the sole determinant of consonance, two clarinet tones should sound more consonant when they are an octave and a fifth apart than when they are an octave apart. Indeed, many other intervals should sound more consonant than an octave. Although this has not been tested with a careful laboratory experiment, the clear sense from hearing clarinet tones is that the intervals that are the most consonant (the octave, for example) are the same as with other instruments. Once again, this must be because of the effect of prior exposure to other instruments and human speech, which do contain even-numbered harmonics. One can only speculate about how the various intervals would sound if our only auditory exposure was to clarinet-like timbres.

One is compelled to conclude that there is much more to the perception of harmony, and the schematic expectations that are such a salient part of it, than is determined by the structure of sound and the mechanical properties of the ear. But it is a mistake to discount these factors completely. Since the time of Helmholtz (1885/1954), the notion that relationships in harmony can be explained by aspects of the structure of sound and processes in early audition has been a leading hypothesis and remains so today (see Parncutt, 1989). It would be surprising if the conventions that have been established were chosen arbitrarily. Factors such as spectral overlap and the consonance and dissonance it engenders may have played a role in the early establishment of the conventions that today drive our perception. One can imagine musicians in ancient and medieval times experimenting with combinations of tones and finding certain combinations to be more consonant than others, based entirely on spectral overlap. The ensuing choices then became convention, and today we are so inundated with music that adheres to those conventions that our internalization of those conventions can compensate to some extent when spectral overlap fails.

How Expectations May Be Learned: Neural Net Modeling

The above evidence forces us to conclude that tonal expectations must be either innate or learned. There are obvious problems with the innateness hypothesis. First, although it is axiomatic that we must be innately endowed with a mechanism capable of supporting schematic expectations, it is difficult to think of the evolutionary pressures that would have given rise to the specific schematic expectations that occur in the perception of Western tonal music by Western listeners.

Cross-cultural studies would, of course, shed some light on how different or similar schematic expectations are around the world.[16] It is important to note,

however, that universality does not imply innateness (see Bharucha & Olney, 1989). Studies with infants can only be suggestive because perceptual learning can occur very early, possibly even in utero.

Perhaps the most compelling argument against the innateness hypothesis is the existence of a plausible learning hypothesis. If schematic expectancies can be easily learned by mere exposure, there is no reason for them to have been wired innately. Much of the work in music cognition (as well as work on artificially intelligent musical systems) consists of postulating rules. This approach is most pronounced in the case of grammars. This work is invaluable because the rules serve as crystallizations of the constraints on the system. In particular, they characterize the knowledge that a musical schema must exhibit. Psychologists are often interested in also understanding the mechanisms that underlie the encoding of this knowledge. From this point of view, it is interesting to ask how the properties that are captured by rules are learned by passive exposure.

Recent advances in our understanding of how brainlike systems might learn provide an opportunity to explore how musical schemas might be learned (Rumelhart & McClelland, 1986). Models of brainlike systems are broadly referred to as neural nets, connectionist models, or parallel distributed models. These are, in turn, a special subset of a larger class of models that may simply be called associative networks.

In associative models, objects or features in the world are represented by units (or nodes). Representational units are linked together to form a network. The network as a whole represents the complex array of relationships between the objects represented by the units. The state of activation of a unit represents the degree to which the represented object is attended (suggested, implied, or expected).

If a network contains units that represent musical objects such as tones and chords, the connections between these units collectively encode the relationships that hold between these tones and chords as they are typically used. The state of activation of a unit represents the degree to which that tone or chord is currently being attended. A unit may be activated directly by a stimulus in the environment, such as a tone or chord, or indirectly through an associative network of such units. When a unit is indirectly activated, that tone or chord is suggested, implied, or expected.[17]

There are many arguments in favor of understanding music cognition in terms of associative networks. First, they easily accommodate ambiguities, with which music is rife. Many units can be active simultaneously to varying degrees, representing varying degrees to which different tones, chords, or keys are suggested. Second, they fill in missing pieces that are parts of typical patterns. For example, if the root and fifth of a triad are played, a network will suggest the major and minor third in proportion to their association with the prior context. Or if an F major chord is followed by a G major chord, the representational unit for C major will be strongly activated, representing a strong expectation for C major.

There are at least two additional arguments in favor of neural net models specifically. First, they are based on fundamental principles of neural organization in the brain. Second, and most important, they can learn.

Learning in a neural net model occurs by changing the strength of the connections between representational units. Consider a neural net that receives its input via units that represent octave-equivalent pitch classes (shown at the bottom of Figure 9.6a). Each such unit is said to be tuned to a particular pitch class. This is a valid assumption given that there are neurons in the auditory system that are tuned to specific frequency ranges and are laid out spatially according to frequency.[18]

Now suppose that this set of units is connected to another set of units that initially do not have any specialization (labeled "unspecialized" in Figure 9.6a). Each pitch class unit is connected to each unspecialized unit (the connections are not shown in the figure), such that the strengths of the connections are initially random. When a combination of tones is sounded, say an F-sharp major chord, the units representing the tones F-sharp, A-sharp, and C-sharp are activated (as shown by filled circles in Figure 9.6b). They in turn activate the unspecialized units. Since the connection strengths are initially random, the activations of the activation levels of the unspecialized units will be random.

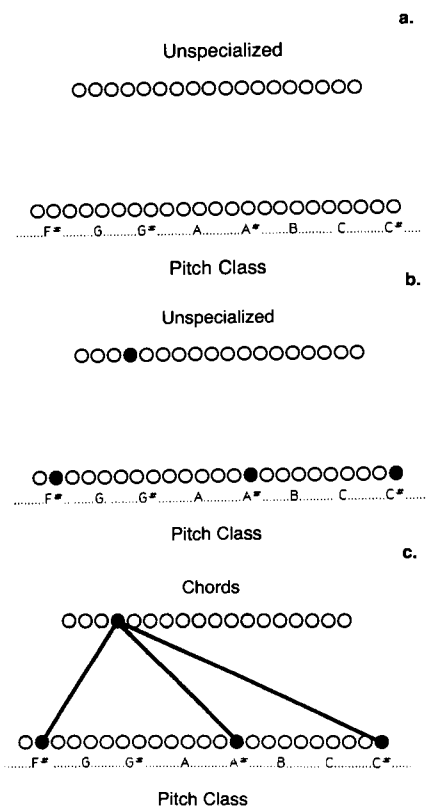

FIGURE 9.6. A neural network learning to represent typical combinations of tones. (a) Pitch class units in the bottom layer are connected to unspecialized units in the top layer via connections with random strengths. (b) In response to a combination of tones (F-sharp, A-sharp, C-sharp), the corresponding pitch class units are activated, and in turn activate the specialized units, one of which wins over the others. (c) The connections between the activated pitch class units and the winning unspecialized unit are strengthened, producing a unit that is now specialized for that combination of pitch classes.

A principle found in many parts of the brain is that units within a layer inhibit each other in proportion to their activation. The consequence of this is that only the most highly activated unspecialized unit remains active, and the others are shut down. So in response to the F-sharp major chord, some arbitrary unspecialized unit (the filled circle in Figure 9.6b) is going to win over the others in that set.

At this point, learning occurs by changing the strengths of the connections between the pitch class units and the winning unspecialized unit. The strengths are changed according to Hebb's (1949) rule: A connection becomes stronger in proportion to the product of the activations of the two units it connects. Since the F-sharp, A-sharp, and C-sharp pitch class units are the only pitch class units activated, their connections to the winning unit become strengthened (indicated by bold lines in Figure 9.6c) and the other connections to the winning unit become weakened. This winning unit has now become specialized to respond to F-sharp major chords. It will be even more likely to win the next time an F-sharp major chord occurs and will be even less likely to win in response to some other chord.

In this way, specialized representational units can form for all combinations of musical events that occur with great regularity. This process can be continued to yet another set of units to which the newly formed chord units are connected. This third set can become specialized to respond to typical combinations of chords, such as tonic, dominant, and subdominant.

Consider an idealized end-product of this learning scheme. It consists of pitch class units connected to units representing their parent chords, and chord units connected to units representing their parent keys, as shown in Figure 9.7 (see Bharucha, 1987a, 1987b, for details). The minor chord units are shown below the pitch class units for convenience only. Furthermore, the chords are shown in a systematic order for illustrative convenience only. What's important is the pattern of connectivity between units, not the layout of the units themselves.

After learning, the network can be tested to see if it has any interesting properties. When presented with the tones C, E, and G, units representing the chords that contain any of these tones are activated. These chord units in turn activate all units representing tones that are contained in these chords and keys that contain these chords. The activated key units in turn activate all units representing chords that are contained in these keys, and so on. The activation process eventually dissipates, and the network reaches an equilibrium state.

At this point, the activations of the chord and key units represent the degree to which chords and keys are suggested or expected. In response to three tones comprising a major triad, the expectations generated by the network are exactly in accord with the circle of fifths: chords and keys closest around the circle are most highly expected. In response to two major chords in succession whose roots are a whole tone apart (e.g., F major followed by G major), the network most strongly activates the key (C major) of which these chords are subdominant and

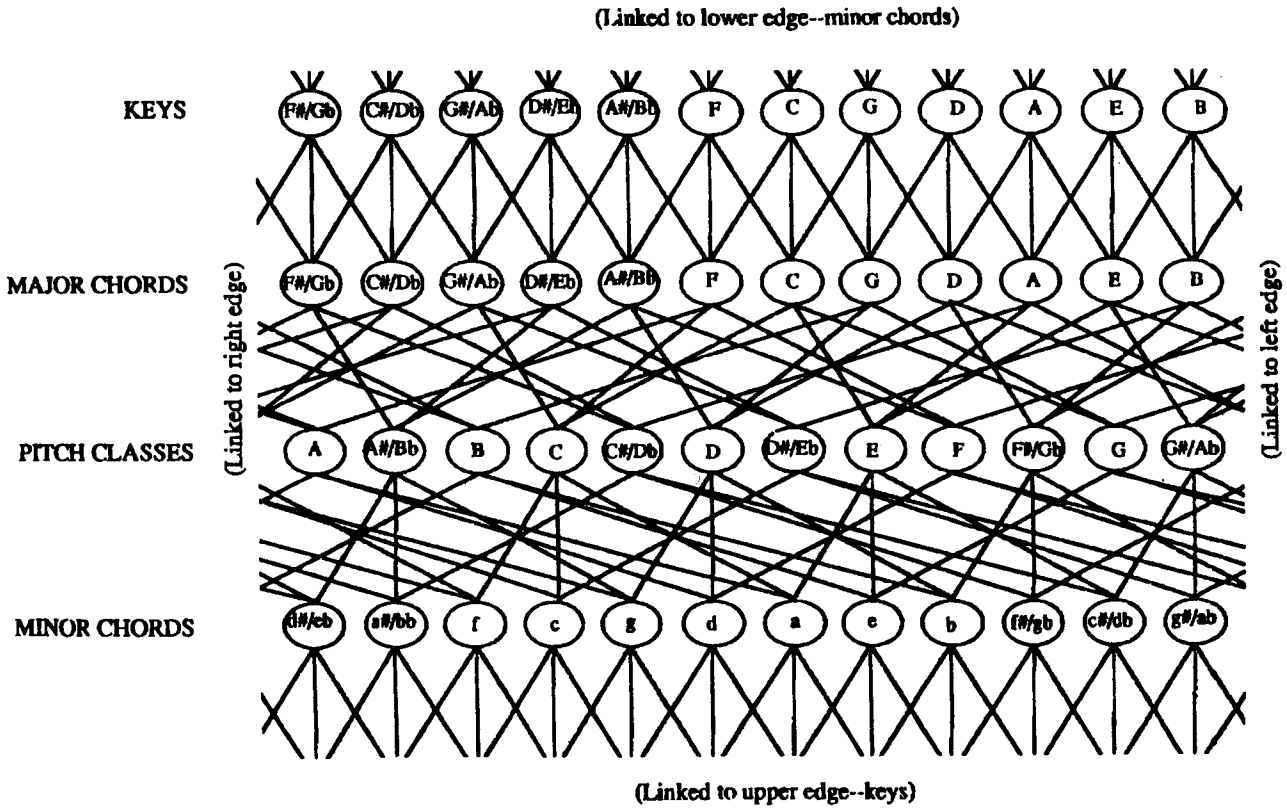

FIGURE 9.7. A network resulting from learning by exposure to typical combinations of tones as found in Western music. (Adapted from Bharucha, 1987a. Copyright by the Cognitive Science Society.)

dominant, and generates a strong expectation for the tonic chord. Finally, in response to a key-establishing context such as a major chord or a final cadence, the network generates expectations for the diatonic tones in that key. To this extent, the network can be seen to generate tonal hierarchies.

The network exhibits the patterns of expectation found in experiments on chord priming. The indirect activation of a chord unit represents an anticipatory processing of the represented object, resulting in faster and more accurate judgments about that chord, as observed in priming.

These complex behaviors of the network cannot be seen immediately by simply examining a diagram of the network such as Figure 9.7. They emerge from computer simulations of the activation process operating on the network. The network thus has emergent properties—that is, properties that are not directly evident from the initial assumptions but emerge from the way in which these assumptions interact. Emergent properties that are in accord with experimental data and music theory, as they are in this case, constitute strong support for a theory. Most theories that consist of rules (such as Lerdahl and Jackendoff's theory) postulate those rules explicitly and do not provide an account of how those rules are acquired. In a neural net, in contrast, the system behaves in accord with rules that weren't postulated explicitly but instead emerge from the complex interactions of more elementary processes that are themselves learned.

Neural nets thus offer the potential to understand how tonal schemata may be learned by passive perceptual learning, thereby giving rise to the schematic expectations that form such an integral part of our musical experience.

NOTES

1. These include (but are by no means limited to) Zarlino (1558/1968), Fux (1725/1943), Schenker (1935/1979), Schoenberg (1954/1969), Meyer (1956), Lerdahl and Jackendoff (1983), Narmour (1990), and Butler and Brown (Chapter 8 in this volume).

2. As opposed to rhythmic or melodic expectations.

3. In keeping with the goals of this book, I shall attempt to avoid detail and excursions in favor of elucidating a clear line of reasoning. The reader is directed to other sources for details, for additional work, and for alternative explanations that bear on the question of harmonic expectation. These include Deutsch and Feroe (1981), Sloboda (1985), Dowling and Harwood (1986), Handel (1989), and, most relevant to some of the material covered in this chapter, Krumhansl (1990). For details about the work of the author, see Bharucha (1987, 1991; Bharucha & Todd, 1989).

4. It should be noted that there is some debate about whether "emotion" is the appropriate term to describe the often subtle and ineffable experiences induced by the fulfillment and violation of tonal expectations. Whether one is willing to call these experiences emotions, however, they are clearly affective.

5. There is no known reason to suppose that one cannot have more than one musical culture.

6. Many cognitive psychologists would consider a schema to be a memory system,

too. For the sake of simplicity, however, we shall restrict the term "memory" to memory for pieces of music.

It may be possible for the schematic expectations to emerge from the memory instead of requiring a completely distinct structure. One way in which this might occur has been explored by Bharucha and Todd (1989). Other methods might generate the schema by an average or composite (e.g., Metcalfe, 1982) of all individual memory traces. Whether the schema and the memory are part of the same physical structure or separate structures is still an open research question. In this chapter it will be assumed that they are separate.

7. This conclusion must await further research, however, since the empirical determination of this issue is very tricky. When a piece of music is recalled from memory in order to perform or imagine it, the schema is activated just as it would be by the sound itself, thereby generating the event hierarchy. It therefore seems redundant to store the elaboration in memory, since it is generated automatically every time the piece is recalled. This is what makes an empirical answer to the question so difficult.

8. This is based on the probability with which chords follow each other in the musical genre to which the subjects have been most extensively exposed (Western tonal music for the subjects in these experiments). C major is most often followed by G major or F major and least often by F-sharp major. Hence, for these subjects, G and F are objectively more highly expected than is F-sharp, following C.

9. The figure shows root position triads in close position as an example only. Although the original experiments employed "Shepard" tones (Shepard, 1964), which render tones more ambiguous with respect to their particular octave, subsequent experiments (Stoeckig, 1990) have shown that the results from this priming experiment are quite robust for different inversions, positions, and voice leading. Thus the effect seems to truly capture the perceptual properties of the triads as wholes.

10. In the case of the linear spatial representation of pitch height this is true! Such a *tonotopic* representation of pitch height is found not just in the inner ear, but even in the cerebral cortex.

11. The information contained in a circle can be encoded by a computer in many possible ways, including a string of symbols specifying the mathematical equation of the circle. Similarly, the brain might encode this information in terms of a particular arrangement of neurons, even though this arrangement may not itself be circular. Cognitive psychologists explore mental representations at different levels of information abstraction, spatial representations being some of the most abstract and neural representations some of the least abstract. The advantage of abstract representations is that the essence of the information can be captured without worrying about the representational medium. The advantage of less abstract representations is that the causal mechanisms involved in encoding the information can be addressed.

12. The strength of a correlation of two profiles is given by a single number, the correlation coefficient, r, that ranges between -1 and 1. A correlation coefficient of zero signifies no correlation.

13. There is nothing mystical about a four-dimensional space. Mathematically, to say that more than three dimensions are required to capture all the relationships between major and minor keys simply means that more than three factors are needed for a complete description of these relationships. The difficulty of depicting the four-dimensional key space stems only from an attempt to illustrate the space in terms of a model that can be visualized.

14. Parncutt's (1989) theory of the psychoacoustic foundations of harmony predicts this outcome.

15. This is not the same as being able to imagine music after becoming completely deaf, which only requires auditory imagery. The familiar account of Beethoven continuing to compose while deaf doesn't in and of itself discount the spectral overlap hypothesis. If sounds are stored in memory in terms of their spectra, then, while imagining music, the imagined spectra would overlap or not, just as would real spectra.

16. See Bharucha (1987b) for a report of a preliminary priming experiment using Indian music and Indian subjects.

17. See Deutsch (1969) for an early model of this kind. Unlike more recent models, it couldn't learn, since the mechanisms by which neural nets might learn were not then well understood.

18. This is called a tonotopic mapping, and can be found all the way from the inner ear to the auditory cortex.

Perception, Production, and Imitation of Time Ratios by Skilled Musicians

SAUL STERNBERG AND RONALD L. KNOLL

Introduction

The rhythmic element of music has always been a central topic for musicians (Cooper & Meyer, 1960; Yeston, 1976; Kramer, 1988; see Jaques-Dalcroze, 1972, for applications of rhythm to theories of music pedagogy). Psychologists, however, have shown increased interest in this area only in the last few years. Early research in the perception of rhythm was based more on the research in the perception of motor control and time (Lashley, 1951; Fraisse, 1963) than on rhythm within a musical context (reviewed in Fraisse, 1987).

A number of psychological studies have investigated the perception of polyrhythms, namely: sequences of rhythmic patterns occurring simultaneously (see Handel, 1984, for an overview). These experiments did not utilize musical stimuli, but rather sequences of tapping played at different pitches. They evaluated the listeners' ability to describe verbally what they heard, or to demonstrate by tapping one rhythmic pattern selected from several rhythms heard simultaneously.

Researchers have provided models of how listeners perceive rhythm, meter, and time. Steedman (1977) proposed a computer model of how listeners perceive musical rhythm and meter that utilized the occurrence of relatively long notes and the repetition of melodic phrases as cues to infer the meter of unaccompanied melodies. Steedman applied this model to analyze the metric structure of the 48 fugue subjects of *The Well-Tempered Clavier* by J. S. Bach.

Longuet-Higgins and Lee (1982) set forth a model that explained how listeners perceive the rhythms of note sequences based on the relative length

From J. Gibbon & Lorraine Allan (Eds.), *Timing and Time Perception*, Annals of the New York Academy of Sciences, vol. 423, copyright © 1984. Reprinted by permission.

of the notes. According to this model, after hearing the first two notes of a sequence, listeners already have in mind some hypothetical grouping, which they revise or confirm as they continue hearing the sequence of notes. The influential research of Mari Riess Jones has dealt with models of time perception and attention within music (Jones, 1987a, 1987b, 1992; Jones & Boltz, 1989).

The two chapters that follow illustrate how musicians perceive aspects of rhythm and timing. In "Perception, Production, and Imitation of Time Ratios by Skilled Musicians," by Sternberg and Knoll, the research is carried out in a laboratory setting, while in "The Interpretive Component in Musical Performance," by Shaffer and Todd, it is evaluated within musical performances.

"Perception, Production, and Imitation of Time Ratios by Skilled Musicians" summarizes a series of experiments that measured the abilities of musicians to reproduce, judge, and imitate (by tapping or by reproducing a note on the violin) a brief fraction of time corresponding to a nonstandard subdivision of the beat. The data showed that the subjects were inaccurate in reproducing, judging, and imitating the small fraction of time required by the experimental task.

The results demonstrate how tasks on the perception of timing that are psychologically very pertinent do not necessarily translate into tasks that are musically as pertinent. Subjects who are experts in responding to rhythm and timing within a musical framework cannot necessarily transfer their skills when making judgments or providing tapping responses to fractions of time in a context devoid of musical significance (vitality).

Regardless of their inability to be on target with the required experimental tasks, these expert musicians will nevertheless perform as skilled soloists and/or as a fine ensemble in a musical setting. In other words, they will all come in slightly early or slightly late, but they will all make their musical entrances *together,* as a group. In listening to music, listeners are not sensitive to how performers respond to a fraction of a second, but rather to their ability to *synchronize* their performances (Rasch, 1988).

Among the human skills in which timing and time perception are critical, musical skill is distinctive: for most players a notation specifies temporal pattern explicitly and provides a criterion to which performance can be compared. Because of their years of practice in the use of this notation, the behavior of professional musicians can plausibly reveal some of the ultimate capacities and constraints of human timing mechanisms. We have examined the performance of skilled musicians in three laboratory tasks designed to capture temporal aspects of music. We focused on the short time intervals—fractions of a second—that are among the shortest durations specified by musical notation. As in Western music, these intervals occurred in the context of a train of periodic beats and were defined as fractions of the beat interval. Our three tasks—perception, production, and imitation—all appear to be required of musicians during ensemble rehearsal and performance, for example. It is plausible that because players try to "keep together," ensemble experience would cause performance in the three tasks to become at least consistent and probably correct as well (that is,

consistent with the notation). Neither of these expectations was borne out by our experiments; instead, we observed surprisingly large systematic errors and inconsistencies.

The principal subjects were three professional musicians: a flutist, a cellist, and Paul Zukofsky (PZ), violinist and conductor. We also obtained a small amount of corroborative data from Pierre Boulez, composer and conductor. A detailed report of our results is available, based on group data.[1] In the present chapter we describe only our more interesting findings, illustrated with data from PZ, who is the most musically experienced of our principal subjects, whose performance we examined in a wider variety of procedures than the other subjects, and whose data are more consistent than theirs, both within and across experiments. The picture generated by the group data is somewhat less clear, but leads to the same conclusions.

Three Tasks of Temporal Psychophysics

We used two kinds of stimuli, shown on the left of Figure 10.1. A *time pattern stimulus* contained two or more *beat clicks* separated by a *beat interval*. The beat interval was usually 1 sec. One or more of the beat clicks was followed by a *marker click* after a *fractional interval*, *f*, that defined a fraction of the beat. A *fraction-name stimulus*, *n*, was presented both as a numerical fraction and in musical notation, where a quarter note was defined as one beat. On the right of the figure are shown the two kinds of response. In making a *fraction-name response*, *N*, the subject would select a category such as "less than 1/8 beat" or "between 1/8 and 1/7 beat." In making a *timed response*, the subject tapped his finger after a beat click, thereby producing a fractional interval, *F* between beat click and tap.

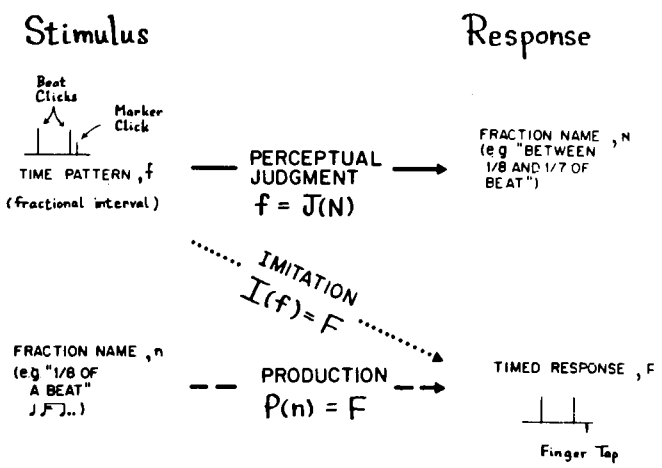

FIGURE 10.1. Stimuli, tasks, and responses.

Stimuli and responses were linked by three different tasks, as shown in the center of the figure. In *perceptual judgment* the subject assigned fraction names to time patterns. He thereby generated a *judgment function*, $f = J(N)$, that maps fraction names onto their subjectively equivalent fractional intervals. In *production* the subject made a timed response to produce a fractional interval associated with a specified fraction name. He thereby generated a production function, $P(n) = F$. In *imitation* (sometimes called the "method of reproduction") a time-pattern stimulus elicited a subjectively equivalent timed response. We thereby obtained an imitation function, $I(f) = F$. To permit performance to stabilize, conditions in all experiments remained constant for at least 25 trials.

Perceptual Judgment of Beat Fractions

The stimulus pattern in our first perception experiment is shown in Figure 10.2. Two pairs of beat clicks separated by two beat intervals (a *rest*) were followed by a single marker click. For each of a set of fraction names we used an adaptive psychophysical procedure to determine the fractional interval that is subjectively equivalent to it. The resulting judgment function is labeled J, in Figure 10.3. The fractional interval, f. is plotted as a function of fraction name, N. Both scales are logarithmic.[1] If stimulus and response agreed, data would fall on the straight line with unit slope. Instead, our subject radically overestimated fractions less than 1/4 beat (or 250 msec). Consider the case of 1/8 beat, for example. Accurate performance would assign this fraction name to a fractional interval of 125 msec; instead, it is assigned to an interval of about 67 msec, or 1/16 beat. Thus, for small fractions, the assigned fraction name is larger than the fractional

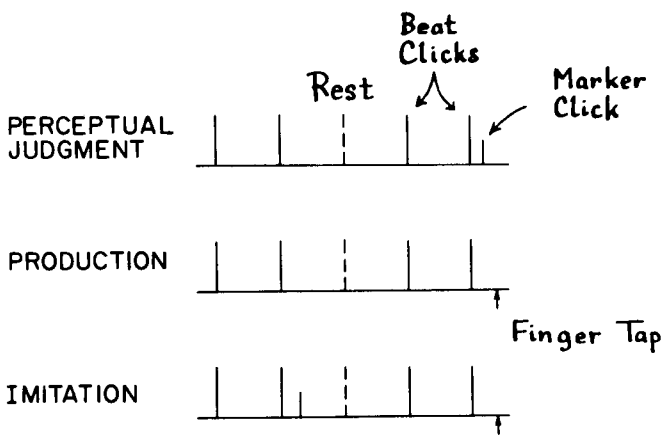

FIGURE 10.2. Sequences of beat clicks, marker clicks, and finger taps in experiments J_1, P_3, and I_5.

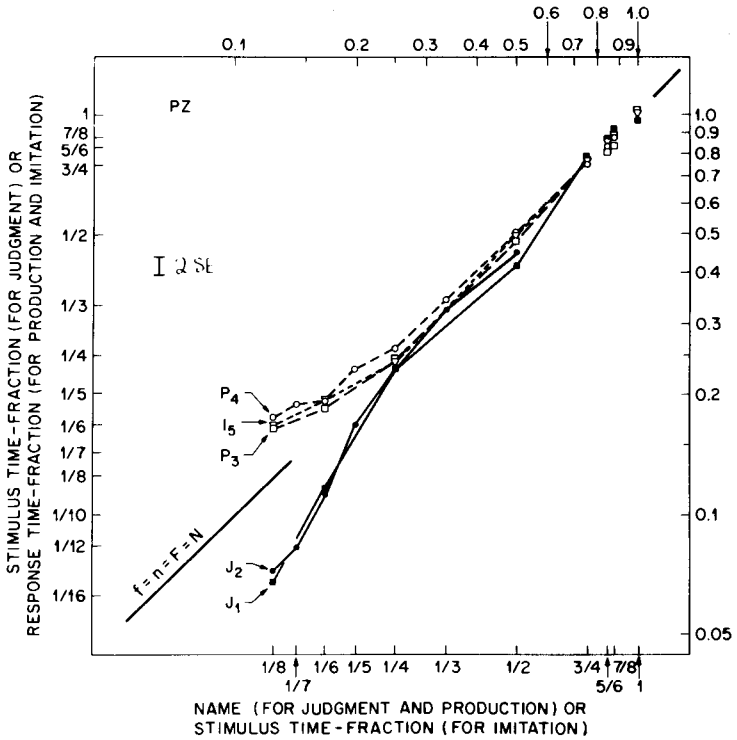

FIGURE 10.3. Results for subject PZ from five experiments: judgment (J), production (P), and imitation (I). Ordinate (*abscissa*) values are given as fractions on a logarithmic scale on the left (bottom) and as decimal values on the right (top). Error bar indicates approximately 2 S.E. based on between-session variability. If the ordinate value is regarded as a function of the abscissa value, the functions shown are estimates of $f = J^{-1}(N)$, $F = P(n)$, and $F = I(f)$.

interval.[2] The *N*-value grows more slowly than the *f*-value, however, coming into approximate agreement at about 1/4 beat. Despite the poor *accuracy* for small fractions, judgment *precision* is high: the difference threshold at 1/8 beat was only 4.3 msec (about 6%), for example.

Production of Beat Fractions

The large errors in the *perception* of small fractions make it particularly interesting to examine musicians' accuracy in *producing* such fractions. One appealing possibility is that production is mediated by a simple feedback process in which the subject judges the fraction he produces with respect to the fraction name he is trying to produce, and adjusts later productions accordingly. Suppose also that

produced fractions are judged by means of the same perceptual mechanism used in the judgment task. The production function should then approximate the judgment function: $P(n) = J(N)$ when $n - N$. Thus, overestimation of small fractions (assigning fraction names that are too large) would lead to underproduction (producing fractional intervals that are too small).

The events on each trial in our first production experiment are shown in Figure 10.2. They are the same as in the perception experiment, except for replacement of the marker-click stimulus by a finger-tap response.[3] With each tap the subject heard the thump of his finger striking a hard surface. The production function we obtained is labeled P_3 in Figure 10.3. The expectation from a feedback mechanism is violated dramatically. For small fractions the intervals produced are too large rather than too small. That is, we have overproduction rather than underproduction. Whereas the subject *judged* 67 msec to be 1/8 of a 1-sec beat, for example, he *produced* a mean fractional interval of 164 msec for the same fraction name. Furthermore, he seemed satisfied with his responses, and did not experience his taps as being late.[4] For small fractions in the perception task we have seen that the fraction stimulus, *f*, that is subjectively equivalent to a fraction name, *N*, changes more rapidly than the *N*-value. In contrast, the fraction, *F*, produced changes more slowly than the *n*-value.

Several analyses and experimental variants were directed at understanding the large systematic errors we had found in judgment and production, as well as their inconsistency. In the present report we consider nine of these. Others, together with these, are considered in greater detail in the full report (Sternberg, Knoll, & Zukovsky, 1982).

Further Analysis of Perceptual Judgment

Psychophysical Procedure

One concern is whether aspects of the judgment data may depend on special features of our psychophysical procedure. In any block of trials in the adaptive procedure, subjects judged time fractions with respect to just one fraction name, and the fractional intervals were concentrated in the range where judgments were the most difficult. In a second experiment we used a method more akin to traditional psychophysical scaling in which both these features were altered. The subject categorized a wide range of time-pattern fractions into one of eight categories of fraction names, ranging from "less than 1/8 beat" to "greater than 1/2 beat," in each trial block. Also in contrast to the first experiment, two beat clicks rather than only one were followed by marker clicks, providing two observations of the fractional interval on each trial. Results are labeled J_2 in Figure 10.3. The two judgment functions are almost identical, despite the differences between procedures.[5]

Fractional Interval Defined by Subjective Onset Versus Offset of Marker

A second attempt to discover a source of the judgment errors was based on the possibility that the internal representation of a brief click may have a longer duration than the click itself. Suppose that when beat and marker clicks are close together, the subjective duration of the fractional interval is defined by the *onset* of the internal representation of the beat and the *offset* of the internal representation of the marker. Such a mechanism could then produce overestimation of the kind we observed. To test this possibility we compared judgments of our normal stimuli, in which clicks were 5-msec tone bursts, with stimuli in which the marker duration was prolonged by about 60 msec. Contrary to the idea that offset time is important, this variation produced no change in the judgments, for either small or large fractions.[6]

Further Analysis of Production

We next turn to five of our efforts to understand the systematic errors in the production task and the inconsistency between production and judgment performances for small fractions.

Opportunity for Adjustment to Feedback

As mentioned above, our subject did not report experiencing his finger tap responses as being late for either small fractions or large. Nonetheless there may have been discrepant feedback from the perception mechanism, but too little opportunity to adjust to it, given only one production per trial. On each trial in a second production experiment the subject produced timed responses after each of 10 successive beat clicks. We found no tendency for the error to be reduced over the 10 successive responses. Mean produced fractions based on all the responses are labeled P_4 in Figure 10.3. Performance agrees closely with the first production experiment. If anything, the tendency toward overproduction is slightly greater.

Subjective Delay of Tap versus Click

A second potential source of inaccuracies in production might be a difference between two critical subjective delays. One is the interval between the occurrence of a click and its perceptual registration. The second is the interval (possi-

bly negative) between our measurement of a tap and when the subject perceives it to have occurred. If these two delays differed, then direct comparison of the intervals between beat click and marker click in perception and between beat click and tap in production would be inappropriate. To estimate the difference between the two subjective delays we asked subjects to tap in synchrony with one or more beat clicks. The difference can be estimated by the mean asynchrony between tap and click; the asynchrony was small—about 10 or 20 msec, depending on the procedure—clearly too small to explain the observed effects. On the assumption that the difference between subjective delays does not depend on the beat fraction, the production data in Figure 10.3 have been corrected by these small amounts.

Improved Feedback from Finger Tap

The disparity between performances in perception and production led us to question a feedback model of production, which suggested in turn that we scrutinize the feedback itself. The feedback from tapping the finger included tactile, proprioceptive, and auditory cues, but not the marker click used in the perception task. In additional production experiments with both single- and multiple-tap procedures, but limited to the fraction 1/8 beat, each finger tap generated a marker click. The sequence of clicks in judgment and production thereby became identical. The production performance was virtually unchanged, however; we found only a 10-msec change in the mean interval produced.

Musical Instrument Response

Another potential source of the production error might have been our choice of finger-tapping as a response. (The subject was a skilled violinist but not a skilled finger-tapper, at least at the start of these experiments.) We ran the single-response production experiment again, but now the response was to play a single note on the violin after the final beat click. We measured the onset time of the note as the subject attempted to produce the fractions 1/8, 1/2, and 1 beat. The amount of overproduction of the small fraction did not decrease. (In fact, it was nonsignificantly greater by 12 ± 11 msec for PZ.)

Minimum Reaction Time

The potential sources discussed above of the production error and the production-perception disparity had to be considered. However, we had little *a priori* reason to expect that even if they had been important, their effects would have depended on fraction size. One constraint that might have such differential effects is the existence of a minimum reaction time (RT). The minimum RT to auditory stimuli is between 100 and 150 msec. Furthermore, there are delays

between excitation of a musical instrument and its acoustic response. The combination of these two effects makes it virtually impossible to produce a note 125 msec after a signal to respond (such as a beat click) when the signal is the event that initiates the response timing process. If we assume that the timing of an offbeat response starts with the immediately preceding beat, it follows that the notation often calls for production of discriminably different response delays, some of which are less than the minimum RT. One solution would be to bias productions just as we have observed, so that for different small fractions the mean intervals produced are greater than the minimum RT, but still distinct.

A test of this explanation is provided by variances of the finger-tap delays, *Var*(*F*), together with an argument suggested by Snodgrass, Luce, and Galanter (1967). We assume that as its mean increases, the variance of a response delay also increases, where the delay is measured from the event that initiates the timing process. If the responses for all fractions were timed from the final beat click, we would therefore expect *Var*(*F*) to increase with fraction size. Instead, we found it to vary as a *U*-shaped function of fraction size, with a minimum between $n = 1/4$ and $n = 1/2$.[7] This pattern of variability would be expected if small fractions, but not large ones, were timed from the penultimate beat; if so, overproduction cannot be explained as compensation for a limited speed of response.

Production of Multiple Subdivisions of the Beat

How can the existence of large production errors for small fractions be reconciled with our belief that musicians are able to fill a beat interval accurately with a sequence of equally spaced actions? Could the production error depend on our use of a single, isolated response?[8] To address this question we studied the three conditions shown in Figure 10.4 in a new production experiment. The beat interval here was 1/2 sec instead of 1 sec, incidentally testing the generality of our effects. One of the conditions required an isolated offbeat response, with a target fraction of 1/4 beat, equivalent to a fractional interval of 125 msec. There were two multiple-response conditions. In one the subject started with a tap on the beat, and alternated between index fingers to fill the beat interval with quarter-beat taps. An unusual interval between the first two taps here would reveal any general distortion of subjective time near the beat. In another condition the initial on-beat tap was withheld. If overproduction depends on response isolation, then the presence of later taps within the same beat interval should eliminate it, especially since the final tap was supposed to be made on the next beat.[9]

Consider first the results from the 5-tap condition. All tap delays, and in particular the delay of the second tap, fall close to the fitted line. There appears to be no general distortion of subjective time near the beat. Furthermore, the slope of the linear function is less than unity, giving a value of 435 rather than 500 msec for position 5. (Since the subject felt satisfied with his productions, we

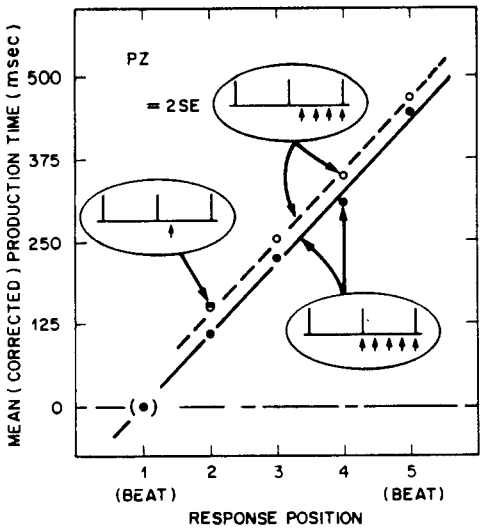

FIGURE 10.4. Stimulus and response patterns in three conditions in an experiment on multiple subdivisions of the beat, together with results. Mean response delays have all been corrected by the mean delay (−34.7 msec) between the second beat click and the first tap in the 5-response condition. Data from the two multiple-response conditions have been fitted by parallel lines. The displayed ± S.E. bar is appropriate for assessing adequacy of the fitted lines.

must assume that the subjective beat interval was shorter than the actual beat interval by about 13%.) In other words, with multiple subdivisions starting on the beat there is no evidence for overproduction of the small fraction. Consider next the 1-tap condition. Just as in our other experiments the response is delayed relative to the correct response time of 125 msec. Because of the shortening of the subjective beat interval, the amount of overproduction is even greater when referred to the second tap in the 5-tap condition. Consider finally the 4-tap condition. The first response—the tap in position 2—is delayed here as much as in the 1-tap condition. The overproduction effect therefore does not depend on the offbeat response being isolated. Instead, it appears to result from an onbeat response being withheld.

The displaced parallel lines provide a good description of performance in the two multiple-response conditions, indicating that every tap in the 4-tap condition is delayed relative to the 5-tap condition, and by about the same amount. This phenomenon seems best described as *displacement of the subjective beat*. As in some circadian phenomena, the phase of a periodic process has been changed with no alteration in its period. We find it especially remarkable that the delay of the first tap is propagated all the way through the last tap, despite the presence of a final beat click.

Conjectures About Failure of the Feedback Model of Production

The beat-displacement effect suggests one possible source of failure of the feedback model. It is plausible that subjects judge their response delays relative to the

subjective train of beats. If so, the beat displacement associated with the delayed offbeat response would reduce the apparent delay of this response. Such an effect might explain a subject's inability to recognize and correct his overproduction. It would be too small an effect, however, to explain the major part of the discrepancy between overproduction and the underestimation we observed in the judgment task, which would require that the magnitude of beat displacement *exceed* the delay of the offbeat response, rather than merely equaling it.

The expectations from the feedback model of production that were violated depend on the assumption that the time-perception processes that accompany production are the same as those used in the judgment task. The beat-displacement effect leads us to question this assumption. The existence of the effect reminds us that in production the fractional interval terminated by the finger tap must not only be timed, but must also be placed in proper phase relation to the train of beats. Performance of small fractions in the production task therefore requires the timing of both a beat interval and a beat fraction within the same sequence. In contrast, there is no reason to believe that *judgment* of a beat fraction depends on concurrent judgment of a full beat interval.[10] It is possible that this difference between tasks contributes to the failure of the feedback model.

Results from a final judgment experiment provide weak evidence that favors this possibility, indicating that if successive long and short intervals must both be judged, the perception of at least one of them may be dramatically altered. We used click patterns like those shown in Figure 10.5, with a 1-sec beat interval, and asked whether judgment of the large interval between the final beat click and the pair of marker clicks would be influenced by the requirement also to judge the small interval between markers. On each trial the subject had to judge whether the interval between markers was large or small relative to 1/8 beat, and then also to judge whether the interval between the final beat click and the markers was large or small relative to a full beat. Judgments of the small beat

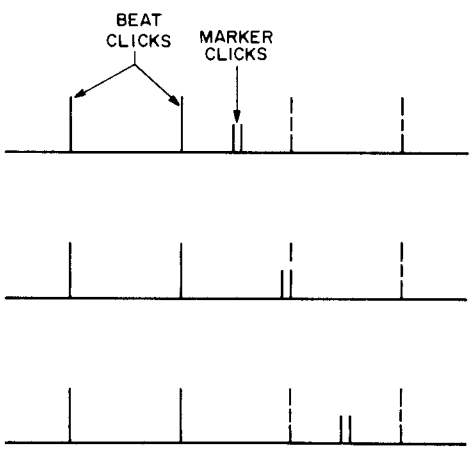

FIGURE 10.5. Examples of sequences of beat clicks and marker clicks in a dual-judgment experiment. Broken lines represent beats for which no beat click was presented.

fraction were very similar to performance in a single-judgment control condition. Judgments of the larger interval were enormously more variable than in its control condition, however: The difference threshold was increased by a factor of 10, from about 4% of the beat interval to about 40%.[11]

Imitation of Beat Fractions

Imitation of beat fractions is of interest partly because it provides a further opportunity to determine the sources of error in perception and production. In judgment and production tasks, subjects must associate beat fractions with fraction names. In imitation (see Figure 10.1), the stimulus of the judgment task is mapped onto the response of the production task; fraction names are not explicitly involved. If the errors in judgment and production are due to the input or output of fraction names, it follows that imitation performance should be accurate.[12]

Such accurate imitation of time intervals is one possibility that has been considered in previous research (Carlson & Feinberg, 1968). A second possibility that has been advanced is that imitation is accomplished by concatenating two processes, a judgment process that covertly assigns a name to the time pattern, and a production process that converts this name into a timed response (Thomas & Brown, 1974). Given our findings of overestimation as well as overproduction of small fractions, this *full-concatenation model* implies that the response fraction in imitation will be too large by the sum of the errors in the other two tasks; we call such an outcome *strong overimitation.*

The imitation data are labeled I_5 in Figure 10.3. Results conform to *neither* possibility. Instead, responses to small fractional intervals in imitation were virtually identical to responses to the names of these fractions in production. The significance of this outcome is best explained in the context of the following model of performance in our three tasks.

An Information-Flow Model of the Perception, Production, and Imitation of Beat Fractions

In the skeleton model diagrammed in Figure 10.6 we limit ourselves to accounting for the relations among performances in our three tasks. Each task involves processes that perform input, output, and possibly translation functions. Parsimony leads us to postulate the minimum number of processes consistent with our data, and hence the maximum number of processes shared between tasks.

The processes underlying perceptual judgment are shown by the two upper boxes. A time-pattern stimulus generates an internal fraction representation. This representation is converted into a fraction name to generate the required response. The processes underlying production are shown by the two lower

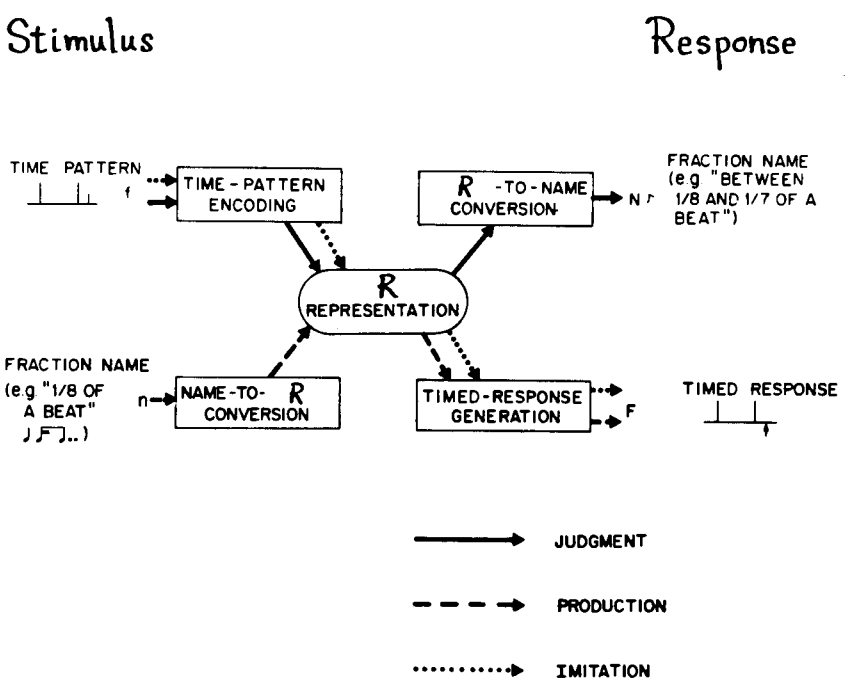

FIGURE 10.6 An information-flow model of perception, production, and imitation of beat fractions. The model incorporates four processes that convert time-pattern (*f*) or fraction-name (*n*) stimuli into time-pattern (*F*) or fraction-name (*N*) responses, and that make use of a common internal fraction-representation. Paths of information flow for the three tasks are represented by *arrows*.

boxes. A fraction name is converted into an internal representation of the same kind as in the judgment task. This representation is then used to produce the required timed response. A full-concatenation model of imitation would most naturally be represented by a mechanism in which the upper and lower pairs of processes made use of distinct internal representations. In such a mechanism information could not flow directly from time-pattern encoding to timed-response generation. Instead, to connect those two operations the covert output of the pair of processes used in judgment (a fraction name) would become the input for the pair of processes used in production. Because such a model can be rejected, we adopt a *partial-concatenation model* in which imitation makes use of a common internal representation, and shares only the encoding process with the judgment task and only the response-generation process with the production task.

Each of the four processes in the model can be thought of as a function or transformation that maps its input onto its output. Qualitative aspects of our data restrict the relations among these transformations. The most important of these relations is based on the close agreement of the data from production and

imitation. When time-pattern and fraction-name correspond, they lead to the same timed response, so that P ≅ I. This in turn means that they must have produced the same internal representation, thus the two input transformations are the same. The internal representation therefore creates a veridical mapping between the two kinds of stimuli.[13] By a complementary argument from the finding that responses to the same fractional interval in imitation and judgment are *not* the same (J ≠ I) we conclude that the two output transformations are distinct.

Both the production and judgment tasks generate psychophysical scales that describe the subject's mapping of musical notation onto time fractions. As we have already seen, neither of these scales is veridical, and, moreover, they disagree with each other. Both scales are *explicit*, in that the subject's response is identified directly with one of the terms in the psychophysical function. By combining results from imitation, $F = I(f)$, and production, $F = P(n)$, which involves the same response, we generate an *implicit* psychophysical scale that relates musical notation, n, to time fractions, f, when both are presented as stimuli: $n = P^{-1}I(f)$. Our data indicate that this implicit scale is veridical, despite the systematic errors in each of the three explicit relations, J, P, and I.[14]

Summary

We have described our exploration of the judgment, production, and imitation of fractions of a beat by skilled musicians, illustrating our findings with data from violinist and conductor Paul Zukofsky. For small fractions we found systematic and substantial errors. In the judgment task small stimulus fractions are associ-

Summary of principal expectations and findings

For Small Fractions (<¼ Beat)	
Perceptual Judgment	
Results: Overestimation	$f = J(N) < N$
Production	
Expectation:	
Underproduction	$F = P(n) < n$
(Feedback Model)	
Results: Overproduction	$F = P(n) > n$
Imitation	
Alternative Expectations:	
a) Veridical	$F = I(f) = f$
b) Strong Overimitation	$F = I(f) >> f$
(Full-Concatenation Model)	
Results: Overimitation	$F = I(f) > f,$
and, for $f = n$.	$I(f) = P(n)$

ated with names that are too large (overestimation). In both production and imitation tasks the fractions produced were too large (overproduction, overimitation). A summary of our findings and of the expectations they violate is provided in the table on page 254.

The temporal patterns we used are perhaps the simplest that qualify as rhythms, incorporating just a beat interval and a fraction. The phenomena we discovered in relation to these simple patterns, and their implications for underlying mechanisms, must be considered in attempts to understand the perception and production of more complex rhythms, as in actual music.

We explored and rejected several plausible explanations for the overestimation and overproduction of small fractions. Although we have as yet no satisfactory explanations of the errors themselves, relations among the errors have powerful implications for human timing mechanisms. The relation between the errors in judgment and production requires us to reject a feedback model of production, in which a subject uses the same processes as in the judgment task to evaluate and adjust his performance in the production task. An explanation of the inconsistency between judgment and production seems most likely to lie in a change in time perception induced by the production task. Together with the existence of systematic errors in judgment, the equality of the errors in production and imitation argues that imitation is not accomplished by concatenating all the processes used in judgment and production. Our results are instead consistent with a model containing four internal transformation processes, in which judgment and production share no process, but do involve the same internal-fraction representation, and in which imitation shares one process with judgment and another with production.

ACKNOWLEDGMENTS

We thank Paul Zukofsky, coauthor of the full report (Sternberg, Knoll, & Zukovsky, 1982) for significant contributions both as subject and collaborator. We are also grateful to Marilyn I. Shaw for helpful comments on the manuscript.

NOTES

1. Power functions appear as straight lines on such a plot.

2. Figure seven provides an outline of our principal findings.

3. Note that although infrequent in earlier music, the playing of a note after the beat without playing a note on the beat is not unusual in the music of the past 60 years.

4. This is an informal impression, not based on analysis of systematically collected data.

5. The procedural differences did influence judgment precision; however, difference thresholds were about twice as large in the second (multiple-fraction) experiment.

6. The measured mean change in $f = J(N)$, averaged over six fraction names, was 0.6 ± 1.9 msec. There was neither a mean effect of marker duration nor an interaction of marker duration with fraction size. This finding may reflect a general property of the perception of timing and rhythm in music, the dominance of the sequence of time intervals between successive *attacks*, and the relative unimportance of *release* times.

7. Because imitation performance is virtually identical to production, in variability as well as mean, a good estimate of the effect of fraction size on the variability of tap delay is provided by $Var(F)$ averaged over the two production experiments described above and the imitation experiment to be described [later]. Fractions that were examined in all three experiments include 1/8, 1/6, 1/4, 1/2, 3/4, 5/6, and 7/8; for PZ the corresponding RMS values of the S.D. are 21.3, 20.3, 16.7, 25.2, 32.4, 42.2, and 42.4 msec, respectively.

8. Musicians could perhaps learn to fill an interval evenly, without accurate perception or production of isolated beat fractions, by employing judgments of evenness and synchrony, together with the ability to count actions.

9. The first tap in the 5-tap condition provided the synchronization correction that we used to adjust all taps in the three conditions. Application of the correction in this way requires us to assume that the location of the initial subjective beat as well as the subjective beat rate depend only on the beat clicks, and are influenced neither by whether there is a tap on the beat not by the number of taps that follow.

10. Judgment of a fractional interval could use a stored representation of the beat interval. Alternatively, the beat interval might not be directly represented at all, but would determine the calibration of a mechanism that assessed beat fractions.

11. In further work along these lines it will be important to force high accuracy in judgments of the large interval and to search for effects on both mean and variability of judgments of small fractions.

12. The converse does not follow: if imitation were accurate, we would know only that the function that relates stimulus fractions to their internal representations must be the inverse of the function that relates internal representations to produced fractions.

13. By a mapping of psychophysical scale that is veridical we mean one that associates the beat fraction $1/n$ with the fractional interval b/n, where b is the beat interval.

14. Given our model it is tempting to inquire whether "error" or "distortion" in any single constituent in the model can account for the performance errors in all three tasks, and their relations. Such an inquiry succeeds qualitatively: The only such single constituent that could be responsible is the internal representation, R, since this is the only constituent common to the three tasks. Suppose that for small fractions, R is "expanded" so as to correspond to a larger fraction. Examination of Figure 10.6 reveals that such an expansion, alone, would produce the three effects we observed: overestimation, overproduction, and overimitation. Quantitatively, however, this explanation fails, because it requires that $J^{-1} = 1$, a relation we can reject reliably if we use the full range of data. The explanation might succeed, however, if we limited it to small fractions.

The Interpretive Component in Musical Performance

L. H. SHAFFER AND NEIL P. McANGUS TODD

Introduction

"The Interpretive Component in Musical Performance," by L. H. Shaffer and N. P. Todd, represents a line of studies that address the perception of rhythm and timing utilizing actual performances of music (see Gabrielsson, 1987a, for a review). With the aid of computerized equipment, this research analyzes the nuances in the rhythmic patterns that pianists display in repeated performances of a composition, and traces a profile of their rhythmic and expressive interpretations. Musical performance research is very valuable to psychologists and musicians alike (see Davidson's Chapter 4 and Sloboda's Chapter 6 in this volume for a discussion of musical skill and performance. See also Clarke, 1982, 1989; Gabrielsson, 1987b; Palmer, 1989; Shaffer, 1981, 1992; Shaffer, Clarke, & Todd, 1985; Sloboda, 1983; Repp, 1990).

Todd (1985) has suggested that pianists reflect the hierarchical structure of a piece by slowing down at points of stability in the piece. In the research described in this chapter, Shaffer and Todd used repeated performances of works by Chopin, J. S. Bach, and Satie to demonstrate that pianists are consistent in reproducing the musical expressions they wish to convey. The performers repeatedly utilize timing to convey and emphasize the structure of the compositions. Psychologically, the performers' overall consistencies indicate that their motor system has a definite representation of the timing parameters. Musically, this research illustrates that nuances such as *rubato* and deviations in tempo reflect a clear musical plan on the part of the performing artists.

Musical performance can be creative in a variety of ways. A jazz or classical musician can improvise on a tune, theme, or chord sequence, to embellish it, provide a set of variations, or construct a fugue. With a little less freedom, a player can extemporize on the harmonic skeleton of a figured bass. These feats may appear to be in contrast with that of a musician playing from a score, but the freedom to improvise is different in kind rather than in degree. Scores vary in explicitness and often do little more than adumbrate a musical form, stating a metre and giving pitch and time values for a sequence of notes. Parameters of tempo, intensity, and articulation of notes—the manner of their sounding and the extent to which they are connected or detached—are usually left to the discretion of the player, and it is implicitly understood that even the written pitch

and time values of notes may be deformed in order to convey or enhance aspects of musical meaning. Thus the emphasis on creativity shifts from musical invention to the subtle shaping of sound.

There are, to be sure, differences of opinion among both composers and players, on the interpretive license given to the player. At one extreme a score is viewed as a text to be transcribed as accurately as possible. On this view there is an authentic interpretation and only this fully realizes the composer's intention. At the other extreme a score is seen as providing a series of basic forms the musical meaning of which can be re-created each time by the player. The sparse notation of a Bach or Scarlatti score suggests that these composers encouraged more license in interpreting their music than, say, Beethoven.

Interpreting a piece of music, then, requires a good working knowledge of the musical intentions of the composer in relation to the conventions and styles of his period, but it is an axiom of performance that it should clearly convey the meaning of the music. A pleasant feature of the world of music is that players are happy to take this axiom as a working brief when the concept of musical meaning is poorly defined. There is no paradox in this, since a player can have a tacit concept that is more definite than the public version. The corollary, however, is that different players can have different concepts. This raises the empirical questions of what players contribute in interpreting a piece of music, whether there is significant agreement in the interpretations of a piece by different players, and what consistent principles may players bring to playing different pieces. Some of these questions are taken up here. They are of interest, though perhaps in different ways, to students of cognitive science and music theory.

Though the concept of musical meaning is inexplicit, we can at least agree with Meyer (1956) that it is a manifold concept having major components that relate to formal structure, emotion, and physical movement. We shall not consider music such as song, theatre music, and tone poem, that is literary in origin or descriptive of the external world. In these it is the programmatic origin rather than the music itself that is likely to govern the use of expression. Putting them aside, what remains is a vast repertoire of absolute music, mainly concerned with developing musical ideas. Such music can convey nuances of mood through choices of tempo, key, modality, pitch register, and pitch contour. It can also suggest kinds of physical movement or gesture by abstractly imitating the rhythms of dancing, walking, speaking, and so on (Gabrielsson, Bengtsson, & Gabrielsson, 1983). Indeed the titles or Italian markings in a score often indicate these nonmusical references, allowing a three-beat measure to be differentiated into the swirl of a Viennese waltz or the more stately stepping of a minuet. It is further claimed that some kinds of ethnic music are based on the motor gestures that are formally required in playing them on a particular instrument (Bailey, 1985). Similar claims may be made for some of the Etudes of Chopin and Debussy, written as virtuoso pieces to capture complex patterns of movement on the keyboard.

Thus even absolute music makes reference to external states and events in conveying mood or physical movement. In these referential functions it acts as an alternative to natural language. Perhaps the major sense of musical meaning, however, lies in the structure of the music itself, and in this sense music is a closed system making reference only to its own sonic domain (Lerdahl & Jackendoff, 1983). The structures have their own meaning, and this autoreferential function of music is in contrast to natural language, in which syntax provides only a key to a more abstract semantics (Lyons, 1981). The structures of music are contained in its metre, rhythm, melody, and harmony and they can act both independently and together in patterning the music.

The different aspects of meaning must all enter into the planning of a performance. There is scope for giving prominence to one or other of these but ignoring or misjudging any of them carries the risk of leaving the musical listener baffled or unsatisfied. Altering the mood of a piece or giving a dance a song-like character (these are not independent factors) may give the music an arbitrary flavor. Failure to convey its structure may leave it without shape, a directionless concatenation of sounds. Simple monodic pieces can look after themselves, as long as they are accurately transcribed, but the more complex the texture of the music the more relevant this last point becomes.

This chapter looks at some of the ways in which concert pianists make expressive use of timing to convey musical structure. The exercise requires two things, the ability to capture sensitively the pianist's use of timing and the ability to describe musical structure in a way that is informative and relatively unequivocal. Difficulties arise on both points. Objective timing is easily measured, but subjective timing for both player and listener may depend on a subtle blend of real time, intensity, tone quality, and the articulation of successive sounds. Also, although there has been progress in the description of musical structure (Lerdahl & Jackendoff, 1983; Schenker, 1969) the methods of description still require a degree of musical intuition in their application and there are not yet accepted canons for describing even relatively conventional tonal music. Nor can it be claimed that the current alternatives are variants that can be generated by a common abstract formalism. Thus lowering our sights a little we shall concentrate on a particular expressive device, the use of slowing to indicate the boundary of a musical group. This device is ubiquitous in music (Seashore, 1938; Shaffer, 1980) and speech (Klatt, 1976), but it gains its effect by being used with discretion. Some of the factors that govern its use are examined here.

The Data

The performances were given on a Bechstein grand piano modified to obtain computer recordings without affecting the sound or touch of the instrument (Shaffer, 1981). Photocells placed in vertical pairs opposite each of the hammers

in the action provide recordings of both the timing and intensity of every key-press. The timing gives information about note duration and the legato/staccato articulation of its succession.

Chopin: Prelude in F-Sharp Minor

The pianist, PB, had recently practiced this piece for a recital. She gave two performances of the Prelude in a single recording session. The first few measures of the piece are shown in Figure 11.1. It is a four-beat measure and there is a fixed rhythmic pattern at each beat that recurs throughout the piece. This allows us to consider the performances in a hierarchy of musical units and we have chosen the beat as the basic unit of timing. The graph in Figure 11.1 shows played duration on the ordinate for each beat on the axis, for all but the last measure. Note that if there were no expressive timing the graph of a performance would be a horizontal line.

The departure from metrical timing is immediately apparent in the graph and its magnitude is quite large. The median beat duration is about 800 ms, and the duration ranges between 600 and 1600 ms, excluding the final rallentando. What is impressive, and important for a cognitive theory, is the very high agreement of timing between the two performances. The shapes of the two curves are almost identical. They differ occasionally in the degree of speeding or slowing but are almost unanimous in where these occur. Such precision has been repeatedly found in studies of concert musicians since the work of Seashore (1938). What it demonstrates is that an expressive form can have a precise mental representation and can be precisely executed. This in turn implies the presence in the brain of an excellent timekeeper and a very good way of coding expression. The musical interest lies more perhaps in the shape of the curves. This reveals a patterning of timing that is responsive to a hierarchy of musical units. There is a typical gesture of acceleration and slowing that can be seen in the beats in a measure, the measures in a four- or two-measure phrase, the phrases in a section and indeed the sections in the piece. Thus the gesture has been used recursively in each level of the hierarchy. Furthermore, there is the stronger result that at each level, the amount of slowing at a boundary tends to reflect the depth of that boundary in the hierarchy. This last result becomes clearer when assigning the parameters to a mathematical model in order to simulate the expressive form, the result of which is shown in Figure 11.2.

The model takes a structural description of the music as its input and generates an expressive form from this. Its success in simulating the data rests on the validity of two factors, the choice of a parabola to represent a basic timing gesture, and the choice of a structural description setting the parameters and hence the shape of each parabola. The assignment of structure makes use of the idea of time-span reduction discussed by Lerdahl and Jackendoff (1983), but with a piece as harmonically complex as the Chopin Prelude some intuition is in-

volved in using evidence of cadence and parallel structure to assign the hierarchy.

Bach: Prelude in C

The first Prelude in the first book of Bach's *Well-Tempered Clavier* is familiar to any pianist and it was given two performances here by the pianist RH with little prior practice. Like the Chopin Prelude the piece has a fixed rhythmic pattern recurring (almost) throughout. Again there is a hierarchy that contains repeating eight-note patterns within four-beat measures, and four-measure phrases, except for an elision at the beginning that makes the last measure of the first phrase also the first measure of the second. Thus there is some reason to expect that expressive patterns should be similar in performances of the two pieces. The timing of the performances of the Bach, taking the measure as the timing unit, is shown in Figure 11.3. There is less agreement of tempo and rubato between the two performances than in the Chopin. This may reflect a willingness to experiment with tempo and rubato in a piece that the pianist plays seldom, and it will later be shown that in more practiced pieces his timing is much more consistent. There is an additional factor obscured by the different timescales of the graphs in Figures 11.1 and 11.3: all the time differences shown in Figure 11.3 are small and of a lower order than in Figure 11.1. Bar duration in the second, faster, performance had a median of about 2500 ms and ranged between 2400 and 2600 ms, excluding the final rallentando. Hence in the Bach there was relatively little departure from metrical timing, apart from the final rallentando, the last measure of which is omitted from the graph.

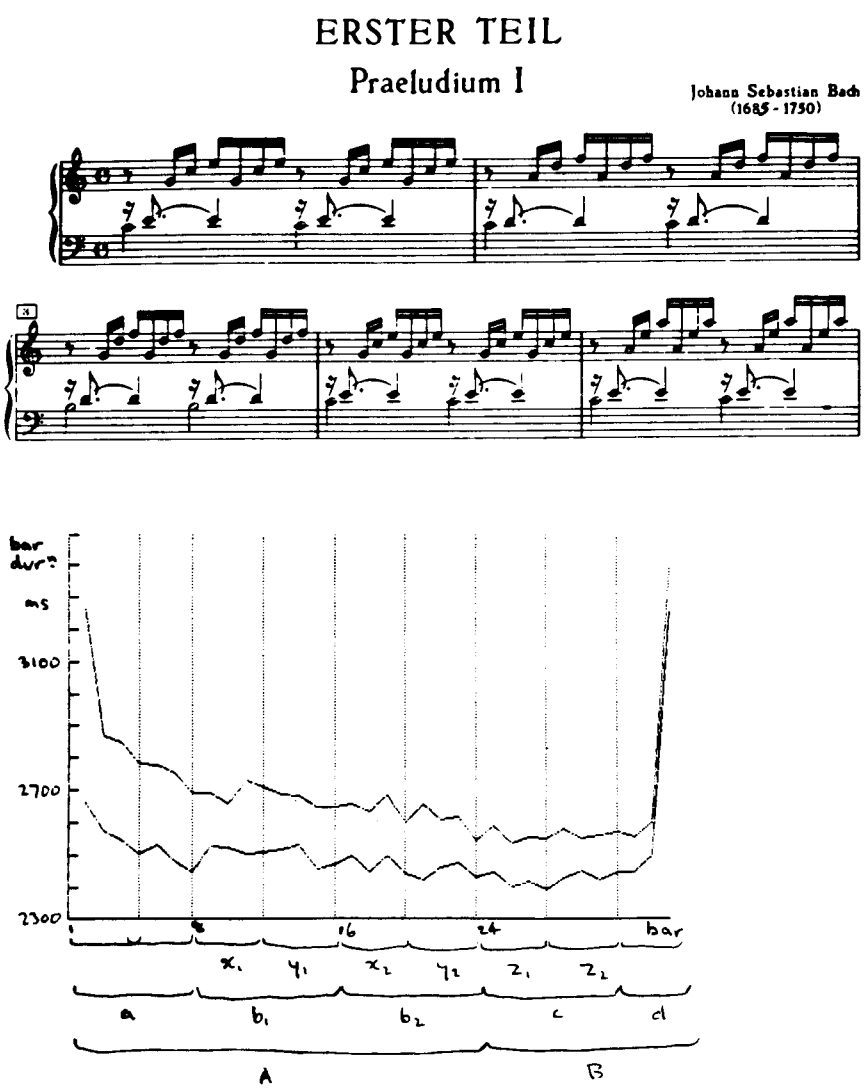

FIGURE 11.3. The first five measures of the Bach Prelude in C and a graph of played measure duration in two performances of the whole piece by RH. The boundaries of bars and phrases, and a hierarchic grouping for these are indicated.

The musically relevant result is that contrary to what was expected the timing gesture of acceleration and slowing was not used to convey hierarchy in the musical structure. Instead there was a single parabolic gesture embracing the whole piece. Yet there are cadences at the phrase boundaries marking intermediate points of rest in the music, which are not always present in the Chopin

Prelude. Unlike that piece, however, the Bach Prelude never properly leaves its home key and it has only a rudimentary melodic line. It can be interpreted, then, as a didactic exercise in exploring the varieties of sonority and progression made possible by inverting and chromatically altering chords, sometimes thereby creating secondary dominants, of the key of C. This didactic function can be underlined by playing the piece as a single tonic to dominant to tonic trajectory (cf. Schenker, 1969).

Satie: Gnossienne No. 5

The pianist JM has recorded the piano music of Satie, including this piece, for the gramophone. He gave three performances here of the Gnossienne among other pieces recorded during the session (Shaffer, Clarke, & Todd, 1985).

In contrast to the other pieces described so far, the Gnossienne has a simple periodic rhythm in the left hand but the right hand has a melodic rhythm that changes continually, embracing a wide variety of rhythmic figures and note durations. Also, whereas the Bach has a clear tonal center throughout and the Chopin much of the time, the Satie appears to vacillate between G and its relative, E minor, without establishing either and so remaining tonally ambiguous, except in a brief bridging passage that is clearly in C. Nor is there a simple relationship between melodic grouping and metre. Hierarchic structure can be discerned only in terms of the recurrence of melodic groups (see Shaffer et al., 1985).

The timing in the three performances, taking the beat as the unit, is shown in Figure 11.4. Again we see the precisely reproducible timing that a concert musician brings to a practiced piece. As in the performances of Bach, there is little use of rubato, the beat duration ranging between 2000 and 2400 ms, nearly half of which is accounted for by a tempo drift described below. However, there is almost an inversion of expressive gesture: the underlining of grouping is now reserved for the lowest level of unit, motivic groups of notes, marked in the score by slurs; there is also a rallentando at the end and, tentatively, before the recapitulation. The other notable feature of timing is that the performances drift throughout to a progressively slower tempo, as if to emphasize the essential lack of harmonic direction of the music. Thus the player appears to have interpreted the piece as a concatenation of musical fragments, an interpretation consistent with a melodic rhythm that alternates groups of short notes with long notes, acting as pauses.

Chopin: Mazurka in A Minor

In order to establish a more direct comparability between players and pieces, we turn to performances of the same piece by the pianists PB and RH, who played the Chopin and Bach preludes, respectively. PB gave one performance of the Mazurka and RH gave two.

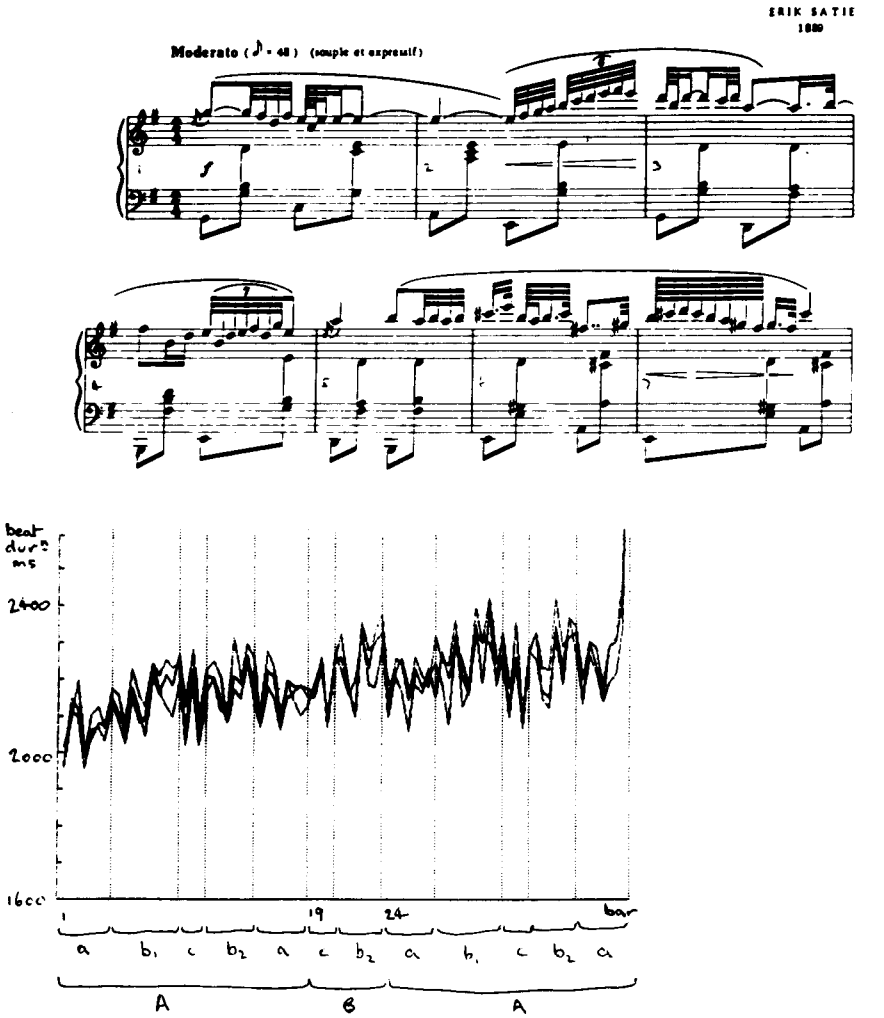

FIGURE 11.4. The opening measures of Satie's Gnossienne No. 5, together with a graph of played beat duration in three performances of the whole piece by JM. Boundaries of the melodic groupings are indicated. (The score reproduced by permission of Editions Salabert, Paris/UMP.)

The graphs in Figure 11.5 show timing based on the unit of a measure. The opening and closing phrases are omitted, because the use of rests in the music makes it difficult to estimate measure duration. Several points can be made from the graph. The first is that, in contrast to his Bach performances, RH demonstrates a very high order of timing consistency in the repeat performances of the more often practiced Mazurka, and he also shows a greater freedom in using

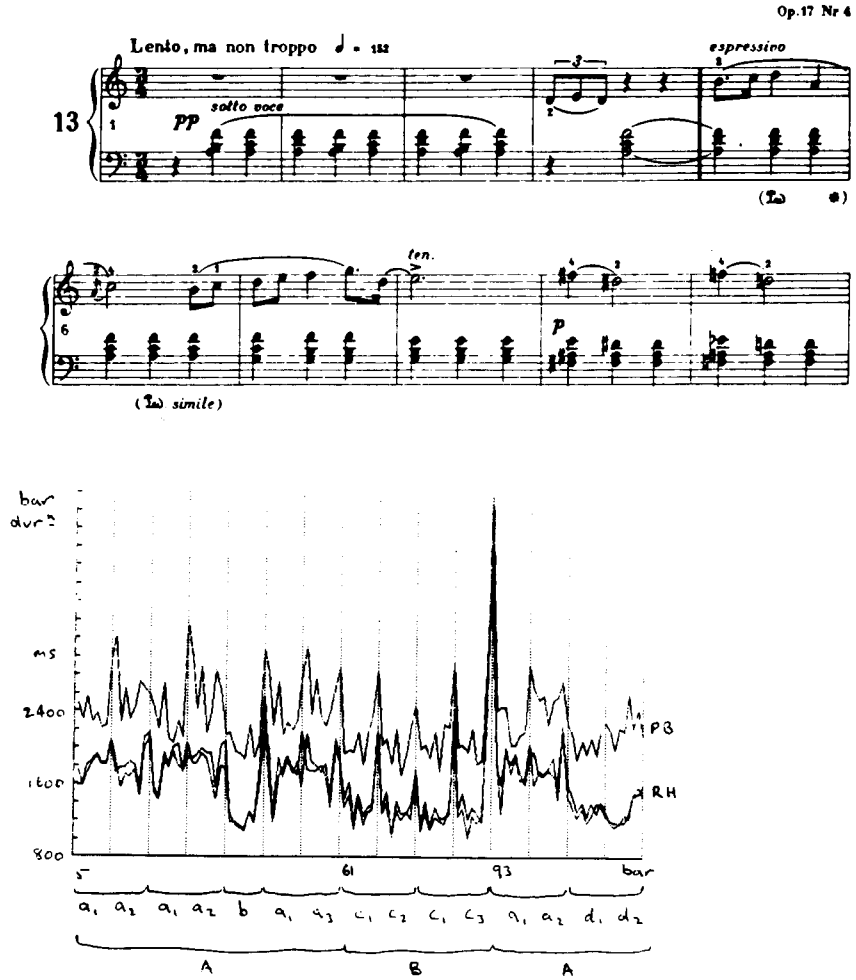

FIGURE 11.5. The opening measures of the Chopin Mazurka in A minor, together with a graph of played measure duration in two performances of the whole piece by RH and one by PB (shown as the uppermost curve). The boundaries of bars, phrases and their hierarchic groupings are indicated (excluding the opening and closing phrases). (The score reproduced by permission of PWM Editions (Alfred A. Kalmus Ltd.))

rubato, though still more restrained than PB. The two players choose different tempi, reflected in measure durations around 2300 ms for PB and 1600 ms for RH. The range of variation in using rubato is about 1200 ms for both players, excluding the rallentandi at the recapitulation and end. Yet RH reserves rubato more to mark phrase boundaries. The effect of these and other timing differences is that RH plays the piece more consistently as a dance. Despite such differences

in interpretation they agree in marking the boundaries of the eight-measure phrases and, at the sectional level, the imminence of the recapitulation. If anything it is RH who more punctiliously observes the hierarchy in the musical structure. The players also agree in playing the themes (marked b, c, and d in Figure 11.5) that alternate with the major theme (marked a) at a faster tempo. Note that in the b theme the music modulates from the minor to the major mode, and in the c and d themes there is a higher degree of restlessness in the music produced by harmonic dissonance.

Discussion

It would be preferable to have data of each pianist playing all pieces to enable direct comparisons of players and pieces, but the elegance of experimental design is not easily arranged with concert pianists having different repertoires. Luckily PB and RH both have a special interest in the music of Chopin.

A result reiterated in this study and confirming the findings in earlier studies is that a concert musician has a very precise means of reproducing tempo and its variation in playing a practiced piece of music. At the cognitive level, this implies that the motor system has access to a stable and accurate timekeeper together with a fairly definite representation of the relevant timing parameters. At the musical level it demonstrates that tempo and rubato are not matters of current whim but are the outcome of coded decisions of interpretation. The timing profile in playing a piece typically has a complex pattern, and so we can suppose that it stands in some definite relation to properties implicit in the musical notation. The alternative would be that the player has to memorize a large number of arbitrary parameters.

We have concentrated on the way in which timing is used expressively to convey, or emphasize, musical structure. It has long been known that slowing is used to convey the boundaries of musical units, and the present results extend the picture of this, showing it to depend on a number of factors. It is too early yet to say whether there may be systematic principles governing its use, but the results suggest where to look for these.

Most music can be shown by analysis to contain hierarchic structures, and the results demonstrate that the player can convey one or more of these hierarchies by a recursive and hence graded use of slowing at a boundary. Rather than make this an invariant principle of performance, which would turn this form of expression into a somewhat pedantic exercise, the player may choose which aspects of hierarchy to reveal so as best to characterize the music. This character may in turn relate to a structural or referential component of musical meaning. Fortuitously, the Bach Prelude and the Satie Gnossienne provide almost a polar contrast in musical purpose, the one developing a linear thesis that invites a single trajectory of musical tension in its performance, the other dissipating its trajectory in a series of tonally ambiguous gestures, encouraging an

interpretation in terms of overall stasis. It is also worth noting that in these performances, in contrast to the Chopin, the selective use of boundary slowing is associated with an overall limited compass of rubato. One may argue that a decision to restrict the compass limits the scope for discriminating hierarchy, or conversely that a decision to ignore hierarchy allows a smaller use of rubato, but it is also possible that the association is accidental and neither variable constrains the other. We shall require many more performances of different pieces before we can settle on the rules that best describe, or generate, these results. What is clear from the performances of the Mazurka by different players is that the use of structural information is not arbitrary.

The Perception of Musical Compositions

12

Can Listening to Music Be Experimentally Studied?

RITA AIELLO

Introduction

Research in the perception of music has been influenced by research in psychoacoustics and psycholinguistics (see Chapter 2 in this volume; for reviews see Deutsch, 1982; Dowling & Harwood, 1986; and Sloboda, 1985). This led to many experiments that focused on the perception of isolated musical variables and used very brief, computerized musical stimuli. In most cases, to control the variables, the musical stimuli were extremely impoverished, and therefore they did not represent the richness of music as we all experience it.

This chapter discusses some of the valid methodological reasons that originally favored the reductionistic approach to the research in the perception of music. Furthermore, it addresses some of the difficulties that must be considered if we investigate listening to actual performances from the repertoire, and reviews some recent experiments that used recorded performances of musical works as stimuli. Finally, it argues that research in the perception of music cannot remain research in the perception of isolated musical variables couched within very brief stimuli because music is more than the sum of its parts and is experienced over a temporal continuum. The perception of actual musical compositions or excerpts ought to become a priority for the research in the psychology of music.

Interested readers may ask: Does the research in the psychology of music explain how the listener perceives an actual musical composition? Which experiments describe this process, and how? Such questions are valid indeed. Musicians, musicologists, and music educators have always emphasized the value of listening and describing music (Corredor, 1956; Meyer, 1956, 1967; Copland, 1957; Sessions, 1970; Brendel, 1976; see also the first six chapters in this volume). But despite the major advances in the psychology of music in the last two decades, music psychologists have been reluctant to investigate how listeners perceive actual pieces of the repertoire. Therefore, little is known about the processes that take place while listening to a composition.

By and large, psychologists have addressed music listening theoretically. Several authors have proposed models of how a listener may listen to tonal music in general, or to certain tonal compositions specifically (Deutsch & Feroe, 1981; Lerdahl & Jackendoff, 1983; Marsden, 1987; Jackendoff, 1991). These models have been based on the hierarchical or perceptual processes that the authors theorize to be inherent in music compositions or fragments of music, and not on empirical data gathered from the listeners' experiences.

There are several reasons why researchers have not conducted in-depth investigations of listeners' perceptions of musical compositions. Let us examine some of them.

The Influence of Psychoacoustics

First, speaking from a historical perspective, research in the psychology of music developed mainly from the research in psychoacoustics. Therefore, early studies in music psychology addressed mainly the psychoacoustical attributes of isolated pitches. Although psychoacoustical studies have proven to be most valuable for our understanding of isolated sounds, they aimed to describe exclusively the parameters of single pitches or of a few pitches heard together.

The psychoacoustical influence favored the construction of brief musical stimuli that have been used in the experiments, and allowed sound variables to be clearly manipulated. But this has happened too often at the expense of the aesthetic qualities of the musical stimuli themselves. Referring to the tradition to use brief and artificial sequences as stimuli, Clarke and Krumhansl (1990) pointed out:

> There are certain obvious advantages in this very controlled kind of approach, and it has proved extremely powerful and productive for advancing our understanding of tonal and metric hierarchies. However, it has left untouched a range of issues concerned with listeners' understanding of more extended and elaborate structures in which a considerable degree of interaction between different parameters can be expected. (p. 214)

In the past, to suit experimental goals, stimuli were often designed at the expense of musical aesthetics. Deliège and El Ahmadi (1990) write:

> The usual practice, in our field, as in any scientific discipline, is to isolate the variable that one wishes to study and to incorporate it in a series of brief and repetitive sound sequences (that are called musical), constructed by the psychologist for the needs of the experiment, in order to be able to identify it afterward, in appropriate manner, in the statistical analysis of the data. . . . Unfortunately, many studies in the field of psychology of music scarcely achieve their aims because a musical objective is being sought through the use of material that is both too simple and too trivial. (p. 22)

The Influence of Psycholinguistics

The psychology of music has also been influenced by developments in psycholinguistics. As in psycholinguistic research, the emphasis in the psychology of music has been on investigating the phonetic and the grammatical levels of brief strings of words without an in-depth look at the perception of entire discourses, so research in the cognitive psychology of music has examined the perception of brief melodies or sequences of musical stimuli, and has not thoroughly investigated the perceptual processes that take place when listening to longer musical excerpts. The psychology of language emphasizes research on the perception of isolated sentences. Similarly, the psychology of music, for the most part, has looked at the perception of single musical phrases not occurring within a full musical context. Generally, the length of the experimental stimuli has ranged from a few notes to one or two phrases. This limitation does not replicate the actual musical experience.

Perhaps it was premature to expect that we could have built a house without foundations. Therefore, the reader who sincerely asks about the perception of genuine musical compositions can consider the last two decades of the research in the psychology of music as a foundation on which to build better investigations. Notwithstanding music psychology's good intentions, however, questions regarding how listeners perceive actual musical compositions still remain to be answered and it becomes much more pressing to ask them now. We must face that to do full justice to the laboratory, the psychology of music has not yet done justice to the concert hall or the cassette player.

Several researchers have already voiced concerns along these same lines (Sloboda, 1985; Deliège, 1989; Clarke & Krumhansl, 1990; Deliège & El Ahmadi, 1990; Butler, 1992; see also Nicholas Cook's chapter in this volume). But in order to research how one listens to a composition there are methodological difficulties to address. It is very difficult for the psychologist to design an experiment that investigates what may occur while listening to an actual musical composition. Performing, composing, and writing about music produce palpable results: a composition, an interpretation, an article, or a book—all evidence of what has actually happened between the individual and the music. But lis-

tening to music, *per se* does not yield such evidence, does not lay bare the intellectual and emotional responses of the listener, gives us no product to manipulate and analyze. Therefore, it is much more difficult to research music listening adequately (Sloboda, 1985: 151–54). Sloboda writes: "when I go to a symphony concert or listen to a gramophone record there may well be a lot of 'mental' activity, but there is not necessarily any observable physical activity. The principal end-product of my listening activity is a series of fleeting, largely incommunicable mental images, feelings, memories and anticipations" (p. 151). Nevertheless, can we say anything about how we perceive music? How can we research and measure what occurs when we listen to a musical piece?

When we listen to a composition, we hear an array of very complex temporal stimuli. Many musical variables occur simultaneously. It is a difficult task for the listeners themselves to listen attentively to a music performance. But unless there is control of variables, to what could we ultimately attribute the experimental results? "Musical material . . . cannot offer dimensions that are in all points controllable and systematically repeatable" (Deliège & El Ahmadi, 1990: 23). On the other hand, listening to an actual piece, *not* to artificially controlled laboratory stimuli, is what has provided us with the knowledge and the richness of our musical heritage.

I believe that when we listen, consciously or subconsciously, we *choose* what to focus on. This may be because of outstanding features of the music itself, certain features that are emphasized in the particular performance we are hearing, or because we just choose to focus on this or that element during that particular hearing. A piece of classical music is filled with more information than a listener can process in a single hearing. Music has a temporal, horizontal dimension (melody and rhythm), a vertical dimension (harmony), and a depth dimension (including combinations of dynamics, timbre, orchestration, and interpretation). Which among these dimensions does the listener choose to attend to from time to time? In designing an experiment, how can the freedom on the part of the subjects and the complexity on the part of the temporal stimulus be accounted for properly? How can they be tested and analyzed? If the psychologist asks the subjects to focus on this or that detail, already the task does not resemble listening as it occurs when we listen at our own discretion.

Given the complexity and the richness of the musical stimulus, listening implies choosing which elements to attend to. The artificial musical stimuli used in experiments limit the choices that a listener can make. For the reasons stated above, experimentally, the musical possibilities have been greatly impoverished in favor of reliable, controllable results. Clearly, many methodological difficulties must be considered in addressing listening to actual music, but shouldn't the music listening experience be at the very heart of the psychology of music?

In summary, listening to music in a laboratory condition does not duplicate listening to music outside of the laboratory. The experimental experience and the actual experience may differ in the complexity of the stimuli, their lack of aesthetic value, their brevity, and the very validity of the task. The research of the

last decades has provided a valuable foundation for understanding how we perceive controlled, brief, auditory sequences. What are needed are ways to develop a more sensitive understanding of the music listening experience and the mental representation of listening. The psychology of music must strive toward these goals.

Recently, there has been a growing interest in using excerpts or entire musical compositions as stimuli (Cook, 1987; Ruggieri & Sebastiani, 1987; Smith & Witt, 1989; Asada & Ohgushi, 1991). A number of studies have focused on examining some properties of live piano performances. With the help of computerized equipment, these studies investigate the similarities between the patterns of expressive characteristics that pianists display during repeated performances of a piece (Shaffer, 1981; Clarke, 1982; Gabrielsson, 1987).

In the remainder of this chapter I will review five recent studies that investigated aspects of music listening using recorded performances from the musical repertoire, all of which are approximately the same duration. All these studies investigated how listeners listen to music *as the music unfolded*. They did not ask the subjects only to respond post facto. By the nature of the required tasks, all these studies aimed to look at the subjects' perception of music as they heard the music.

Pollard-Gott (1983) researched whether repeated listening changes a listener's perception of a piece by focusing on the perception of musical themes. She asked musically trained and musically naïve subjects to rate the similarity of pairs of brief passages from the Franz Liszt Piano Sonata in B minor. This piece is in a single movement, structured around two principal themes and three minor themes. The standard division of a sonata in exposition, development, and recapitulation are all combined into a single, closely structured movement. In this study, the subjects heard the first 12 minutes (ending on measure 328) of a recording by Vladimir Horowitz.

The piece begins with the presentation of theme A (measures 8–13), a gap-filled melody, which is immediately followed by a contrasting, staccato theme B (measures 13–17). The piece continues with three variations of theme A and theme B in the following order: theme A, theme B, first variation on a2, a3, b2, b3, a4, and b4. The experimenter selected four examples of each of the two principal themes and recorded them separately.

The subjects were asked to write observations while listening, and, after listening to the first 12 minutes of the piece, they were asked to compare pairs of passages from the sonata judging their similarity on an 11-point scale (1 extremely dissimilar, 11 extremely similar). The listeners were also asked to decide whether each passage was best described as an example of theme A or theme B. It was found that, with repeated listenings, subjects improved in rating the similarity between the themes and also became more able to apply their understanding of the piece to passages that occurred much later in the same composition. Subjects with some musical background seemed to perceive the importance of the thematic material more quickly than the musically naïve subjects.

Clarke and Krumhansl (1990) have investigated how musically experienced subjects segment music, focusing on how they identify boundaries, locate excerpts within the overall piece, and estimate their duration. The researchers used performances of two stylistically different compositions as the stimuli: Karlheinz Stockhausen's *Klavierstücke IX*, and W. A. Mozart's Fantasie in C minor, K. 475. Both pieces are for solo piano, in a single movement, and contain a variety of different musical ideas. Each piece lasts approximately 10 minutes. Stockhausen's *Klavierstücke IX*, composed in 1961, is an atonal piece organized according to the principles of 12-note serialism. It is broadly divided in three regions, with the middle region being the most developed. Rhythmically and dynamically it is highly varied, alternating sections at different tempi. Mozart's Fantasie in C minor, K. 475 is also extremely varied rhythmically. There is tonal diversity and a multiplicity of different musical ideas. It may be divided in five sections, each one marked by different tempi and meter. The piece reflects the improvisatory style suggested by its title and displays many contrasts and sharply demarcated transitions from one section to the other.

To investigate the identification of boundaries, the subjects, after hearing each piece in its entirety, were asked to indicate where segmentation occurred in the music by pressing a foot pedal immediately after hearing a boundary. In later trials, they were asked to mark in the score the location where they perceived that segmentation had occurred, and were asked to describe briefly the features of the music that helped them form the boundaries. In general, the listeners agreed on the relative strength of the boundaries in both pieces, and reported this task to be quite easy. They cited similar criteria for making their judgments of where boundaries occurred in both compositions.

To investigate how listeners located brief excerpts in relation to the entire piece, the researchers first presented the piece in its entirety to the subjects, and then followed it with the presentation of brief segments. The subjects were asked to mark on a horizontal line on a piece of paper where they thought each segment occurred in the piece considering the left of the line to represent the beginning of the piece and the right of the line to represent the end.

The segments that occurred toward the beginning and toward the end of the piece appeared to be located closer to the center of the piece than was actually the case. This finding was true for both the atonal and the tonal composition. Clarke and Krumhansl propose that these results may be due to systematic changes in attention in the course of listening to music. In subsequent experiments, the subjects were asked to estimate the approximate duration of brief excerpts, being told that on average they lasted 30 seconds. The listeners were quite accurate in judging the relative duration of the excerpts in both pieces.

Deliège and El Ahmadi (1990; see also Deliège, 1989) have addressed listening and the perception of musical form. Specifically, these researchers investigated how musical cues help the listeners perceive boundaries in a musical composition, and whether there may be perceptual differences between musi-

cally trained and musically naïve subjects. The piece chosen as the stimulus was a recorded performance by Walter Trampler of *Sequenza IV*, a composition for solo viola by the contemporary composer Luciano Berio. This work is in six main sections and is characterized by contrasting structures. It fully exploits the timbre of the viola. The experiments presented the composition to the subjects three times. The first hearing was meant for the subjects to familiarize themselves with the piece, the second and third hearings were intended for the collection of the experimental data. The playing of the piece was synchronized with a timing mechanism on a microcomputer, and the subjects were asked to indicate where they perceived segmentation by depressing a key on the computer console.

The data revealed that the listeners utilized two organizing principles in their analytical hearings of this piece: "sameness" and "difference." The principle of sameness helped them constitute groups out of what they heard, while the principle of difference helped them differentiate what they listened to. Both musicians and nonmusicians showed important similarities in their perception of the composition.

Deliège also investigated how these same subjects located excerpts within this piece (reported in Deliège, 1989). In a subsequent experiment, first she explained to them that the piece was in six main sections, and then played for them 47 brief excerpts from the piece, ranging from 5 to 10 seconds. The subjects were asked to indicate after each excerpt in which of the six main sections of the piece each excerpt occurred. Significant differences were found in the accuracy with which some excerpts were localized. In general, the results were quite uniform for all subjects, regardless of their musical training. However, nonmusicians localized excerpts that occurred in the opening and the closing sections of the work better than they localized excerpts from the middle of the piece.

I am particularly interested in understanding how musicians with extensive training perceive music. Given the complexity of music, musicians are the ones who, potentially, have at their disposal the vocabulary necessary to describe what is occurring in the music. I am also interested in the perceptual freedom that one exercises when listening to music, and in understanding the differences among listeners. How do musicians capture what is happening in the music *as* the music unfolds? Given the scarcity of literature on this topic, this is a question that is as fascinating as is it difficult.

In a recent experiment (Aiello, Tanaka, & Winborne, 1990) we began to address what information musicians select from the music as it unfolds over time. Specifically, this experiment looked at which musical elements musicians report focusing on when listening to a complex musical work if they were free to report any of the elements present in the music. Graduate music students from the Juilliard School served as subjects in this study. They were asked to name on a sheet of plain notebook paper (not music paper) which musical elements they heard as they listened to a recording of the first movement of W. A. Mozart's

Symphony in G minor, K. 550, a work well known to all of them to eliminate any potential familiarity bias. The performance was by the London Symphony Orchestra, Carlo Maria Giulini conducting.

The subjects were asked to listen to this performance twice: during the first hearing, they were asked only to listen attentively. During the second hearing, *as* the music unfolded, they were to write down what they heard using any musical term that they wished. It was emphasized that they could write down any musical element that they wanted, and that this investigation addressed only the analytical aspect of listening to music.

The data were analyzed by grouping the musical elements listed by the subjects into categories. Strong individual differences emerged: some musicians' data reflected a gestalt holistic mode of perception, while the responses of other subjects showed an analytical, more segmented approach. These latter subjects focused on smaller details of the musical work. Regardless of the quantity of elements that the subjects reported listening to, they all reported attending most often to musical elements that are very salient in this movement: tonality, rhythm, and the use of specific chords. In addition, the data indicate that the listening strategies of each subject were not related to his or her major performance instrument or training in composition.

In a series of subsequent experiments (Aiello, Palij, and Gerstman, manuscript in preparation) we addressed whether the perceptual strategies of musicians remain consistent over repeated hearings of a piece, and evaluated their responses to compositions of different musical styles. The overall procedure was the same as that of our previous experiment, except that now subjects repeated the experiment listening to the very same pieces after approximately six weeks. In addition, we evaluated the subjects' responses to compositions of different musical styles presenting Mozart, Beethoven, Chopin, and a jazz improvisation by Miles Davis.

Generally, the data indicate that the subjects seem to write down less during the second experimental session. We think that this finding may be attributable to the nature of the experimental task. Perhaps, when the subjects repeat the experiment, they may wonder what they should write during the second time that is different from what they wrote during the first experimental session. In general, these subjects seem to list more elements when listening to Mozart than when listening to the other composers.

In my experiments, as well as in the other ones that I have reviewed here, the subjects listen to "real" musical stimuli, but their responses may or may not duplicate their actual experience when listening to music in a nonexperimental situation. But I look at all these data as steps being taken toward a direction, toward a kind of research in the psychology of music that addresses the ecological validity of listening to performances of the repertoire, and considers the processes that occur while listening to music.

In summary, I believe that listening to performances from the repertoire is what shapes our sensitivity to music. Many methodological difficulties must be

solved to investigate thoroughly how we perceive actual performances rather than controlled laboratory stimuli. But, unless we address these methodological difficulties we will never find potential solutions to them. Research in the psychology of music has begun to consider the importance of listening to musical performances, and there is much to discover.

Advance Praise

"It is a demanding and rewarding book. I find it a unique and scholarly document, an exegetic anthology of various perspectives and perceptions of that most mysteriously abstract art—Music. It is a break-through to the clarification of once considered dead-ends. Philosophically sound and scholarly researched, this is a formidable accomplishment."

—David Diamond, *Professor and Lecturer of Composition, The Juilliard School*

"This collection should be welcomed by students and teachers of music, particularly in conservatories and in colleges and universities. Too often we overlook the psychology of hearing and listening and the relationship between modes of perception and methods of analysis. This collection brings to the reader in a concise way the widest range of issues, presented through both historic and new essays, about how we hear and understand music. This overview will be useful for practicing musicians and historians, as well as for students of psychology and philosophy."

—Leon Botstein, *President of Bard College and Music Director and Conductor of the American Symphony Orchestra*

About the Editors

Rita Aiello, Ed.D., is a professor at the Juilliard School, an adjunct associate professor in the Department of Psychology at New York University, and an adjunct professor at the Manhattan School of Music. Dr. Aiello, a pianist, researches the perception and cognition of music.

John A. Sloboda, Ph.D., is Professor of Psychology at the University of Keele, Staffordshire, and is author of *The Musical Mind* (Oxford, 1985).

Agradecimientos

Estoy sumamente agradecido a los muchos que me ayudaron en la realización de este libro. En particular, quisiera agradecer a E.M. Bestwick la información sobre la discriminación del sexo de los pollitos; a Jonathan Dancy, por sus comentarios sobre el capítulo 13; a John Coleman, que hizo los dibujos e ilustraciones; a Margaret Woodward y Dorothy Masters, por todas las horas de paciente y sufrido mecanografiado y, finalmente, a todos los que aportaron su esfuerzo en las interminables revisiones y con su apoyo constante.

Prefacio

"El hombre es la medida de todas las cosas", decía el filósofo griego Protágoras; y, si dejamos de lado la política sexual de la terminología empleada (ver también más abajo), sus palabras deberían proporcionar a los psicólogos alimento para el pensamiento. Lo que Protágoras parece haber querido decir es que toda comprensión se realiza, finalmente, en términos humanos, y esto no podría ser más cierto que en el caso de la psicología. Es verdad que mucho de lo que aprendemos sobre la psicología humana lo hacemos mediante comparaciones con otras especies, estudiando las propiedades de las células nerviosas o de conjuntos de células, o buscando analogías entre los seres humanos y las máquinas. Todos esos emprendimientos contribuyen a aumentar nuestra comprensión de las formas en que funcionan los seres humanos. Sin embargo, en el análisis final, las habilidades y los logros humanos deben comprenderse solamente en términos humanos. En esta introducción a la psicología cognitiva habrá oportunidades para referirnos a estudios realizados con animales, a hallazgos de las neurociencias y a la importancia de las computadoras para comprender la mente, pero estas oportunidades serán relativamente pocas. Nuestro interés se centrará fundamentalmente en el ser humano y en sus habilidades.

Este libro ofrece un análisis de las habilidades humanas, las formas en que éstas se adquieren y las técnicas mediante las cuales se las puede mejorar. El foco estará puesto fundamentalmente en habilidades cognitivas comunes tales como hablar, recordar y razonar; como éstas son habilidades que se suelen considerar naturales, pueden aparecer, superficialmente, irrelevantes. Es importante no equivocarse en este sentido. Por ejemplo, la capacidad de leer y escribir o la de correr maratones son ejemplos extremos de habilidades que en una época se creían sólo eran accesibles a unos pocos individuos pero que, en la actualidad, muchos dominan. La frecuencia con la que se despliega una habilidad dentro de una población depende de factores ajenos a la dificultad intrínseca de esa habilidad, del mismo modo que los límites del desempeño experto se van ampliando constantemente mediante el ejercicio del ingenio humano. Las habilidades comunes pueden ser tan notables como las no comunes; en los próximos capítulos el lector podrá admirar las complejas acciones de las que son capaces tanto él mismo como otras

personas. La investigación psicológica ilumina los detalles de estas acciones y sus descubrimientos ayudan a justificar el orgullo legítimo por nuestros logros, que todos tenemos derecho a disfrutar.

El libro comprende dieciséis capítulos escritos especialmente por integrantes del Departamento de Psicología de la Universidad de Keele. Cada capítulo puede servir independientemente como introducción a un tópico en particular y por lo tanto el libro podría leerse, al menos teóricamente hablando, en cualquier orden. De todos modos, hay varios temas que se desarrollan y elaboran a través de todo el libro. Estos temas enlazan los diferentes capítulos y les proporcionan unidad y coherencia. Debido a esta organización, es conveniente que al menos los primeros tres capítulos se lean en orden, antes de encarar otras partes del libro.

El capítulo 1 ofrece una introducción a los conceptos de *cognición* y *habilidades cognitivas*, los métodos que se pueden usar para estudiarlas y la naturaleza del conocimiento que constituye la psicología cognitiva. Dos temas fundamentales del libro cobran una importancia especial en este capítulo. Primero, la cognición es una cuestión de habilidad y las habilidades cognitivas son análogas en muchos sentidos a las habilidades corporales. Segundo, el psicólogo cognitivo debe jugar roles gemelos: el de científico y el de entrenador.

En los capítulos 2 y 3 se encaran en mayor detalle las ideas sobre las habilidades en general y sobre las habilidades cognitivas en particular. Se identifican las características de la habilidad y se describen diversas formas de adquisición de las mismas. También se presentan ciertas nociones sobre cómo organizamos nuestra conducta en la persecución de los objetivos cotidianos. Más adelante, en el capítulo 4, se examinan y ejemplifican todos estos aspectos de la habilidad con respecto a la lectura. Se identifican varias habilidades de lectura, mostrando diferencias para distinguir los lectores expertos de los inexpertos; también se hacen algunas sugerencias para mejorar la lectura.

Los capítulos 5 a 8 se ocupan de la memoria. En cada uno de ellos se destaca otro tema del libro: las habilidades deben entenderse en su contexto social. En primer lugar, se ofrece al lector una introducción al tópico de la memoria, así como también al lenguaje y los métodos con que los psicólogos intentan analizarlo. A continuación, el capítulo 6 describe cómo los niños, empezando por las habilidades pasivas de la memoria que los humanos comparten con otros animales, se las arreglan para desarrollar las técnicas memorísticas con fines determinados según se practican en su propia cultura. En el capítulo 7 se analiza en detalle la destreza excepcional de una tarea, y también la destreza memorística específica. El capítulo 8 está dedica-

do a analizar cómo lo que se sabe sobre la memoria puede usarse para mejorar su rendimiento en todos, en general, en los niños con retardo mental leve (educables), en personas con lesiones cerebrales y otros.

La comunicación y la comprensión son el tópico común de los capítulos 9, 10, 11 y 12. El capítulo 9 describe los muchos niveles de habilidad que debe dominar el individuo para poder hablar de manera coherente y comprensible. El habla resulta especialmente apta para un análisis en términos de habilidad. También lo es al escuchar, tema del capítulo 10. El oyente es presentado como un receptor activo (no pasivo) de información, que ejercita habilidades complementarias a las del hablante.

Muy vinculadas a las habilidades de lenguaje de ambos tipos (del hablante y del oyente) están las habilidades sociales, que constituyen el tema del capítulo 11. Se identifican las señales inconscientes que los actores sociales transmiten y reciben constantemente, y se describen y evalúan métodos recientemente diseñados para mejorar las habilidades sociales. El aumento y la mejora de las habilidades existentes es también tema fundamental del capítulo 12. En este caso, se analizan las habilidades aplicadas al estudio; se describen investigaciones sobre la naturaleza de las habilidades de estudiar y aprender, seguidas nuevamente por una evaluación de los métodos para mejorarlas.

Los capítulos 13 a 16 se centran en el pensamiento y las habilidades para la resolución de problemas de diferentes tipos. El primero de estos capítulos examina algunas clases de razonamiento que suelen resultar difíciles, algunos que siempre se hacen automáticamente y la relación entre ambos. Una vez más, resulta evidente el carácter social de las habilidades cognitivas: lo que es "natural" para un miembro de una cultura puede resultar extraño para alguien de una cultura diferente. En el capítulo 14, el punto central es la resolución de problemas en general, sus principales características importantes y los hábitos inconscientes que pueden actuar como obstáculos con mucha facilidad. Una vez más, se plantea la cuestión de si se pueden enseñar y entrenar con éxito las habilidades cognitivas de este tipo. El mismo tema aparece en el capítulo 15, en relación con la creatividad y la resolución de problemas. Este capítulo se basa en registros históricos y en estudios de laboratorio. Se examinan varios aspectos del pensamiento creativo pensando en sugerencias para su mejoría. Finalmente, el capítulo 16 se concentra en la analogía entre las computadoras y la mente y en la cuestión de si se puede (o si alguna vez se podrá) decir que las máquinas piensan. Aunque las ideas tomadas de la computación informan gran parte del análisis y la teorización en los capítulos anteriores, el capítulo 16 ofrece la posibilidad de considerar

en profundidad la analogía con la mente. Sin embargo, aun aquí se mantiene el énfasis en la dimensión humana de la cognición.

Estos son, entonces, los temas fundamentales del libro: la cognición se entiende mejor en términos de habilidad; las habilidades deben verse en sus contextos sociales; mediante el entrenamiento pueden lograrse mejoras deliberadas en la habilidad; es función del psicólogo cognitivo tanto investigar la naturaleza de las habilidades como aplicar el conocimiento obtenido para ayudar a los que desean mejorar sus habilidades cognitivas.

Sección 1

La naturaleza de las habilidades

1

Cognición y psicología

Angus Gellatly

Aunque en este libro nos concentraremos en la habilidades cognitivas y en otras que también nos resultan familiares a todos, es útil, para entender inicialmente la naturaleza de la habilidad, comenzar con dos ejemplos bastante exóticos. El primero es de una habilidad relativamente simple pero limitada a unos pocos miembros de la población. El segundo es de una habilidad extremadamente compleja que ha sido desarrollada en una cultura diferente de la nuestra y que, también, sólo realiza un número relativamente escaso de practicantes.

Dos ejemplos de habilidad

El sexo de los pollos

La granja es una actividad competitiva y, por varias razones, resulta económicamente conveniente determinar las identidades sexuales de los pollos tan pronto como sea posible. Como los machos y hembras pequeños son visualmente muy parecidos, incluso en la apariencia de sus órganos genitales, en Occidente se pensaba que la determinación del sexo de los pollos sólo era posible después de que los machos comenzaban a tener cresta. Pero durante el primer cuarto de este siglo los granjeros de Occidente empezaron a escuchar rumores sobre la existencia en Japón de "expertos en el sexo de los pollos", que eran capaces de discriminar machos de hembras al día siguiente de nacer. Estos rumores continuaron difundiéndose en el decenio 1930-1940. Se invitó a los expertos japoneses a exhibir sus habilidades en los Estados Unidos y en Europa y, a continuación, a dar instrucciones a sus anfitriones. Los japoneses demostraron que sosteniendo los pollos de la manera adecuada para revelar mejor la zona genital se podía aprender a distinguir machos de hembras. Más aun, los expertos podían clasificar los pollos a gran velocidad y con mucha precisión.

Como consecuencia de este encuentro entre Oriente y Occidente, se establecieron en los Estados Unidos y en Gran Bretaña escuelas para enseñar a determinar el sexo de los pollos. Lo habitual era que los alumnos se entrenaran durante un período de entre 4 y 6 semanas antes de obtener un título habilitante. En esta etapa, el nuevo profesional podía fijar el sexo de unos 200 pollos en 25 minutos, con una precisión del 95% o más (Lunn, 1948). Después de años de experiencia, la cifra podía aumentar a 1000 o 1100 pollos por hora, y se informó sobre el caso de un experto que llegó a determinar el sexo de hasta 1400 pollos en una hora, con una precisión del 98%. La tarea de determinar el sexo de los pollos es sumamente repetitiva y exige un alto nivel de atención, pero permite el desarrollo de sorprendentes niveles de habilidad.

En los años posteriores al establecimiento de las escuelas de entrenamiento, a fines del decenio 1930-1940, los graduados podían aspirar a empleos bien pagados, con la perspectiva adicional de ingresos todavía superiores en la medida en que se convertían en expertos en la tarea. Pero en los años cincuenta y sesenta el mercado laboral sufrió una aguda retracción. Esto se debió fundamentalmente al éxito de técnicas de reproducción que llevaron al desarrollo de cepas de pollos con diferencias de color según el sexo. Ahora resultaba fácil distinguir a los machos de las hembras y ya no se necesitaban los costosos servicios de los profesionales en la determinación del sexo de los pollos. La matrícula en la escuelas de entrenamiento cayó marcadamente cuando se deprimieron los ingresos y las posibilidades de empleo. Parecía que la historia del experto en pollos en Occidente iba a ser breve. Pero entonces, hacia fines del decenio 1960-1970, hubo un nuevo vuelco, otra vez a partir de las actividades de los productores. Los experimentos que se desarrollaron con apareamiento selectivo habían producido pollos con huesos más livianos y que por lo tanto requerían menos alimento para alcanzar su peso de madurez. Estas nuevas cepas resultaron populares entre los productores masivos conscientes de los costos, que criaban animales para consumo. Pero muchas de las nuevas cepas sufrían una falla particular. En la búsqueda de animales con huesos más livianos, el vínculo entre el sexo y el color de los pollos se había roto. Los expertos en la determinación del sexo de los pollos volvieron al mercado.

Algunas características de la habilidad

Puede parecer extraño comenzar un libro sobre la psicología de la cognición con una breve historia sobre un aspecto bastante desconocido de la granja. Pero, de hecho, la determinación del sexo de los pollos es un ejemplo excelente de una habilidad humana relativamente simple, que muestra muchas de las características comunes a todas las habilidades. Una de ellas es la aparente imposibilidad, a los ojos del no iniciado, de la tarea que ha de desempeñar.

En el circo, los logros de malabaristas, acróbatas y trapecistas parecen sorprendentes, pero en la vida cotidiana también abundan las habilidades sorprendentes. Algunas de ellas, como caminar y hablar, son tan comunes que no llaman la atención, mientras que otras, aunque están confinadas a unos pocos ejecutantes, sólo se realizan fuera de la vista del público, como el trabajo de tornería de precisión. Pero hay algunas habilidades, y esto es especialmente cierto en lo que hace a las habilidades cognitivas y perceptuales en tanto opuestas a las físicas (motrices), que pasan inadvertidas porque su realización no tiene aspectos públicos. Pensar es el primer ejemplo de ello, especialmente el pensamiento que no lleva al discurso o la acción, como cuando uno ensaya en silencio un argumento o una obra musical.

Otra característica que la determinación del sexo de los pollos comparte con otras habilidades es su dependencia de la práctica intensiva. Aprender a realizar la tarea exige experiencia práctica. Aun cuando se haya logrado una destreza considerable, puede llevar años de práctica alcanzar los niveles de pericia más elevados, especialmente en lo que tiene que ver con la velocidad de realización (capítulo 2).

Finalmente, para nuestros propósitos, la historia de la discriminación del sexo de los pollos ilustra una tercera característica, absolutamente esencial, de la habilidad humana: su dependencia del contexto social. Ya hemos advertido que ciertas habilidades, como caminar y hablar, están tan ampliamente representadas que son casi características de la vida humana misma. Pero en su especificidad, incluso estas habilidades están determinadas socialmente. Un idioma puede convertirse en una lengua muerta si en la gente cesa la necesidad social de hablarlo; una forma de caminar puede ser profundamente emblemática de una sociedad o un régimen particulares. En habilidades cognitivas menos universales, su inserción social es todavía más evidente. Las exigencias perceptuales y cognitivas varían drásticamente entre diferentes hábitats. El rastreo de animales en la selva y la organización del sis-

tema de tránsito de una ciudad son habilidades configuradas por sus respectivos ambientes físicos y sociales. En el caso de la determinación del sexo de los pollos, la habilidad llegó a Occidente sólo como consecuencia del rápido crecimiento del comercio y los lazos culturales con Japón, a comienzos de este siglo. La difusión de la habilidad en Gran Bretaña y los Estados Unidos dependió luego de la existencia de una intensiva industria de aves de corral que había crecido para satisfacer las necesidades de una sociedad urbana cada vez más grande y con buen transporte y redes de comunicación. Finalmente, la suerte cambiante de los expertos en la discriminación del sexo de los pollos fue determinada por las actividades de otro grupo dentro de la misma industria: los criadores. Las habilidades humanas se elaboran en respuesta a las condiciones sociales y pueden caer en desuso y perderse rápidamente cuando esas condiciones cambian.

La determinación del sexo de los pollos es una habilidad de clasificación perceptual relativamente simple; requiere lo que en muchos sentidos son discriminaciones menos complejas que las que debe hacer quien combina diferentes tipos de té o un catador de vinos. Nuestro segundo ejemplo es de una habilidad mucho más compleja, que aquí sólo podemos esbozar brevemente.

Habilidad para la navegación

Los isleños de Puluwat son famosos por su habilidad para la navegación sin instrumentos. Su hogar se encuentra en el océano Pacífico, a unos 1600 kilómetros al nor-nordeste de Nueva Guinea, y la navegación juega un papel esencial en la cultura Puluwat. Gladwin (1970) describe la importancia que se otorga a la construcción y mantenimiento de canoas con flotadores laterales, las funciones sociales esenciales de los viajes entre islas y el respeto especial acordado a los capitanes de canoas que han logrado destreza en su arte. Todos los habitantes de Puluwat participan en los viajes pero sólo unos pocos son capaces de pilotear una nave en 300 o 500 kilómetros de mar abierto y, más aún, de hacerlo en casi cualquier circunstancia climática y sin estar del todo sobrios. ¿Cómo lo logran?

Hay tres hechos preliminares en la descripción que Gladwin hace de las habilidades de navegación de Puluwat. En primer lugar, se necesita mucho tiempo para convertirse en un navegante experto: veinte o treinta años. En segundo lugar, la habilidad está localizada en el grupo de islas al que pertenece Puluwat, una superficie de unos 650 km de norte a sur y 1600 km de

este a oeste. En tercer lugar, el sistema de navegación es altamente conservador. Gladwin (1970) subraya que los Puluwat no corren riesgos, los navegantes utilizan muchas clases de conocimientos que se refuerzan mutuamente para asegurar la precisión de su calculada navegación.

El conocimiento es, de hecho, el rasgo característico de la navegación Puluwat. Los navegantes son, antes que nada, conocedores de la ubicación de las estrellas en el cielo, los lugares por donde salen y las trayectorias que siguen. Como está cerca del Ecuador, el cielo nocturno sobre Puluwat cambia poco con las diferentes estaciones, y las estrellas, cuando son visibles, ofrecen guías confiables. Pero los navegantes también pueden fijar cursos a seguir durante el día. Al partir de una isla con destino hacia cualquier otra, los Puluwat saben qué hitos, cuando están alineados, les darán el curso que necesitan; esta técnica es conocida como retrovisión. Incluso en la oscuridad y en días nublados, los navegantes pueden guiarse distinguiendo entre tres tipos de olas, que se originan en el este, el norte y el sur, respectivamente. Un navegante pilotea sintiendo estas olas bajo su canoa y por los intervalos característicos entre ellas.

Durante su etapa de aprendizaje, los navegantes también aprenden las posiciones y los contornos de todos los arrecifes importantes en su zona del océano, algunos de los cuales se encuentran a más de 30 metros de profundidad. Aprenden a identificar los efectos que un arrecife tiene sobre el agua y, por lo tanto, sobre los movimientos de la canoa. Allí donde un extraño sólo vería una amplia extensión oceánica, los navegantes de Puluwat ven claras señales que marcan caminos por el mar. También están familiarizados con la conducta de las aves marinas: saben cuáles vuelan directamente hacia tierra cuando termina el día y las usan para dirigirse a destinos a veces muy precisos. Finalmente, también dominan una compleja teoría de navegación que les permite calcular la distancia recorrida cuando avanzan contra el viento. La teoría utiliza islas de referencia, que a menudo están sobre el horizonte, y representa a la canoa como estacionaria mientras el océano y las olas se mueven pasando junto a ella. La teoría es el aspecto más puramente cognitivo (en tanto opuesto a lo perceptual) de la navegación Puluwat.

¿Qué es la cognición?

La expresión habilidad "cognitiva" se ha usado varias veces en las páginas anteriores, sin explicación. Pero, ¿qué es la cognición?

Si se reflexiona brevemente sobre algunas palabras cotidianas, se po-

drá tener cierta idea de la respuesta. Hablamos de reconocimiento (en inglés, recognition) cuando se identifica a alguien o algo que ya se conocía. O decimos que una persona viaja "de incógnito" cuando se esfuerza por ocultar su identidad. Estos ejemplos ayudan a aclarar que la palabra "cognición" se refiere a las actividades de conocer, recoger, organizar y utilizar el conocimiento. Cuando un encuentro con alguien nos da una sensación de familiaridad, decimos que es un acto de re-conocimiento (en inglés, re-cognition); conocemos al individuo de nuevo. Pero la cognición incluye muchos tipos de actividad además del reconocimiento de la identidad. Recordar que uno tiene una cita con el dentista al día siguiente, calcular el descuento en un artículo que uno está comprando o encontrar el camino a casa desde el trabajo sin perderse son formas de cognición. También lo es el jugar una partida de ajedrez, tratar de diagnosticar por qué el auto no arranca, comprender lo que otra persona está diciendo o entender qué más quiere decir esa persona además de lo que pone en palabras. En realidad, cualquier cosa que involucre percepción, memoria, aprendizaje o pensamiento es parte de la cognición, lo cual significa que casi cualquier cosa que una persona haga tiene, al menos, un componente cognitivo.

Pero uno no debe sentirse muy desilusionado al enterarse de que "cognición" es un término tan amplio. Primero, se puede dar por sentado que el alcance de los temas de este libro será selectivo. Segundo, aunque el campo de la cognición es amplio, hay un número relativamente pequeño de principios básicos. De hecho, un tema central de este libro es que la cognición en todas sus manifestaciones es una cuestión de habilidad y que, por lo tanto, todos los logros cognitivos se pueden analizar según ciertos principios involucrados en la adquisición de la habilidad (ver capítulos 2 y 3). En tercer lugar, como la cognición prácticamente entra en todo lo que hacemos, hay muchas oportunidades para usar bien esos principios, para mejorar nuestras propias habilidades cognitivas. Por ejemplo, muchas personas suelen decir que, aunque recuerdan muy bien la fisonomía de los rostros, encuentran dificultades para memorizar los nombres que les corresponden. Sin embargo, como veremos, hay ciertas cosas que se pueden hacer para mejorar esta habilidad cognitiva (capítulo 5).

El estudio de la cognición

El trasfondo histórico

¿Cómo podemos estudiar la cognición? Una respuesta obvia podría ser que podemos estudiarla de manera directa, observando nuestras propias mentes en funcionamiento mediante la introspección, o de manera indirecta, preguntándole a otros sobre lo que observan qué sucede en de sus mentes cuando trabajan, es decir, recogiendo informes de sus introspecciones. Ciertamente, la introspección es un método importante y muy usado para estudiar la psique. Gran parte de nuestro conocimiento de sentido común sobre la percepción, el pensamiento y la memoria se basa en los informes introspectivos de gente reflexiva, desde los antiguos griegos hasta nuestros días. Además, cuando hacia fines del siglo XIX la psicología se constituyó como ciencia de la psique independiente, separada de la filosofía o de cualquier otra rama de investigación, la introspección fue adoptada como su método natural. Sin embargo, no se suponía que cualquiera podía convertirse en psicólogo sólo haciendo introspección en sus propias cogniciones. Por el contrario, las observaciones de la experiencia consciente tenían que hacerlas individuos muy bien entrenados en técnicas introspectivas desarrolladas especialmente, y debían encarar temas teóricos significativos. Entender el funcionamiento de la mente iba a convertirse en una cosa seria.

Para ser justos con estos psicólogos tempranos, sus ideas sobre la técnica y el entrenamiento no estaban tan motivados por el deseo de marcar un territorio y cercarlo con prácticas restrictivas como por la convicción de que las observaciones introspectivas podían valer la pena sólo dentro del marco de una metodología especialmente construida. Esta convicción halló eco, unos años más tarde, en las técnicas observacionales cuidadosamente elaboradas de la etología, la disciplina que estudia la conducta animal (incluyendo la humana) en sus ámbitos naturales. Al desentrañar el secreto de la danza de las abejas y darle sentido a la conducta de los peces, los gansos y muchas otras especies, los etólogos demostraron cuántas cosas pueden saberse mediante la observación (que un observador sin guía puede perder). Pero en tanto los logros de los etólogos iban a obtener reconocimiento en 1973 mediante la entrega de un premio Nobel, los psicólogos introspectivos hicieron pocos progresos con sus observaciones sistemáticas de la conciencia. (En el capítulo 9 hay brillantes análisis, recientemente realizados, sobre las habilidades del habla, basadas fundamentalmente en observaciones de errores del discurso que ocurren naturalmente.)

Puntos débiles y fuertes de la introspección

Hay muchos motivos por los que la introspección sola no resulta adecuada como método para revelar la naturaleza de la cognición. Probablemente, el defecto más serio es que hacer introspección en la propia conciencia nos expone a alterar el contenido de esa conciencia. Más que tomar conciencia de la actividad cognitiva corriente, uno toma conciencia del hecho de que está haciendo introspección. El problema se vuelve particularmente agudo cuando hay que traducir cogniciones no verbales a palabras, para un informe introspectivo, ya que quizá no sea posible capturar su naturaleza esencial en términos verbales.

Un segundo problema, relacionado con el anterior, es el que señala Neisser (1976). Destaca que cualquier psicología de importancia debe tener algo que decir sobre lo que de verdad la gente hace y piensa en situaciones reales y culturalmente significativas. Sin embargo, es probable que ésas sean las situaciones en las que la gente está demasiado ocupada como para realizar una introspección cuidadosa. Como resultado, la introspección puede aplicarse sobre todo a tareas artificiales en ámbitos de laboratorio. Neisser culpa fundamentalmente a esta esterilidad —la falta de lo que se suele denominar "validez ecológica"— de la decadencia del método introspectivo. Pero no es difícil detectar otras fallas. Por ejemplo, una observación común (al menos desde que Freud enfatizó especialmente el hecho) es que la conducta suele estar determinada por motivos inconscientes. A veces, un observador perspicaz puede tener mejor idea de los motivos de las acciones de una persona que la propia persona. Aunque la psicología cognitiva no se ocupa mucho de los motivos, tiene un lugar importante para las cogniciones inconscientes. Lo inconsciente no posee, en este sentido, la connotación de represión intencional asociada con la noción freudiana del "inconsciente". Más bien se refiere al simple hecho de que no tenemos conciencia de muchos de los procesos que regulan nuestras funciones físicas y psíquicas. Un ejemplo de esto puede ser la oxigenación de la sangre en nuestro músculo cardíaco o los procesos involucrados en el reconocimiento y la comprensión de las palabras de esta página podría ser otro. Como en el caso de los motivos inconscientes, el mensaje es claro. Lo que sucede fuera de la conciencia no puede revelarse mediante introspección, no importa con cuánto cuidado se realice.

Es evidente que, como método, la introspección presenta muchas deficiencias. Ya hemos enumerado varias, pero también debemos admitir que posee ciertos puntos fuertes. Es definitivamente cierto, por ejemplo, que las

descripciones introspectivas de la actividad cognitiva pueden ser muy útiles e informativas en las circunstancias adecuadas. Algunas personas son capaces de comunicar sus propias técnicas al encarar problemas cognitivos específicos. Los demás nos beneficiamos con la forma en que estas personas razonan sobre las fallas en el encendido o la estrategia adecuada para encarar un problema matemático, los mecanismos que facilitan las interacciones sociales o el mejoramiento de la memoria para retener la información importante y los detalles a los que prestan atención cuando evalúan la fuerza de un caso legal o hacen un diagnóstico basándose en radiografías. Hemos aprendido demasiado acerca del funcionamiento de la mente mediante la introspección para querer omitirlo por completo. Aunque hay un permanente debate sobre la situación precisa de varios tipos de informe introspectivo (Evans, 1982), los psicólogos cognitivos siguen confiando en ellos. Debería también destacarse que todos los "sistemas de conocimiento experto", que representan uno de los mayores logros de la investigación en inteligencia artificial, se basan en las introspecciones de los especialistas humanos. La lección que se debe aprender del fracaso de la psicología introspectiva temprana no es que el método no tiene valor sino que se lo debe ver tan solo como uno entre los muchos métodos posibles de investigación de la cognición.

El estudio contemporáneo de la cognición

Entre las dos guerras mundiales, el conductismo dominó la psicología en los Estados Unidos y, en menor medida, en Gran Bretaña. No sólo decayó el introspeccionismo sino también todo el estudio de la cognición. Los conductistas destacaban correctamente la importancia de los datos objetivos y especificaban cuidadosamente métodos experimentales. Esto los llevó a promover explicaciones según estímulos y respuestas observables, y a negar la necesidad de referirse a los aspectos cognitivos involucrados. John Watson, padre fundador de la psicología conductista, supuso que pensar no era más que discurso subvocal, como hablarse a sí mismo. Se esperaba que medidas suficientemente delicadas de la actividad de la musculatura del habla confirmarían este supuesto, pero el conductismo no facilitó otros medios para investigar el pensamiento y nada dijo sobre el pensamiento no verbal.

Sin embargo, en la Europa continental surgía un cuadro algo diferente. El introspeccionismo no fue sucedido por el conductismo sino por la psicología de la Gestalt, preocupada especialmente por los procesos cognitivos in-

ternos y por fenómenos como el del *insight* (ver capítulo 14). Además, primero en Francia y luego en Suiza, Jean Piaget inició sus estudios, que resultarían profundamente influyentes sobre el desarrollo cognitivo de los niños. Un tema básico de la teoría de Piaget consistiría en que el pensamiento se desarrolla como resultado de la internalización. La conducta previamente manifiesta, tanto en las acciones como en el discurso, podía internalizarse plenamente, sin dejar manifestaciones externas. De modo que mientras los conductistas buscaban crear una psicología de la conducta observable que resultara metodológicamente convincente, Piaget enfatizaba, al mismo tiempo, la continuidad existente entre la conducta y la cognición.

La psicología cognitiva moderna combina el rigor metodológico de los conductistas con el énfasis piagetiano en los procesos internos que sostienen a la conducta evidente. También incluye a una tercera rama importante.

La metáfora de la computadora para la mente

A pesar de Piaget, el interés de los psicólogos por los procesos cognitivos no revivió hasta mediados del decenio de 1950, cuando se produjo un explosivo crecimiento de la investigación, que no se ha detenido en la actualidad. Indudablemente, la causa más importante de este cambio fue la rápida evolución y difusión de la computadora digital. Una máquina que desempeña operaciones complejas sin la ayuda de partes móviles recuerda inmediatamente los procesos internos de la mente. En la entrada *(input)* a la máquina se producen operaciones no observables, que se pueden especificar precisamente y tienen efectos demostrables en la conducta de los dispositivos de salida *(output)*. Para entender de qué es capaz la computadora, no se puede depender sólo del conocimiento de lo que sucede dentro y lo que sale de ella. Es necesario saber qué le está haciendo hacer el programa a la máquina, qué transformaciones y manipulaciones de la entrada codificada se están realizando, qué objetivos se supone que debe alcanzar el programa (capítulo 16). Pero si tal comprensión es posible en el caso de una computadora, ¿por qué no también en la mente humana? Dada la computadora como modelo, repentinamente los procesos cognitivos de la percepción, el pensamiento y la memoria parecían más reales, menos etéreos. Así como las máquinas de partes móviles han ofrecido con frecuencia metáforas fértiles para las funciones corporales (por ejemplo, el corazón como una bomba), el nuevo tipo de máquina sugiere una metáfora para la mente.

Durante los últimos veinticinco años, los psicólogos cognitivos han explorado ampliamente la metáfora de la computadora para la mente, y los libros contemporáneos sobre cognición suelen escribirse en lenguaje informático. Esto hace que su lectura resulte, con frecuencia, ardua. También puede dar la impresión de que los psicólogos cognitivos están más preocupados por la naturaleza de la computadora que por la naturaleza de la cognición humana. Sólo los aspectos de la cognición que se pueden discutir plausiblemente con terminología de programación reciben atención; los puntos desemejantes entre las computadoras y la mente son por lo tanto borrados de la conciencia del lector (y de la del autor). Por este motivo, en este libro se intenta cuidadosamente evitar la metáfora y su jerga asociada. Esto no resulta fácil ya que la metáfora de la computadora ha invadido gran parte de nuestro pensamiento, especialmente en la psicología cognitiva. De vez en cuando recurriremos a la metáfora, pero sólo la retomaremos y analizaremos explícitamente en el último capítulo.

Cognición y conducta

Si no vamos a valernos del lenguaje y las analogías de la computación, ¿cómo pensamos hablar de la cognición? ¿Cómo pueden describirse los procesos psíquicos no observables? La respuesta ya se ha sugerido antes, cuando nos referimos al énfasis piagetiano en la continuidad entre conducta y pensamiento. Muchas cogniciones pueden considerarse acciones internas. Son acciones que se han vuelto tan practicadas que podemos "llevarlas a cabo en nuestras cabezas" (por ejemplo, contar con los dedos deja paso luego a la aritmética mental); o, si se construyen sobre conocimientos y destrezas previas, podemos haber aprendido a hacer cálculos mentalmente desde el primer momento. Las metáforas de acción para el pensamiento, y más particularmente las metáforas manipulativas, que se refieren al uso de las manos, son comunes en el lenguaje cotidiano. Cuando hablamos de "aferrarse a una idea" o acusamos a alguien de "hacer una excepción", entra en juego implícitamente la noción de acción internalizada. Sin embargo, no todas las cogniciones son afines a las acciones. El lenguaje cotidiano tiene un segundo grupo importante de metáforas para describir las cogniciones, basándose en la percepción, especialmente en la de tipo visual. Las bromas como "Ya veo, dijo un ciego" se valen de estas metáforas, del mismo modo que expresiones como "Esa es una idea brillante". La prevalencia de los dos tipos de metáfo-

ra no es coincidente. Al habérselas con el mundo, un organismo tiene que percibir lo que está sucediendo a su alrededor y realizar las acciones adecuadas, como alimentarse, copular o huir. En las criaturas simples, tanto las percepciones como las respuestas tienden a ser incorporadas, y las percepciones activan automáticamente las respuestas. Pero en los animales con sistemas nerviosos más complejos aparece un elemento de elección, ya que en la mayoría de las circunstancias hay más de un curso de acción posible. La actividad nerviosa que interviene entre la percepción y la respuesta se torna elaborada, evoluciona en lo que se denomina cognición. Mediante los dos tipos de metáfora, el lenguaje común reconoce muy sensatamente que la cognición comparte características de la percepción y la acción. Las metáforas visuales y manipulativas predominan porque para los humanos los ojos son el canal principal de información perceptual y las manos ofrecen el medio más flexible y delicado para actuar sobre el mundo.

Cognición y habilidad

Seguir la idea de Piaget sobre la relación existente entre cognición y conducta no implica necesariamente, por lo tanto, abrir nuevos caminos. Hace mucho que el lenguaje común ha reconocido la relación. Sin embargo, hay una característica aún más importante que debemos destacar aquí. El psicólogo Bartlett (1958) señaló que el pensamiento —o, más generalmente, la cognición— es en muchos sentidos similar a la conducta entrenada en el uso de habilidades. Las habilidades perceptivo-motrices, como jugar al tenis, involucran la percepción e interpretación de alguna parte del mundo (por ejemplo, la trayectoria, la velocidad o el giro de la pelota de tenis) y la realización de alguna acción motriz (por ejemplo, pegarle a la pelota hacia algún punto conveniente en el campo del adversario). Tanto la percepción como la respuesta requieren un grado de habilidad mayor. De manera similar, muchas actividades cognitivas que consideramos naturales son desempeños expertos. Aunque nuestras cogniciones pueden parecer, a veces, bastante absurdas e inconexas, en su mayoría son sumamente controladas, y como adultos casi todos hemos logrado la percepción, el recuerdo, el pensamiento y la comprensión de unos con otros. Estos logros cognitivos serán el tema central del presente libro.

De hecho, no puede trazarse un límite firme entre las habilidades perceptivo-motrices y las cognitivas. Casi todas las conductas motrices están bajo control cognitivo y muchas cogniciones sirven para actuar en el mundo.

Esta interacción queda bien clara en un informe clásico de Bryan y Harter (1899) sobre el aprendizaje de la telegrafía Morse, que fue el primer análisis completo del desempeño experto. La telegrafía involucra el aprendizaje de nuevas habilidades percepto-cognitivas para la identificación e interpretación de esquemas de puntos y rayas y la adquisición de nuevas habilidades cognitivo-motrices para manipular la llave de transmisión. Junto con Bartlett, sus sucesores, Bryan y Harter, construyeron los cimientos de una psicología de la habilidad cognitiva.

Conocimiento psicológico

Teoría y práctica

Francis Bacon, pensador del siglo XVI, redactó un plan para un nuevo método de obtención de conocimientos en lo que habrían de ser las ciencias naturales. Bacon se ocupó tanto del conocimiento teórico como del práctico. Como parte de su método, sostuvo que la comprensión teórica clara de un tema debe establecerse primero y que luego pueden derivarse de ella las aplicaciones prácticas. En otras palabras, la ciencia llevaría a la tecnología o, en los términos del propio Bacon, después de la "luz" vendrían los "frutos". Aunque la relación entre teoría y práctica no es tan simple como sugiere Bacon, el indudable éxito de las tecnologías basadas en la ciencia en los últimos trescientos años ha afectado notoriamente nuestras ideas sobre el conocimiento. No es exagerado decir que en la actualidad la validez del conocimiento teórico se evalúa sobre la base de las tecnologías que genera. Raramente se considera que las teorías sin aplicaciones instrumentales constituyan conocimiento.

Una consecuencia de este desarrollo es que los psicólogos cognitivos, como los investigadores de otras disciplinas, están bajo considerable presión para demostrar las aplicaciones prácticas de su trabajo. El público en general, los estudiantes y los administradores de fondos para la investigación tienden a no impresionarse por los atractivos teóricos. Quieren saber para qué sirve la psicología cognitiva. Tampoco es externa toda la presión. Los propios psicólogos se estimulan entre sí, constantemente, a hacer que su disciplina sea más significativa y utilitaria. En lo que queda de este capítulo, examinaremos dos formas posibles de responder a dicha presión para obtener resultados prácticos.

El psicólogo cognitivo como científico

Los psicólogos pueden responder a la presión de dos formas diversas, que suponen la adopción de roles alternativos. Estos roles no necesitan ser excluyentes. Los psicólogos pueden jugar un rol y luego el otro de manera secuencial o, si son inteligentes, ambos a la vez. Los dos roles son: el de científico y el de entrenador.

Una respuesta que los psicólogos dan a veces a la demanda de resultados prácticos de la psicología cognitiva es la de representarse a sí mismos como aún en la primera de las dos etapas planteadas por Bacon; es decir, que todavía están estableciendo una comprensión teórica y necesitan un poco más de tiempo para la investigación pura. El psicólogo-científico es presentado como un especialista cuyo conocimiento pronto lo pondrá en una posición privilegiada en lo que respecta a la cognición. Pero éste no es un cuadro de situación realista. Aunque la cognición debe ser estudiada científicamente, incluso teniendo en cuenta los avances posibles en inteligencia artificial, no hay indicios de que la investigación científica esté a punto de llegar a conmovedoras innovaciones en los usos de nuestras mentes o de que alguna vez logre hacerlo (ver, por ejemplo, Joynson, 1974). La psicología sencillamente no se presta a un modelo baconiano de teoría seguida de práctica. A diferencia, por ejemplo, de la física nuclear (en la que las aplicaciones fueron imposibles hasta que se establecieron teorías precisas), la psicología se ocupa de un asunto en el cual la práctica precedió en mucho a las teorías explícitas. Los expertos, ya sean físicos nucleares o técnicos en reparación de televisores, construyen y reparan cosas que el resto de nosotros no pretendemos entender. Los psicólogos, en cambio, no se sitúan en una relación de expertos con respecto a los demás. Las personas que consultan a un psicólogo ya saben mucho sobre sus propias psiques. La situación es muy diferente de cuando esa misma persona necesita que se le repare el televisor. Es cierto que a veces la gente busca que psicólogos y psiquiatras "arreglen" su psique, pero ésa es una actitud desafortunada de su parte. Los tratamientos por drogadicción a veces pueden servir para controlar el pensamiento psicótico o las perturbaciones del carácter, pero no son curaciones. Los especialistas en salud mental no pueden hacer más que ayudar a las personas a ordenar sus mentes y sus conductas para sí mismas.

Esto no significa que la ayuda de ese tipo no sea importante. En muchos casos, puede ser vital. Lo que queremos decir es que el valor de estudiar la cognición científicamente no ha de hallarse en las nuevas tecnologías. An-

tes bien, su importancia radica en el conocimiento disponible para el psicólogo que actúa con un carácter distinto del de experto científico.

El psicólogo cognitivo como entrenador

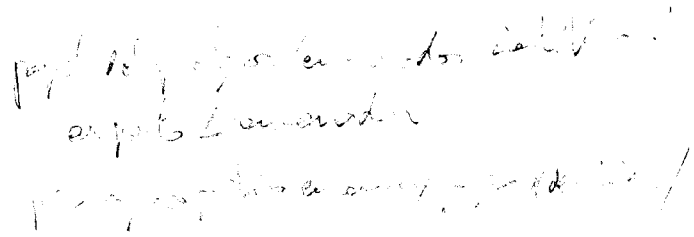
Cuando se trata de la aplicación del conocimiento, el papel de entrenador o maestro ofrece una alternativa al rol de experto tecnológico. Ni los entrenadores atléticos ni los maestros de piano, por ejemplo, tienen teorías formales de las que deducir su práctica, pero su capacidad para contribuir a las mejoras en el rendimiento no está en duda. Este libro sostiene que los psicólogos cognitivos tienen una capacidad similar para ayudar a otros a mejorar sus rendimientos cognitivos. No a la manera del experto sino a la del entrenador.

El papel de entrenador atlético proporciona, de hecho, una analogía útil que demuestra cómo el conocimiento científico puede tener un valor práctico que no es tecnológico en ningún sentido manifiesto. Los entrenadores atléticos se vuelcan cada vez más hacia la medicina del deporte en busca de información; toman cosas de la psicología, la anatomía y la bioquímica y aplican este conocimiento científico a los problemas relacionados con el mejoramiento del rendimiento deportivo. Estas ciencias no nos permiten usos novedosos de nuestros cuerpos pero ayudan a mejorar la eficiencia con la que se ejecutan los viejos usos (correr, nadar, saltar, lanzar). De manera similar, el estudio científico de la cognición jamás va a revelar habilidades cognitivas insospechadas, pero nos proporciona información que puede servir para mejorar la habilidad con la que se ejercitan aptitudes que hace mucho nos resultan familiares.

Para los psicólogos cognitivos, hay muchas ventajas en presentarse a sí mismos como entrenadores. Primero y principalmente, la adopción del papel de entrenador lo pondrá al psicólogo, junto con muchos de sus colegas del asesoramiento y la psicología clínica en el lugar de "socios" de un "cliente". El psicólogo puede tratar directamente con la gente de una manera no autoritaria sino constructiva, proporcionando esencialmente una forma de realimentación sobre la manera en que el cliente está desempeñando la tarea en cuestión. Una segunda ventaja es que el papel de entrenador clarifica dónde radica la responsabilidad en lo que hace al logro de mejorías cognitivas. Como en el caso del tenis, un entrenador sólo puede ayudar a aquellos que están dispuestos a esforzarse por sí mismos. La habilidad no puede inyectarse desde afuera. La tercera ventaja de jugar el papel de entrenador es precisamente que les ahorra a los psicólogos cognitivos la etiqueta de exper-

tes bien, su importancia radica en el conocimiento disponible para el psicólogo que actúa con un carácter distinto del de experto científico.

El psicólogo cognitivo como entrenador



Cuando se trata de la aplicación del conocimiento, el papel de entrenador o maestro ofrece una alternativa al rol de experto tecnológico. Ni los entrenadores atléticos ni los maestros de piano, por ejemplo, tienen teorías formales de las que deducir su práctica, pero su capacidad para contribuir a las mejoras en el rendimiento no está en duda. Este libro sostiene que los psicólogos cognitivos tienen una capacidad similar para ayudar a otros a mejorar sus rendimientos cognitivos. No a la manera del experto sino a la del entrenador.

El papel de entrenador atlético proporciona, de hecho, una analogía útil que demuestra cómo el conocimiento científico puede tener un valor práctico que no es tecnológico en ningún sentido manifiesto. Los entrenadores atléticos se vuelcan cada vez más hacia la medicina del deporte en busca de información; toman cosas de la psicología, la anatomía y la bioquímica y aplican este conocimiento científico a los problemas relacionados con el mejoramiento del rendimiento deportivo. Estas ciencias no nos permiten usos novedosos de nuestros cuerpos pero ayudan a mejorar la eficiencia con la que se ejecutan los viejos usos (correr, nadar, saltar, lanzar). De manera similar, el estudio científico de la cognición jamás va a revelar habilidades cognitivas insospechadas, pero nos proporciona información que puede servir para mejorar la habilidad con la que se ejercitan aptitudes que hace mucho nos resultan familiares.

Para los psicólogos cognitivos, hay muchas ventajas en presentarse a sí mismos como entrenadores. Primero y principalmente, la adopción del papel de entrenador lo pondrá al psicólogo, junto con muchos de sus colegas del asesoramiento y la psicología clínica en el lugar de "socios" de un "cliente". El psicólogo puede tratar directamente con la gente de una manera no autoritaria sino constructiva, proporcionando esencialmente una forma de realimentación sobre la manera en que el cliente está desempeñando la tarea en cuestión. Una segunda ventaja es que el papel de entrenador clarifica dónde radica la responsabilidad en lo que hace al logro de mejorías cognitivas. Como en el caso del tenis, un entrenador sólo puede ayudar a aquellos que están dispuestos a esforzarse por sí mismos. La habilidad no puede inyectarse desde afuera. La tercera ventaja de jugar el papel de entrenador es precisamente que les ahorra a los psicólogos cognitivos la etiqueta de exper-

tos. Ya no necesitan temer las burlas familiares del tipo de: "Así que estudias el pensamiento/la memoria. ¿Y por qué tu pensamiento/memoria no es mucho mejor que el de los demás?" Después de todo, nadie pretende que los mejores entrenadores de tenis hayan sido campeones ni que los campeones de tenis vayan a ser buenos entrenadores.

En el resto de este libro se demostrarán los roles gemelos del psicólogo cognitivo. En la investigación, veremos al psicólogo trabajando como científico, proponiendo y verificando hipótesis, realizando experimentaciones, analizando datos y haciendo observaciones de los estudios de caso. Cuando se trate de aconsejar sobre el modo de mejorar los rendimientos cognitivos, veremos al psicólogo actuando como entrenador: aconsejando, guiando, dirigiendo, utilizando máximas, reglas empíricas y unos cuantos principios generales de la habilidad humana.

Resumen

Este capítulo bosqueja varios asuntos y temas que se elaborarán en el resto del libro. La noción de *habilidad cognitiva* se introduce mediante dos ejemplos: la determinación del sexo de los pollos y la navegación sin instrumentos. Se señala que las habilidades cognitivas pueden parecer casi milagrosas a los no iniciados, que su adquisición requiere práctica intensiva y que estas habilidades están profundamente insertas en su contexto social. Se comenta brevemente de qué manera los psicólogos deben estudiar y estudian la cognición y se compara la cognición con la percepción y la conducta motriz. Se prefiere analizar las cogniciones como un modelo de habilidad perceptivo-motriz antes que hacerlo según la metáfora de la computadora para la mente, aunque se reconocen la influencia y el valor de esa metáfora.

Por fin, se considera brevemente la naturaleza del conocimiento psicológico. Se sostiene que el psicólogo cognitivo debe jugar dos roles: el del científico, cuando está involucrado en la investigación básica, y el de entrenador, cuando aplica su conocimiento a los problemas humanos.

¿Qué es la habilidad?

John Sloboda

En mi casa hay dos habitaciones recientemente pintadas: una la pintó un pintor profesional; la otra, la pinté yo. El pintor es un profesional experto; yo, no. ¿Qué detalles ayudan a detectar la diferencia? Bueno, el producto final ciertamente algo dice al respecto. Si uno mira cuidadosamente las paredes que yo pinté, encontrará una textura despareja; demasiada pintura por aquí, muy poca por allá. Encontrará también leves rayas verticales donde la pintura se ha corrido y desprolijidades en los bordes. Las paredes pintadas por el profesional tienen una textura pareja y los bordes son maravillosamente rectos y prolijos.

No obstante estas diferencias, en realidad me las arreglé para cubrir mis huellas bastante bien. A menos que uno observe detalladamente mis paredes, no encontrará ningún defecto evidente. Pero las diferencias más drásticas entre el profesional y yo habrían sido muy evidentes si se nos hubiera visto mientras trabajábamos.

Para empezar, el profesional terminó su trabajo en la mitad del tiempo que yo necesité. No sólo sus pinceladas eran más rápidas sino que se detenía menos que yo, que necesitaba parar con bastante frecuencia, no por holgazanería sino para poder evaluar lo que había hecho y determinar qué debía hacer a continuación. Tuve también otras demoras. Por ejemplo, me quedé sin pintura cuando aún me faltaba pintar la cuarta parte de la habitación y tuve que ir a comprar más.

En segundo lugar, el profesional hacía que su trabajo pareciera fácil. La pintura fluía sobre la pared en una sucesión serena y coordinada de movimientos. Mi secuencia de movimientos era forzada y espasmódica. Por ejemplo, una pincelada tenía demasiada pintura; la siguiente, muy poca; a veces empezaba con una pincelada ascendente y luego seguía con otra descendente; constantemente me detenía en minucias como derrames y goteos.

Finalmente, la secuencia del profesional era impecable. Ordenaba las cosas de tal manera que no necesitaba mover todo constantemente. Siempre terminaba en el lugar correcto en el momento preciso (por ejemplo, comen-

zaba la segunda capa de pintura justo cuando la primera se había secado lo necesario) y encaraba cada pared de una manera estrictamente sistemática. Yo trabajaba al azar, trataba cada pared de diferente manera, dejaba sectores sin pintar cuando, por ejemplo, la escalera no estaba colocada en el lugar adecuado; constantemente tenía que dejar de pintar para buscar algo que necesitaba o quitar obstáculos del camino.

Las características de la habilidad

Durante mucho tiempo, los psicólogos han tratado de especificar con precisión las características de las actividades que requieren habilidades. Mi ejemplo sobre la pintura incluye de manera informal muchas de las características principales, pero me gustaría ocuparme de ellas de una forma más sistemática, bajo cinco encabezamientos principales: Fluidez, Rapidez, Automaticidad, Simultaneidad y Conocimiento. Para recordarlas, puede ser útil la regla mnemotécnica de la primera letra de cada palabra: FRASC (por reglas mnemotécnicas, ver capítulo 5).

Fluidez

Una actividad es fluida si sus componentes avanzan juntos en una secuencia integrada e ininterrumpida. La palabra "fluidez" suele aplicarse a la microestructura de una tarea (los elementos que se dan en un lapso de unos pocos segundos) más que a la estructura de largo plazo. Por lo tanto, decimos que un traductor es fluido cuando puede realizar una traducción adecuada con un mínimo de pausas o vacilaciones. Un mecanógrafo fluido es el que puede mantener un ritmo de golpes parejo y continuo sobre el teclado.

Parece probable que la fluidez se origine en dos causas. Una es la superposición en el tiempo de una secuencia de movimientos; es decir, los movimientos preparatorios para la acción B se inician mientras se está desarrollando la acción A. La otra causa es la construcción de un conjunto de acciones al modo de un "agrupamiento" simple, que se puede controlar y ejecutar como si fuera sólo una unidad de conducta.

Shaffer (1976) ha demostrado elegantemente que los mecanógrafos expertos hacen estos agrupamientos. En su investigación, los mecanógrafos tenían frente a sí una pantalla de computadora en la que se veía una única línea de texto. Esta pantalla estaba conectada a un teclado de manera tal que cada

vez que los mecanógrafos presionaban una tecla, el texto se movía un espacio hacia la izquierda. Esto significaba que el carácter (o espacio) más a la izquierda "desaparecía" de la pantalla y un nuevo carácter aparecía a la derecha.

Shaffer podía variar tanto el tamaño de la ventana (es decir, la longitud de la línea exhibida) como la cantidad de visión previa (es decir, a qué distancia del extremo derecho de la pantalla se había movido un carácter antes de que fuera necesario escribirlo). Si no había visión previa, el mecanógrafo debía escribir un carácter ni bien aparecía a la derecha de la pantalla. Si había, tipeaba un carácter cuando llegaba a una posición prefijada hacia la mitad de la pantalla. Los mecanógrafos recibieron tres diferentes tipos de texto:

a) prosa normal;
b) prosa mezclada, en la que las palabras aparecían en orden azaroso.
c) palabras mezcladas, donde el orden de las letras era azaroso.

En la Figura 2.1 se ilustran estos tres tipos de texto.

Figura 2.1. Tipos de texto usados en el estudio de Shaffer sobre mecanografía

La línea vertical indica la posición de la letra que debe mecanografiarse, con una visión previa de 8 caracteres:

a) en Córdoba. Le dije a Juan sobre la reunión y | también

b) reunión dije le. Juan a también Córdoba en so|bre la y

c) unióren djie el. Nuaj a tmbinéa ódroCba ne br|ose al y

Shaffer halló que los mecanógrafos necesitaban ver unos 8 caracteres previos para poder alcanzar su máxima velocidad. Ver más de esos 8 caracteres no daba como resultado incremento alguno de la velocidad o la precisión. Las máximas velocidades uniformes fueron de unos 10 caracteres por segundo (100 palabras por minuto) en los ejemplos del tipo (a) y (b) pero sólo de 2 caracteres por segundo en el caso (c). Aparentemente, los mecanógrafos expertos pueden encarar las palabras familiares mucho mejor que las cadenas de letras sin sentido. Podemos lograr una mejor comprensión de por qué se tipean más rápido las palabras si observamos lo que sucedió cuando Shaffer redujo la visión previa a menos de 8 caracteres. En el caso (c), la re-

ducción hasta 0 no tuvo efecto alguno en la velocidad, que se mantuvo a un ritmo de 2 caracteres por segundo. Pero esa reducción tuvo un efecto drástico en los otros dos casos, que cayeron directamente, también, a 2 caracteres por segundo.

Aparentemente, la fluidez en el mecanografiado depende de que el mecanógrafo pueda ver la totalidad de una palabra promedio[1] antes de escribirla. Recién entonces puede ensamblarse en una única unidad de realización todo el conjunto de movimientos de los dedos necesario para escribir la palabra. Semejante unidad puede expresarse con rapidez. Cuando no hay visión previa, o cuando las letras no forman palabras familiares, el agrupamiento no es posible y el trabajo debe hacerse letra por letra.

La falta de diferencia entre los casos (a) y (b) también es interesante. Demuestra que estos mecanógrafos no podían formar agrupamientos mayores que las palabras individuales (a diferencia de los hablantes; ver capítulo 9). Si lo hubieran podido hacer, lo lógico habría sido que en la situación (a) fueran más veloces que en la (b). Aparentemente, en general, cualquier par dado de palabras adyacentes aparece con muy poca frecuencia como para agruparlo tal cual se hace con las palabras individualmente. Sin embargo, es probable que secuencias de palabras como "estimado señor" o "saludo atentamente" logren la condición de "agrupamientos" para algunas secretarias.

En el mecanografiado fluido se producen dos niveles de agrupamiento. Uno de ellos es lo que podría denominarse agrupamiento de *entrada* (el acto perceptual de agrupar letras en unidades tales como las palabras); el otro sería el agrupamiento de salida (el ensamble de secuencias de movimientos coordinados). Quizá la mejor manera de apreciar la naturaleza de la fluidez de esta salida sea experimentar su pérdida. Una forma efectiva de interrumpir la fluidez es perturbar la realimentación sensorial que normalmente recibimos de la conducta motriz. Esto interfiere con la capacidad de ensamblar entre sí los movimientos separados. Por ejemplo, supongamos que hablamos por un micrófono que alimenta unos auriculares que, al mismo tiempo, estamos usando. En esta situación es posible introducir una demora, de manera tal que en vez de oír la propia voz mientras uno está hablando, la oiga un poco después. El retraso de la realimentación auditiva de la propia voz en 0,2 segundos suele provocar graves fracturas del discurso. Lleva al tar-

---

1. El experimento se realizó en inglés, lengua en la que las "palabras promedio" tienen unas 6 letras. (N. del T.)

tamudeo, la repetición de sonidos y las pausas excesivas entre palabras y sílabas. La conducta fluida depende crucialmente de que la realimentación normal llegue en tiempo normal. En lo cotidiano, la pérdida de la fluidez se experimenta cuando estamos nerviosos. Tropezamos y tambaleamos con las palabras. La fluidez suele ser el último rasgo que se adquiere en una habilidad y su pérdida es el primer signo de fractura, debida a enfermedad, intoxicación o miedo.

Rapidez

La mayoría de las habilidades incluyen la capacidad de ofrecer una respuesta adecuada rápidamente. El jugador de tenis experto no sólo debe llegar al lugar correcto y elegir el golpe adecuado sino que debe hacerlo en un lapso increíblemente corto. La capacidad de ofrecer la respuesta correcta casi inmediatamente es característica en todas las habilidades.

Uno de los estudios más importante y más citados, que demuestra la velocidad del desempeño experto, es un estudio sobre jugadores de ajedrez, realizado por Chase y Simon (1973). Tomaron personas con diferentes niveles de dominio del juego (desde principiantes hasta grandes maestros) y les mostraron tableros de ajedrez en los que se reproducía una partida real, ya empezada, jugada entre expertos. Se les permitió ver el tablero durante 5 segundos. Luego se retiraron las piezas y se les pidió que reconstruyeran las posiciones sobre el tablero vacío. Como promedio, los principiantes pudieron volver a poner 4 de cada 20 piezas correctamente. Los maestros, en cambio, pusieron 18 de cada 20 piezas.

Como todos vieron el tablero durante el mismo lapso, los resultados demuestran que un maestro puede aprovechar la misma información mucho más rápidamente que un principiante. Una segunda parte de la investigación arrojó luz sobre los mecanismos involucrados. Los tableros que se mostraron esta vez a los individuos contenían piezas colocadas al azar, de una manera que jamás podría haberse dado en una partida lógica. Enfrentados a semejantes tableros, los principiantes tuvieron el mismo rendimiento que en el primer experimento, y colocaron correctamente 4 de 20 trebejos. Los maestros, por su parte, mostraron una drástica caída en su rendimiento, de 18 a 4 piezas, de cada 20. En estos tableros azarosos el maestro no fue superior al principiante.

Esto nos muestra que la habilidad del maestro no depende simplemente de una percepción superior o de la memoria sino que está vinculada con la detección en el estímulo de esquemas familiares y relevantes para el juego.

El maestro "entiende" inmediatamente lo que ve en términos significativos, de manera que, por ejemplo, un grupo de 5 piezas en determinada posición se convierte para él en un "enroque", otro grupo en un "jaque doble", etc. Esto se confirma por la forma en que el maestro realiza la tarea de reconstrucción. Tiende a colocar conjuntamente los grupos asociados y hace pausas más largas entre los diferentes grupos. La capacidad del jugador experto para percibir esquemas significativos sobre el tablero es análoga a la capacidad de un espectador experto de fútbol para reconocer, en medio de la frenética actividad de un partido, movimientos cuidadosamente ensayados.

Automaticidad

Una de las características más universales de la habilidad es la forma en que se vuelve "fácil" para quienes la practican. Ya no experimentamos esfuerzo alguno cuando llevamos a cabo alguna habilidad bien aprendida (como caminar). Sólo "sucede", sin que tengamos que pensar en ella. Si no fuera así, nuestra capacidad para actuar en el mundo se vería drásticamente limitada. Pasaríamos todo el tiempo ocupándonos de las cosas más elementales.

La *repentización*[2] en piano es una habilidad compleja. En un estudio sobre profesionales de la repentización, Wolf (1976) entrevistó a varios ejecutantes y les preguntó cuáles eran los principales problemas de la repentización. Un pianista contestó: "Para mí, personalmente, ninguno". Esto no es arrogancia sino una respuesta honesta sobre una habilidad altamente automatizada. Es el tipo de respuesta que la mayoría de nosotros tendría que dar si se nos preguntara sobre los problemas que tenemos para caminar. Sin embargo, caminar es una habilidad de una complejidad comparable a la de la repentización en piano, que exige a los niños un largo tiempo de aprendizaje.

Una de las formas de comprobar si una habilidad está automatizada es ver si el ejecutante puede resolver adecuadamente una situación, aun cuando no esté concentrado o no espere que ésta se presente. Así, por ejemplo, un conductor experto sería capaz de frenar rápidamente ante un riesgo potencial, aun cuando su mente hubiera estado en otra cosa en los momentos previos.

La Berge (1973) ofreció una clara demostración experimental de este tipo de fenómenos. Los sujetos debían mirar un símbolo. Después de un breve lapso, el simbolo desaparecía y otro lo reemplazaba. Los dos símbolos podían ser letras familiares (como a, b, p, d) o caracteres no familiares (como 1↓).

2. *Ejecución de una obra musical a la primera lectura.*

A uno de los sujetos se le pidió que juzgara si ambos símbolos eran iguales o diferentes y que apretara un botón (de dos posibles) para indicar su decisión tan rápidamente como pudiera, después de la presentación del segundo símbolo. Se midió el tiempo transcurrido entre la presentación del segundo símbolo y la respuesta. Este tiempo suele denominarse tiempo de reacción y es una medida usada con frecuencia en el estudio de todo tipo de habilidades. La Figura 2.2 resume los resultados de La Berge. En esta tarea, no se encontró diferencia en el tiempo de reacción entre los símbolos familiares y los no familiares. La Berge sostuvo que el primer símbolo ofrecía una pista al sujeto sobre el tipo de símbolo que podía esperar en la segunda presentación, facilitando la decisión sobre si ambos eran de la misma forma, sin importar su familiaridad.

Pero, en algunas pruebas, La Berge introdujo algo inesperado. En lugar del segundo símbolo, presentó un par de símbolos. En los casos en que hizo esto, se pidió a los sujetos que ignoraran el primer símbolo y se concentraran en el par de símbolos. Debían juzgar si los miembros de este par eran idénticos o no. En esta tarea inesperada, La Berge halló una diferencia significativa entre el tiempo de reacción entre pares familiares (por ejemplo, bd) y no familiares (por ejemplo, ⅂ ⅃). Los sujetos respondieron más rápidamente a las letras familiares. La Berge sostiene que este resultado muestra que, en los lectores experimentados, el reconocimiento experto de letras es automático mientras que el reconocimiento de símbolos nuevos y no familiares no lo es. Cuando se presenta una tarea inesperada, sólo se pueden procesar rápidamente las letras. Los símbolos no familiares se asocian con respuestas más lentas precisamente porque no se los puede reconocer automáticamente.

Figura 2.2: Tareas y resultados de La Berge

	tarea esperada		tarea inesperada	
	1.	2.	3.	4.
primer estímulo	a	⅂	a	a
segundo estímulo	a	⅂	bb	⅂⅂
velocidad de reacción	rápida	rápida	rápida	lenta

Otra característica de las habilidades automáticas parece ser que, en algunos casos, son obligatorias. Es decir, un estímulo desencadena su respuesta automática sin importar si la deseamos. Cuando vemos escrita una palabra familiar, no podemos evitar el pensar en su significado. También nos re-

sulta igualmente imposible no reconocer un rostro familiar, como el de una persona que conocemos, y verlo en su lugar como un mero conjunto de rasgos individuales.

La tendencia de las habilidades automáticas a entrar en juego "a pesar de nosotros mismos" puede llevar a veces a situaciones embarazosas y graciosas, que han sido estudiadas en el contexto de la "distracción" (por ejemplo, Reason y Mycielska, 1982). La madre de una familia numerosa cuenta que una vez, en una fiesta, se encontró cortando en pedacitos la comida de su sorprendido vecino de mesa, mientras charlaba con otra persona. Si eso nos causa gracia, deberíamos reirnos con la desafortunada madre (y no de ella) ya que los estudios han demostrado que la mayoría de la gente puede recordar muchos deslices de este tipo en su vida cotidiana. Los resultados no siempre son tan embarazosos, pero el principio es el mismo. Los deslices de esta naturaleza parecen consecuencias inevitables de la automatización de la conducta experta.

Simultaneidad

Todavía recuerdo con horror mi primera lección para aprender a conducir. Mi instructor intentaba enseñarme cómo cambiar de velocidad. Esto incluía una complicada secuencia de movimientos que involucraban al embrague, el acelerador y la palanca de cambios simultáneamente. Por si esto no era suficiente, mi instructor no dejaba de gritar: "¡Mantén la vista en el camino! ¡No sueltes el volante!". Las múltiples demandas a mi atención parecían imposibles de satisfacer. Ahora, cuando ya han pasado unos 20 años, todo parece trivialmente sencillo. Cambiar de marcha es una secuencia de movimientos fluida y coordinada que puedo realizar mientras mantengo una discusión de alto nivel intelectual con mi pasajero sobre algún tema que nada tiene que ver.

La simultaneidad es una característica de la habilidad en dos sentidos. En primer lugar, los componentes de una actividad experta pueden ejecutarse simultáneamente (como el ejemplo de los movimientos conjuntos de manos y pies para cambiar la marcha del auto). En segundo lugar, debido al alto grado de automaticidad, suele ser posible desarrollar una actividad no relacionada al mismo tiempo que se realiza una actividad experta. Una de las formas que usan los psicólogos para comprobar cuánto se ha automatizado una habilidad consiste en medir el efecto sobre el rendimiento del agregado de una segunda tarea, simultánea, para que el sujeto la realice.

Allport, Antonis y Reynolds (1972) ofrecieron una de las demostraciones antiintuitivas más sorprendentes, en un experimento en el que analizaban el rendimiento en dos habilidades: la repentización en piano y la "persecución" en prosa. Los sujetos del experimento eran repentizadores experimentados. Primero, se les pidió que ejecutaran cada tarea por separado. En la prueba de repentización, se colocó frente al sujeto una partitura para piano no familiar, y se le pidió que la ejecutara sin ensayo previo. En la prueba de "persecución", el sujeto escuchaba un fragmento en prosa a través de auriculares y debía repetirlo en voz alta mientras lo oía. Luego, se combinaron las dos tareas. Se le pedía al sujeto que realizara ambas tareas a la vez lo mejor posible.

Después de muy poca práctica, los sujetos podían realizar las dos tareas a la vez sin fallar en ninguna. Aun más sorprendente fue la comprobación de que ninguna de las dos tareas afectaba seriamente a la otra. Cada tarea fue realizada en la situación dual con la misma destreza que en la realización por separado.

Un largo debate se abrió en la psicología sobre si se puede prestar atención a dos cosas a la vez. Algunos teóricos sugirieron que la atención es como un rayo indivisible: sólo se puede apuntar hacia una cosa por vez. La realización de dos tareas debe explicarse, entonces, como el rápido cambio de la atención de una tarea a la otra (Broadbent, 1982). Otros lo han visto más como una cantidad de recursos que se pueden dedicar íntegramente a una tarea o que se pueden dividir entre varias. Los defensores de ambos puntos de vista concuerdan ampliamente en que las tareas automáticas necesitan que se les destine poca o ninguna atención. Por lo tanto, cuando al menos una de dos actividades que se desarrollan simultáneamente es automática, hay capacidad de atención suficiente como para realizar ambas. En el experimento recién comentado, parece probable que la repentización haya logrado un alto grado de automaticidad.

Conocimiento

Cuando discuto algún tema que me resulta entrañable, no siempre gano. Mientras curo mis heridas después de la discusión, suelo encontrar la respuesta exacta que debería haber dado ante el golpe aparentemente devastador de mi oponente. Pero en el calor del debate no puedo llegar al conocimiento adecuado, al argumento que quisiera expresar. De manera similar, los alumnos en un examen suelen comprender, minutos después de salir del aula, lo que deberían haber escrito.

Uso estos ejemplos para subrayar que la habilidad no es una mera cuestión de posesión del conocimiento. Se necesita que ese conocimiento esté disponible en el momento adecuado, en respuesta a la situación que exige su uso. Por ejemplo, lo importante al conducir un automóvil es disminuir la velocidad inmediatamente al ver que la luz verde del semáforo está cambiando a amarilla. No sirve de nada tener el conocimiento conceptual de que la luz amarilla significa "alto" si no se lo puede aplicar a la hora de conducir. Recientemente, los psicólogos cognitivos se han estado ocupando del papel posible en la conducta experta de lo que ellos llaman pares asociativos de *modelo-acción*. Estas asociaciones son algo similar a reglas que un organismo puede aplicar en situaciones particulares. Tienen la siguiente forma: *Si se cumple la condición X, debe realizarse la acción Y.* Se parecen a la relación estímulo-respuesta que tiene una larga historia en las explicaciones conductistas del aprendizaje animal. Pero en estas "reglas de producción", X no necesita ser un simple estímulo externo y, por su parte, Y no tiene que ser una conducta evidente. Podemos incluir cosas tales como los estados psíquicos internos y los objetivos. De modo que la regla "Si ves un auto de policía por el espejo retrovisor, entra en pánico", es una regla de producción, aunque preferiríamos que no existiera.

Un conjunto de reglas de producción suficiente para realizar alguna tarea coherente puede convertirse en un *sistema de producción*. Una de las razones fundamentales por las que los psicólogos han comenzado a pensar en las habilidades en términos de sistemas de producción es el hecho de que semejantes sistemas pueden estimularse muy fácilmente en una computadora. Volveremos a analizar la utilidad de esto en el capítulo 16.

La teoría de los sistemas de producción ofrece una forma útil de comprender cómo puede organizarse el conocimiento al servicio de la habilidad en varios niveles diferentes. Primero, a nivel de las acciones individuales. Ciertos esquemas ambientales pueden gatillar inmediatamente conocimientos sobre lo que se debe hacer en determinada circunstancia. Al conducir, por ejemplo, una luz verde que cambia al amarillo gatilla una aplicación inmediata de los frenos. Sobresalen dos hechos significativos en semejante conocimiento. Uno es que el conocimiento puede ser completamente inaccesible (u "olvidado") hasta que se dan las circunstancias que requieren su empleo. Por ejemplo: ¿sabe usted, sin intentar hacerlo, qué músculo usaría primero si se levantara desde una posición de sentado? El segundo hecho es que nuestra capacidad para adquirir nuevos pares esquema-acción parece ilimitada.

Un estudio realizado sobre conductores de taxímetros (Chase, 1983) nos habla claramente de la accesibilidad. Se llamó al laboratorio a taxistas experimentados de Pittsburgh y se les pidió que describieran los mejores caminos entre pares de puntos de la ciudad. Se trataba de algo que podían hacer. Sin embargo, las rutas que eligieron no fueron en todos los casos las mejores ni las que tomarían los conductores realmente. Esto se demostró repitiendo el estudio en la vida real: se les pidió a los taxistas que condujeran desde A hasta B. Al hacerlo, solían recordar atajos mejores que los que habían mencionado en el laboratorio. Estos atajos parecían impulsados por la experiencia de llegar a determinados lugares. Los conductores hacían comentarios como: "Por supuesto que, si doblo a la izquierda aquí, puedo evitar aquel cuello de botella". Esto, naturalmente, es completamente adaptativo. Los taxistas necesitan encontrar buenos caminos cuando están trabajando, no cuando están pensando en ello.

Una habilidad cognitiva compleja, como jugar al ajedrez, también puede someterse al estudio de los procesos de producción. Podemos suponer que el maestro de ajedrez tiene muchos miles de reglas de producción que vinculan cada esquema concurrente o agrupamiento con una buena movida asociada con ese esquema. De esta forma, los grandes maestros sienten que las buenas jugadas "surgen del tablero". Los malos jugadores tienen que luchar contra las consecuencias de muchos malos movimientos antes de tropezar con uno bueno.

La estructura de las habilidades

También podemos usar la idea de proceso de producción para conocer la naturaleza de la planificación y la estructura de la habilidad, y la capacidad de seguir la pista de dónde está uno. Para esto, además de las reglas de producción, debemos postular un sistema de memoria operativo en el cual se puede "apilar" un conjunto de objetivos (ver capítulo 5). Un ejemplo simple de una habilidad común es la capacidad de viajar por un país industrializado. Si, por ejemplo, estoy en un ámbito rural y necesito llegar a una gran ciudad rápidamente, puedo fijarme el objetivo de "llegar a Londres". Este objetivo puede actuar como condición X de una regla de producción que podría ser: *"Si el objetivo es llegar a Londres, fijar el objetivo de llegar a la estación de tren más cercana"*. De este modo, el objetivo de llegar a Londres es "empujado hacia abajo" en la pila y el segundo objetivo, —"llegar a la estación"—, pasa arriba de la pila como objetivo actual. Ahora, el objetivo es "lle-

gar a la estación". Esto puede requerir otra regla, que diga: *"Si el objetivo es llegar a la estación, fijar el objetivo de conseguir un taxi"*. Ahora, "conseguir un taxi" se convierte en el objetivo actual, con dos objetivos no logrados apilados debajo. Esto puede requerir otras reglas, como "buscar el número telefónico de la compañía de taxis". En algún punto habrá un objetivo que ponga en juego una regla de producción implicando a la conducta para que alcance el objetivo superior. Cuando esto ocurra, dicho objetivo podrá eliminarse de la pila y el siguiente objetivo se convertirá en el actual. Entonces podrá cumplirse este objetivo, y así con toda la pila hasta que ya no quede ninguno. La pila de objetivos da estructura y dirección a la conducta total.

Sin la estructuración de una pila de objetivos, la conducta tendería a ser incoordinada y plenamente dirigida por la situación en curso. De hecho, cuando la conservación de objetivos en la pila es inadecuada, tiene lugar una falla parcial en la conducta. Podemos observar esto mediante una clase peculiar de error de distracción. Esto nos sucede a la mayoría: entramos a un negocio y nos quedamos allí parados, tontamente, tratando de recordar para qué entramos. El objetivo de "comprar X" nos llevó al nuevo objetivo de "ir al negocio", pero en el camino empezamos a pensar en otras cosas y esta actividad mental interviniente nos llevó a perder el objetivo original de la pila.

En la vida real, la mayoría de la gente no persigue sólo un conjunto de objetivos como los que se describen arriba sino muchas objetivos dispares. A veces resulta difícil tenerlos a todos en mente, y jamás podemos trabajar de manera directa en más de un par de ellos a la vez. En consecuencia, la capacidad de recordar los múltiples objetivos que uno tiene y en qué etapa está en el logro de cada uno de ellos es una importante habilidad por sí misma. Todos conocemos individuos que siempre parece estar olvidándose de hacer cosas mientras que hay otros que siempre se manifiestan capaces de cumplir con una amplia variedad de compromisos diferentes y complejos. El papel de las ayudas externas a la memoria resulta muy importante aquí: las agendas, los nudos en los pañuelos, las listas de cosas para hacer y las notas dirigidas a uno mismo (ver capítulo 8). Podemos ver a la movilización de estas ayudas como un reconocimiento explícito del hecho de que los estímulos externos son los mejores y más confiables disparadores de la acción. Ser hábil para cumplir múltiples compromisos supone ser hábil para manejar el propio entorno, sobre todo la memoria necesaria en el lugar y el momento correctos.

3

La adquisición de la habilidad

John Sloboda

En el capítulo anterior vimos algunas de las características de la conducta experta. Nos ocuparemos ahora de una cuestión relacionada con ella: ¿qué tiene que hacer uno para convertirse en experto? El animal humano es único en cuanto a la cantidad de habilidades que adquiere mediante el aprendizaje. También somos únicos en la diversidad de nuestras habilidades. Algunos seres humanos son matemáticos expertos, otros son músicos expertos y otros, mecánicos expertos. ¿Cómo es posible que la gente sea tan diferente en su perfil de habilidades?

Muchos animales parecen extremadamente hábiles. Obsérvese, por ejemplo, la forma en que un gato caza un pájaro. Se agazapa para que el suelo disimule su presencia y se mueve lenta y silenciosamente hacia su presa; luego, cuando ya es difícil permanecer oculto, salta con las garras extendidas para dar a su presa el mínimo tiempo de reacción posible. La habilidad de mi gato en esta operación queda demostrada por la cantidad de pájaros y ratones muertos que deposita con orgullo en el suelo de la cocina de mi casa. Podría aprender mucho sobre técnicas de caza observando cuidadosamente a mi gato.

¿De dónde proviene la habilidad del gato? Hasta donde sabemos, la mayoría de las habilidades animales son heredadas y no aprendidas. Los gatitos criados en aislamiento muestran también un buen repertorio de conductas de acecho y cacería (Hinde, 1966). Parecen instintivas. Además, todos los individuos de una especie dada parecen heredar globalmente el mismo conjunto de habilidades.

¿Es posible que las habilidades humanas también sean heredadas? En la primera sección de este capítulo, examinaremos el punto de vista según el cual la adquisición de habilidades se atribuye al talento como potencial innato. Luego, contrastaremos este punto de vista con otro, según el cual el talento es menos importante que la oportunidad y la práctica. Concluiremos echando una mirada a un estudio de caso de una habilidad excepcional, que muestra que realmente necesitamos las dos perspectivas para comprender bien la adquisición de habilidades.

El talento y la adquisición de habilidades

Es indiscutible que las personas dotadas tienden a tener hijos dotados. A veces, talentos específicos (como el talento para la música) parecen correr en las familias durante varias generaciones. Por desgracia, hace mucho que se sabe que este hallazgo, en sí, dice muy poco sobre cómo se adquirió la habilidad. Podría ser que el hijo de un músico hubiera heredado cierta propensión especial hacia la música. De la misma forma, también es posible que un padre músico proporcione a su hijo más oportunidades y aliento para que pueda adquirir habilidades musicales que un padre no músico. En la vida real, las influencias de la herencia y el medio están inseparablemente unidas, y es muy difícil establecer qué influencia en particular resultará decisiva. Gran parte de la investigación psicológica seria en este campo se ha centrado en la noción de inteligencia y ha sido objeto de grandes controversias. Una de estas controversias se refiere a si existe alguna capacidad o facultad unitaria que constituya el fundamento para la acción inteligente o si, en cambio, la inteligencia es sólo la conjunción de varias habilidades distintas e independientes. Quienes sostienen el primero de dichos puntos de vista apuntan al hecho de que aquellos que son buenos en un tipo de cosas tienden a ser buenos también en toda otra gama de cosas. La base de los tests de inteligencia reside en esto. Precisamente porque muchas habilidades se correlacionan entre sí, podemos obtener una imagen útil de la capacidad de una persona mediante el muestreo de unas pocas habilidades. Pero la correlación no es perfecta y encontramos en casi todas las personas áreas de habilidad que son mucho mejores o mucho peores de lo que se podría predecir sobre la base de las mediciones de su inteligencia. Un buen ejemplo de esto (sobre el que volveremos en el próximo capítulo) es el del disléxico, que lee mucho peor de lo que se podría predecir a partir de sus otros logros intelectuales. Gardner (1983) ofrece una visión accesible de los aspectos que rodean a esta controversia general.

Un segundo punto controvertido es la medida en que podemos hallar medios confiables para evaluar los efectos separados de la herencia y el medio. Este tópico está lleno de dificultades metodológicas y teóricas. También es un campo minado en lo político e ideológico, ya que frecuentemente se lo vincula con la cuestión de las diferencias del racismo y la herencia (Eysenck versus Kamin, 1981). Muy poca gente llega al tema sin prejuicios. Sin embargo, me arriesgaré y diré que hay probablemente tres formas en que las características heredadas podrían tener un efecto significativo sobre la adquisición de habilidades:

a) Hay algunas condiciones transmitidas genéticamente que provocan retardos mentales irreversibles, presumiblemente como consecuencia del desarrollo anormal del cerebro o el sistema nervioso (por ejemplo, el síndrome de Down). Estas condiciones pueden destruir aptitudes esenciales para algunas habilidades. Todas esas condiciones, desgraciadamente, tienden a imponer impedimentos a quienes las poseen. No hay condiciones conocidas de este tipo que confieran ventajas significativas.

b) Las características físicas heredadas son indudablemente un factor para la determinación del logro en algunas habilidades. Las posibilidades para que alguien se convierta en cantante de ópera dependerán mucho de la forma de la cavidad vocal de esa persona; las posibilidades de que una persona se dedique a la danza dependerán mucho de la conformación de su esqueleto, etc. También es probable que sean importantes las características físicas heredadas del sistema nervioso.

c) Hay todo un conjunto de lo que se podrían denominar factores de disposición y motivación que podrían tener un efecto indirecto sobre la adquisición de habilidades. Desde su más tierna infancia, los niños parecen diferir en su nivel de actividad, la cantidad de horas de sueño que necesitan, su temperamento primario, etc. Las investigaciones sobre la personalidad adulta muestran significativas diferencias individuales en factores tales como la capacidad de concentración en tareas aburridas durante períodos largos. También hay evidencias de que existen preferencias estables por ciertos campos de actividad. Algunas personas parecen tener tendencia a las actividades visuales y otra a las verbales. Estas preferencias pueden vincularse a la infancia temprana, donde se observan significativas diferencias en el perfil evolutivo (Kagan, Lapidus y Moore, 1978). Algunos niños desarrollan la habilidad del lenguaje tempranamente, pero su desarrollo físico se retrasa. Otros muestran una tendencia inversa. Todos estos factores podrían tener una fuerte influencia tanto sobre el tipo como sobre el nivel de habilidad adquiridos. Podemos suponer que es más probable que el extrovertido físicamente precoz adquiera habilidades futbolísticas mientras que el introvertido verbal podría desarrollar más fácilmente habilidad para la poesía. Esto no es una cuestión de capacidad. Más bien, representa la cantidad de esfuerzo que una persona puede estar dispuesta a destinar a tipos peculiares de actividad. Algunas actividades parecen "ir contra la naturaleza de la persona", mientras que otras parecen intrínsecamente gratificantes.

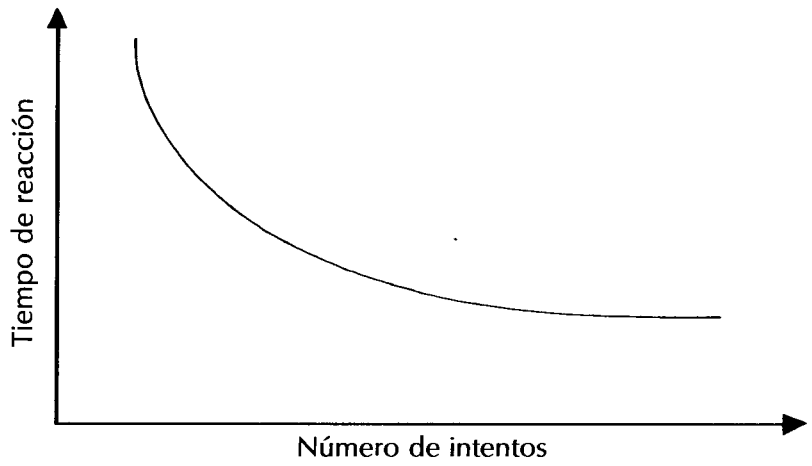
La práctica y la adquisición de habilidades

Paul Tortelier es uno de los principales violonchelistas profesionales del mundo. Sus padres eran obreros con escasos recursos económicos y sin logro musical peculiar alguno. Antes de que Paul naciera, decidieron que su hijo debería lograr grandes cosas en el mundo y que iban a formarlo como violonchelista. Mediante el esfuerzo, los ahorros y el sacrificio personal llegaron a comprarle instrumentos, pagarle lecciones y ofrecerle todo tipo de apoyo, y su hijo logró lo que sus padres querían.

Semejante carrera de la pobreza a la riqueza toca una cuerda íntima en muchos de nosotros y sugiere la siguiente pregunta. Supongamos que al pequeño Tortelier lo hubieran arrancado de su cuna al nacer y lo hubieran reemplazado por otro niño, elegido al azar entre toda la población; supongamos, además, que sus padres no hubieran advertido el cambio y lo hubieran criado como si fuera su hijo, ¿habrían podido convertir a cualquiera en un violonchelista de nivel mundial?

Si nos inclinamos a responder que "sí" a esta pregunta, estaremos basando nuestra respuesta en el supuesto de que las habilidades no se adquieren en virtud de lo que uno es sino de lo que uno hace. Cualquiera puede adquirir una habilidad si hace lo necesario para ello.

Es imposible, en la práctica, hacer el experimento de la sustitución hipotética del niño. Pero lo que podemos hacer es observar cómo se comportan los individuos en el proceso de adquisición de habilidades y preguntarnos si hay algo que parezca ligado a la adquisición exitosa de una gran variedad de habilidades para una gran cantidad de personas. No resultará sorprendente enterarnos de que el factor simple más importante que los psicólogos conocen es la práctica. De la misma manera, la práctica es el ingrediente que más destacan los entrenadores deportivos y los maestros de piano.



Muchas investigaciones se han ocupado de los efectos de la práctica en las habilidades perceptivo-motrices simples. Un experimento muy usual es aquel en el que se mide el tiempo de reacción para apretar un botón en respuesta a una luz que se enciende. A veces sólo hay un botón y una luz, mientras que en otros experimentos puede haber varios botones y luces y los sujetos deben responder quizá a una luz por vez o a varios esquemas de luz que aparecen juntos. Un estudio de Siebel (1963) resulta representativo: los sujetos veían 10 luces ordenadas en una fila horizontal; debajo de cada luz había un botón; los sujetos debían apoyar sus dedos sobre las teclas y mirar las luces; después de una señal, se encendían algunas de las luces, de mane-

ra azarosa, y los sujetos debían presionar las teclas correspondientes a las luces encendidas (y no otras). Esta tarea fue repetida más de 40.000 veces.

Siebel midió el tiempo de reacción medio para presionar la combinación correcta de teclas. Como vimos en el capítulo anterior, la rapidez en la respuesta es una característica crucial de la habilidad, y por eso muchos investigadores han usado el tiempo de reacción como medida primaria del nivel de habilidad. Cuanto más rápido responde uno, más hábil (o experto) es, siempre y cuando, naturalmente, las respuestas sigan siendo correctas. Siebel descubrió que el tiempo de reacción disminuía de un nivel inicial de unos 2 segundos a 0,4 segundo después de tanta práctica. Es difícil imaginar que esta tarea revistiera algún interés para los sujetos que realizaban el experimento, y sin embargo la repetición pura y persistente fue causando una continua mejoría a lo largo de los 40.000 intentos.

Se puede obtener información más detallada haciendo un gráfico en el que las variables sean el tiempo de reacción (TR) y el número de intentos. La figura 3.1 muestra el resultado que se obtiene al hacerlo. Ejemplifica lo que a veces se denomina "ley de los resultados descendentes". La práctica temprana da como resultado grandes ganancias en la velocidad, pero la misma práctica más adelante sólo ofrece pequeñas mejorías. A veces este achatamiento en la curva de adquisición se da porque se llega a los límites fisiológicos; por ejemplo, la velocidad fija a la que los nervios conducen los impulsos. Pero más frecuentemente el achatamiento comienza mucho antes de acercarnos a esos límites.

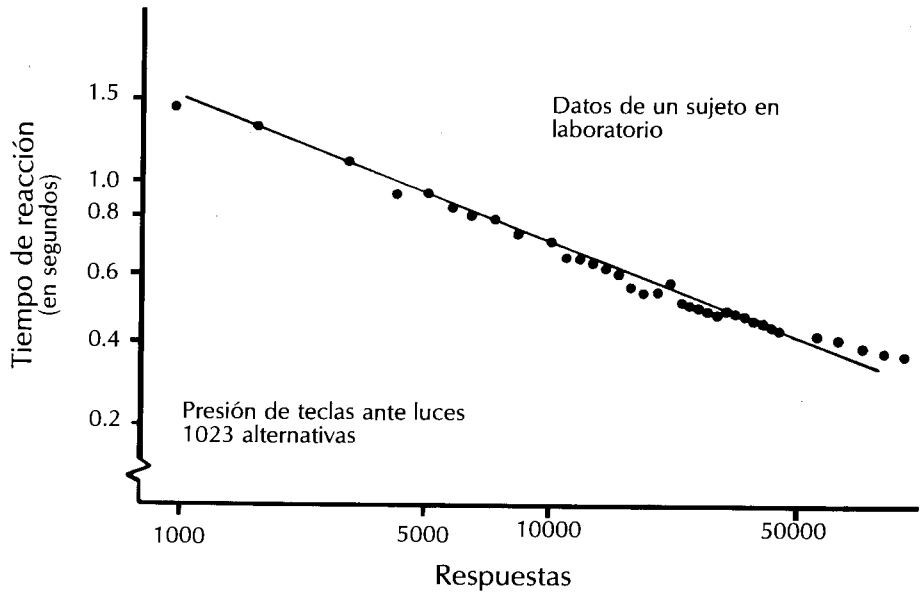


Figura 3.1: Gráfico típico de tiempo de reacción contra cantidad de ensayos

¿Por qué las mejoras disminuyen con la práctica? Una posibilidad sería que la gente se concentra cada vez menos mientras repite una tarea y no logra obtener beneficios de los intentos en la misma medida que al comienzo. Esta podría ser una explicación plausible para la declinación en una sesión. Pero no explicaría una caída pareja en 40.000 ensayos realizados en un lapso de muchos días. Si el aprendizaje dependiera enteramente de la concentración, deberían verse muchos altibajos, en la medida en que la propia concentración los sufriera.

Antes de considerar una explicación más probable, es importante notar que las curvas obtenidas experimentalmente, como la que se muestra en la figura 3.1, frecuentemente se aproximan a una función logarítmica. Si se las vuelve a organizar sobre ejes logarítmicos, se convierten en líneas rectas. La Figura 3.2 muestra los datos de Siebel así reorganizados.

Figura 3.2 Datos de Siebel reorganizados sobre ejes logarítmicos. (Según Fitts y Posner, 1967.)

Explicación de la ley de las mejoras decrecientes

Newell y Rosenbloom (1981) ofrecieron una explicación para las mejoras decrecientes; se basa directamente en las nociones de agrupamiento y las reglas de producción modelo-acción que ya hemos explorado en el capítulo 2. Sostienen que mientras un sujeto desarrolla alguna tarea como en el experimento de Siebel, continuamente intenta agrupar las luces en esquemas. Cada agrupamiento se asocia a su vez con un conjunto de dedos determinado para la respuesta. Para empezar, el conjunto se procesa como diez luces individuales y las respuestas se dan ante cada luz por separado. A medida que pasa el tiempo, el sujeto empieza a responder, por ejemplo, a pares de luces como si fueran unidades simples, luego a grupos de tres, etc., hasta llegar a un techo teórico en donde las 10 luces se ven como un conjunto único (así como al aprender a leer los alumnos progresan desde la lectura letra por letra hasta la lectura de palabras completas — ver capítulo 4). Si suponemos, por cuestiones de simplicidad, que lleva un tiempo constante percibir y responder a un agrupamiento simple, observamos que cuanto mayores sean los agrupamientos, menos tiempo toma responder al conjunto total.

Es bastante fácil ver intuitivamente que cuantos más agrupamientos aprenda una persona, más rápida será su respuesta a cualquier conjunto de luces dado, porque más posibilidades tendrá de detectar un esquema familiar. Por lo tanto, la práctica aumentará la velocidad de la tarea. Lo que resulta menos fácil de ver es por qué esta noción también predice la ley de las mejoras decrecientes, pero en realidad lo hace. Se debe a que un agrupamiento pequeño determinado se repetirá con mayor frecuencia que uno grande, y por lo tanto se lo puede aprender y poner en práctica más rápidamente.

Para ver qué importancia tiene esto, consideremos primero qué sucede cuando agrupamos al conjunto en cinco grupos de un par de luces adyacentes cada uno. Cada grupo (es decir, cada par de luces) tiene cuatro configuraciones posibles (apagada-apagada, apagada-encendida, encendida-apagada, encendida-encendida). Hay 5 pares, de modo que hay 5 veces 4 configuraciones, lo que da un total de 20 posibilidades. Hay que aprenderlas todas junto con sus 20 esquemas de respuesta. Si en cualquier intento del experimento se encienden al azar la mitad de las luces, es probable que cualquier configuración de un par determinado aparezca, como promedio, una vez cada cuatro ensayos. De manera que como cada uno de los 20 grupos aparece frecuentemente, hay muchas posibilidades de ver y aprender a responder a cada uno de ellos. Dado nuestro supuesto de que se necesita un tiempo constante para responder a cualquier agrupamiento, una persona que

ha aprendido estos 20 esquemas de pares podrá reducir su tiempo de respuesta, viendo siempre al conjunto como 5 agrupamientos y no como 10 luces independientes. Este es el motivo por el cual las primeras etapas de la práctica pueden dar como resultado grandes ganancias en el rendimiento.

Consideremos ahora lo que incluiría el aprendizaje para responder al total como 2 conjuntos, cada uno de los cuales contuviera 5 ítem. Hay 32 configuraciones diferentes posibles de encendido y apagado para un conjunto de 5 luces. Hay 2 grupos en el total de 10, de modo que hay 64 configuraciones para aprender en total (2 veces 32). Si en cualquier ensayo al azar se encienden la mitad de las luces, cada configuración de un grupo sólo aparecerá una de cada 32 veces. Hay más esquemas para aprender y muchas menos posibilidades de observar cualquier esquema determinado. Por lo tanto, le tomará a una persona mucho más tiempo pasar de procesar el total como 5 grupos a procesarlo como 2 grupos que lo que le tomó pasar de 10 a 5 grupos. El primer movimiento reduce el tiempo de reacción a la mitad, de 2 segundos a 1 segundo. El segundo movimiento reduce el tiempo de reacción en 3/5, de 1 segundo a 0,4. No sólo habrá tomado más tiempo realizar el segundo pasaje sino que también habrá producido un aumento absoluto menor en la velocidad. Esto explica el fenómeno de las mejoras decrecientes y su aproximación a la función logarítmica.

Estudios como el de Siebel y la teorización construida en torno a él ofrecen oportunidades para la reflexión matemáticamente precisa sobre las habilidades. Muestran con especial elegancia porque hace falta tanto tiempo para llegar a ser de verdad bueno en algo. Y, sin embargo, esos estudios tienen varios defectos. En primer lugar, las habilidades estudiadas son muy simples. Requieren una respuesta simple a un estímulo y no una secuencia coordinada. En segundo lugar, los propios estímulos carecen de esquema y estructura naturales. Es muy raro en el mundo real que la materia con la que tratamos sea tan impredecible. Hay semejanzas entre las situaciones nuevas y las viejas, que ya conocemos. Podemos hacer suposiciones y planes informados. Algunos esquemas aparecen con mucha mayor frecuencia de lo que esperaríamos por casualidad. En tercer lugar, normalmente tenemos la posibilidad de decidir cómo practicaremos una habilidad. En la tarea de Siebel, los individuos debían responder a diez luces en todos los intentos. Aprender las respuestas para cada mano separadamente podría ser una buena estrategia.

Esto nos lleva a la cuarta crítica. En experimentos como el de Siebel, los individuos suelen trabajar totalmente solos; la habilidad carece por completo de contexto social. Como se observa en el capítulo 1, esto no sucede

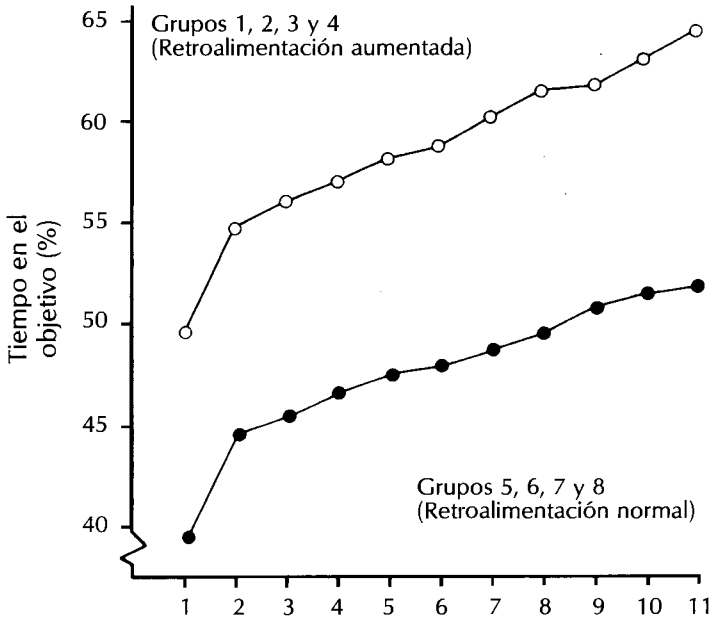
con las habilidades de la vida real. Usualmente, tales habilidades se aprenden con la ayuda de algún tipo de entrenador. Puede ser alguien que hace mucho practica la habilidad, un libro o quizá sólo el deseo de copiar lo que una vez se vio hacer. Sin embargo, por lo general se cuenta con alguna fuente de comentarios y sugerencias. Por todos estos motivos, el grado de progreso en una tarea como la propuesta por Siebel probablemente muestre un cálculo pesimista de nuestra capacidad de adquirir habilidades en la vida real.

Mejorando los efectos de la práctica

En esta sección, nos ocuparemos brevemente de algunas cosas que han demostrado ayudar a que muchos tipos de práctica resulten más eficaces. Son características de la práctica en torno a las que se debe construir cualquier programa de entrenamiento. La primera y principal es la retroalimentación (*feedback*).

Retroalimentación

La retroalimentación es, sencillamente, conocimiento de lo que se ha logrado con las propias acciones. Puede ser de dos tipos, intrínseca y extrínseca. La retroalimentación intrínseca es la que se obtiene como consecuencia directa del movimiento y las sensaciones corporales. Si uno mueve un brazo, puede sentir el resultado por sinestesia y puede también ver dónde está el brazo por medio de la vista. La retroalimentación extrínseca es la proporcionada por alguna fuente o agente externo, que suele ser un entrenador o un maestro. Que a uno le digan si una respuesta que ha dado es correcta o incorrecta es una forma de retroalimentación extrínseca. La retroalimentación de una u otra clase es esencial para la adquisición de cualquier habilidad. Uno no puede mejorar a menos que tenga manera de juzgar su rendimiento actual y en qué dirección se deben producir cambios.



Hay varias formas de aprovechar la retroalimentación para una mejor adquisición de la habilidad. La primera es prestar verdadera atención a la retroalimentación existente. Esto puede ser algo tan simple como revisar lo que uno ha escrito cuando está haciendo una carta o una composición. Muchos estudiantes (y mucha gente, en general) no lo hacen, y sufren las consecuencias. La segunda es asegurarse de que la retroalimentación sea inmediata. Los comentarios sobre una composición devuelta después de varias semanas resultan poco útiles, porque el autor probablemente ya se ha olvida-

do de los pasos precisos que dio en la preparación del texto. Ya no es posible relacionar la retroalimentación con aspectos específicos de la conducta. En un mundo ideal, el tutor supervisaría cada paso del proceso de escritura de una composición, proporcionando los comentarios pertinentes en cada etapa. Esto significa que las dos personas tendrían que estar en contacto estrecho y prolongado, con la probabilidad de que se desarrollara una relación intensa. Y las relaciones intensas son familiares en los contextos en los que hay un maestro y un aprendiz, un entrenador y un atleta o un profesor de teatro y un alumno. Un ejemplo en la literatura es la relación entre Svengali y la cantante joven, Trilby, en la novela homónima de Du Maurier.

Más exóticas que la retroalimentación común son las formas de ayudar a la gente a darse cuenta de que tienen sensaciones internas de las que normalmente no son conscientes. Utilizando una muestra visual que controle algún aspecto de nuestro estado corporal (como, por ejemplo, el latido del corazón) se puede aprender a identificar las sensaciones corporales que acompañan a los cambios en estos estados, y alguna gente es capaz de controlar estos estados aun cuando la realimentación aumentada (conocida como bioretroalimentación) desaparece.

A veces, la retroalimentación tiene un efecto básicamente motivador. Proporciona información que no es esencial pero que parece aumentar el compromiso en la tarea. Por ejemplo, Smode (1958) realizó una investigación en la que se practicaba lo que se conoce como "tarea de localización": había que mantener una aguja de movimiento azaroso sobre un punto central, rotando un dial con movimientos compensatorios. Después de cada intento, todos los sujetos recibían retroalimentación "normal", en la que se les decía el tiempo que habían logrado mantener la aguja centrada durante ese intento. Además, a un grupo se le proporcionó retroalimentación "aumentada", con un contador en el que se acumulaba su puntaje total en la suma de intentos. Esta retroalimentación aumentada tuvo un efecto drástico en el rendimiento, como lo demuestra la figura 3.3. La ventaja se mantuvo aun después de eliminar la retroalimentación aumentada. En un segundo día de aprendizaje, en el que todos los sujetos recibieron retroalimentación normal, los que habían recibido retroalimentación aumentada el primer día siguieron obteniendo mejores resultados.

Figura 3.3

Espaciamiento

Si uno puede dedicarle seis horas a la práctica de una habilidad determinada, ¿hay que dedicarle seis horas de trabajo continuo o seis horas separadas en días diferentes? En general, parece mejor espaciar la práctica en varias sesiones que amontonarla toda en una sola sesión (Welford, 1968). Hay varias razones para hacerlo. Una es que, cuando se realiza una tarea repetitiva, tienden a aparecer la fatiga y la disminución de la atención. Como consecuencia, pueden formarse malos hábitos y la práctica posterior reforzará esta conducta indeseable. Los descansos frecuentes pueden lograr que la fatiga y los malos hábitos se disipen. Por otra parte, cuando la motivación es alta, es muy posible sumergirse totalmente en una tarea durante muchas horas sin pérdida evidente de la atención, de modo que la regla de espaciar la práctica no es de nigún modo universalmente beneficiosa.

Actitud

Un tercer tema es la cuestión de qué actitud o actividad psíquica debe acompañar a la práctica. ¿Debe uno repetir una tarea mecánicamente, con una actitud esencialmente pasiva, pretendiendo fijar la habilidad por mera repetición? ¿O debe estructurar la tarea activamente, buscando patrones y semejanzas y adivinando lo que podría seguir? Esta es una pregunta algo inquietante, y los psicólogos no han podido ofrecer hasta hoy respuestas definitivas. Es muy evidente que la repetición pura e insistente tiene efectos beneficiosos (ver el estudio de Siebel que se describió antes). También se habla mucho, en campos como el de la psicología del deporte, sobre la importancia de no ser demasiado cerebral y permitir que el cuerpo "se haga cargo". Hay muchas evidencias de que hacemos las cosas mejor si podemos llevarlas al nivel del control automático y permitir que sea el sistema el que "se ocupe"; y es posible que donde haya movimientos físicos, parte de semejante proceso sea la recuperación de esquemas de movimiento tempranos y parcialmente instintivos que hayan sido reprimidos por intentos erróneos de controlarlos (Tinbergen, 1974).

Incluso en un nivel cognitivo más complejo, gran parte del aprendizaje de habilidades resulta sólo incidental y casual. A veces parece que si uno está lo suficientemente interesado en una actividad, su compromiso dará como resultado, por sí mismo, la adquisición de cierto grado de habilidad. Cuando uno intenta adquirir una habilidad vinculada con una actividad que no le interesa intrínsecamente, hace falta un sustituto para el interés. En el capítulo 12 se presentan algunas de las formas en las que los investigadores de la educación han llegado a establecer la naturaleza de las estrategias y habilidades de estudio eficaces, así como también las estrategias de enseñanza necesarias para apoyarlas. Puede resultar útil ver estas estrategias como formas de lograr que el alumno no motivado haga aquello que (con motivación) haría naturalmente. Si alguien piensa que esto construye una falacia para que la gente estudie lo que realmente no le interesa y una acusación a nuestro sistema educativo, no estará solo (Illich, 1973). Pero este punto de vista es por sí mismo incompleto. Porque aun cuando nos interese dominar una habilidad determinada, también podemos aprovechar el consejo y la retroalimentación. En la adquisición de habilidades, la función del entrenador es proporcionarlos.

Un talento excepcional - un estudio de caso

Me gustaría terminar este capítulo describiendo una habilidad bastante extraordinaria que he estado estudiando recientemente (Sloboda, Hermelin y O'Connor, 1985). El sujeto de este estudio, a quien llamaremos NP, es un joven autista de poco más de 20 años de edad. Como muchos autistas, tiene un retardo mental grave. Casi no tiene lenguaje espontáneo, manifiesta retracción social y otros patrones de conducta extraños y necesita el cuidado pleno de una institución especializada. Lo que lo hace diferente de la mayoría de los autistas es que en una pequeña región de su cerebro es cualquier cosa menos un retardado. Tiene una sorprendente capacidad para memorizar música para piano.

En las pruebas que realizamos, NP fue capaz de memorizar prácticamente nota por nota una pieza para piano clásica (Grieg, Op. 47, Nº 3) de más de 2 minutos de duración... en 12 minutos. Lo hizo simplemente escuchando segmentos de una grabación de la obra y repitiendo en el piano lo que oía. Al día siguiente, sin que hubiera tenido posibilidades de ensayar, todavía podía reproducir la obra casi a la perfección. En ningún momento vio la partitura o a otra persona interpretando la obra; tampoco recibió ningún otro tipo de retroalimentación externa. No se le dijo en qué clave estaba la obra, pero de inmediato fue capaz de elegir las notas correctas y tocarlas con la combinación correcta de dedos, aunque probablemente nunca la había oído antes y obviamente jamás había intentado interpretarla.

Este nivel de habilidad de memoria es muy raro, incluso entre los músicos de inteligencia superior al promedio. Probablemente sólo lo igualan los logros legendarios de unos pocos prodigios, como Mozart y Erwin Nyerghihazi (Revesz, 1925). NP es un caso de prueba ideal para algunas de las preguntas que hemos planteado en este capítulo sobre la adquisición de habilidades.

En primer lugar, podemos preguntar si la habilidad se ajusta a las nociones de talento heredado que hemos analizado al comienzo de este capítulo. Ciertamente, hay pocas evidencias de logros musicales en el medio familiar inmediato de NP, carente casi por completo de recursos. Sin embargo, NP demostró gran precocidad para la música sin tener mucho apoyo familiar. Las grabaciones que se conservan de cuando tenía 6 años muestran un nivel de habilidad muy superior al de cualquier niño de esa edad. Aunque en su casa no había piano, tuvo un buen desempeño en su primera exposición pública al instrumento. Por lo que sabemos sobre sus circunstancias, la posibilidad de entrenamiento secreto puede descartarse casi por completo. Todavía

hoy hay un sentido real en el que a NP no se le puede enseñar. Sus "lecciones" consisten en piezas que su maestro toca para que él memorice. Nadie le ha enseñado a memorizar como lo hace (ver capítulo 6). Nadie sabe cómo lo hace y él no puede explicarlo. Se le han dado posibilidades, pero NP debe ser uno de los ejemplos más puros de experto autodidacta existentes.

A primera vista, NP parece proporcionar fuertes evidencias de la existencia de un talento heredado para la música. Su carencia de logros en cualquier otro campo de habilidad lo hace parecer un don específico para la música. Pero las apariencias engañan y convendría examinar más cuidadosamente este "don". Lo primero que se observa es que la medida del don es igualada por lo que podemos llamar obsesión de NP por la música. Cuando puede elegir libremente una actividad, casi siempre quiere escuchar música (en la radio, en grabaciones, etc.) o interpretarla. También parece que, cuando no está haciendo ninguna de esas dos cosas, está pensando en la música. No sería absurdo suponer que su mente está ocupada con música, con una concentración intensa, de 5 a 6 horas por día. Como para Mozart, la música es su amor y su vida. Es difícil saber de dónde proviene esta fascinación obsesiva por la música. Podría tratarse de una disposición genuinamente heredada o provenir de alguna experiencia temprana crucial. Una característica general de la personalidad autista parece ser la obsesividad; y hay quienes tienen habilidades excepcionales similares en otras áreas, como la del cálculo mental. Quizá la mente autista esté conformada para aferrarse a una obsesión, pero la obsesión específica a la que se aferra puede estar totalmente determinada por las circunstancias.

Un segundo argumento para no tratar la habilidad de NP como un don musical específico proviene de un análisis más estrecho de la forma en que memoriza música. Además de interpretarle piezas clásicas como la de Grieg, lo probamos con una obra atonal de Bartok, que rompía muchas de las reglas de la música "normal". Aunque esta pieza de Bartok (Mikrohosuios, Escalas Tonales Totales del Libro 5) tenía muchas menos notas que la de Grieg, a NP le resultó casi imposible de memorizar. Entendemos que esto demuestra que la habilidad memorística de NP se basa en la capacidad de agrupar la música convencional en esquemas de nivel superior. Cuando estos patrones están ausentes, como en el caso de Bartok, el rendimiento se ve gravemente perjudicado. Esto es igual que en los estudios sobre ajedrez de los que hablamos en el capítulo 2, donde la memoria del gran maestro para las posiciones de las piezas en el tablero era superior a la del principiante sólo cuando el tablero estaba tomado de un juego real y no construido al azar. Es-

to lo confirma el análisis de los pocos errores que NP cometió en la obra de Grieg: casi todos fueron errores estructuralmente plausibles, en los que reemplazó un agrupamiento musicalmente adecuado por algo similar y también adecuado (de la misma forma en que uno puede recordar mal una oración, sustituyendo una palabra por un sinónimo).

Toda la evidencia que tenemos (ver también la descripción de la adquisición de la habilidad de la memoria en Steve Falloon, en el capítulo 7) es que la práctica intensa es el camino único e inevitable para la formación de agrupamientos que posibiliten habilidades tan impresionantes. Pero, como lo demuestran los datos de Siebel, este proceso de agrupamiento funciona con cualquier material y no parece muy diferente para la música que para cualquier otra materia específica. El caso de NP confirma la ecuación general *Motivación + Práctica = Habilidad.* Las raíces de las motivaciones específicas son casi por completo desconocidas, pero fácilmente podrían tener un componente hereditario. Sin embargo, la práctica puede realizarse sin motivación particularmente fuerte y, por lo menos en apariencia, nuestro sistema cognitivo responderá agrupando las entradas y las salidas de cualquier tarea que bastante suficientemente. De todos modos, la práctica necesaria para ganar experiencia es casi siempre insostenible sin una fuerte motivación. Incluso en el mejor de los ámbitos del mundo real, la mayoría de nosotros fracasaría en el intento de adquirir muchas habilidades, no porque seamos incapaces de hacerlo sino más bien porque, para nosotros, no parecen importar demasiado.

La lectura: un estudio de caso de habilidades cognitivas

John Sloboda

En los capítulos 2 y 3 nos ocupamos de algunas características generales de las habilidades, usando ejemplos tomados de diferentes habilidades específicas. Esto nos ha proporcionado una imagen global de lo que comparten la mayoría de las habilidades. Pero cada habilidad es única, en algunos sentidos, y plantea problemas psicológicos también únicos. En este capítulo sometemos una habilidad muy importante a un escrutinio más detallado que el que ha sido posible hasta ahora. Semejante escrutinio es necesario para recordarnos que las habilidades humanas son más variadas y complejas que cualquier afirmación general sobre ellas.

Hay varias buenas razones para considerar a la lectura una habilidad representativa. En primer lugar, para todos los que viven en nuestra cultura, saber leer tiene una importancia vital. Pese a ello, muchas personas tienen dificultades para aprender a leer y muchas más sienten que no lee tan bien o tan rápido como quisiera. Comprender lo que conlleva la lectura experta bien puede sugerir algunos remedios que ayuden a superar las dificultades de la lectura.

Un segundo motivo para elegir el análisis de la lectura es que se han hecho muchas investigaciones sobre ella. Esto refleja en parte su importancia cultural y educativa, pero también la facilidad relativa con la que se puede construir material textual bien controlado para trabajo experimental. La tecnología moderna nos permite ejercer un control experimental casi absoluto sobre las características relevantes del entorno de un lector y verificar hipótesis específicas acerca de la forma en que los individuos procesan estas características durante la lectura. Esto no sucede con muchas otras habilidades, como, por ejemplo, jugar al fútbol.

En tercer lugar, la lectura también presenta, en una forma particularmente aguda, un problema que domina gran parte de la investigación cognitiva: que la lectura en silencio casi no implica conducta observable alguna. Los psicólogos han tenido que diseñar métodos ingeniosos para seguir los

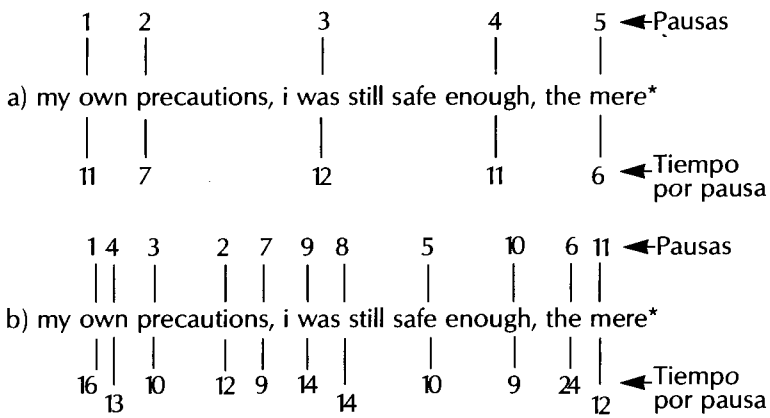
procesos psíquicos sin interrumpir o alterar la conducta en estudio. La dificultad se incrementa porque, para la mayoría de nosotros, gran parte de los subprocesos de la lectura no están abiertos a la inspección consciente. Los procesos de la lectura son rápidos y automáticos. Somos conscientes en primer lugar del sentido que "salta de la página" hacia nosotros, no del proceso por el cual lo comprendemos. Mientras usted, lector, lee esta oración, vea si puede responder, por sus propias observaciones, alguna de las siguientes preguntas:

a) ¿Sus ojos se mueven suavemente a lo largo del renglón mientras lee?

b) ¿Cuánto tiempo necesita desde que ve una palabra hasta que la identifica?

c) ¿Descubre usted el sonido de una palabra antes que su significado o es a la inversa?

d) ¿En qué medida usa sus conocimientos previos para que lo ayuden en la identificación de palabras?



A menos que usted sea una persona muy poco común, no creo que sea capaz de usar sus propias introspecciones sobre lo que está haciendo para contestar semejantes preguntas, aunque pueda tener algunas opiniones sobre respuestas posibles. Esta inescrutabilidad del proceso de lectura hace que resulte muy difícil para cualquier lector experto ofrecer muchos consejos útiles a quien no posea la misma habilidad. Usualmente, un lector honesto dirá: "No sé cómo lo hago pero lo hago". Como psicólogos cognitivos necesitamos y, de hecho, podemos ofrecer, mejores respuestas.

Los movimientos oculares en la lectura

El estudio de los movimientos oculares es útil para comenzar porque es la única conducta evidente que acompaña a casi toda actividad de lectura. Se puede medir la dirección de la mirada en cualquier momento, usando combinaciones de registros fotográficos y eléctricos y sin restringir los movimientos oculares normales. Semejantes estudios han demostrado que cuando vemos cualquier escena estática, contenga objetos o texto, el ojo se mueve en pequeños saltos rápidos (conocidos en inglés como *saccades*) con pausas más largas (llamadas *fijaciones*) en el medio. Cada *saccade* dura unos 50 ms (1/20 de segundo) y una *fijación* dura unos 200-250 ms (de 1/5 a 1/4 de segundo). La visión más útil tiene lugar durante las fijaciones, así que podemos pensar en la experiencia de la lectura como una serie de "instantáneas" de pequeñas porciones de texto.

La figura 4.1 muestra cómo se distribuyeron las fijaciones en un único renglón de texto leído por un experto lector y por otro que no lo era. Los números superiores muestran el orden de las fijaciones; los de abajo, sus duraciones. Esto ilustra varias características típicas: los buenos lectores hacen menos movimientos oculares regresivos, *saccades* más grandes y fijaciones más cortas. Cada una de estas características significa que un lector experto leerá el mismo pasaje más rápidamente que uno inexperto. ¿Podemos deducir, a partir de esto, que las diferencias en los patrones de los movimientos oculares son responsables de las diferencias en la habilidad de lectura? Desafortunadamente, no. Hacer menos y más cortas fijaciones sólo será posible si un lector puede manejar la información de las fijaciones con más eficacia. De lo contrario, el aumento de la velocidad de los movimientos oculares sólo llevará a la pérdida de la comprensión. Los sistemas de lectura veloz que se concentran en entrenar a las personas para que economice movimientos oculares (por ejemplo, derecho hacia abajo por el centro de la página, en lugar de hacerlo de lado a lado) raramente llevan a una mejoría duradera de la velocidad que no esté acompañada de una pérdida en la comprensión (Crowder, 1982; Gibson y Levin, 1975). Más adelante, en este mismo capítulo, nos ocuparemos de evidencias adicionales que muestran que los lectores expertos superan a los inexpertos en algunas tareas de lectura en las que no se requieren movimientos oculares. La economía de movimientos oculares es un síntoma de la habilidad de lectura y no su causa.

Figura 4.1. Distribución de las fijaciones en un lector bueno y uno malo (según Tinker, 1965).

La lectura como aplicación de conocimientos

Cuando leemos, no estamos simplemente *adquiriendo* conocimientos nuevos de la página, sino que estamos utilizando muchas formas diferentes de conocimiento que ya poseemos. En los capítulos 2 y 3 vimos que todas las habilidades dependen de la movilización de los conocimientos adecuados. En la lectura, nuestro conocimiento del lenguaje nos permite reconocer palabras en las que no se han identificado todas las letras. Las "completamos" con lo que esperamos ver, como lo demuestra el bien documetando fenómeno del "error de los correctores de pruebas". Consiste en no advertir errores de copia u ortografía en el texto (como el que aparece en la oración anterior: documetando en vez de documentado). Por suerte, la redundancia del lenguaje hace que la mayoría de esos errores sean inofensivos. Obsérvese, por ejemplo, qué fácil resulta leer esta oración: lxs pxlxbrxs pxsxblxs pxxdxn xdxntxfxcxrsx fxcxlmxntx xxnqxx nx hxyx vxcxlxs prxsxntxs. En este caso, el contexto nos permite descubrir lo que el texto no ofrece.

Morton (1964) proporcionó una de las demostraciones clásicas del papel del contexto en la identificación de palabras. Mostraba a la gente oraciones a las que les faltaba una sola palabra (por ejemplo, "Entró a su casa y colgó su _____"). Luego exhibía muy brevemente la palabra faltante en un taquitoscopio (un simple equipo de laboratorio que presenta estímulos visuales para duraciones breves controladas con precisión). La duración de la exposición aumentaba gradualmente hasta que la palabra era reconocida. Morton halló que las palabras coherentes con el contexto precedente (es decir, por ejemplo, "abrigo") eran reconocidas más rápidamente que las palabras que no tenían nada que ver (por ejemplo, "barco").

Para que el contexto sea efectivo, una persona debe tener conocimiento de la situación a la que se está haciendo referencia. Su conocimiento debe llevar a esa persona a hacer deducciones sobre continuaciones posibles. Cuanto más sepa de aquello de lo que se está hablando, mejores serán sus inferencias y más eficiente su lectura. En igualdad de condiciones, es probable que el graduado en Psicología lea este libro más rápidamente que el estudiante principiante. En todas las etapas podrá usar los conocimientos que ya posee para darle sentido a lo que lee. Algunas partes del libro le resultarán familiares y le alcanzará con una lectura superficial de las mismas. Otros fragmentos usarán terminología o argumentos que ya tienen un significado bien articulado para él. Los buenos docentes de lectura saben esto y ayudan a sus alumnos eligiendo materiales de lectura iniciales que se relacio-

nen con situaciones que ya sean familiares para sus alumnos. De este modo, los alumnos pueden hacer anticipaciones inteligentes, a partir del contexto, que los ayudan a identificar las palabras que no reconocen; el éxito que obtienen les sirve para aumentar su confianza.

Una serie de estudios realizados por Sanford y Garrod (1981) ilustran muy bien el papel del conocimiento en la lectura. En estos estudios, los lectores veían historias simples, presentadas en una computadora, de a un renglón por vez. Cada lector marcaba el ritmo de su propia lectura apretando un botón cada vez que quería una nueva oración. De esta forma, los experimentadores podían medir el tiempo utilizado para leer cada oración. Veamos un ejemplo del tipo de historia que utilizaron:

Juan iba a la escuela.
El colectivo avanzaba muy lentamente.
No tenía ganas de dar lección de Matemática.
Después de todo, no era una tarea habitual para un celador.

La mayoría de los lectores experimenta una leve sensación de confusión y desorientación al leer la tercera y la cuarta frases. Esperamos que Juan sea un alumno, no un docente. Cuando hemos hecho los reajustes necesarios a la nueva información, nos enteramos de que, en realidad, es celador. Sanford y Garrod mostraron que este reajuste toma un tiempo mensurable. La tercera oración de la historia requirió más tiempo de lectura que otra ("No tenía ganas de tener clase de Matemática") coherente con la idea de que Juan era un alumno. La prosa normal bien construida no suele violar las expectativas de la forma en que decidieron hacerlo Sanford y Garrod. Sus resultados muestran que haciendo las inferencias adecuadas a partir del texto se puede luego leer oraciones con más rapidez, suponiendo que, en general, no se violen las expectativas.

Conocimiento específico de la lectura

Las fuentes de conocimientos que acabamos de analizar no son específicas de la lectura. Tienen que ver con las formas en que operan el lenguaje (en general) y el mundo, y entran en juego cuando escuchamos hablar, cuando intentamos interpretar una escena visual y en muchas otras ocasiones. Pero también hay fuentes de conocimientos más específicas. Por ejemplo, los lectores llegan a adquirir conocimientos sobre la forma usual en que se unen las letras en su idioma, y resulta evidente que éste es un conocimien-

to específico de la alfabetización. Un lector hispanohablante sabe que es posible que TRENO sea una palabra, mientras que ONETR y OTENR no. Gibson, Pick, Osser y Hammond (1962) han demostrado que semejante conocimiento afecta la eficacia de la lectura. Presentaron estímulos hechos de cadenas de letras ante diferentes lectores y les pidieron que dijeran todas las letras que podían recordar. Los lectores podían recordar las letras de estímulos regulares (como TRENO) con una exposición a ellas más breve que la que necesitaban para los estímulos irregulares (como ONETR).

Otro campo que involucra conocimientos específicos de lectura es el uso de los espacios entre las palabras. Hochberg (1970) informa sobre un experimento en el que se pidió a niños de diverso nivel de lectura que leyeran textos normales y textos en los que los espacios entre palabras habían sido completados con "x", de la siguiente forma: Recurrióxaxdosxgruposxdexlectores,xbuenosxyxmalos.

Aunque los buenos lectores fueron en general más rápidos que los otros, su velocidad de lectura se redujo notablemente con las "x". En cambio, los malos lectores avanzaron más o menos a la misma velocidad (lenta) en ambos tipos de texto.

¿Por qué los espacios ayudan a los lectores expertos? Los datos proporcionados por O'Regan (1979) muestran que los lectores experimentados hacen movimientos oculares *sacádicos* más largos cuando la palabra situada a la derecha de la fijación es larga que cuando es corta. Tales lectores usan el espacio a la derecha de la palabra en la periferia de la visión como marcador para planificar el siguiente movimiento del ojo. Esto se hace, naturalmente, de una forma por completo automática. Un lector no es consciente de la medida constantemente fluctuante de sus movimientos *sacádicos* o de la información que rige a tales movimientos. Como sucede con muchas habilidades, nuestro sistema cognitivo parece capaz de aprender reglas complejas y adaptativas sin nuestra intervención consciente. Todo lo que tenemos que hacer es ofrecerle la posibilidad de construir estas reglas mediante la exposición frecuente a una amplia gama de situaciones relevantes.

El consejo más confiable (aunque aburrido) que se le puede dar a cualquiera que desee mejorar su lectura es que lea mucho, con frecuencia y durante mucho tiempo (igual que para cualquier otra habilidad). En un nivel de mayor detalle (y bastante menor confiabilidad) hay más que decir al respecto, especialmente si se está diseñando un programa de práctica para un individuo en particular. Quiero centrar el resto de este capítulo en tres tópicos, cada uno de los cuales proporciona información relevante para posibles

causas de problemas en la lectura: el papel del discurso en la lectura; la incapacidad de lectura y las estrategias particulares que adopta un individuo cuando lee para estudiar.

El papel del discurso en la lectura

La difundida capacidad para leer en silencio no tiene una larga historia. En la Edad Media, mucha gente pensaba que la lectura silenciosa era un logro inexplicable y que quienes eran capaces de hacerla estaban poseídos por el demonio. Parecía increíble afirmar que las marcas negras sobre el papel podían tener significado si antes no se los convertía en los sonidos discursivos que representaban. Semejante punto de vista probablemente sería compartido por algunos lectores principiantes en la actualidad, especialmente aquellos entrenados dentro de una filosofía educativa denominada "fónica", según la cual uno aprende a leer aprendiendo los sonidos típicos de las letras y grupos de letras. Si se unen estos sonidos se producen sonidos de palabras, que luego "el oído de la mente" puede reconocer.

Otros aprenden con filosofías diferentes, a una de las cuales se la ha llamado "de mirar y decir". En este enfoque, los niños aprenden pares objeto-palabra mediante contacto visual directo, sin una enseñanza sistemática sobre correspondencias letras-sonidos. Así, las paredes de un aula "de mirar y decir" estarán cubiertas de ilustraciones de objetos familiares, cada uno junto con la palabra correspondiente. El reconocimiento rápido de palabras sigue al constante ensayo de estos pares.

La discusión entre quienes apoyan estas dos filosofías ha sido larga y feroz. Quienes defienden lo fónico sostienen que el otro método no proporciona al niño recursos para elaborar el sonido (y, consecuentemente, el significado) de palabras que no ha visto antes. Quienes defienden el "mirar y decir" afirman que la ortografía inglesa no tiene la regularidad suficiente como para que la simple traducción letra-sonido funcione de manera confiable[2]. Ambos puntos de vista son válidos. Consideremos, por ejemplo, la siguiente oración: "Lah mashoría dhe loz hautos tienem kuatro rruedaz"[3]. Aunque la oración no tiene ninguna palabra castellana, es de todos modos comprensi-

---

2. Las vocales y los grupos vocálicos tienen, en inglés, diferentes pronunciaciones, que no los hacen fácilmente predecibles para el lector principiante.

3. El ejemplo usado en el original en inglés dice: "Moast xahs hav foor weels"; hemos intentado mantener la misma idea en castellano. (N. del T.)

ble como representación de una oración en nuestra lengua. A menos que pudiéramos realizar traducciones letra-sonido, la comprensión sería imposible.

Por otra parte, sabemos que no siempre se pueden invocar reglas letra-sonido en la lectura. No hay nada en tales reglas que nos diga que *tough* y *bough* suenan de manera completamente diferente[4]. Hay otras palabras que son imposibles de leer por el camino letra-sonido, porque necesitamos establecer su significado antes de poder asignarle el sonido correcto. La palabra inglesa *tear* se pronunciará de manera diferente según se refiera a una gota (o una lágrima) o a una rotura (o desgarro).

Leer con y sin sonido

Aunque es evidente que los lectores expertos no tienen que pronunciar en voz alta las palabras de la página, eso no significa necesariamente que la lectura basada en lo visual se apoye en la existencia interna del "sonido". De hecho, hay evidencias experimentales de lectura "sin sonido". Green y Shallice (1976) demostraron que el tiempo que se necesita para tomar una decisión sobre una palabra, basada en su significado, no depende del número de sílabas de la misma. Por ejemplo, al pedirles que presionaran un botón para demostrar que habían considerado que SALTAMONTES era un insecto, los lectores necesitaban el mismo tiempo que para la palabra MOSCA. Green y Shallice sostienen que si el sonido tuviera que ver, SALTAMONTES debería haber necesitado más tiempo por su mayor número de sílabas.

Como ocurre con muchas controversias en Psicología, la creciente complejidad de nuestro conocimiento ha demostrado que no podemos sacar una conclusión simple, ya sea en favor de la lectura basada en el sonido o en lo visual. La situación real es demasiado compleja como para poder hacerlo. En cuanto a los métodos de enseñanza, las investigaciones no han logrado demostrar ventajas claras en favor de ninguno de los dos métodos. En cambio, el factor más importante para el logro de una lectura experta es el docente (Williams, 1970). El buen docente probablemente usa una mezcla pragmática de enfoques, junto con la capacidad de simpatizar con sus alumnos y alentarlos. En lo que respecta a los lectores adultos expertos, el consenso generalizado afirma que estos disponen tanto de un proceso basado en el sonido como de uno basado en la visión directa para llegar al significado de las palabras, y que eligen el camino según la circunstancia. Además, actualmente se cree que no existe sólo un tipo de relación basado en el sonido si-

4. En una transcripción fonética aproximada, la pronunciación de estas palabras sería: "taf" y "bau". (N. del T.)

no que, más bien, puede haber tanto una forma abierta de compromiso discursivo asociada con movimientos de la laringe como una más encubierta de imaginación semejante a la del discurso, que operaría en un nivel totalmente subvocal. Esto se comprende mejor analizando los estudios de los efectos sobre la lectura de lo que se denomina *supresión articulatoria*.

Kleiman (1975) realizó una investigación en la que pedía a la gente que fuera repitiendo secuencias de dígitos que escuchaba a través de auriculares. Esto incluía la pronunciación en voz alta de los dígitos a medida que los iban oyendo. Pero semejante tarea restringe el sistema sonido-discurso. Mientras los sujetos repetían, se les pedía que emitieran diversos tipos de opinión sobre las palabras que se les presentaban visualmente. Una tarea consistía en que juzgaran si pares de palabras visualmente similares rimaban o no (por ejemplo: CASA-PASA, sí; ÚLTIMA-ULTIMA, no). Aunque la repetición de lo que oían disminuía la velocidad, los sujetos podían emitir opiniones correctas. Esto sugiere decididamente que no es necesario el sistema de sonido-discurso abierto para hacer juicios basados en el sonido. Parece existir algún proceso "interior" más profundamente asentado. Como observa Baddeley (1979): "Es muy evidente para mí que cuando leo, mi lectura va acompañada de algo parecido a una imagen auditiva o articulatoria de las palabras que se están procesando. Esto ocurre con o sin supresión articulatoria".

El hecho de que algunos aspectos de la lectura basados en el sonido puedan tener lugar sin el compromiso evidente del sistema discursivo no significa, sin embargo, que el sistema discursivo no tiene importancia alguna en la lectura. Veamos un estudio de Hardyck y Petrinovich (1970), que emplearon la biorretroalimentación (ver capítulo 3) para entrenar a los individuos en la supresión de la articulación. Descubrieron que la supresión articulatoria no tenía efectos adversos sobre la comprensión del material de lectura fácil pero que dificultaba la comprensión del material difícil. Podemos concluir que el discurso manifiesto (si es silencioso) ayuda a la comprensión de los pasajes difíciles. Probablemente, la mayoría de nosotros somos conscientes de esto por nuestra propia experiencia. Con textos difíciles, podemos tender a pronunciar las palabras en voz alta. Pero, ¿a qué se deberá esto? Crowder (1982) sugiere que semejante discurso resulta útil para mantener las primeras palabras de las oraciones complejas en la memoria de corto plazo, mientras se lee el resto de la oración. Esto es necesario porque uno frecuentemente necesita leer el final de una oración antes de que el significado de su primera parte quede claro (ver capítulos 5 y 10).

Este hallazgo también tiene un aspecto opuesto. Si la articulación no es particularmente útil para leer material fácil, podría resultar un obstáculo para la lectura más veloz. La tasa máxima de discurso es, quizá, de unas 4 o 5 palabras por segundo. Por lo tanto, la lectura con articulación no puede desarrollarse a una tasa mayor que unas 300 palabras por minuto. Sin embargo, hay considerables evidencias de que los lectores consumados pueden leer material simple a más del doble de esa velocidad sin pérdida de comprensión. Esto sólo se puede lograr si se suprime la articulación. Si usted tiene la impresión de que articula durante la lectura, puede convenirle practicar lectura sin vocalización. Una forma simple de obligarse a uno mismo a no vocalizar lo que lee consiste en repetir alguna palabra una y otra vez mientras se lee (por ejemplo, "doble-doble-doble", etc.).

Dificultades en la lectura

Las dificultades de lectura pueden producirse por muchas razones. Algunos psicólogos creen que deberíamos hacer una distinción entre aquellos cuyas dificultades de lectura van acompañadas de toda otra gama de dificultades intelectuales y aquellos cuya incapacidad parece limitarse solamente a la lectura. Estos psicólogos sostienen que la palabra *disléxico* debería reservarse para la gente de este segundo tipo. En consecuencia, un disléxico es aquel individuo de capacidad intelectual promedio o superior al promedio que tiene dificultades de lectura. Curiosamente, alrededor del 80% de ellos son hombres. Otros lectores inexpertos, que tienden a no desempeñarse tan bien como el promedio del espectro intelectual, pueden ser tanto hombres como mujeres (Jorm, 1983).

Otros psicólogos desconfían de una categorización tan prolija y les resultaría difícil distinguir entre disléxicos y otro tipo de malos lectores. En todo caso, muchas investigaciones no hacen esta diferenciación al elegir sus sujetos. En este ensayo, usaré la palabra dislexia para referirme a cualquier incapacidad crónica de lectura que se resista a los métodos de enseñanza normales.

¿Hay algo específico que tienda a funcionar mal en la dislexia? Parece que a muchos disléxicos les cuesta elaborar los sonidos de las palabras que intentan leer: el camino hacia el significado basado en los sonidos. Así, por ejemplo, los disléxicos tienen un desempeño particularmente pobre en la pronunciación de palabras absurdas e inexistentes como BLEN, PORSUN y TELD. Un experimento realizado por Perfetti, Goldman y Hogaboam (1979) demostró que los disléxicos tienden a compensar esta dificultad apoyándose

mucho más en el contexto que los lectores normales. Se midió el tiempo que les llevaba a los niños pronunciar palabras impresas. En un caso, se les presentaron palabras sueltas; en un segundo caso, se les presentaron palabras incluidas en un cuento. La tabla 4.1 muestra los tiempos promedio de lectura por palabra en los dos grupos, en ambos casos. Aunque ambos grupos se beneficiaron con el contexto, los lectores inexpertos se beneficiaron más. Aparentemente, los lectores inexpertos intentan compensar su dificultad con el "camino del sonido" asignando mayor peso a la información contextual.

Tabla 4.1. Tiempos promedio de lectura por palabra (ms)

	Sin contexto	Con contexto
Buenos lectores	786	665
Malos lectores	1069	751

El déficit de lectura en el método basado en el sonido formaría parte de una dificultad mayor que la que tienen los disléxicos para utilizar la memoria de corto plazo (u operativa), que, según se sabe, es la responsable de retener información verbal de manera acústica (ver capítulo 5). Parecen ser menos capaces de recordar la redacción precisa (en oposición a la esencia) de cuentos que acaban de oír, y la duración de su memoria de corto plazo suele resultar más baja que el promedio. En la sección previa afirmamos que la capacidad de retener material verbal en la memoria de corto plazo ayuda a la comprensión del material difícil. Por lo tanto, un déficit en la capacidad de usar memoria de corto plazo bien puede llevar a dificultades en la comprensión.

¿Cuál es el origen de la dislexia? Hay ciertos indicios sobre la existencia de un componente genético. La desigual distribución por sexo es típica de ciertos rasgos que se transmiten genéticamente. La condición también tiende a darse en familias, y la incidencia conjunta de la dislexia en los gemelos es mayor que en los mellizos (Hermann, 1959). Aunque no es posible descartar las explicaciones ambientales para estos hechos, es significativo que los niños disléxicos tengan con frecuencia hermanos y hermanas que son muy buenos lectores, pese a crecer en el mismo medio.

La cuestión de importancia práctica más apremiante es: ¿puede ayudarse a los disléxicos a mejorar su lectura? Y, si la respuesta es afirmativa, ¿cómo? La respuesta a la primera parte de la pregunta parece ser un cauteloso "sí". Aunque pocos son capaces de superar sus dificultades por completo, algunos

programas de entrenamiento ayudan a los disléxicos a conseguir mejorías duraderas cuando se los compara con grupos de control que no han recibido ese entrenamiento. El enfoque más exitoso parece ser el que ofrece al lector la posibilidad de practicar precisamente aquellas habilidades en las que tiene dificultades, es decir los procesos basados en los sonidos (Naidoo, 1970). Pero algunos investigadores han sostenido que también se puede tener éxito alentando a los lectores inexpertos a utilizar mejor sus puntos fuertes (como su capacidad para aprovechar el contexto). Desafortunadamente, no hay estudios de evaluación suficientes para tener un juicio definitivo sobre este punto.

Es difícil obtener conocimiento científico confiable en el campo de la dislexia porque el docente/investigador se enfrenta a un dilema: ¿debe ofrecerse al alumno (en un juicio considerado pero subjetivo) el mejor enfoque y el más factible para el docente? ¿O debe ofrecérsele algo que no esté bien probado (o que no tenga, de hecho, "control" comparativo alguno) con el objeto de avanzar en los conocimientos científicos? No se puede culpar a quienes elijan la primera opción. Los dilemas de este tipo son comunes en muchas ramas de la Psicología. Explican en parte por qué, pese a todas las investigaciones hay, en este campo, menos respuestas definitivas que las que nos gustaría tener.

Las estrategias de lectura y el estudio

Supongamos que uno es un lector experimentado, que lee razonablemente rápido y sin vocalización excesiva, tiene un vocabulario amplio y conocimientos generales buenos. ¿Hay algún motivo por el que podría tener dificultades con las exigencias que plantea la lectura para el estudio? Por desgracia, sí. Smith (1967) les pidió a lectores-alumnos expertos e inexpertos que leyeran textos para obtener: a) impresiones generales, b) detalles. Descubrió que los buenos lectores ajustaban sus procedimientos de acuerdo con las instrucciones. Cuando leían en busca de detalles, releían cosas del tipo de nombres y fechas. Al leer para obtener impresiones generales, se detenían a evaluar ideas al terminar los párrafos y, si releían, leían secciones enteras en vez de puntos individuales. Los lectores inexpertos, en cambio, recurrían a procedimientos mucho más parecidos en los dos casos. (Este es un ejemplo de la importancia de las habilidades metacognitivas - ver capítulo 12).

Una clave para la lectura eficiente parece ser la noción de economía. Los alumnos de bajo nivel de rendimiento pierden tiempo leyendo material que no es esencial en un nivel de detalle demasiado elevado. En cambio, es

muy probable que los lectores expertos recorran el material superficialmente, notando lo que es irrelevante para sus propósitos y aquello que deben releer para tener más detalles. Semejante conducta presupone una clara idea sobre cuál es el propósito de la lectura. Así, cuando el docente pide: "Lea el capítulo 5", el lector experto debe saber correctamente el propósito de lectura del capítulo 5 y realizar ese modo de lectura eficiente.

En lo que concierne a la lectura superficial, es conveniente hacer una advertencia. Si se pide a alguien que lea algo "sólo para saber las ideas básicas", la lectura superficial no hará el trabajo por sí sola. No es posible seguir un argumento destacando una palabra o una frase especial cada tanto. Antes bien, la lectura superficial sirve más como "análisis" preliminar, particularmente útil cuando uno tiene en mente un conjunto específico de propósitos.

Conclusiones

Éste es, quizá, el punto adecuado para terminar nuestro análisis de la lectura. Aunque la cuestión de la evaluación del resultado de la lectura es crucial para el estudio efectivo, se lo encarará más adelante en el contexto más amplio de las habilidades de aprendizaje (capítulo 12). Apenas hemos recorrido superficialmente la vasta literatura existente sobre lectura, pero espero que por lo menos cinco características importantes de la lectura experta hayan quedado claras:

1) La lectura involucra una compleja interacción del conocimiento en muchos niveles, desde el conocimiento del mundo hasta el de las reglas ortográficas.

2) Este conocimiento está ampliamente automatizado y se aplica sin tener conciencia de ello.

3) No hay sólo un modo de leer sino una variedad de procesos y estrategias entre las que los lectores expertos pueden elegir según su propósito y las circunstancias.

d) Las dificultades de lectura pueden asociarse, con frecuencia, a deficiencias en los subcomponentes específicos del proceso total, como la traducción de símbolo a sonido.

e) La mejora de las habilidades de lectura en los adultos puede lograrse mediante la eliminación de la vocalización innecesaria y mediante una mayor conciencia de las posibilidades de adaptar la propia estrategia de lectura a objetivos de lectura formulados específicamente.

Lecturas adicionales

CROWDER, R.G. (1982) *The Psychology of Reading: an Introduction.* Nueva York: Oxford University Press.

Clara y concisa introducción al tema; particularmente buena en lo que hace a conocimientos específicos de la lectura.

SANFORD, A.J. y GARROD, S.C. (1981) *Understanding Written Language*: Explorations in comprehension beyond the sentence. Chichester: Wiley.

Complementa al libro de Crowder, ya que se ocupa fundamentalmente del papel de los conocimientos contextuales.

BRYANT, P.E. y BRADLEY, L. (1985) *Children's Reading Problems.* Oxford: Blackwell.

Evaluación crítica actualizada de las investigaciones sobre la dislexia y problemas afines.

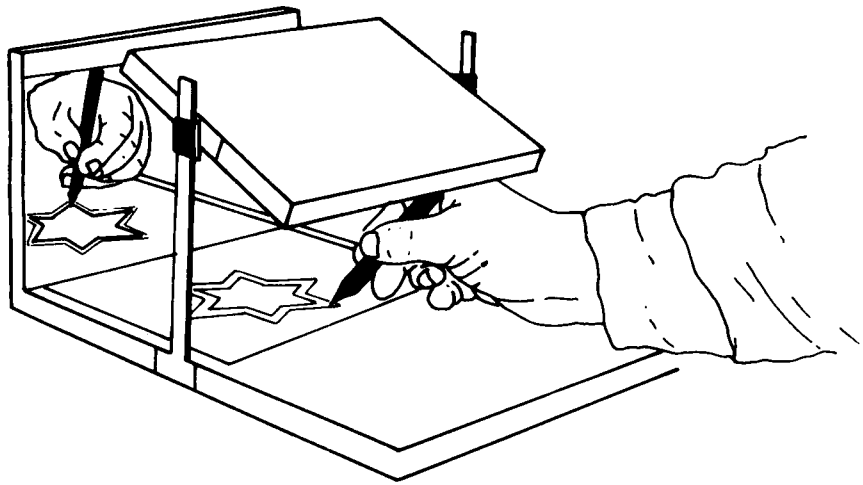
Sección 2

Las habilidades de la memoria

5

La naturaleza de la memoria

Angus Gellatly



Una "buena" memoria

Harry Lorayne, memorizador profesional, solía hacer lo siguiente: mientras las personas del público iban entrando al auditorio en el que realizaba su función, les decía sus nombres; luego, cuando ya había cientos de personas sentadas, Lorayne señalaba a cada uno y recordaba con precisión cómo se llamaba. A diferencia de la mayoría de nosotros, Lorayne no tenía problemas para asociar nombres con rostros. En realidad, su hazaña memorística es tan sorprendente que podríamos suponer la existencia de alguna facultad innata especial que explicara su desempeño y decir que estaba dotado de una muy "buena" memoria. Pero semejante explicación no es, por supuesto, explicación alguna (ver capítulo 3). El propio Lorayne insiste en que cualquiera que esté preparado para hacer el esfuerzo puede adquirir la misma habilidad. ¿Cómo se hace y qué nos dice sobre la naturaleza de la memoria y las habilidades memorísticas? En el presente capítulo ofreceremos respuestas a estas preguntas. Pero antes de que tales respuestas puedan tener sentido, es necesario saber algo sobre cómo estudian la memoria los psicólogos. Para ello, también será útil considerar un caso muy diferente del de Lorayne, en el que el rendimiento de la memoria es muy inferior al normal.

Una "mala" memoria

Este ejemplo se ocupará del caso de un paciente típico, a quien nos referiremos como K., que sufre de una enfermedad conocida como síndrome de Korsakoff. Esta enfermedad se relaciona con el alcoholismo prolongado, que lleva a daños en el sistema límbico cerebral. Los pacientes que sufren del mal de Korsakoff muestran diversos síntomas, según su grado de deterioro cerebral y sus personalidades individuales. De todos modos, hay varios síntomas típicos que pueden atribuirse a nuestro paciente ideal, K.

Figura 5.1. Aparato de dibujo en espejo

Imaginemos que K. está sentado en la guardia del hospital cuando viene a buscarlo una enfermera a quien conoce bien. Sin embargo, K. no demuestra reconocerla en absoluto. Cuando la enfermera le pregunta si ha desayunado, K. responde cautelosamente que no está seguro. Luego, lo llevan a un laboratorio en otra parte del hospital y lo sientan frente a un aparato de dibujo en espejo (ver figura 5.1). K. niega estar familiarizado con el laboratorio o con el aparato, aunque ha estado en este lugar cada uno de los últimos días para practicar dibujo en espejo. Se le explica que tendrá que usar un lápiz para delinear una forma mientras ve su mano en un espejo. (En esta tarea, la persona recibe una retroalimentación invertida especular de la posición y el movimiento de sus manos, y le resulta difícil controlar lo que está haciendo; después de unas pocas sesiones de práctica, adquiere destreza y ya no experimenta problemas.) K. niega con la cabeza y afirma que le parece muy difícil; inmediatamente, empieza a delinear la figura con precisión. Se desempeña como la persona adiestrada que es, pero no recuerda haber intentado realizar esta tarea previamente. Su memoria sobre cómo hacer dibujos en espejo se ha disociado de su memoria de haberlo hecho previamente.

Memorización automática y esforzada

Lorayne y K. se ubican en los extremos de lo que se denomina "buena" y "mala" memoria, pero la diferencia entre ellos no es meramente una diferencia de grado. Son, respectivamente, bueno y malo recordando diferentes tipos de información. La habilidad de Lorayne radica en haber dominado una técnica para fijar en la memoria cosas que la mayoría de las personas suelen olvidar, mientras que la deficiencia más soprendente de K. es con cosas que los demás recuerdan automáticamente y sin esfuerzo alguno.

Hasher y Zacks (1979) han sugerido la existencia de un continuo desde la información que se codifica en la memoria automáticamente, sin necesidad de atención consciente, hasta aquella que sólo se codifica con esfuerzo. Lo que sugieren es una aplicación al área de la memoria de las ideas generales de habilidad y automaticidad analizadas en el capítulo 2. El tipo de información que probablemente se codifique de manera automática en la memoria tiende a ser de naturaleza elusiva (cosas como olores, sabores y climas emocionales). Hasher y Zacks sugieren que el contexto espacio-temporal de los acontecimientos también puede codificarse automáticamente. Esta es la información que le permite a un organismo orientarse en el tiempo y el espacio. Sin memoria para la información espacio-temporal, el suave discurrir de la conducta natural se vería interrumpido, porque semejante conducta exige que se reconozcan los contextos familiares y se responda a ellos inconscientemente. Los errores en este procesamiento inconsciente del contexto pueden llevar al tipo de conducta distraída de la que hablaba John Sloboda en el capítulo 2. La codificación y el subsiguiente reconocimiento del contexto espacio-temporal también son importantes para ese sentido de familiaridad que no poseen, trágicamente, los enfermos de Korsakoff. Incluso los supuestamente normales no se sienten seguros de haber reconocido un rostro a menos que puedan "ubicarlo", identificando tanto el lugar como la ocasión en que lo encontraron antes.

A diferencia de la memorización y el reconocimiento automáticos, que son aspectos constantes y discernibles del mundo natural, la memoria esforzada es algo extraño. es la característica de un animal que actúa sobre su medio así como también dentro de él. La memoria esforzada requiere la invención de técnicas artificiales para complementar las habilidades innatas de la codificación automática. Esas técnicas constituyen el interés central de este capítulo y de los tres siguientes.

Más sobre la jerga de la memoria

Harry Lorayne es un *mnemotécnico* y las técnicas que usa para lograr sus sorprendentes hazañas se denominan mnemotécnicas. La idea de mnemotecnia hace referencia a cualquier recurso para ayudar a la memoria; un ejemplo común en nuestra cultura es el famoso "Treinta días trae septiembre...", que hace uso de las propiedades mnemotécnicas de la rima y el ritmo. Todos nosotros somos mnemotécnicos en varios sentidos, pero pocos pueden alcanzar el nivel de profesionalismo de Lorayne.

K., por su parte, es un amnésico. Sufre de *amnesia*, término universal para todo tipo de pérdida de la memoria. Todos sufren, en mayor o menor medida, de *amnesia infantil*, la incapacidad de recordar los primeros años de la vida, pero la palabra amnésico se reserva para aquellos que tienen una forma anormal de pérdida de la memoria. Hay dos categorías mayores de amnesia. En la amnesia retrógrada, no se recuerdan los acontecimientos anteriores al trauma o daño relevante. En la amnesia *anterógrada*, lo que no se recuerda son los acontecimientos posteriores al trauma. Frecuentemente, ambos tipos de amnesia coexisten pero en K., como en la mayoría de los pacientes que sufren de Korsakoff, la pérdida anterógrada es mucho peor que la retrógrada (Kolb y Whishaw, 1985). K. puede recordar mucho sobre los acontecimientos previos a que sufriera el daño cerebral, pero bastante poco de lo que le ocurrió a él y al mundo desde entonces.

Esta forma típica de pérdida lleva a otras distinciones. Muchos psicólogos piensan que la memoria se da en tres etapas. La nueva información debe ser ingresada (o codificada) en la memoria, luego debe almacenarse en algún lapso de retención y, finalmente, para poder ser de utilidad, debe estar sujeta a recuperación cuando se la requiera. En los casos de amnesia es posible preguntarse en cuál de los tres estadios tiene lugar el déficit. Como K. sigue siendo capaz de retener y recuperar recuerdos de acontecimientos distantes, parecería que es en la codificación de la nueva información donde tienen problemas los enfermos de Korsakoff. La noción de codificación se irá elaborando a lo largo de este capítulo, pero debemos hacer otra diferenciación relacionada con la hipótesis de que la amnesia anterógrada es consecuencia de un problema de codificación.

Si se le lee a K. media docena de palabras, puede repetirlas normalmente, pero a los cinco minutos ya no recordará ninguna de ellas ni será capaz de recordar que se le hubiera leído algo. Su memoria de corto plazo no tiene problemas pero luego cae drásticamente. Como el protagonista de *El castillo*, (la

novela de Kafka), K. puede darle sentido al momento presente pero está aislado de la continuidad y los patrones de acontecimientos de largo plazo. Esta observación nos lleva a la distinción que hacen los psicólogos entre la *memoria de corto plazo* (MCP) y la *memoria de largo plazo* (MLP). No se puede definir con precisión ninguna de estas dos expresiones, pero la recuperación o el reconocimiento de información más de unos minutos después de que se presenta suele tomarse como prueba de almacenamiento de MLP. La hipótesis del déficit de capacidad de codificación sugiere que aunque K. puede codificar la información en la MCP, es deficiente en la codificación en la MLP. Este caso se opone al de Lorayne, que tiene un alto grado de eficiencia en la codificación en la MLP, al menos en lo que concierne a nombres.

La naturaleza de la memoria de corto plazo

Supongamos que uno ve que dos hombres salen corriendo de un banco y se suben a un auto que inmediatamente huye a toda velocidad. Si uno es rápido, puede tomar nota mental de la patente del auto. Pero, ¿y luego? Si no se coloca ese número de patente en alguna forma de almacenamiento más duradera, tendrá que seguir repitiéndoselo constantemente o lo olvidará. El número de patente está en la memoria de corto plazo, que globalmente corresponde a aquello en lo que estamos pensando, o de lo que somos conscientes, en algún momento en particular. Como se la suele entender, la memoria de corto plazo (MCP) tiene una capacidad limitada; puede retener sólo un número fijo de ítem, o agrupamientos, por vez. Miller (1956) estimó que esta capacidad para los adultos era de siete ± dos agrupamientos, y la naturaleza de un agrupamiento depende de la familiaridad de la persona con la materia en cuestión. Para alguien que no sepa castellano, A-M-I-G-O-S podría consistir en seis agrupamientos, mientras que para un lector experto de castellano sólo sería uno (ver capítulo 2).

El método usual para medir la MCP consiste en encontrar el mayor número de palabras, letras o dígitos que una persona puede recordar con precisión en el 50% de sus intentos. Esta cifra es la duración de la memoria de una persona. Como la mayoría de los adultos tiene una cifra cercana a los siete ítem, se suele considerar a la MCP una especie de caja con una cantidad fija de ranuras. Sin embargo, los niños de 3 años tienen una capacidad medida de sólo tres ítem y el nivel adulto no se alcanza hasta los 12 años de edad, aproximadamente. ¿Significa esto que la cantidad de ranuras de la MCP au-

menta con la edad? Casi seguro que no. El aumento de la cifra con la edad es precisamente paralelo al aumento de la tasa de velocidad a la que pueden hablar los niños (Hulme, Thompson, Muir y Lawrence, 1984). Esto sugiere que un test de duración no mide el número de ranuras en un hipotético espacio de almacenamiento sino la capacidad de la persona para hacer el test. Para la mayoría de las personas, el nivel de capacidad en las pruebas de duración de la MCP está determinado por su habilidad para hablar rápido y por lo tanto por su tasa máxima de ensayo subvocal. (En el capítulo 7 se describen algunos otros medios por los que los individuos pueden lograr duraciones muy largas de su MCP.)

El punto antedicho señala un obstáculo mayor para la investigación de las aptitudes cognitivas. Todas las pruebas diseñadas para detectar y evaluar una aptitud específica desafían al sujeto a desarrollar nuevas habilidades cognitivas para mejorar el rendimiento en esa prueba, a menudo usando medios no anticipados por el experimentador. Inversamente, el bajo rendimiento puede no reflejar falta de aptitud sino, como se verá en el capítulo 6, falta de práctica en la selección y puesta en operación de la mejor estrategia para encarar la prueba.

Memoria operativa

Seguramente ya estará claro que la naturaleza precisa de la memoria de corto plazo es problemática. Nadie sabe bien cómo se caracterizaría mejor, pero es difícil de negar la existencia de un almacenamiento de corto plazo de poca capacidad. Uno puede apreciarlo por sí mismo si piensa en cómo haría un cálculo mental, como multiplicar 36 x 36. Hay que realizar toda una serie de operaciones, incluyendo el almacenamiento y la subsiguiente utilización de los resultados intermedios. Sin un almacenamiento de corto plazo de alguna naturaleza, ¿cómo podría lograrse? Y si ese almacenamiento no tiene capacidad limitada, ¿por qué será tan difícil acordarse de todo cuando se multiplican números mayores? No es sólo en la aritmética mental en donde se encuentran estas necesidades de almacenamiento de corto plazo. Todo tipo de actividades cognitivas involucra almacenamiento de corto plazo de la información.

Debido a los tipos de dificultades recién delineados, Baddeley y Hitch (1974; Hitch, 1980) sostuvieron que la MCP debe ser más compleja de lo que previamente se creía. Más que un almacenamiento unitario, sugirieron la posible existencia de un sistema de memoria de corto plazo con varios componen-

tes. A este sistema lo denominaron memoria operativa. Sobre la base de experimentos que no tenemos espacio para detallar aquí, determinaron que la memoria operativa tiene por lo menos cuatro componentes: un sistema de salida del discurso, que juega un papel fundamental en las pruebas de duración de la memoria de corto plazo; un sistema de entrada de la audición que mantiene un registro del discurso recientemente escuchado, para que el comienzo de una oración esté aún disponible cuando se llega a su fin; un sistema de entrada visual para mantener impresiones visuales en el corto plazo; y un sistema de control que utilice los demás componentes. El modelo de memoria operativa es obviamente bastante complicado y los psicólogos aún lo están evaluando. Lo importante es que, sea cual fuere su complejidad, parece existir alguna clase de sistema para el almacenamiento de la información en el corto plazo.

La naturaleza de la memoria de largo plazo

Ya que la MCP resulta una entidad no unitaria, no debería sorprendernos que sucediera lo mismo con la memoria de largo plazo (MLP). De hecho, ya hemos visto que para K. la capacidad de aprender, y por lo tanto de recordar, cómo ejecutar una tarea motriz está disociada del recuerdo de haber enfrentado ya antes la tarea. Nuestro análisis de las subclasificaciones de la MLP puede empezar por esta observación.

Memoria motriz

La memoria motriz subyace a todo tipo de habilidades motrices, desde escribir a máquina hasta pintar paredes. Su naturaleza y organización se han investigado más profundamente en términos de adquisición de habilidades motrices, como las descritas en el capítulo 2. La característica más sorprendente de la memoria motriz es su durabilidad. Una vez aprendidas, habilidades como andar en bicicleta o conducir un automóvil no se olvidan. Por este motivo, a veces se ha pensado que la memoria motriz difiere fundamentalmente de otros tipos de memoria de largo plazo. Sin embargo, lo notable de la mayoría de las habilidades motrices es que se practican mucho (se sobreaprenden); éste es el motivo por el que son tan resistentes al olvido.

Cuando una persona llega finalmente a dominar una bicicleta o un automóvil, no suele dejar la actividad. Por el contrario, con frecuencia la reali-

za repetidamente, de manera que se sobreaprende. No siempre sucede lo mismo con tipos de aprendizaje más cognitivos. En este caso, se suele practicar la materia hasta algún nivel, por ejemplo la sensación de que se la puede sacar a relucir en el examen del día siguiente, y de ahí en más se la elimina de la mente. Cuando meses después se la requiere una vez más, no está disponible. Pero éste no tiene por qué ser el destino de la materia cognitiva. El sobreaprendizaje puede darse tanto en las habilidades motrices como en las cognitivas. Habilidades cognitivas sobreaprendidas como entender un discurso, reconocer la identidad de rostros humanos o multiplicar cifras largas no se olvidan.

Debido a que las habilidades cognitivas y las habilidades motrices sobreaprendidas comparten las características de durabilidad, agrupamiento, fluidez y demás, se las puede unir como ejemplos de conocimiento procesal o memoria procesal (Ericsson, 1985). Ambos son ejemplos de *recordar cómo más que de recordar qué*. En este sentido, contrastan con el siguiente tipo de almacenamiento de largo plazo.

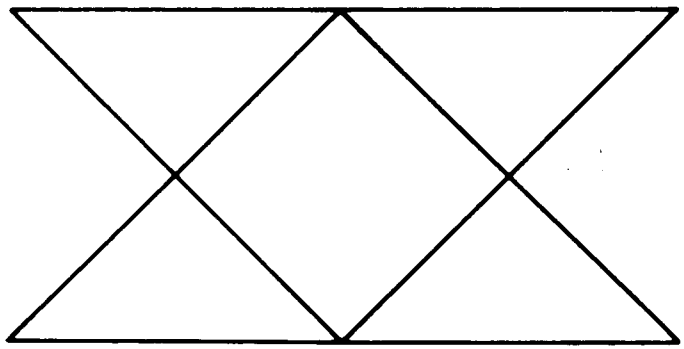
Memoria episódica

Tulving (1972, 1984) fue quien introdujo la expresión "memoria episódica" para referirse a la memoria para acontecimientos (o episodios) de la vida cotidiana. Se trata de una memoria autobiográfica, ya que es el registro de nuestra propia vida y de aquellas cosas de las que hemos tomado conciencia. En el caso de K., parecería que no han existido (o que han existido muy pocos) agregados a este registro desde que sufrió el daño cerebral. La memoria episódica es aquello a lo que probablemente se refiere la mayoría de la gente cuando habla de "buena/mala" memoria, o lo que piensan ante la expresión MLP (memoria de largo plazo). Cuando dijimos que Lorayne estaba especialmente entrenado en la codificación de información en la MLP, estábamos refiriéndonos a la MLP episódica.

Una característica de la memoria episódica es que la información (codificada automáticamente o con esfuerzo) se almacena según el contexto espacio-temporal. Esto ya se ha dicho antes. Otra característica de la información en la memoria episódica es que generalmente se codifica según su significado más que según su forma superficial. El registro de un episodio durante el día se hará de acuerdo con la esencia de lo que se dijo (o se dejó de decir); por lo tanto, no será equivalente a una grabación. Esto se opone a la

MCP, en la que la retención precisa se juzga según el recuerdo al pie de la letra. De hecho, la información en la memoria episódica suele ser más *reconstruida* que recordada. Los relatos de acontecimientos pasados se organizan sobre la base de cómo se los interpretó en su momento, cómo se los ha llegado a interpretar desde entonces y usando como sistema los "libretos" (o "guiones") que todos tenemos sobre la forma en que se suelen desarrollar los acontecimientos. Esto no significa afirmar que la gente no puede hacer citas textuales de poemas o discursos, pero eso sólo puede construirse sobre la práctica intensa, y son ejercicios de memoria procesal. Como lo demuestra el dibujo especular de K., las memorias procesal y episódica pueden separarse.

Memoria semántica



Tulving (1972) contrastó la memoria episódica con la semántica. Mientras que la memoria episódica es de naturaleza personal y contextual, la memoria semántica es conceptual y abstracta. Mantiene muchos tipos de información en diferentes clases de relaciones: el significado de las palabras, las reglas gramaticales, los hechos empíricos (como que el agua encuentra su propio nivel), los "libretos" de los que hablábamos antes, los nombres de los meses del año, etc.

Todos los usos de la memoria episódica incluyen un componente semántico, y el rendimiento en una tarea episódica está determinado por la riqueza de las estructuras semánticas del campo de conocimiento en cuestión (Ericsson, 1985). Para expresarlo con claridad, a la mayoría de las personas le resulta más fácil recordar una lista de palabras con sentido que una lista de palabras sin sentido (como MAFER), de la misma forma en que los maestros de ajedrez recuerdan configuraciones de partidas reales mejor que configuraciones azarosas (capítulo 2). Sin embargo, las memorias episódica y semántica pueden disociarse, como en la amnesia retrógrada y en la anterógrada. En el caso de K., el paciente recuerda cómo hablar y pensar, lo cual debe involucrar memoria semántica, pero su memoria episódica es gravemente deficiente.

Baddeley (1984) ha cuestionado la forma en que se hace la distinción entre memoria episódica y memoria semántica. Sostiene que la información de la memoria semántica es conocimiento *procesal* sobre el que se basan habilidades cognitivas tales como hablar, escuchar y pensar. El conocimiento procesal puede tener la forma de reglas de producción (como se describe en el capítulo 2) que el individuo no puede establecer en palabras. En contras-

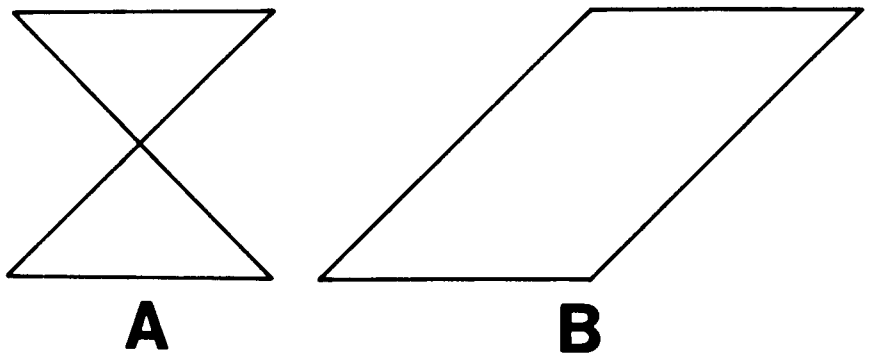
te, Baddeley afirma que la información en la memoria episódica es conocimiento declarativo. El conocimiento declarativo es aquel que puede verbalizarse; es conocimiento de que la cosa es de determinada manera más que conocimiento de cómo hacer algo. Actualmente, no está claro si es conveniente pensar que la MLP tiene tres componentes (motriz, semántico y episódico) o que es dicotómica (memoria procesal y memoria declarativa)

Figura 5.2. Una figura ambigua

Codificación y recuperación

La codificación de la información es la forma en que ésta se retiene. La influencia de la codificación en la memoria subsiguiente queda demostrada examinando la Figura 5.2 y luego –más adelante– la figura 5.3. El reconocimiento de la forma en 5.3A tiende a ser mucho más rápido que el de la forma de 5.3B. Aunque ambas formas estaban presentes en el original, 5.3A es más comparable con la codificación o interpretación usual de 5.2. Como se dijo antes, la codificación de palabras en la MCP tiende a ser acústica, mientras que la MLP tiende a codificar según significado, semánticamente. Craik y Lockhart (1972) teorizaron que quizá no hubiera diferencia entre la MCP y la MLP excepto en las formas de codificación. Supusieron que la durabilidad de la memoria para acontecimientos, palabras o rostros era una función de la "profundidad de procesamiento" de los ítem originalmente recibidos y que

un código acústico era menos profundo que uno semántico. Craik y Tulving (1975) hicieron preguntas sobre: a) la estructura física de una palabra ("¿Está escrita con mayúscula?"); b) el sonido de una palabra ("¿Rima con carnada?"); o c) el significado de una palabra ("¿Podría usarse en la oración: 'Encontró un _____ en la calle'?"). Luego, dieron a los sujetos un test de memoria (no anticipado) para todas las palabras que habían visto, y el rendimiento mejoró en las tres situaciones según la profundidad de procesamiento supuesta, apoyando así la hipótesis original (ver capítulo 2).



Craik y Tulving (1975) demostraron también que si todas las palabras presentadas eran codificadas semánticamente, luego el recuerdo dependía del nivel de elaboración de esa codificación. Cuando se pidió a los sujetos que juzgaran si la palabra *reloj* encajaba en una oración muy elaborada ("El anciano tropezó y se le cayó su valioso _____") la recordaron mejor que cuando se les preguntó si *reloj* encajaba en una menos elaborada ("Se le cayó el _____"). Cuanto mayor es la red de asociaciones en la que se inserta la palabra en la codificación, mejor es la memoria para ella. De modo que tanto la profundidad como la elaboración son importantes.

Pero el rendimiento de la memoria no depende sólo de la codificación. También depende del contexto de recuperación, de cuántas son las pistas de recuperación que se tienen para ayudar a la memoria. Smith (1979) presentó en una investigación listas de palabras y luego probó su recuerdo un día después, en la misma habitación y en otra diferente. El recuerdo fue mucho mejor en la misma habitación, lo cual demuestra la importancia de las ayudas externas (ver capítulo 2). Las ayudas internas también son importantes. Eich (1980) analiza evidencias para demostrar que el recuerdo es mejor cuando el humor o la situación (por ejemplo, de ebriedad) es igual al momento en que se codificó. Más aun, incluso el valor del procesamiento más profundo depende del tipo de test de memoria que se emplee. Morris, Bransford y Franks (1977) repitieron el descubrimiento de Craik y Tulving de que el procesamiento más profundo proporcionaba un mejor rendimiento en una prueba de reconocimiento directo. Sin embargo, en una prueba en la que los sujetos debían elegir palabras que rimaran con palabras previamente presentadas, se obtuvieron mejores resultados en los casos en los que la codificación se había hecho según la rima y no según el significado.

En síntesis: la forma de codificación ideal de la información dependerá de para qué se la va a usar y, por lo tanto, de las condiciones en las que se la habrá de recuperar. No obstante, es globalmente cierto que probablemente una codificación más profunda y elaborada resulte más eficiente. Po-

demos ver cómo esta generalización se sostiene en el caso de la sorprendente memoria para los nombres de Harry Lorayne.

Figuras 5.3A y 5.3B: componentes alternativos de la figura 5.2.

Un sistema para recordar nombres

En uno de sus libros (Lorayne y Lucas, 1974), Lorayne detalla su sistema para recordar nombres. Como muchos sistemas mnemotécnicos, el suyo se basa en el empleo de imaginería visual y se lo puede desglosar en etapas (ver capítulo 8). La etapa inicial es muy directa y tiene que ver con asegurarse, en primer lugar, de que se ha oído el nombre que se quiere recordar. Muchas veces, no es que se olvide el nombre de alguien que a uno le acaban de presentar sino que nunca se lo registró. Así que la primera regla de oro es asegurarse de escuchar correctamente el nombre, incluso si ello implica pedir que lo repitan o repetirlo uno mismo, como cuando se dice: "Encantado de conocerlo, Sr. Acuña".

La segunda etapa es la sustitución del nombre por una palabra (o palabras) de sonido similar y fácil de recordar. Así, "Acuña" podría convertirse en "La-cuña". Luego, en la tercera etapa, es necesario examinar la cara de la persona y elegir su característica más distintiva; por ejemplo, sus grandes orejas. Finalmente, en la cuarta etapa, debe vincularse la característica elegida

con la palabra sustituta mediante una imagen tan clara como sea posible. En este caso, se podría imaginar la cara del Sr. Acuña con dos inmensas cuñas en lugar de orejas. Una vez hecho esto, la próxima vez que vea al Sr. Acuña y vuelva a notar sus orejas le vendrá la imagen a la mente y podrá recordar su nombre.

El de Lorayne es un sistema simple que cualquiera puede emplear. Pero manipular efectivamente el sistema exige más que una familiaridad superficial con las etapas que lo componen. La clave aquí (como en todo) radica en la práctica intensa. El libro de Lorayne incluye una lista de palabras sustitutas para casi seiscientos de los apellidos más comunes en los Estados Unidos. Si se recuerdan los pares, de modo que cada nombre sugiera inmediatamente su sustituto asociado, se habrá automatizado una de las etapas del proceso. Del mismo modo, la experiencia facilitará la generación de imágenes para vincular palabras sustitutas con características faciales.

El sistema de Lorayne para recordar nombres ofrece un ejemplo más que pertinente de habilidad memorística. Primero, el sistema mismo es simple y fácil de comprender. Segundo, la necesidad de recordar nombres es común y, sin embargo, pocos reflexionan sobre las exigencias de la tarea y cómo pueden satisfacerse. Tercero, recordar nombres no es sólo una habilidad cognitiva sino una habilidad cognitiva socialmente importante. Se dice que uno de los últimos presidentes de los Estados Unidos debió su triunfo electoral menos a su perspicacia política que a la lealtad que inspiraba por recordar los nombres de los trabajadores humildes de su partido. Aquí tenemos, entonces, una habilidad de memoria simple e importante en la que casi todos podemos mejorar nuestro rendimiento. Tristemente, es también una habilidad en la que nuestro paciente, K., tiene graves deficiencias.

Amnesia anterógrada

Se han intentado diversas formas de explicar la amnesia anterógrada. Muchos incluyen la idea de que hay un déficit en las aptitudes de codificación de los pacientes amnésicos (Mayes y Meudell, 1983; Squire y Cohen, 1984). En diferentes momentos, se ha afirmado que los pacientes amnésicos directamente no pueden codificar en la memoria episódica (o declarativa), que sólo codifican en niveles superficiales y no profundos y que codifican acontecimientos pero no sus contextos espacio-temporales. Hay evidencias a favor y en contra de cada una de estas ideas. Parte de la dificultad para deci-

dir entre ellas es que el rendimiento de pacientes como K. depende en mucho de la tarea que se les encargue y también de las instrucciones sobre cómo se la debe realizar. Por ejemplo, Cermak, Butters y Moreines (1974) hallaron evidencias de que los pacientes a los que se les daban listas cortas de palabras para recordar fallaban en la codificación semántica, es decir, en un nivel profundo. Pero Winocur, Kinsbourne y Moscovitch (1981) descubrieron, con una tarea similar, que los pacientes podían codificar la información semántica cuando las instrucciones subrayaban la importancia de hacerlo. Pareciera que los límites del rendimiento amnésico no fueran fijos y no hubiera una pérdida absoluta de ninguna aptitud de codificación.

Ante este esquema de datos tan confuso, Hirst y Volpe (1984) han hipotetizado que lo que no funciona bien en amnésicos como K. es la automaticidad de la codificación. Se necesita esfuerzo para retener información que por lo común se codifica de manera automática (como el contexto espaciotemporal). Pero el consumo de esfuerzo en este sentido sólo puede hacerse a costa de otros tipos de información que normalmente podrían codificarse con esfuerzo. Lo que se codifica, y se recuerda, depende de dónde se pone el esfuerzo. Una persona normal a la que se le presentan diferentes imágenes de objetos simples puede prestar atención para recordar la identidad de los objetos, y sus ubicaciones espaciales se registrarán automáticamente. Pero para los amnésicos no es lo mismo (Hirst y Volpe, 1984). Parece que los amnésicos tienen que hacer una elección sobre cómo distribuir el esfuerzo entre los diferentes tipos de información que podrán recordar.

Esta idea de Hirst y Volpe es todavía una hipótesis que espera evaluación a la luz de futuras investigaciones. Por la misma razón que los procesos automáticos no están abiertos a la inspección consciente, puede resultar difícil para el lector imaginar cómo esos procesos podrían fracasar en una persona que estaba prestando atención al material experimental. La forma en que esto podría suceder se comprenderá mejor en el próximo capítulo, en el que examinaremos el desarrollo de las aptitudes mnemotécnicas. Algunas pueden automatizarse tanto que tal vez nos sorprenda descubrir que no todos las poseen.

Resumen

En este capítulo nos hemos ocupado de mucha información. Hemos explorado las ideas de habilidades de memoria automática y memoria con esfuerzo, con referencia a los logros y deficiencias mnemónicos de Lorayne, el mnemotécnico, y de K., el amnésico. También presentamos parte de la terminología y las distinciones empleadas en el estudio de la memoria. Le hemos prestado especial atención a las variedades de almacenamiento de memoria de corto y largo plazo que reconocen los psicólogos, así como también a la importancia de las variables de codificación y los factores de recuperación para el rendimiento de la memoria en distintas circunstancias.

Adquisición de habilidades de la memoria

Angus Gellatly

La memoria: ¿qué desarrolla?

Aunque a veces se atribuye a los niños pequeños una capacidad excepcional para ciertos tipos de pruebas de memoria (ver más abajo), generalmente la memoria se incrementa a medida que el niño va creciendo. Podemos preguntarnos, entonces, ¿por qué? ¿Qué es lo que tiende a mejorar con la mayoría de edad?

Esta pregunta fue planteada por el psicólogo John Flavell en 1971, cuando convocó a un simposio con el título: "¿Qué desarrolla el desarrollo de la memoria?" En síntesis, la respuesta que surgió del simposio fue que el desarrollo de la memoria es parte del desarrollo cognitivo general. Hay, por supuesto, técnicas memorísticas especializadas (estrategias), pero el desarrollo de la memoria implica mucho más que la mera adquisición de estas estrategias. La memoria no puede divorciarse del pensamiento y la comprensión, del conocimiento del mundo físico y el mundo social y del conocimiento de la propia capacidad para actuar en estos mundos. El desarrollo de la memoria depende del desarrollo de otras áreas de la cognición y se realimenta con ellas. Refleja el creciente control del niño sobre la dirección de su atención, su naciente conciencia de sí mismo como actor social y su mayor dominio de la importancia de la planificación para la memorización activa.

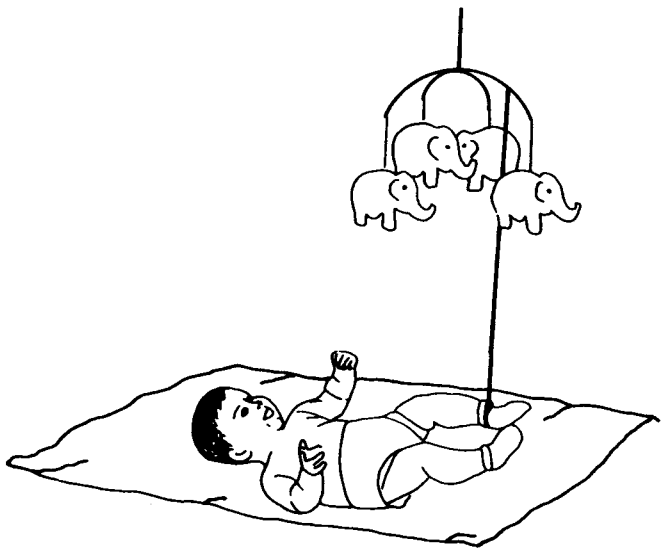
La pregunta de Flavell y los términos en los que fue respondida han configurado mucha de la investigación posterior sobre la memoria en los niños (Chi, 1983). En gran parte, este capítulo se ocupará de ampliar los roles jugados en el desarrollo de la memoria por las estrategias, el conocimiento y la comprensión de las propias aptitudes mnemotécnicas. Pero, antes de continuar, conviene considerar cierto proceso muy básico de la memoria al que los colegas de Flavell le han prestado muy poca atención. Su interés se centraba en las memorizaciones activas de los niños que ya han adquirido el lenguaje. Sin embargo, estos son logros relativamente sofisticados que tienen su

origen en potencialidades no lingüísticas que pueden atribuirse a otros animales, además de los humanos. Los fenómenos de aprendizaje asociativo como el *condicionamiento* y la *habituación* son de esta naturaleza. Se los puede observar incluso en casos en los que la palabra "memoria" casi no parezca siquiera aplicable. Tanto en la evolución como en el desarrollo individual, la memoria se desarrolla de lo simple a lo complejo. En sus formas más elementales, la memoria es pasiva y automática. La mayor complejidad llega con la intervención de la intención y el esfuerzo, como bien observara Flavell (1971). Pero para empezar este capítulo podemos echar una mirada a algunos de los ejemplos menos intencionales del recordar.

Habituación

"Habituación" es la palabra usada para denotar la pérdida de respuesta de un organismo a estímulos repetidos o continuos. Por ejemplo, si ponemos un objeto extraño en la jaula de un ratón, puede provocar miedo y respuestas evasivas, pero en poco tiempo el ratón se habituará al objeto y no mostrará respuestas evidentes ante él. A nivel celular, el estímulo eléctrico repetido de una neurona puede llevar a una disminución de la respuesta ante estímulos posteriores (Kandel, 1976). Semejantes casos de habituación celular pueden explicarse en términos de bioquímica celular alterada y probablemente no atraigan la etiqueta de "memoria". Pero en el nivel de los animales completos, la habituación suele definirse como la pérdida del interés (o de la atención) ante un estímulo auditivo o visual repetido. El efecto suele explicarse por el establecimiento de alguna representación interna del estímulo, que permite el reconocimiento inconsciente en intentos posteriores; aquí parece hacer falta la palabra "memoria".

La técnica de mirada selectiva suele usarse para demostrar habituación en los niños. Primero, se le permite al niño ver un modelo, como un ojo de buey, durante algún período extenso. Luego, tras cierto tiempo, se le presenta el mismo ojo de buey junto a un nuevo modelo, como un tablero de ajedrez, y se cuenta cuánto tiempo se fija cada estímulo. En estudios de esta naturaleza se ha demostrado que niños de entre 1 y 4 días de vida demuestran una preferencia selectiva por los estímulos nuevos sobre los previamente vistos (Kail, 1984). Incluso los recién nacidos, entonces, pueden tener recuerdos que duran más de los breves lapsos que son típicos en los experimentos de mirada selectiva, y otros estudios han señalado que se pueden ob-



servar efectos que duran horas o días en niños de apenas dos meses de vida. Sin embargo, debe destacarse que aunque esta forma simple y pasiva de memoria puede notarse en los muy pequeños, el efecto se hace más evidente con el aumento de la edad.

Condicionamiento

El *condicionamiento clásico* es la forma en que una respuesta natural a un estímulo puede llegar a asociarse con un segundo estímulo neutral, que predice la llegada del primero. El ejemplo más famoso es el del perro de Pavlov, que aprendió a generar saliva al oír una campana cuyo sonido precedía al momento en que le daban la comida. ¿Se pueden obtener efectos similares con los niños? A veces, se ha pensado que los niños de menos de 6 meses tenían un déficit en el condicionamiento clásico debido a inmadurez cortical. Pero en los últimos veinte años se ha demostrado que, en circunstancias controladas, el condicionamiento clásico del niño no difiere mucho del de un adulto (Rovee-Collier y Lipsitt, 1982). De modo que, una vez más, el potencial para la memoria pasiva se ve como algo inherente a los muy pequeños.

En el *condicionamiento instrumental* hay una forma más activa de aprendizaje y memoria. Esta expresión hace referencia al hecho de que si se recompensa a un animal por alguna acción, probablemente la repita. En este caso, el ejemplo más famoso está dado por las ratas de Skinner, que aprendieron a presionar una palanca para obtener alimento. El condicionamiento instrumental es la base para la mayor parte del entrenamiento animal y al menos parte del aprendizaje humano, pero ¿es discernible en los recién nacidos? Nuevamente, la respuesta es sí. Siqueland y Lipsitt (1966) pudieron condicionar el movimiento de la cabeza en niños de dos a cuatro días de vida, usando una solución de dextrosa como recompensa. Rovee-Collier y sus colegas (citado por Kail, 1984) lograron aumentar la frecuencia de movimiento de piernas de los niños, recompensándolos con el movimiento de un móvil atado a la pierna por un hilo (ver figura 6.1). Los niños de dos meses "recordaban" esta contingencia durante tres días y los de tres meses, durante ocho días.

Figura 6.1 Preparación para el movimiento de piernas condicionado. (Según Kail, 1984.)

Para concluir esta sección: los niños son capaces de más de un tipo de aprendizaje desde muy poco después de nacer, y por lo tanto deben venir equipados con el potencial para formas simples de memoria. Sin embargo, en los tres casos que hemos examinado (habituación, condicionamiento clásico y condicionamiento instrumental) la memorización no ha sido intencional de parte de los niños. Incluso en el caso del aprendizaje instrumental, donde parece haber una intención de ganar más comida o el movimiento del móvil, no parece haber memorización intencional. El niño no elige recordar que el movimiento de su pierna puede producir el del móvil. La memoria es un subproducto del intento de producir el movimiento del móvil. En el pasaje progresivo de la memoria pasiva y automática hacia la memoria esforzada e intencional es donde los niños, como los adultos, encuentran dificultades.

Estrategias de ensayo y categorización

Supongamos que a una persona le muestran una lista de ítem identificables y categorizables (por ejemplo, cuatro animales, cuatro alimentos y

cuatro colores) y le dicen que en unos segundos le pedirán que los recuerde. Casi con seguridad, en ese lapso hará dos cosas: los repetirá para sí mismo y, al hacerlo, los agrupará según sus categorías. El ensayo y la categorización son estrategias mnemotécnicas tan obvias y automáticas que uno casi podría sentir que no puede considerarlas estrategias intencionales. En ese caso, puede resultar sorprendente enterarse de que los niños pequeños de nuestra cultura, y las personas mucho mayores de otras culturas, no usan de manera espontánea el ensayo y la categorización.

Flavell, Beach y Chinsky (1966) usaron la lectura de labios para hacer un índice del ensayo en una tarea que exigía el recuerdo de imágenes. Descubrieron que el 10% de los niños de 5 años, el 60% de los de 7 años y el 85% de los niños de 10 años realizaban ensayos. Estudios posteriores demostraron que el hecho de no utilizar el ensayo no implica necesariamente incapacidad para hacerlo. Los niños de 6 y 7 años que no muestran ensayo espontáneamente pueden ser entrenados para seguir la estrategia y, como consecuencia, su rendimiento en el recuerdo aumenta hasta el nivel de aquellos de su misma edad que lo realizan espontáneamente. Pero, aunque son totalmente capaces de usar la estrategia, los que no lo hacen de manera espontánea tienden a abandonarla cuando no los alienta un experimentador. Al no usar una estrategia disponible cuando es adecuada, exhiben lo que se conoce como "deficiencia de producción".

Otros experimentos demuestran que incluso cuando los niños pequeños producen el ensayo espontáneo, no lo hacen muy bien (ineficiencia de producción). Con los ítem no categorizables existe la tendencia a repetir solamente una palabra por vez antes que recitar sucesiones de palabras que podrían vincularse entre sí rítmicamente (Ornstein, Naus y Stone, 1977). También es interesante observar que los enfermos de Korsakoff evidencian además ineficiencia en este tipo de ensayo.

Cuando se usan imágenes categorizables como estímulo para el recuerdo, se observa un patrón similar de deficiencia de producción seguida de ineficiencia de producción. Los niños de menos de 10 años tienen poca tendencia a agrupar los ítem en categorías mientras los estudian para su posterior recuerdo (Moely, Olson, Halwes y Flavell, 1969). Además, cuando se les proporcionan pistas de recuperación similares a los nombres de las categorías, los niños más pequeños no las usan eficientemente para organizar su recuerdo (Kobasigawa, 1974). Mientras que los niños de 11 años intentan recordar todos los miembros de una categoría antes de pasar a la siguiente, los niños de 6 y 8 años tienden a recordar sólo uno de ellos antes de seguir ade-

lante. Los niños más pequeños saben a qué categorías pertenecen los ítem pero *no saben cómo usar su conocimiento* para mejorar el rendimiento en la tarea memorística.

Todo lo antedicho podría servir para sugerir que el hecho de no emplear estrategias mnemotécnicas se debe fundamentalmente a una cuestión técnica de motivación. Después de todo, la mayoría de nosotros sabemos que tomar notas puede ayudar a recordar los contenidos de un libro que estamos estudiando, pero no siempre nos tomamos la molestia de hacerlo. De manera similar, algunos niños pueden no sentirse motivados para esforzarse en una insignificante tarea de recuerdo propuesta por un psicólogo.

Aunque ésta es una explicación posible de las deficiencias e ineficiencias de producción, hay muchas razones por las que probablemente no sirva en la mayoría de los casos. En primer lugar, muchos niños pequeños parecen ansiosos por desempeñarse bien en las tareas que encaran. En segundo lugar, incluso los estímulos económicos producen pocas mejoras en el rendimiento. En tercer lugar, hay una explicación alternativa que dará cuenta tanto de las diferencias culturales como de las etarias en la habilidad memorística.

Diferencias culturales en el rendimiento de la memoria

Todos los experimentos a los que hemos hecho referencia en la última sección investigan el rendimiento de niños educados en una cultura occidental. También se han hecho estudios del recuerdo de listas categorizables en gente no escolarizada y analfabeta de la tribu Kpelle, de África Occidental (Cole y Scribner, 1974). En esos estudios, se descubrió que el recuerdo era pobre y se recurría poco a la categorización. No hubo signos de mejorías drásticas con la edad, típicas de la cultura occidental, y los adultos Kpelle se desempeñaron muy poco mejor que los niños pequeños de cualquiera de las dos culturas.

El hecho de que incluso los adultos Kpelle usaran poco la categorización en el recuerdo es un descubrimiento particularmente útil. En nuestra cultura, la categorización es una forma tan obvia de encarar el recuerdo que la no agrupación automática de ítem en categorías se interpreta, a veces, como evidencia de daño cerebral (Goodglass y Kaplan, 1979). Los enfermos de Korsakoff exhiben precisamente este déficit (Hirst y Volpe, 1984). Sin embargo, se requiere una explicación muy diferente para saber por qué los Kpelle no muestran categorización espontánea en el recuerdo.

La respuesta al dilema ha sido resumida por Hunter (1985). Junto con Cole y Scribner, sostiene que la gente desarrolla habilidades mnemotécnicas que resulten útiles en su propia cultura y, por lo tanto, en su vida cotidiana. El recuerdo de un conjunto arbitrario de cosas por el sólo hecho de recordarlo es el tipo de tarea que la gente occidental educada enfrenta repetidamente en la escuela. Como consecuencia de ello, los occidentales educados desarrollan las estrategias adecuadas de ensayo y categorización hasta el punto en que se tornan automáticas. No sucede lo mismo entre los Kpelle. Por otra parte, la narración de historias es un arte muy practicado en la cultura Kpelle y es esperable que sus miembros sean narradores expertos. Cuando Cole y Scribner insertaron las palabras que se debían recordar en una historia (en lugar de presentarlas en una lista aislada), los Kpelle mostraron una alta capacidad de recuerdo y, también, recordaron los ítem por categoría. Puede verse que la gente no escolarizada puede recordar listas de palabras y utilizar categorías de información, pero en circunstancias diferentes de aquellas en las que la gente escolarizada hace lo mismo.

Otro estudio intercultural de la memoria, según el informe de Kearins (1981), fue realizado con niños aborígenes del desierto y niños blancos criados en la ciudad. En este experimento, se daban 30 segundos a un niño para que viera un conjunto de 5 por 4 cuadrados en los que había 20 objetos simples y luego se le mostraban los objetos desordenados y debía volver a ponerlos en sus posiciones originales. En todos los grupos etarios, desde los 6 hasta los 16 años, y con varios tipos de objetos, el rendimiento de los niños aborígenes fue notoriamente superior. Pero no sólo estos niños reubicaron los objetos mejor sino que, además, encararon la tarea de manera diferente. Los niños blancos intentaban recordar las posiciones de los objetos ensayando sus nombres en orden; cuando se les permitía empezar a reconstruir el conjunto, empezaban con mucho apuro, como si tuvieran miedo de olvidarse rápidamente de la información relevante, y después de colocar un objeto en el tablero solían cambiarlo de posición. En cambio, los niños aborígenes no realizaban ensayos verbales, no tenían apuro en comenzar la reconstrucción y, una vez que habían colocado un objeto en un cuadrado, muy raramente lo cambiaban de lugar. Kearins sugiere que, a diferencia de los niños blancos, que intentaban aplicar una estrategia verbal, los niños aborígenes se basaban en una estrategia visual-espacial.

Para nuestros propósitos, dos puntos del estudio de Kearins resultan particularmente relevantes. En primer lugar, como se dijo antes, la tendencia automática a adoptar una estrategia de ensayo verbal no es universal ni con-

fiere siempre ventajas. En segundo lugar, las estrategias de memoria que no entendemos son mucho más intrigantes que las que usamos. No se comprende claramente cómo actúan tan bien los niños aborígenes en la tarea propuesta por Kearins y, por lo tanto, su capacidad parace muy destacable. Sin embargo, puede suponerse que a los Kpelle también les resultaría impresionante la capacidad de los occidentales educados para recordar cantidades relativamente grandes de palabras categorizables en una lista aislada, especialmente si el ensayo se realizara en silencio y sin movimiento de labios. La conclusión es que la gente desarrolla habilidades mnemotécnicas en las que está ejercitada por la vida cotidiana en su cultura.

El concepto de metamemoria

Las últimas dos secciones han destacado la importancia de las estrategias de memorización para adecuar el rendimiento en una serie de tareas de laboratorio. Se ha descubierto que los niños pequeños, que aún no han dominado estas habilidades, suelen tener un bajo rendimiento en las tareas. Sin embargo, sería un error exagerar las debilidades de los más pequeños. Como señala Kail (1984), los niños en edad preescolar suelen exhibir una excelente memoria para los hechos de sus propias vidas. Y muchos padres podrán confirmar que sus hijos frecuentemente recuerdan acontecimientos y comentarios en circunstancias socialmente incómodas. ¿Por qué, entonces, habrá esta discrepancia entre la memoria de los niños pequeños para los episodios naturales y para los ítem presentados en experimentos?

Kail señala que los niños de cuatro años obtienen mejores resultados en las pruebas de reconocimiento aunque su rendimiento en las pruebas de recuerdo sea asombroso. Bien puede deberse a que muchos de los ámbitos naturales en los que los niños pequeños exhiben sus aptitudes de memoria incluyen reconocimiento, como cuando el niño señala un edificio o un barrio de la ciudad en el que ya ha estado antes. Incluso cuando hay recuerdo (por ejemplo: "Sí que dijiste que la Sra. Pérez bebía demasiado", dicho en presencia de la Sra. Pérez) puede haber múltiples pistas en el contexto físico y social que promuevan el recuerdo. Estas suposiciones quieren sugerir que cuando los niños pequeños demuestran buen recuerdo, es probable que sea de naturaleza pasiva. En la mayoría de los casos, los recuerdos le ocurren al niño. En cambio, cuando se requiere que el niño almacene o recupere información intencionalmente, el rendimiento resulta pobre (Flavell, 1985).

Si se acepta la argumentación, se explica la discrepancia entre los resultados de laboratorio y las experiencias cotidianas. Pero, en ese caso, persiste la pregunta de por qué los niños pequeños tienen tan bajo rendimiento en el recuerdo intencional. Sabemos que no usan espontáneamente estrategias básicas, pero también sabemos que pueden hacerlo si se les dan las instrucciones adecuadas. ¿Por qué muestran, entonces, deficiencias de producción?

Para Flavell, los niños pequeños tienen dificultades con la metamemoria. Metamemoria es el conocimiento de cualquier cosa que tenga que ver con la memoria. Se refiere a nuestro conocimiento personal de cómo funciona el recuerdo en diversas circunstancias. Incluso los niños de 4 y 5 años tienen cierto control de la metamemoria. Comprenden la diferencia entre adivinar y recordar (Johnson y Wellman, 1980) y saben emplear ayudas memorísticas externas, como dejar en lugar visible un objeto que se quieren llevar (Kreutzer, Leonard y Flavell, 1975). Sin embargo, no resulta sorprendente que los niños pequeños carezcan de muchos aspectos de la metamemoria. Son especialmente malos en la predicción de la dificultad de hasta la más simple tarea de memoria. Como los Kpelle, los niños de 4 años tienen poca experiencia en el recuerdo de listas arbitrarias de palabras y por lo tanto no saben en qué pueden resultar beneficiosos el ensayo y la categorización. Esta carencia de metamemoria, la capacidad de diagnosticar las exigencias mnemónicas de diferentes tareas, provoca deficiencias de producción. En algunos casos, puede llevar a discrepancias extrañas. Istomina (1982) halló que los niños podían recordar más ítem si jugaban a "ir de compras" que cuando sólo se les pedía que recordaran las palabras aisladamente. Ir de compras era algo que los niños podían comprender y que automáticamente promovía intentos de recordar, pero la tarea de recuerdo por el recuerdo mismo les resultaba extraña y sin sentido. No provocaba ensayo automáticamente, y como los niños sabían poco sobre la función del ensayo y las exigencias de las tareas de recuerdo, no podían llegar a esa estrategia mediante el pensamiento consciente.

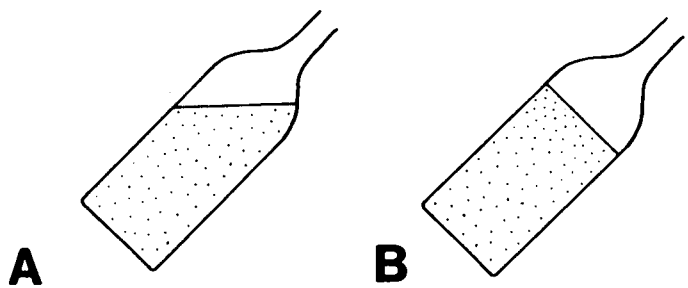
El desarrollo de la metamemoria probablemente continúe durante toda la vida, y deberíamos sentir cierta simpatía por el niño que encara una prueba de memoria. Aun si se les diera una semana entera, pocos adultos sabrían cómo encarar el aprendizaje del papel de Hamlet; sin embargo, los actores pueden lograr notables hazañas de este tipo: como consecuencia de la experiencia, han descubierto las exigencias mnemotécnicas del aprendizaje de papeles y tienen las estrategias y la metamemoria necesarias.

La naturaleza de la metamemoria

La metamemoria es un campo de estudio complejo y aquí sólo podemos hacer un breve esbozo del mismo. Flavell (1977) distingue dos categorías principales de metamemoria. Una es la sensibilidad a las exigencias mnemónicas de las diferentes actividades. El niño debe aprender que, para recordar cosas, es necesario esforzarse por memorizarlas. La segunda categoría es el conocimiento de las propias habilidades, cómo funcionan en las diferentes tareas, qué estrategias usan con mayor eficiencia. En esta categoría se encuentra la capacidad de controlar la propia experiencia, saber que algo que por el momento no se puede recordar está igualmente disponible, o prever que aunque ahora se puedan repetir las instrucciones que se acaban de recibir, dentro de una hora no será posible hacerlo. La metamemoria incluye la capacidad de predecir el propio rendimiento futuro.

Como se dijo antes, los recuerdos pueden aparecer porque las pistas externas lo imponen. Puede haber pistas de entrada (o de codificación) de la información y pistas para recuperarla. La exigencia de juzgar si un rostro parece honesto o deshonesto actúa como pista de codificación; da como resultado un mejor reconocimiento de ese rostro más adelante, aunque no hubiera habido intención de memorizarlo al principio (Bower y Karlin, 1974). El aroma de un perfume puede actuar como pista para la recuperación no intencional de muchísmos recuerdos.

Todos estamos a merced de las pistas de la memoria en los medios físico y social, incluyendo las demandas implícitas de los roles sociales ("recordar nuestro lugar"). Ellas proporcionan un andamiaje externo a nuestra experiencia. La habilidad mnemotécnica reside en la capacidad adicional de proporcionar nuestro propio andamiaje interno y externo y ejercitar así cierto control intencional sobre la experiencia presente y futura. La adquisición de la metamemoria es parte de este proceso.



La metamemoria se encuentra estrechamente ligada a las exigencias mnemónicas que la vida cotidiana impone al individuo. En una cultura escolarizada, uno se torna sensible a las exigencias de memoria de las tareas de tipo escolar y aprende sobre las propias aptitudes al respecto (ver capítulo 12). En una sociedad de cazadores y recolectores, o en una cultura en la que la narración de historias sea una actividad significativa, se explorarán tareas muy diferentes. La gente desarrolla las habilidades memorísticas que su forma de vida necesita y la metamemoria correspondiente a esas habilidades. Actualmente, los investigadores se ocupan de cómo se puede acelerar el de-

sarrollo de la metamemoria mediante la provisión de experiencias de aprendizaje adecuadas (Flavell, 1985).

Memoria y conocimiento

El rendimiento en las pruebas de memoria no sólo está determinado por estrategias memorísticas y la metamemoria. Como sucede con otras habilidades, el conocimiento juega aquí un papel importante (Chi, 1985). Esto es muy evidente en un experimento de Piaget en el cual se pidió a algunos niños que reprodujeran una ilustración que se les había mostrado una hora antes (ver figura 6.2A). Los niños de menos de 8 años con frecuencia no logran dibujar una reproducción precisa del original. Cometen ciertos errores típicos. Uno de los más comunes es el que se ilustra en la figura 6.2B. Aquí, el nivel del agua es dibujado paralelo al fondo de la botella y, por lo tanto, oblicuo en vez de horizontal. Al tratar de recordar la apariencia del original, el niño reconstruye sobre la base de un conocimiento inadecuado del mundo físico. Sin embargo, si al mismo niño se le vuelve a pedir que dibuje la imagen unos meses después, la nueva reproducción bien puede ser correcta. La memoria, paradójicamente, ha mejorado con el paso del tiempo. La mejora se debe a un aumento en la comprensión y esto, según Piaget e Inhelder (1973), es consecuencia del desarrollo de las estructuras cognitivas que se supone subyacen al pensamiento del niño.

Figuras 6.2. Ilustración original y una de las reproducciones obtenidas en el experimento de Piaget.

La prueba del nivel del agua es un buen ejemplo del papel de la reconstrucción en la memoria. A veces recordamos mal hechos pasados (o disentimos con otra gente sobre ellos) debido a la reconstrucción. Recordar es con frecuencia reordenar informaciones parciales o usar los conocimientos lógicos y empíricos para decidir cómo debe haber sido todo. Como señala Luria (1974), el niño inicialmente aprende a pensar recordando; luego, más adelante, aprende a recordar pensando.

Otra demostración experimental de la importancia del conocimiento para el rendimiento en las pruebas de memoria fue la de Chi (1978), quien utilizó una prueba de recuerdo de dígitos y la tarea de reconstrucción del ajedrez que se describe en el capítulo 2. Un grupo de adultos con alto nivel de educación pero sin conocimiento alguno sobre ajedrez y un grupo de niños entrenados en ajedrez actuaron como sujetos del experimento. En el recuerdo de dígitos, se observó la superioridad adulta usual; pero al reconstruir configuraciones significativas de piezas de ajedrez, aquellos que conocían el juego, aunque eran menores, fueron mucho más eficientes. Este resultado no es sorprendente; por el contrario, es lo esperable por la destreza de los niños en el ajedrez. Sin embargo, proporciona un ejemplo evidente de que el conocimiento suele ser el factor determinante de la capacidad mnemónica. Los adultos demuestran por lo general un mejor rendimiento que los niños en las pruebas de memoria porque tienen más práctica en ese tipo de pruebas y por lo tanto son mnemotécnicos más diestros, y también porque usualmente conocen más el campo en el que se está probando la memoria.

Aptitudes de memoria especiales en los niños

Al comenzar este capítulo dijmos que, a veces, se atribuye a los niños pequeños una capacidad excepcional para ciertos tipos de pruebas de memoria. El análisis posterior enfatizó las deficiencias de memoria en los pequeños y las formas en que estas deficiencias son concomitantes inevitables del conocimiento y la práctica insuficientes. ¿Cómo se concilia, entonces, esta supuesta capacidad excepcional con la imagen que se ha hecho del niño como aprendiz mnemotécnico? Intentaremos responder la pregunta en esta sección, examinando dos tareas que incluyen memoria visual-espacial y de las que se dice que muestran a los niños bajo una luz más positiva.

La primera no es una tarea inventada por psicólogos curiosos sino un juego que disfrutan tanto niños como adultos. Este juego recibe varios nombres: pares, "memotest" o memory. En una versión simple, se mezcla un ma-

zo de cartas y luego se las esparce con la figura hacia abajo sobre una mesa. A su turno, cada jugador debe dar vuelta dos cartas y dejarlas a la vista de todos los demás. Si esas cartas forman un par, el jugador se las queda y tiene un turno más; si no, debe volver a ponerlas con la figura hacia abajo. El ganador es el jugador que termina llevándose más pares de cartas; evidentemente, el juego exige recordar qué cartas se encuentran en qué posiciones. Varios autores (por ejemplo, Meacham, 1972; Gardner, 1982; Wood, 1983) han escrito que los niños suelen vencer a los adultos en el juego pero en ningún caso han aportado datos que lo corroboren. Para rectificar esta omisión, se hicieron estudios en niños de 5, 7 y 9 años y en estudiantes universitarios que practicaran una versión individual del juego, usando como índice de su rendimiento el tiempo y la cantidad de intentos (Gellatly, Jones y Best, en prensa). Los resultados demostraron que los niños de 5 y 7 años tenían un rendimiento marcadamente más bajo que los demás, pero entre los otros grupos no hubo diferencias significativas. Más aún, el bajo rendimiento de los niños de 5 y 7 años fue visto como resultado de la dificultad de implementar confiablemente una estrategia típica de los niños mayores y los adultos. Naturalmente, algunos niños de 5 años son muy buenos en el juego, pero las evidencias demuestran que el rendimiento en la tarea mejora con la edad de la misma forma en que lo hace en otras tareas de memoria y debido a un tipo de desarrollo similar. No es necesario atribuir habilidad especial a los muy pequeños en este caso.

La segunda habilidad especial que se dice que tienen los niños pequeños —y que a veces se cita como explicación del alto rendimiento en este juego (Gardner, 1982)— es la de la imaginería eidética. Una imagen eidética es una imagen de memoria particularmente vívida y detallada de una ilustración o escena vista recientemente. En general, esas imágenes se experimentan como "estando allí" más que en la mente, y se las puede proyectar en un muro o en una pantalla. Se las describe en presente y no en pasado, se las puede escudriñar visualmente y se pueden superponer pares de imágenes para que formen un compuesto que contiene información que no está presente en ninguna de las dos imágenes por separado (Haber, 1979). La imaginería eidética casi no existe en los adultos pero se encuentra en alrededor del 5% de los niños de 6 a 12 años. Su naturaleza no está muy clara pero parece representar una instancia genuina de niños pequeños que demuestran mejor memoria que los adultos.

Aunque resulta interesante por sí misma, la imaginación eidética es diferente de los tipos de memoria que hemos tratado en este capítulo, ya que

constituye un registro incidental de información más que una forma activa e intencional de memorización. Aunque su desaparición antes de llegar a la edad adulta sigue resultando incomprensible, la existencia de la imaginación eidética no es incoherente con la consideración del desarrollo de la memoria como adquisición de estrategias intencionales de memorización, crecimiento de la metamemoria y acumulación de conocimientos.

Conclusión

En este capítulo hemos analizado el desarrollo de la memorización intencional desde sus orígenes en la memoria pasiva. Se ha enfatizado el modo en que una forma de vida se asocia con la adquisición de habilidades de memoria específicas. Se ha visto su adquisición, en este sentido, como algo más o menos fortuito, ya que las habilidades reales se adquieren simplemente como consecuencia de las actividades cotidianas. En los capítulos 7 y 8 analizaremos cómo las habilidades mnemotécnicas pueden desarrollarse mediante entrenamiento y práctica intencionales.

La habilidad de memoria excepcional

Ian M. L. Hunter

Este capítulo se ocupa de aquellos que logran notables hazañas con su memoria. El objetivo es destacar el papel que, en tales hechos, juegan el conocimiento y la habilidad previamente adquiridos.

Consideremos un ejemplo real. Un artista visita el museo del Louvre en París, observa cuidadosamente el retrato de Erasmo pintado por Holbein y luego hace una reproducción del retrato, de memoria. Este hecho está descrito por Boisbaudran (1911) en un libro que incluye fotografías del retrato original y de la reproducción. Bien podemos decir que el artista "tiene una memoria sorprendente". Si con esto sólo queremos decir que lo que hizo es poco común e irrealizable para la mayoría de la gente, nuestro comentario será correcto. Pero si queremos decir que la naturaleza lo ha dotado de una facultad especial de memoria visual-espacial, estaremos sugiriendo algo que va más allá de las evidencias e ignorando que, de hecho, el artista ha pasado por un largo entrenamiento en la observación de cuadros, lo que lo ayuda para poder copiarlos de memoria.

La idea general es la siguiente: los hechos inusuales de memoria no implican, necesariamente, que la persona que los realiza sea constitucionalmente anormal, es decir, dotada por la naturaleza de un don, una facultad o una aptitud cualitativamente especiales. Es posible que esos dones biológicos existan, aunque es difícil establecerlo con certeza. Pero hay dos cosas seguras. En primer lugar, la práctica intensiva puede llevar a habilidades de memoria verdaderamente sorprendentes. En segundo lugar, quienes realizan hazañas memorísticas inusuales son con frecuencia personas que han practicado mucho.

Para dar sustento a las afirmaciones generales que acabamos de hacer, nos centraremos en una investigación en la que un estudiante de una universidad estadounidense, Steve Faloon, se convirtió en un experto en la tarea de memorizar dígitos (ver capítulo 5). Chase y Ericsson (1981) hicieron el relato más completo de esta investigación; sus implicaciones fueron elaboradas por Chase y Ericsson (1982), Ericsson y Chase (1982) y Ericsson (1985).

La hazaña de Steve con la memoria

Steve escucha una sucesión de dígitos leídos en voz alta a una velocidad de uno por segundo. Han sido seleccionados al azar, de manera que no puede saber cuál será el número siguiente. Sigue escuchando hasta que se le han mencionado 80 dígitos. Luego, los repite todos. No comete errores en los dígitos ni en la secuencia y no olvida ninguno.

Este hecho es evidentemente excepcional. Cuando la mayoría de los adultos normales encara la tarea, la cantidad de dígitos que puede repetir correctamente es, como promedio, siete (más o menos dos dígitos). También se sabe, en términos generales, por qué la capacidad de recordar dígitos es normalmente tan pequeña. Tenemos dos tipos de sistemas de almacenamiento en los que podemos contener información (ver capítulo 5). Uno es la memoria de corto plazo (MCP), que es temporaria y tiene una muy baja capacidad de almacenamiento. El otro es la memoria de largo plazo (MLP), que es más duradera y tiene, virtualmente, una capacidad de almacenamiento infinita. Cuando percibimos información nueva y le prestamos atención, podemos mantenerla disponible durante un breve lapso, pero luego la perdemos irremediablemente a menos que le volvamos a prestar atención, es decir, que la ensayemos de alguna forma. Por ejemplo, si buscamos un número telefónico, podemos retenerlo mediante ensayo atento hasta que llegamos al teléfono pero, si algo nos distrae, lo olvidaremos. En cambio, si aprendemos el número en la memoria de largo plazo, estará disponible durante más tiempo sin necesidad de que le prestemos atención de manera constante. En la tarea de memorización de dígitos, las personas por lo general recurren a la MCP y su capacidad muy limitada se debe fundamentalmente a la pequeña capacidad de almacenamiento de este tipo de memoria.

Para descubrir qué hay detrás de las hazañas memorísticas de alguna persona, debemos analizar dos aspectos clave. Primero, el trasfondo biográfico y social; segundo, los procesos usados durante la hazaña. Las próximas dos secciones se ocupan de estas cuestiones en relación con la hazaña de Steve.

Trasfondo biográfico y social

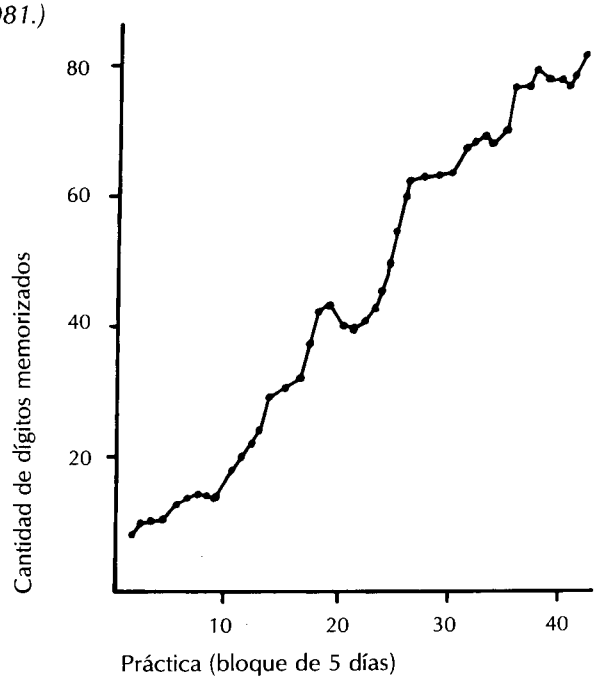
Steve realizó su hazaña memorística en el ámbito de una investigación psicológica de laboratorio, realizada a fines de los años setenta en la Univer-

sidad Carnegie-Mellon, en los Estados Unidos. Los tres participantes en esa investigación fueron: William Chase y Anders Ericsson, psicólogos experimentales, y Steve Faloon, que actuó como sujeto. Steve era un estudiante de poco más de 20 años de edad. Tenía altas calificaciones y, en cambio, no demostraba aptitudes extraordinarias para un estudiante brillante. Pero era corredor de fondo, de distancias largas. Esto le daba una actitud competitiva y una ambición de ruptura de récords y también un conocimiento de los tiempos de carrera, que habría de capitalizar cuando encarara la tarea de recuerdo de dígitos. Pertenecía a los equipos de pista y campo y de maratón de su universidad. Se entrenaba corriendo entre 16 y 20 kilómetros por día y, en los últimos nueve años, había competido en muchas carreras de larga distancia. Sus mejores carreras eran la de 3 millas (aproximadamente 5 km), la de 5 millas (aproximadamente 8000 metros) y el maratón; sus mejores tiempos en estas carreras eran, respectivamente, 14'39", 25'40" y 2h 39'36".

Cuando comenzó la investigación, el objetivo era darle a Steve un par de semanas de práctica en la tarea de recuerdo de dígitos y averiguar los efectos que producía. Pero la práctica resultó tan interesante que los tres participantes quisieron seguir adelante. La investigación siguió extendiéndose y llegó a durar dos años. En ese período, Steve concurrió al laboratorio para sesiones de una hora de dos a cinco días por semana.

En cada sesión, la rutina usual consistía en probar el recuerdo de dígitos de Steve mediante el método de fluctuaciones ascendentes y descendentes. Oía una lista de dígitos al azar leídos a una velocidad de uno por segundo y luego intentaba repetirlos. Si tenía éxito, la lista siguiente contenía un dígito más; si no tenía éxito, la lista se acortaba un dígito. Este método lo mantenía trabajando cerca de los límites de su capacidad.

Inmediatamente después de tratar de recordar una lista, se le pedía que comentara los procedimientos que había utilizado. Al final de cada sesión (de una hora de duración) se le pedía que recordara todo lo que podía sobre las listas leídas ese día. A veces, se reemplazaba la rutina usual por sesiones experimentales que exploraban aspectos de su rendimiento. Todos los procedimientos de esta investigación ampliada eran grabados.



Steve no recibió entrenamiento específico en lo que debía hacer pero constantemente se esforzaba para aumentar el número de dígitos que recordaba. Como un atleta en entrenamiento, enfrentaba barreras para progresar y probaba formas de superarlas. Si una forma funcionaba, la conservaba, la dominaba y seguía adelante hasta que aparecía el siguiente obstáculo. Si no funcionaba, intentaba de otro modo. Para él, entonces, la tarea de memori-

zación de dígitos era un desafío estimulante y, a medida que ganaba experiencia, aparecían nuevas situaciones y el desafío aumentaba. Además, informaba con regularidad y minuciosamente sobre los detalles de su desempeño, y los experimentadores, a su vez, hacían comentarios sobre estos detalles y su progreso. En resumen, la investigación de laboratorio creó un ámbito social que alentaba a Steve a ganar más experiencia creativa en la tarea de memorización de dígitos.

El progreso de Steve se presenta en la tabla de la figura 7.1, que muestra que, en 215 sesiones de práctica, su recuerdo aumentó de 7 a 80 dígitos. Todo indica que, si la práctica hubiera continuado, habría hecho más progresos aún. Aparentemente, el número de dígitos que se recuerda puede aumentar indefinidamente.

El punto clave de esta sección es que la hazaña de Steve se realizó en un ámbito social y biográfico que lo alentaba a ampliar su práctica y su experiencia en algo considerado importante. Los logros de las personas suelen tener que ver con aquellas cosas que les resultan útiles para su vida cotidiana. Para la mayoría de las personas, recordar una gran cantidad de dígitos es inútil y no tienen oportunidades ni incentivos para involucrarse en actividades que los llevarían a mejorar en ello. Pero supongamos un mundo social en el que los récords en la memorización de dígitos fueran tan valorados como los récords deportivos. En semejante ámbito, indudablemente mucha gente lograría recordar largas listas de dígitos. (Chase y Ericsson trabajaron con un segundo sujeto, también corredor de larga distancia, que llegó a recordar 100 dígitos.) Pero lo más extraordinario de la memoria de Steve es que tuvo la oportunidad, la motivación y la persistencia necesarias para lograrlo. Nos recuerda drásticamente que las capacidades humanas se desarrollan a partir de las interacciones entre individuos cuyos entornos ofrecen las posibilidades y los incentivos necesarios para nutrir las aptitudes en cuestión.

Figura 7.1. Mejoría en el recuerdo de dígitos de Steve Faloon con práctica extendida. Los 43 bloques de práctica aquí mostrados representan unas 215 horas de práctica. Intercaladas entre estas sesiones de práctica hay aproximadamente 75 horas de sesiones experimentales (no mostradas). (Según Chase y Ericsson, 1981.)

LOS PROCESOS INVOLUCRADOS

Durante esta investigación, Steve desarrolló nuevas formas de encarar la tarea. En esta sección bosquejaremos cuatro desarrollos fundamentales:

a) Codificación significativa.
b) Estructuración.
c) Rol más importante de la memoria de largo plazo.
d) Aumento de producción.

Obsérvese, de paso, que estos cuatro aspectos son ingredientes esenciales de todos los sistemas mnemotécnicos conocidos, de los cuales el más famoso es el *Método de loci* (ver Lorayne y Lucas, 1974; también, capítulo 8).

Codificación significativa

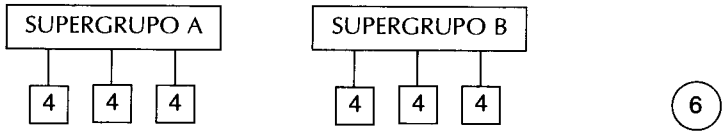
Al principio, Steve encaró la tarea de la misma forma que la mayoría. Intentó retener la secuencia de dígitos fonémicamente, ensayando hasta recordarlos. Observaba patrones ocasionales, como una serie de números ascendentes, pero se basaba fundamentalmente en el ensayo atento de la memoria del corto plazo (MCP) y lograba recordar 7 dígitos. Durante las primeras cuatro sesiones no superó esa cifra. En la cuarta sesión, comentó ampliamente que había llegado a su límite y ya no había mejora posible.

Luego, en la quinta sesión logró recordar 10 dígitos y, por primera vez, se refirió a una codificación significativa. Para ejemplificarlo, consideremos la secuencia 4131946273. Trató a los primeros cuatro dígitos como un grupo y pensó en él como "cuatro-trece-coma-uno: el tiempo de una milla"; es decir, 4 minutos, 13 segundos y 1 décima, que es el tiempo que a un atleta le lleva correr una milla. Luego pensó en el segundo grupo de cuatro dígitos como "nueve-cuarenta-y-seis-coma-dos: el tiempo de dos millas". Para su regocijo, descubrió que ahora podía recordar una lista de 10 dígitos como dos grupos codificados de cuatro dígitos cada uno, más otros dos dígitos sueltos al final.

Así, en la quinta sesión, Steve empezó a considerar a los grupos de dígitos números que resultaban significativos si los pensaba como tiempos de carrera. Luego, siguió construyendo un repertorio cada vez mayor de números significativos; la mayoría de ellos eran tiempos de carrera, pero también edades de personas y fechas históricas. Usó estos números para codificar casi cualquier secuencia de tres o cuatro dígitos que se le presentaba. Su empleo de la codificación significativa cobró un propósito claro. Al escuchar los dígitos que se le leían, no esperaba hasta oír los cuatro dígitos para buscar una codificación significativa sino que, al escuchar el primero, empezaba a apuntar hacia una codificación posible y, con cada dígito que oía, estrechaba el campo de búsqueda hasta que, al oír el cuarto dígito o poco después, lograba una codificación adecuada.

Estructuración

Para la sesión 30, Steve ya recordaba 18 dígitos codificando tres grupos de cuatro dígitos cada uno y reteniendo los últimos seis dígitos como grupo no codificado de dos triples. Pero ahora se enfrentaba a un nuevo obs-



táculo. Cuando aumentaba la cantidad de grupos codificados de tres a cuatro, no podía retener el orden secuencial de los cuatro grupos. En la sesión 32 logró vencer este obstáculo cuando, por primera vez, armó los grupos. Llamemos "supergrupo" a cada agrupamiento de grupos. Veamos su nueva técnica para encarar la memorización de 20 dígitos: pensó en dos grupos, de cuatro dígitos cada uno, que conformaban un supergrupo; luego, dos grupos de tres dígitos cada uno, que integraban un segundo supergrupo; finalmente, un grupo no codificado de seis dígitos.

En las semanas siguientes, mejoró su uso de la técnica de los supergrupos. Pasó a usar supergrupos que no contenían dos sino tres grupos codificados cada uno. Su capacidad de memorización fue aumentando gradualmente hasta llegar a los 40 dígitos. Y entonces apareció otro obstáculo. Cuando intentaba usar supergrupos que contenían cuatro grupos cada uno (en vez de tres), no podía recordar el orden secuencial de los cuatro grupos. En la sesión 109, salvó este obstáculo. Usó supergrupos que sólo contenían tres grupos codificados cada uno e introdujo un nuevo agrupamiento, de nivel superior, que contenía dos supergrupos.

Para aquellos que no conozcan en detalle el rendimiento de Steve, quizá resulte difícil comprender su uso de supergrupos y de grupos de nivel superior, pero el principio general es simple. Steve estaba imponiendo una estructura jerárquica a la lista. Veamos cómo Steve, el experto, encaraba una lista, y recordemos que en todo momento era consciente de qué longitud tendría cada lista.

Incluso antes de escuchar el primero de los dígitos, Steve decidía la estructura exacta y completa que habría de imponer. Con una lista de 30 dígitos, por ejemplo, podía imponer la estructura que se presenta en la figura 7.2, que contiene seis grupos de cuatro dígitos combinados en dos supergrupos y seis dígitos sin codificar al final. A medida que iban apareciendo los dígitos, Steve los incluía en su estructura predeterminada. Cuando, más tarde, recordaba la lista, lo hacía recorriendo la estructura sistemáticamente, usándola de modo que le proporcionara pistas para la recuperación (ver también el capítulo 8).

Figura 7.2. Representación de la estructura de una lista. Se combinan grupos de cuatro dígitos en tríos, para formar supergrupos. El círculo representa seis dígitos sin codificar.

Al terminar la investigación, Steve estaba familiarizado con estructuras que podían incluir hasta 80 dígitos y las usaba con suma destreza. Podía hablar de ellas y dibujarlas esquemáticamente. Además, sus estructuras se reflejaban en el ritmo al que recordaba las listas. Al recordar las listas, no mantenía un ritmo de un dígito por segundo sino que los recitaba en "ráfagas" de tres o cuatro dígitos con pausas de diferente longitud entre cada ráfaga. Cada una de estas ráfagas correspondía a los grupos de dígitos, y las pausas dependían de la estructura de la lista; por ejemplo, hacía pausas más largas cuando pasaba de un supergrupo a otro que cuando pasaba entre grupos dentro de cada supergrupo.

Papel mayor de la memoria a largo plazo

¿Steve aumentó la capacidad de almacenamiento de su MCP? No hay evidencias de que lo haya hecho. En esencia, aumentó la cantidad de dígitos que podía recordar adquiriendo recursos de la MLP que le permitieron obviar las persistentes limitaciones de la MCP. Como novato, su capacidad de recuerdo dependía fundamentalmente de su MCP porque no tenía recursos de la MLP aplicables a la tarea. Con la práctica, construyó recursos de la MLP que podían aplicarse. Como experto, su capacidad de memorización de dígitos pasó a depender fundamentalmente de la MLP; así lo demuestran las siguientes evidencias.

En primer lugar, al terminar cada sesión de una hora, Steve intentaba recordar las listas que se le habían presentado en esa sesión. Cuando el experimento recién comenzaba, no podía recordar prácticamente nada. Cuando su pericia aumentó, recordaba virtualmente todo. Era capaz de recitar las

listas que se le habían presentado. Podía volver a contar cómo había encarado las listas, las estructuras que les impusieron, los grupos que formó y las codificaciones realizadas. Si se le daba cualquier grupo de cuatro dígitos de la lista, frecuentemente podía contar cómo lo había codificado y dónde lo había colocado en la estructura de la lista; es decir, si lo había puesto al principio, en la mitad o al final de un supergrupo. Si se le pedía que recordara porciones seleccionadas de la lista, podía recordarlas sin tener que recorrer toda la lista desde el principio. Usaba la estructura de la lista para moverse selectivamente por ella.

La segunda evidencia surgió de lo que hacía inmediatamente después de que se le presentaba una lista. Cuando era novato, no perdía tiempo y empezaba a recitar los dígitos de inmediato. Como experto, esperaba entre treinta segundos y dos minutos antes de empezar a recitarlos. En esta pausa, consolidaba su comprensión de la lista, la revisaba y ordenaba sus detalles y su estructura.

Las dos evidencias que acabamos de mencionar demuestran que Steve, el experto, procesaba las listas que se le presentaban a través de su MLP. Lo hacía usando el cuerpo de conocimientos que había construido con la práctica. Este conocimiento (de códigos, estructuras y técnicas) estaba almacenado en la MLP y él lo tenía "a mano", disponible rápidamente y sin vacilaciones. Usaba este conocimiento para obviar los límites de la MCP que, de todas formas, seguía imponiendo restricciones a su rendimiento. Por ejemplo, Steve nunca codificaba un grupo de más de cinco dígitos, jamás construía un supergrupo que contuviera más de cuatro grupos, siempre trabajaba con pequeños segmentos y, con tanta rapidez como podía, incorporaba cada segmento en su MLP y se ocupaba totalmente del siguiente segmento de la lista.

Un hallazgo importante sobre los recursos de la MLP, de los que dependía la pericia de Steve, fue que eran específicos, es decir, sólo se relacionaban con el tema de los dígitos y no con otros temas. Por ejemplo, cuando se le daban tareas de memorización de letras del alfabeto elegidas al azar, su capacidad de recuerdo era de seis letras, no más que lo normal. Evidentemente, Steve no había adquirido una "memoria superpoderosa" para todo uso, aplicable a cualquier campo de manera indiscriminada.

Aumento de producción

Con la práctica, Steve fue ganando mayor velocidad en la realización de los procesos componentes. El proceso de codificación, por ejemplo, me-

joró muchísimo y no dejó de mejorar durante toda la investigación. Semejante aumento de la producción es, por supuesto, enormemente beneficioso porque permite al individuo planificar y ejecutar maniobras más complejas (ver también capítulos 2 y 3).

Mejora intencional y mejora casual

Al comenzar este capítulo, hice dos planteos generales. En primer lugar, sostuve que la práctica intensa puede llevar a habilidades memorísticas excepcionales. En otras palabras, si empezamos a trabajar con alguien que no demuestra aptitudes memorísticas inusuales, con la práctica podemos lograr que esa persona desarrolle habilidades memorísticas claramente fuera de lo común. Esto se hace evidente en el ejemplo de Steve Faloon. Ericsson y Chase (1982) y Ericsson (1985) presentan otros ejemplos. En segundo lugar, la gente que demuestra tener aptitudes memorísticas inusuales a menudo ha realizado mucha práctica importante para ello. En otras palabras, si trabajamos con alguien que demuestra una aptitud memorística excepcional, con frecuencia veremos que tuvo una larga historia de práctica en el campo en cuestión. Esta sección se ocupa de este segundo tema y, en particular, de la distinción entre mejora intencional y mejora casual de la memoria.

Las habilidades memorísticas de Steve se desarrollaron mientras deliberadamente intentaba aumentar su capacidad de memorización. Durante la persecución de este objetivo explícito Steve incorporó, en su MLP, un variado repertorio de códigos, estructuras y técnicas que le permitió aumentar su capacidad de memorización. Sin embargo, es posible que la gente desarrolle habilidades memorísticas de manera casual, como subproducto de la persecución de objetivos que no apuntan específicamente a la mejoría de la memoria. Semejante mejoría casual de la memoria es una de las características de lo que puede denominarse "efecto memorístico de la pericia"; es decir, que los expertos son buenos para aprender y recordar cosas pertenecientes precisamente al campo en el que son expertos.

Hay muchos campos en los que la gente puede tornarse experta, como el ajedrez, la música, la abogacía, la entomología. La gente llega a ser experta en un campo mediante largas experiencias en él: la materia del campo se torna significativamente familiar. Ahora bien, supongamos que, como psicólogos, elegimos material de cierto campo específico y lo usamos para comprobar cómo puede la gente aprender y recordar este tipo de material.

¿Qué encontramos? Los expertos en ese campo usualmente se desempeñan mejor que los que no son expertos.

Por ejemplo, cuando se les dan tareas de memorización de dígitos a expertos en cálculos mentales, alcanzan cifras dos o tres veces mayores que las comunes. Estos expertos no han practicado estas tareas deliberadamente pero, en el proceso de convertirse en expertos en cálculos mentales, han desarrollado cuerpos de conocimiento y habilidad que les permiten, como subproducto, desenvolverse bien en las tareas de memorización de dígitos. Para dar ejemplos específicos, Hatano y Osawa (1983) probaron las habilidades memorísticas de tres personas que habían ganado en la categoría División Mental en el Campeonato Nacional de Ábacos del Japón. Se les dieron tareas de memorización de letras del alfabeto: los tres campeones memorizaron 5, 8 y 5 letras, respectivamente. Cuando se les dieron palabras en lugar de letras (nombres de frutas), su rendimiento fue de 5, 9 y 5 palabras, respectivamente. Pero cuando se les dieron números, su rendimiento aumentó a 15, 16 y 16 dígitos cada uno. No hay motivos para suponer que pudieran recordar tantos dígitos antes de convertirse en expertos en cálculo mental.

El "efecto memorístico de la pericia" también puede funcionar al revés. Regresemos al artista del que hablábamos al principio de este capítulo. Era uno de los muchos alumnos entrenados por el maestro de arte francés Horace Lecoq de Boisbaudran. Los alumnos pasaban por un entrenamiento que deliberadamente buscaba lograr en los alumnos la capacidad de copiar complejas pinturas de memoria. Adquirían experiencia y práctica en la descomposición de imágenes en componentes que les resultaran familiares y en el uso de estos componentes para reconstituir las imágenes de memoria. En la persecución de este objetivo, adquirían conocimientos y habilidades que podían emplear cuando encaraban una tarea creativa en el campo pictórico. El objetivo de largo plazo de la pericia artística era enfocado a través del objetivo de corto plazo del entrenamiento memorístico en arte.

El caso S.

El caso de S. V. Shereshevskii (conocido como S.) ofrece un ejemplo de pericia memorística de otro tipo. Las extraordinarias aptitudes memorísticas de S. fueron estudiadas por el psicólogo ruso Luria (1969). S. demuestra cuán desafiante (y a veces frustrante) resulta superar lo que implica ser alguien que llama la atención por su excepcional memoria. S. tenía casi 30

años cuando Luria lo conoció. En esa época, a mediados del decenio 1920-1930, S. era periodista de un diario.

> Cada mañana, el editor se reunía con el personal y les entregaba las tareas del día: las listas de los lugares que quería que cubrieran y la información que debían conseguir en cada lugar. La lista de direcciones e instrucciones solía ser bastante larga, pero el editor comprobó con sorpresa que S. jamás tomaba notas. Estaba por reprocharle su falta de atención cuando, en respuesta a su pedido, S. repitió la lista completa, palabra por palabra. El editor, curioso por saber más sobre la forma en que funcionaba su empleado, empezó a preguntarle por su memoria. Pero S. sólo respondió con sorpresa: ¿realmente había algo de raro en el hecho de que recordara todo lo que le decían?... El editor lo envió al laboratorio de psicología para que se hicieran estudios sobre la capacidad de su memoria.
>
> (Luria, 1969, págs. 7-8).

Luria probó a S. dándole largas secuencias de palabras, sílabas sin sentido y números, para que los aprendiera. Si los ítem se presentaban de manera lenta y clara, al final de la secuencia, S. hacía una pausa para revisar mentalmente el material y luego recordaba toda la secuencia sin cometer errores. S. también podía recordar la secuencia en el orden inverso y, si se le daba cualquier ítem de la secuencia, podía decir de inmediato cuál lo precedía y cuál lo seguía. En una sola presentación, S. aprendía la secuencia en la memoria de largo plazo.

Pero cuando Luria intentó descubrir cómo llevaba a cabo S. sus hazañas de aprendizaje y recuerdo, no logró avanzar demasiado. S. dijo que codificaba el material según *características como las de la percepción*. Una palabra, por ejemplo, podía desencadenar complejas imágenes psíquicas que no eran meramente visuales sino también auditivas, táctiles y gustativas. Sin embargo, S. no podía decir mucho sobre los procesos implicados. Tampoco podía hablar del desarrollo de sus procesos memorísticos en el pasado. Por lo que podía recordar, siempre había tenido esas habilidades. En resumen, en esta etapa de la investigación, Luria no podía determinar si las aptitudes de S. se debían a una peculiaridad innata o a una disposición adquirida para encarar los acontecimientos que experimentaba de maneras que llevaban, como subproducto casual, a recordarlos en detalle. En la vida real, hay algunas preguntas para las que no se pueden encontrar respuestas claras.

Algún tiempo después de conocer a Luria, S. decidió aprovechar su habilidad y convertirse en un mnemotécnico profesional que hacía exhibiciones públicas de su capacidad para aprender y recordar cosas que, para la ma-

yoría, no tienen sentido y son difíciles de memorizar; por ejemplo, listas de palabras o números elegidos al azar. Luria descubrió que, para satisfacer las necesidades de estas actuaciones públicas, S. desarrolló formas de operar significativamente modificadas, que curiosamente incluían los cuatro procesos mencionados cuando hablábamos de Steve Faloon. En resumen, S. desarrolló, con la práctica, cuerpos de conocimiento y habilidad que le permitieron, con más rapidez y eficiencia, codificar y estructurar el material presentado.

Básicamente, en sus actuaciones públicas, S. usaba el *Método de loci* (ver capítulo 8). Por ejemplo, se imaginaba a sí mismo caminando por una calle conocida, llena de cosas que le eran familiares (como la calle Gorki de Moscú) y visualizaba cada ítem que se le presentaba asociándolo con cada hito de la calle, sucesivamente. Uno de los procesos para lograr mayor eficiencia tenía que ver con la simplificación de la visualización realizada.

El hecho de que S. pudiera adaptar sus aptitudes de imaginación para satisfacer las necesidades de su nueva profesión nos dice algo sobre la naturaleza de sus habilidades. No podemos saber si su facilidad para las imágenes era innata o adquirida, pero es evidente que se la podía controlar y usar intencionalmente.

> Antes, para recordar algo tenía que recurrir a una imagen de toda la escena. Ahora, sólo tengo que tomar algún detalle que he elegido de antemano y representará a toda la imagen. Digamos que me dicen la palabra *jinete*. Lo único que se necesita es una imagen de un pie con una espuela... Así que mis imágenes han cambiado bastante. Antes eran más definidas, más realistas. Mis imágenes actuales no están tan bien definidas ni son tan vívidas como las de antes... Sólo trato de visualizar algún detalle que necesitaré para recordar una palabra.
>
> (Luria, 1969, pág. 42).

Conclusión

Al terminar este capítulo, sabemos algo de la gente que demuestra tener aptitudes memorísticas excepcionales. Sabemos que esa gente existe. Sabemos sobre la importancia de la codificación y estructuración significativas rápidas. Sabemos que sus sorprendentes hazañas a veces pueden ser realizadas por gente normal que tiene mucha práctica. Pero, hasta el momento, la comprensión acabada de las habilidades excepcionales de la memoria sigue siendo un desafío para los psicólogos.

¿Cómo se pueden mejorar las habilidades de la memoria?

Angus Gellatly

Los últimos tres capítulos han hecho referencia, de una u otra manera, a la mejoría de las habilidades de la memoria. Este capítulo, a diferencia de los anteriores, es prescriptivo en lugar de descriptivo. La atención hasta aquí estuvo puesta en la observación de los individuos cuando encaran tareas memorísticas, con el objetivo de describir el proceso cognitivo que realizan. En general, no se enseñó a los sujetos la forma de lograr la tarea y, cuando se daban instrucciones, el objetivo era teórico: explorar los límites de las capacidades del sujeto antes que lograr una mejora en la memorización por sí misma. Este capítulo tiene un objetivo muy diferente: pondremos el acento en la mejora de la memoria y no en su comprensión teórica. Nos ocuparemos menos del psicólogo como científico y más del psicólogo como entrenador. Naturalmente, sólo se trata de una cambio en el énfasis, puesto que seguimos deseando que las investigaciones teóricas y aplicadas sobre la memoria se sostengan mutuamente.

La tradición mnemónica y la terapia de la memoria

Hace mucho ya que existen los cursos para mejorar la memoria. Actualmente, los periódicos publican avisos sobre estos cursos, pero la explotación práctica y comercial del arte de la memoria tienen una venerable historia (Yates, 1966). Los sistemas mnemónicos fueron un elemento importante en Grecia y, más adelante, en la educación en la antigua Roma. En una época en que la educación estaba reservada para unos pocos y las telecomunicaciones aún no habían sido inventadas, la importancia social de la oratoria pública era mucho mayor de lo que es en la actualidad. Los mejores oradores evitaban el empleo de notas y, por lo tanto, eran muy valiosos los métodos para aprender de memoria la información, y así siguió siendo hasta la Edad Moderna. De hecho, viviendo en una cultura de lápiz y papel, de foto-

grafías y cintas grabadas, es difícil imaginar el papel vital de las técnicas mnemónicas en las sociedades no alfabetizadas, o en aquellas con prácticas de escritura diferentes o menos difundidas que en la nuestra. Por esto, la investigación de los "efectos colaterales" cognitivos de la alfabetización y sus usos sociales ha demostrado ser una fuente de intrigantes profundizaciones en la naturaleza de la memoria y el pensamiento.

El arte tradicional de la memoria y sus descendientes modernos, los cursos publicitados en los periódicos, se han concentrado en la adquisición de técnicas mnemónicas (y lo que ahora denominamos *metamemoria*) en personas normalmente saludables. En cambio, y con la excepción de trabajos como el descrito en el capítulo 7, la investigación moderna del mejoramiento de la memoria se ha centrado en los mnemónicamente discapacitados. Los retardados, aquellos que han sufrido daños cerebrales y los ancianos han sido estudiados desde el punto de vista de la terapia mnemónica, que busca reducir los problemas de la vida que sean consecuencia de las fallas anormales de la memoria. En este trabajo, hay un reconocimiento general de los ideales del estudio controlado y los análisis teóricos, pero en la práctica se necesita una marcada dependencia de las soluciones que ofrece el sentido común. La terapia de la memoria está diseñada para ayudar a pacientes individuales con problemas que, a menudo, son esencialmente cotidianos. Las dificultades que enfrentan los discapacitados son las mismas que tienen las personas normales pero magnificadas, y las soluciones necesarias pueden ser igual de prosaicas. Sin embargo, aunque los trabajos prácticos y de laboratorio actuales no van unidos, hay mucho para aprender sobre los procesos de la memoria a partir de su disolución en quienes sufren daño orgánico. La terapia de la memoria puede demostrar su utilidad para ayudar a los teóricos tanto como a los pacientes.

Ayudas internas y externas para la memoria

Como es poco lo que se puede hacer para mejorar la etapa de retención de la memoria, las mejoras tienen que implementarse en la codificación o en la recuperación. Algunas ayudas mnemónicas (como la repetición pura) tienen efecto en la codificación; otras técnicas (como el ajuste del contexto y las condiciones imperantes para que resulten similares a los que había en el momento de la codificación) pueden considerarse importantes en la etapa de recuperación. Pero, en la práctica, muchas de las mejores técnicas mnemónicas operan tanto en la codificación como en la recuperación. Con

frecuencia, se emplea una estructura conocida para organizar la información en la codificación y luego se recurre a la misma estructura para su recuperación (ver las técnicas de Steve Faloon descritas en el capítulo 7). Un ejemplo de ello es la categorización. Se agrupan en categorías las palabras que se quieren recordar para su ensayo y luego, al recordarlas, también se recuperan según su categoría.

La distinción entre ayudas memorísticas internas y externas (Wilson y Moffat, 1984) se relaciona con esta función de codificación/recuperación, aunque no se superpone completamente. Las ayudas internas son las mnemotécnicas, como las imágenes del sistema de Lorayne para recordar nombres. Son internas a la psique del individuo y pueden funcionar en la codificación, en la recuperación o en ambas. Por su parte, las ayudas externas existen en el medio: las notas escritas para uno mismo, los relojes con alarma, los nudos en los pañuelos y las manipulaciones del medio (como dejar un paquete junto a la puerta de calle para no olvidarse de llevarlo al salir). Aunque algunas ayudas externas pueden actuar como pistas para la recuperación, su propósito más frecuente es promover acciones más que recuperar información.

Las ayudas externas nos recuerdan algo que hay que *hacer*, quizá sugiriendo sólo indirectamente qué es ese algo. Las ayudas internas *pueden* servir como promotoras de la acción (Lorayne y Lucas, 1974) pero esa no es su función usual, al menos en nuestra cultura.

Las ayudas externas suelen emplearse en la vida cotidiana para recordar que tenemos que hacer cosas. Pero hace muy poco tiempo que los psicólogos experimentales han comenzado a estudiar el empleo de ayudas externas y los métodos que la gente usa para ayudarse a sí misma a recordar lo que tienen que hacer (Harris, 1980a; 1984). En parte, esto se debe a la importancia de estos dos tópicos para la terapia de la memoria. También es indicador de la tendencia existente hacia los estudios del rendimiento de la memoria práctica (por ejemplo, Gruneberg, Morris y Sykes, 1978).

Una vez establecida una base para el estudio del mejoramiento de la memoria, veamos ahora algo de lo que se sabe sobre el tema.

Mejora de la memoria de la gente normal

Como se dijo antes, el mejoramiento de la memoria de la gente normal se ha basado, por lo general, en el uso de una u otra técnica mnemónicas. Pero el dominio de un conjunto de técnicas mnemónicas no es lo único

que existe para la memorización inteligente. La capacidad de emplear estrategias (o técnicas mnemónicas) es tan importante como la comprensión de las circunstancias adecuadas para ponerlas en uso, que ya ha sido llamado *metamemoria* en el capítulo 6. Mejorar el rendimiento de la memoria en algún campo de actividad implica, en primer lugar, una evaluación cuidadosa de las exigencias memorísticas que presenta la actividad, las condiciones probables de recuerdo, etc. Una vez terminado este análisis, es posible comenzar a formular un plan de acción, evaluando la viabilidad de las diferentes estrategias y las formas en que éstas podrían adaptarse fructíferamente a la tarea en cuestión. La utilización real de una estrategia mnemónica es el último paso en el proceso de memorización inteligente. Por ejemplo, aprender un idioma extranjero requiere memorización en muchos niveles, desde las palabras hasta las reglas de conjugación y las normas gramaticales. Además, los objetivos y necesidades de los alumnos variarán según sus propósitos: ¿Quieren aprender a leer en la lengua extranjera o a hablarla? ¿O las dos cosas? ¿Necesitarán conversar socialmente o están dispuestos a limitarse a hablar de ciertos temas técnicos? Sin una evaluación de esa naturaleza, las técnicas mnemónicas no pueden proporcionar más que una ayuda fragmentaria. Pero, junto con el análisis completo de las tareas, la aplicación sistemática de las técnicas puede ser una ayuda efectiva para el aprendizaje del idioma (Gruneberg, 1985).

Mnemotécnicas verbales

La estructura impuesta al material por las técnicas mnemónicas verbales suele ser la del ritmo o la de la rima, como en la rima para recordar los días del mes (capítulo 5). El ritmo es un principio natural de organización y muchos sujetos lo adoptan de manera espontánea en los experimentos de recuerdo de dígitos, agrupando de a tres o cuatro ítem que son presentados a un ritmo constante, para su ensayo. Los agrupamientos rítmicos fueron construidos a propósito en el diseño de los códigos postales británicos, la mayoría de los cuales tiene la forma letra-letra-dígito, dígito-letra-letra.

El uso más sorprendente del ritmo y la rima para propósitos mnemónicos se encuentra en las historias y genealogías orales de las culturas sin escritura, como en la epopeya homérica (Lord, 1982; Bateson, 1982). Los bardos expertos pueden recitar muchos cientos (e incluso miles) de versos. Y no lo hacen recordando sus canciones palabra por palabra sino componiéndolas

nuevamente en cada recitado, según fórmulas y temas. Al acotar el proceso de reconstrucción, el metro del verso actúa como guía para la memoria. En las sociedades orales no hay epopeyas en prosa precisamente porque la prosa carece de las propiedades mnemotécnicas del verso.

Naturalmente, la propia trama de la historia es un elemento mnemónico importante de la narración épica. Las virtudes educativas de la narrativa siempre han sido reconocidas y en todas las culturas abundan las fábulas, parábolas y cuentos morales. Si no hay metro, la narrativa adopta una escala menor que la épica, pero hasta la estructura de la historia más simple (comienzo-medio-final) tiene características mnemónicas. Así como los Kpelle demostraban una mejor memoria para las palabras incluidas en una historia que para las mismas palabras en una lista de vocablos aislados, también los occidentales recuerdan más palabras cuando se les pide que creen historias que las vinculen que cuando sencillamente repiten las palabras (Bower, 1972).

Además del ritmo y la narración, algunas técnicas mnemónicas verbales sustituyen las palabras o consonantes por números que se deben recordar. Estos sistemas se desarrollaron especialmente para ocuparse de la memorización de cosas tales como las fechas, aunque en algunos casos se las puede generalizar a otros campos. Hunter (1964) y Norman (1976) ofrecen algunos ejemplos, además de cierto marco histórico.

Mnemotécnicas de imágenes visuales

Los recursos mnemotécnicos con imágenes visuales son los más comunes y utilizados. Quizá el más simple sea el que Hunter (1964) denominó sistema de comparaciones sucesivas. Se lo puede usar para recordar cualquier lista de ítem (como palabras) siempre que cada uno de ellos pueda representarse mediante una imagen visual. Para empezar, los dos primeros ítem deben imaginarse juntos tan vívidamente como se pueda. Luego, se produce una nueva imagen para vincular el segundo ítem con el tercero, y así sucesivamente. Este es un método de encadenamiento muy sencillo y se puede hacer cualquier clase de asociación entre ítem. El método puede generalizarse y usarse no sólo con palabras, sino siempre que se pueda representar todo con imágenes; así, también una secuencia de ideas o de acciones puede memorizarse con este método.

El recurso mnemotécnico de comparación sucesiva es el menos estructurado de todos los que se basan en imágenes visuales, ya que sólo tiene la estructura lineal de conexiones diseñada por el individuo. Otro sistema es el recurso de la "palabra asociada", para el cual hay que aprenderse una rima como la siguiente: "Uno es un tribuno, dos tiene tos, tres está al revés..." y así hasta el diez. El primer ítem que debe memorizarse, entonces, se imagina en interacción con un tribuno. Así, si el primer ítem fuera la palabra "ventana", se podría pensar en un tribuno romano atravesando de un salto una inmensa ventana. Las imágenes producidas deben ser tan detalladas y vívidas como sea posible. Después de este paso, se imagina el segundo ítem "con tos", y así sucesivamente. Este método conlleva cierta estructura, ya que incluye una secuencia hiperaprendida de numerales. Hunter (1964) demostró que un grupo de gente a la que se le enseñara esta técnica recordaría muchas más palabras que un grupo de control al que no se le enseñara. Igual que las comparaciones sucesivas, el método es generalizable a cualquier campo que pueda entrar en la imaginería visual.

El recurso mnemotécnico visual más común es también el más estructurado. Es conocido como método de loci, por la palabra latina *locus*, que significa "lugar". El método, que fue desarrollado en gran detalle por los oradores romanos, se basa en el conocimiento del plano de un edificio en particular, o de los hitos en un camino familiar. Si hay que aprender de memoria una lista de ítem, o una sucesión de ideas para un discurso, lo único que hay que hacer es un recorrido imaginario por ese edificio, depositando (por así decirlo) una imagen de cada idea en cada habitación, sucesivamente. Si el orden en que se recorren las habitaciones es siempre el mismo, las ideas podrán recuperarse serialmente repitiendo la caminata imaginaria. Cuanto más ricas son las imágenes empleadas, más confiable se torna el método, y si se imagina una habitación en detalle, puede depositarse más de una idea dentro de ella, siempre que cada una siga inmediatamente a alguna característica prominente. La esencia de este sistema es que una secuencia conocida de lugares proporciona una estructura en la que se pueden incorporar nuevas informaciones.

El Método de *loci* tiene muchos puntos a favor. El más importante es que es altamente efectivo, incluso cuando se lo emplea por primera vez. Sin embargo, como sucede con toda técnica de memorización, con la práctica del método se obtienen mejoras radicales.

Por qué funcionan los recursos mnemotécnicos

En esta sección nos ocuparemos brevemente de dos preguntas que tienen que ver con los recursos mnemotécnicos. En primer lugar, ¿por qué funcionan estos recursos? En segundo lugar, ¿por qué las historias y las imágenes visuales tienen una importancia mnemónica tan grande?

La respuesta a la primera pregunta es que los recursos mnemotécnicos sirven porque imponen organización al material que se debe recordar. La estructura del sistema mnemotécnico proporciona un plan de recuperación que dirige la búsqueda de la información deseada: actúa como marco.

Esto nos lleva a la segunda pregunta: ¿por qué las historias y las imágenes visuales resultan métodos tan buenos para fijar la información en un determinado contexto? Una posibilidad es que, al crear o comprender una historia, la gente automáticamente genera imágenes del material, de modo que los dos métodos son, en realidad, el mismo. Pero, sean o no distintos, es probable que resulten efectivos porque ambos incluyen un procesamiento profundo y elaborado que, como vimos en el capítulo 5, es importante para determinar la memorabilidad. Una razón para creer que ésta puede ser la función esencial de la enseñanza de imágenes es que, aunque hay grandes variaciones individuales en la capacidad aportada para crear imágenes visuales, los efectos que produce son bastante uniformes.

El mejoramiento de la memoria en los niños con retardo mental leve

Los recientes intentos para mejorar el rendimiento de la memoria de los niños con retardo mental leve ("educables") han estado estrechamente vinculados a las investigaciones sobre el desarrollo de la memoria en los niños normales (ver capítulo 6). Antes, se pensaba que los niños retardados eran neurológicamente diferentes de los normales porque su cerebro no retenía tan bien la información ya codificada, pero el enfoque más reciente considera que el déficit aparece en el mismo proceso de codificación (Kail, 1984). Los niños levemente retardados suelen tener el mismo rendimiento (o casi) que los niños normales en las pruebas de reconocimiento de la memoria. Pero cuando se les pide que realicen la memorización más activa propia de las pruebas de recuerdo, se observa una disminución del rendimiento. Se ha descubierto que los adolescentes con retardo no tienden a involucrarse

en ensayos espontáneos para preparar el recuerdo (Belmont y Butterfield, 1971) y no suelen organizar su recuerdo en categorías (Spitz, 1966). En otras palabras, en estas pruebas los adolescentes con retardos leves demostraron la misma falta de estrategias mnemotécnicas que habían exhibido los niños normales muy pequeños.

Como en el caso de los niños normales pequeños, la siguiente pregunta era si se podía entrenar a los adolescentes con retardo para que emplearan estrategias mnemotécnicas. Una vez más, la respuesta fue afirmativa. Belmont y Butterfield pudieron entrenar a los retardados para que realizaran ensayos y su rendimiento mejoró como consecuencia de ello. Sin embargo, después de una semana el efecto del entrenamiento había desaparecido por completo. Pero cuando se realiza un entrenamiento a largo plazo, sus resultados pueden ser más duraderos y se automatiza —o "hiperaprende"— el uso de estrategias (Brown, Campione y Murphy, 1974). De modo que se puede mejorar el rendimiento de los retardados tanto en el corto como en el largo plazo. Y cuando no sólo se ejercita una estrategia sino que también se explica su objetivo a los niños retardados y se les enseñan hábitos de autocontrol que los niños normales adquieren espontáneamente, se obtienen resultados aún mejores (Wong y Jones, 1982; ver también el capítulo 12). Esos métodos también crean mayores posibilidades de transferir el entrenamiento.

Esa transferencia consiste en ver los nuevos problemas como análogos a los viejos y comprender que las habilidades que ya se poseen pueden utilizarse para resolverlos. El logro de esa transferencia es un problema perenne de toda forma de educación y entrenamiento, pero en las personas con retardo suele ser particularmente pobre. Los primeros estudios hallaron que incluso las habilidades de ensayo simples no se generalizaban espontáneamente a estrategias que apenas diferían del original. Sin embargo, cuando el entrenamiento en estrategias va acompañado de discusión, sugerencias y entrenamiento en habilidades metacognitivas como el autocontrol, se observa una mejor capacidad de transferencia (Campione y Brown, 1984; Wong y Jones, 1982). Lo mismo sucede con los niños y adultos normales, pero en el caso de las personas con retardo la transferencia tiende a ser más limitada, exige ayudas mayores y más explícitas que en los demás y puede fracasar por completo.

Para resumir esta sección: la expresión "con retardo" se aplica a las personas de la que hemos estado hablando. El curso de su desarrollo es normal pero mucho más lento y por lo general se detiene en una etapa temprana. El desarrollo de las habilidades cognitivas se ve inhibido a todo nivel y es-

pecialmente en las habilidades superiores. El aumento del rendimiento en las tareas de memoria simples es posible y se pueden lograr *insights* frágiles en su propio funcionamiento cognitivo, pero estos éxitos son escasos y sigue siendo difícil consolidarlos.

Terapia de la memoria para aquellos que han sufrido daño cerebral

En respuesta a los hallazgos de laboratorio, se ha enseñado a pacientes que han sufrido daño cerebral a codificar la información profundamente, a recurrir a sistemas de "palabra asociada", a emplear el método de loci, a agrupar la información, a aplicar la técnica mnemónica de las primeras letras para listas de compras, a intentar recordar nombres con el sistema de Lorayne y a recurrir a técnicas de estudio desarrolladas para ayudar en el aprendizaje escolar. Todos estos métodos parecen resultar útiles para algunos pacientes en algunas tareas, y su efectividad ha sido evaluada por Powell (1981) y por Wilson y Moffat (1984).

Parte de la destreza del terapeuta radica en adecuar un método en particular a un paciente en particular. Wilson y Moffat sugieren que los pacientes con daño en uno solo de los hemisferios cerebrales, como suele suceder en las apoplejías, pueden adecuarse selectivamente a sistemas mnemónicos apropiados. Se puede alentar a quienes han sufrido daños en el hemisferio cerebral izquierdo y tienen dificultades con el habla a que adopten mnemotécnicas visuales, mientras que a aquellos que han sufrido daños en el hemisferio cerebral derecho y tienen su capacidad de imaginación reducida se les pueden enseñar mnemotécnicas verbales. También se sugiere una adaptación en los pacientes que tienen dificultades específicas para materiales presentados de manera auditiva o visual. En ambos tipos de ajuste, se aprovecha el hecho de que aquello que ayuda a la gente normal a recordar también ayudará, en conjunto, a los que han sufrido daño cerebral. Pero no siempre sucede así. Por ejemplo, varios estudios han hallado que el sistema de memorización de nombres de Lorayne resulta demasiado complejo para el aprendizaje de los pacientes con graves dificultades con los nombres.

Quienes no tengan experiencia con pacientes con daño cerebral pueden tener dificultades para imaginar la magnitud de los problemas que a veces hay que enfrentar. Un ejemplo puede ayudar. Wilson y Moffat describen el caso de un paciente que podía recordar los nombres de tres de sus fisioterapeutas sólo si le decían con qué letra empezaba. Una cuarta fisioterapeu-

ta, llamada Anita, le dijo que podría recordar su nombre fácilmente porque ella tenía *a neater way of doing her hair*[1], y sacudió su cabello. Después de esto, cada vez que ella repetía el gesto, él podía recordar su nombre. Por desgracia, hacía lo mismo con cada mujer que sacudiera su cabello frente a él. El nombre se había ligado a la acción en vez de unirse a la persona.

Cuando se trata de individuos imposibilitados, las mínimas innovaciones pueden devengar, a veces, grandes beneficios, tanto para los pacientes como para quienes los atienden. Harris (1980b) describe cómo en una guardia (más geriátrica que de pacientes con daño cerebral) se redujo la tasa de incontinencia pintando las puertas de los baños de un color distinto al de todas las demás puertas. Esta señal ambiental promovió una conducta adecuada que, de otro modo, no se hubiera producido. De manera similar, los hospitales y centros de rehabilitación suelen recurrir a líneas de tiza en las paredes y el piso para guiar a los pacientes de un sector del edificio a otro. Las señales ambientales de esta clase no son diferentes en principio de las que facilitan muchas conductas automáticas y semiautomáticas en la vida cotidiana. Actúan como ayudas externas y públicas para la memoria (ver capítulo 2).

Wilson y Moffat sugieren que las ayudas externas para la memoria son especialmente aplicables en los casos de amnesia global. Algunas ayudas "obvias", como las agendas de bolsillo, son poco útiles para estos casos porque los pacientes olvidan consultarlas. Una forma de superar este obstáculo es una alarma que suene de vez en cuando y le recuerde así al paciente que debe consultar su agenda. Fowler, Hart y Sheehan (1972) hallaron que después de varias semanas el hábito de consultar la lista se había arraigado profundamente y se podía prescindir de la alarma. En la actualidad, se venden ayudas electrónicas para la memoria, que pueden almacenar información permanente, como el nombre del paciente, su domicilio y demás, y también se pueden programar con mensajes diarios importantes y proporcionar señales recordatorias auditivas. Jones y Adam (1979) han evaluado estas ayudas. En muchos sentidos, muestran pocas ventajas sobre ayudas menos sofisticadas en lo tecnológico, pero se esperan mejoras que las acerquen a tres criterios que Harris ha establecido para lograr ayudas efectivas para la memoria. Estos tres criterios son:

a) la ayuda debe tener su efecto lo más cerca posible antes de la acción deseada;

b) debe ser un recordatorio activo y no pasivo;

---

1. La pronunciación de "a neater" en inglés es muy similar a la del nombre Anita. "A neater way of doing her hair" significa: un peinado más prolijo. (N. del T.)

c) debe especificar la acción requerida (a diferencia, por ejemplo, de un nudo en un pañuelo).

La mejora del testimonio legal

Un campo importante de la investigación en memoria aplicada es el del testimonio legal. Los psicólogos ayudan al menos de dos formas en los procesos legales de evaluación de evidencias. En primer lugar, intentan influir en los procedimientos policiales y de justicia a la luz de los hallazgos de las investigaciones. En segundo lugar, los psicólogos pueden actuar como testigos expertos que aconsejan al juez y al jurado analizando los factores que pueden haber influido en un testimonio en particular. En la práctica, estas dos funciones se superponen y entre ambas cubren una enorme gama de tópicos, de los que apenas mencionaremos unos pocos aquí.

El mejoramiento del sistema

Davies (1981) ha reseñado la historia de los equipos para recuerdo de rostros (como el *identikit*) y subrayado su bajo nivel de confiabilidad. En parte, atribuye su debilidad a que recurren a la memoria de rasgos más que del conjunto del rostro. Las técnicas más modernas, basadas en el método de "rostros enteros" y ayudadas por la flexibilidad de los gráficos de computadora, prometen mejores resultados para el futuro.

La identificación hecha a partir de "modelos" o "fotos de prontuario" suele llevar a la realización de una ronda de reconocimiento, y éste es probablemente el procedimiento legal más estudiado por los psicólogos. La probabilidad de hacer una identificación correcta está sujeta a la influencia de muchos factores (Deffenbacher y Horney, 1981). La composición del grupo puede influir en el resultado. Si un testigo busca un hombre rubio y alto, y en el grupo sólo hay una persona con esas características y los demás son mujeres pequeñas y de cabello oscuro, es muy probable que el testigo lo señale. Pero aun cuando se eviten situaciones absurdas como esa, la composición del grupo que se someterá a una ronda de reconocimiento no es tema trivial. Por ejemplo, un sospechoso que se diferencia del resto del grupo por detalles más sutiles, como su ropa, su postura o su modo de caminar, corre el riesgo de sufrir una identificación incorrecta. La cantidad de personas que inte-

gra el grupo también influye en los porcentajes de detecciones verdaderas y falsas, así como lo que piensa el testigo sobre el grupo: que el sospechoso "indudablemente está" o que "puede estar" entre el grupo. En este último caso, hay menos presiones para llegar a una identificación positiva que en el anterior, y esto puede ser muy importante cuando los testigos buscan un miembro de un grupo étnico para el que su capacidad de discriminación está menos agudizada.

Deffenbacher y Horney (1981) cuentan que en Suecia, si el hecho fue visto originalmente con una visibilidad inferior a la óptima, para el proceso de identificación se reproducen las condiciones ambientales. Además, en la ronda de reconocimiento se puede hacer que el testigo recorra una habitación llena de gente que conversa. Así, no sólo hay características faciales y posturales para ayudar a la memoria del testigo sino también peculiaridades gestuales o faciales y características de la voz. Estos dos procedimientos no tradicionales actúan como una reproducción en el momento del reconocimiento de mayor cantidad de pistas para la recuperación. Proporcionando información adicional a los testigos, es más probable reconocer a los sospechosos culpables y notar que los inocentes difieren de algún modo del criminal original.

El testigo experto

Más que ayudar en los procesos de recolección de evidencias previas a un juicio, el psicólogo puede ayudar en el propio juicio. Se le pueden señalar al juez y al jurado ciertos factores influyentes en el testimonio de un testigo. Por ejemplo, se han hecho experimentos en los que los sujetos: (a) presencian un "crimen", (b) ven una serie de "fotos de prontuario" y (c) se les pide que elijan al criminal en una ronda de reconocimiento. Los resultados demostraron que era más probable que eligieran en la ronda a un "inocente" que habían visto entre las fotos de prontuario que a un individuo cuyo rostro no hubiera aparecido. En otras palabras, los rostros que son conocidos a partir de la sesión de "fotos de prontuario" se confunden con el rostro (o los rostros) del crimen. Así, la identificación de un acusado por un testigo que, en el lapso transcurrido desde el crimen, ha visto fotos del acusado en prontuarios o en los periódicos, es menos confiable que la identificación hecha por un testigo que no ha visto nada de eso.

El psicólogo también puede informar a la corte sobre las investigaciones que muestran que la confianza de los "testigos" experimentales en su testimonio no tiene relación con su precisión literal (Deffenbacher, Brown y Sturgill, 1978). También puede haber ocasiones, además de aquellas que podría observar cualquier abogado competente, en las que puede ser necesario señalar de qué forma la reconstrucción de los acontecimientos de parte de un testigo puede haber sido "guiada" por el tipo de interrogatorio realizado. Por ejemplo, Loftus y Palmer (1974) demostraron que el recuerdo de los sujetos de la velocidad a la que iban dos autos que chocaban, en un accidente filmado, dependía de si se les preguntaba a qué velocidad iban los autos cuando se *estrellaron* (65 km por hora), *chocaron* (63 km por hora), se *golpearon* (61 km por hora) o *entraron en contacto* (51 km por hora).

Ayudas para la memoria en los exámenes

Para terminar este capítulo sobre el mejoramiento de las habilidades de la memoria, nos ocuparemos de un tópico que probablemente resulte importante para la mayoría de los lectores del libro: cómo mejorar el rendimiento en los exámenes.

Beard y Hartley (1984) reseñaron las investigaciones existentes sobre la preparación para los exámenes y los exámenes mismos. Para este capítulo, las ideas fundamentales de estos autores son:

a) que los alumnos deben *organizar* sus actividades de revisión;

b) que los alumnos deben revisar *activamente* en vez de hacerlo pasivamente;

c) que los alumnos necesitan *práctica* de exámenes si quieren mejorar su habilidad en este sentido.

En cuanto a la organización, se sugiere que los alumnos estudien exámenes anteriores para ver cuáles son los requisitos de cada examen en particular, tanto en lo que hace a su estructura como a sus contenidos. Beard y Hartley también sostienen que los alumnos deben pensar en horarios de revisión para poder planificar cómo espaciar su revisión sistemáticamente en vez de repasar apresuradamente todo la noche anterior al examen. (Las ventajas de esta práctica de espaciamiento fueron analizadas en el capítulo 3.) La revisión de último momento puede resultar útil (en especial si antes se ha hecho revisión espaciada) porque:

- se pueden unir los puntos sueltos;
- se pueden obtener perspectivas del curso completo;
- es más eficiente refrescar finalmente la memoria a partir de notas.

Por su parte, la revisión espaciada:

- asegura una cobertura más completa del programa;
- facilita una tarea que intimida, dividiéndola en partes manejables;
- supera el problema del cansancio, las enfermedades, etc., que puede intensificarse o aparecer hacia el final de un curso (James, 1967).

Beard y Hartley también ofrecen una lista de estrategias de revisión activas, que incluyen las bien conocidas actividades de subrayado, resumen y escritura de respuestas a preguntas de exámenes, ya sea en forma de notas o como respuestas completas. También incluyen estrategias menos frecuentes, como la explicación de tópicos a compañeros que no están familiarizados con ellos y las reuniones en grupos pequeños para repasar temas específicos, elaborar respuestas para determinadas preguntas y preparar bosquejos sobre tópicos específicos. Las ventajas del uso de estas estrategias son las que se esbozan en los capítulos 5 y 7: cuanto más profundamente se procese el material y más completamente se lo organice e interrelacione, mejor se lo recordará.

Finalmente, Beard y Hartley señalan que el simple hecho de permitir que los alumnos practiquen los exámenes puede mejorar su rendimiento, y que es posible considerar los exámenes como una habilidad. Como todas las habilidades, hay ciertas subrutinas útiles que conviene practicar, entre las cuales se cuentan la lectura exhaustiva de la pregunta y la recuperación del material adecuado. La práctica, y la automaticidad que de ella se deriva, es especialmente importante, porque los alumnos que rinden exámenes frecuentemente están ansiosos, y la ansiedad interrumpe la ejecución fluida de subrutinas (ver capítulo 2). La tabla 8.1 propone algunas técnicas valiosas para que los alumnos puedan practicar.

Tabla 8.1. Notas sobre técnicas para exámenes (basadas en sugerencias de A.B. Hill).

1. No llegues más de 10 minutos antes de que comience el examen, a menos que sea imprescindible.

2. Cuando llegues, no hables con tus amgios sobre el repaso que tú o ellos hayan hecho.

3. Verifica las instrucciones y luego lee *todas* las preguntas dos veces, lenta y cuidadosamente, antes de elegir las que contestarás.

4. Piensa cuánto tiempo tienes para contestar cada pregunta. Por ejemplo, si tienes que responder tres preguntas en dos horas, significa que dispones de 40 minutos para cada pregunta. *Respeta este límite estrictamente*. Si te queda tiempo después de contestar todas las preguntas, completa las que hayas dejado inconclusas por tu límite de tiempo. Si terminas todas las preguntas y te sobra tiempo, relee tus respuestas y corrígelas.

5. Asegúrate de responder las preguntas obligatorias.

6. Verifica cuidadosamente qué te exigen las preguntas elegidas. Por ejemplo, si la pregunta dice "Evaluá..." o "Realiza un análisis crítico de..." asegúrate de que tu respuesta sea una *evaluación* o *una crítica*. Es fácil dar una respuesta que no es relevante para la pregunta si uno no se asegura exactamente qué es lo que se le pide.

7. Para que tus respuestas sean relevantes y coherentes y para asegurarte de decir todo lo que puedes o todo lo que quieres, confecciona una lista que incluya los puntos importantes *antes de empezar a escribir tu respuesta*. Numéralos en el orden que quieres que tengan y táchalos cuando los vayas incluyendo en la respuesta.

8. *Asegúrate* de responder *todas* las preguntas; es decir, si tienes que responder tres preguntas, *asegúrate* de intentar responder las tres y no sólo dos o dos y media. Si respondes sólo dos de tres preguntas, tu calificación máxima posible (si tus respuestas son perfectas) será del 66,6%.

9. Si puedes elegir entre preguntas que requieran conocimientos específicos y preguntas generales, elige las preguntas específicas a menos que tengas plena confianza en tu capacidad para responder a las generales. Es más fácil responder adecuadamente en ellas.

10. Si te pones nervioso o entras en pánico, intenta calmarte haciendo dos o tres minutos de práctica de relajación.

11. Después de salir del examen, no comentes con tus amigos las preguntas que elegiste o las respuestas que diste.

Resumen

En este capítulo analizamos cómo puede aplicarse lo que se sabe sobre la memoria humana para mejorar su rendimiento en diferentes grupos de gente, en distintas circunstancias. Los recursos mnemotécnicos usados para amplificar los recuerdos de la gente común pueden entenderse dentro del sistema de habilidades de memoria presentado en este libro, y los datos sobre el rendimiento de los que tienen retardo leve también se ajustan bien a la teoría. En el campo de la terapia de la memoria para aquellos que presentan daño cerebral, la teoría ofrece cierta comprensión de los déficit adquiridos pero las ayudas para su mejora deben pensarse en cada caso individual. De manera similar, el rendimiento de los testigos oculares se ve influido por múltiples factores, de los cuales sólo algunos tienen, hasta ahora, explicación teórica.

Sección 3

Las habilidades de comprensión y comunicación

9

Las habilidades del hablante

Don Rogers

En muchos sentidos, hablar es la habilidad humana más característica. Es exclusivamente humana y, además, demuestra fehacientemente muchos de los rasgos de otras habilidades motrices e intelectuales que se comentan en otras partes de este libro (ver especialmente los capítulos 2 y 3).

En el mundo se hablan cientos de lenguas diferentes. Algunas sólo cuentan con unos pocos hablantes nativos en tanto que otras son habladas por millones de personas. Algunos de estos idiomas son muy diferentes de otros: por ejemplo, los que tienen una tradición escrita muy desarrollada tienen también grandes cantidades de palabras poco usadas, que la mayoría de los hablantes de ese idioma no conocen (cosa que se puede comprobar mirando cualquier diccionario grande de castellano); algunos tienen un vocabulario especializado bien desarrollado, del que otros idiomas carecen (por ejemplo, las lenguas esquimales tienen muchas palabras para los diferentes tipos de nieve, mientras que los idiomas de regiones tropicales no las necesitan); y algunos idiomas usan recursos gramaticales muy diferentes. Por ejemplo, idiomas como el inglés indican las relaciones gramaticales como sujeto y objeto mediante el orden de las palabras: *John liked Mary* es diferente de *Mary liked John*, mientras que para los idiomas como el ruso o el latín el orden de las palabras es menos importante y sujeto y objeto se indican mediante las diversas terminaciones de sus sustantivos.

Si bien los idiomas muestran diferencias entre sí, éstas son comparativamente menores. Hay ciertos puntos importantes que se aplican al lenguaje en general y que serán el tema de este análisis de las habilidades del habla. Pero antes, vale la pena hacer dos aclaraciones preliminares. En primer lugar, todos los humanos pueden aprender a usar el lenguaje, aunque con excepciones, ya que algunas formas de evolución anormal pueden asociarse con la incapacidad para usarlo; pero de todas formas es sorprendente que los niños sordos profundos puedan aprender a usar lenguaje de signos, que haya casos de niños que han aprendido a comunicarse lingüísticamente aunque son ciegos y sordos y que existan otros niños que han estado encerrados y no han

hablado los primeros cinco o seis años de su vida pero que, al entrar en contacto con un medio normal, rápidamente han aprendido a hablar de una manera relativamente normal. (Ver Clarke y Clarke, 1976, por detalles sobre algunos de esos estudios.)

En segundo lugar, no hay especie, además de la humana, que parezca capaz de usar el lenguaje. Los loros pueden imitar el habla, los perros saben expresar emociones y deseos, pero nada de esto se acerca al lenguaje. Lo más cercano que parece haber al lenguaje humano es el caso de los chimpancés y otros primates a los que se les ha enseñado a usar lenguaje de signos: el sistema de comunicación usado por los sordomudos en los Estados Unidos. Al principio, estos estudios alimentaron las esperanzas de que los animales podrían aprender a usar el lenguaje de manera plena, pero actualmente parece que, si bien los chimpancés pueden aprender unos cuantos cientos de signos (más o menos equivalentes a palabras), no pueden combinarlos rápidamente para producir "oraciones" nuevas (Terrace y otros, 1980).

Esta productividad combinatoria es lo más impresionante del lenguaje. El lenguaje es creativo. Podemos producir fácilmente una oración que nadie ha dicho antes y no nos sorprende que esa oración resulte comprensible.

El lenguaje obtiene este recurso productivo de la forma en que se estructura. Cualquier lenguaje hablado tiene unos pocos sonidos que pueden combinarse para producir miles de palabras, que a su vez pueden combinarse según la gramática de la lengua y producir infinitas oraciones. Los hablantes de una lengua pueden fácilmente producir oraciones "legítimas" desde el punto de vista de la gramática y pueden entender fácilmente esas oraciones.

Los usuarios del lenguaje pueden ser tanto hablantes como oyentes: productores y receptores de lenguaje. En este capítulo nos ocuparemos de la producción del habla y, en el próximo, de la comprensión.

Hablar como habilidad

Habiendo visto que el lenguaje es una característica exclusivamente humana, analicemos ahora en qué sentido se puede decir que hablar es una habilidad. Recordemos que en el capítulo 2 se señaló que la persona experta es aquella que actúa con fluidez, rapidez, automáticamente (es decir, sin pensar conscientemente en todos los aspectos de la tarea), puede integrar diferentes componentes de la actividad simultáneamente y producir (habitual-

mente) el componente preciso en el momento justo. Lo mismo puede decirse del hablante experto.

Fluidez

Cuando un niño pequeño comienza a hablar, suele empezar diciendo de a una palabra por vez. Por ejemplo, si un niño de unos 18 meses ve a un perro levantando una pelota, quizá diga algo parecido a "perro" o a "pelota". Si tiene más experiencia con el habla, podrá usar ambas palabras, pero no juntas, así que quizá diga: "Perro... pelota". Con el tiempo, podrá unir las dos palabras en una sola emisión: "Perro, pelota"; "Perro, mordió"; etc. El niño mayor puede unir varias palabras en una sola emisión, con una sola curva de entonación, para expresar un pensamiento: "El perrito malo me lamió la mano". Como veremos en este capítulo, el discurso fluido de los adultos no carece de vacilaciones y pausas —según Goldman-Eisler, "dos tercios del lenguaje hablado vienen en grupos de menos de seis palabras" (ver Beattie, 1983)— pero de todos modos, aunque no sea totalmente fluido, el lenguaje de un adulto muestra muchas más palabras entre las pausas que el discurso de un niño pequeño. Y, por supuesto, como se vio en los capítulos 2 y 3, este agrupamiento de salida es una característica típica de todo tipo de habilidad.

Rapidez

Vacilaciones aparte, el hablante de inglés normalmente dice entre dos y tres palabras por segundo. Cada palabra tiene un promedio de cinco sonidos, lo cual significa que el hablante produce unos 12,5 sonidos por segundo. Si cada uno de estos sonidos fuera independiente de los demás, la velocidad de decisión debería ser imposiblemente rápida. Pero, naturalmente, no son independientes: los sonidos se agrupan en palabras; las palabras, en frases; las frases, en proposiciones (una oración puede estar integrada por una proposición o más, cada una de las cuales contiene un verbo). Los sonidos de una palabra y las palabras de una proposición se relacionan entre sí de manera tal que, juntos, los sonidos producen una palabra significativa o las palabras producen una cláusula significativa. Y, como veremos, en vez de tomar una decisión separada independiente sobre cada sonido, el hablante planifica por adelantado, exhibiendo la anticipación que también se observa en todas las demás actividades expertas.

Automaticidad

Una característica del desempeño experto es que el que lo realiza es inconsciente de los detalles de su actuación: sólo le preocupa la planificación de nivel superior y los detalles se resuelven mediante un "piloto automático". Como veremos, el habla posee la misma característica jerárquica: el hablante se ocupa de contar una historia, transmitir información, convencer a alguien de su inocencia o lo que sea; no planifica conscientemente el uso del plural o del singular para el sustantivo que está usando. Esto se lo deja a una subrutina bien ejercitada; y, si no hay perturbación, intoxicación o dificultad alguna; suele ser lo adecuado.

Simultaneidad

Igual que manejar un auto, hablar implica hacer varias cosas diferentes al mismo tiempo. Esto es evidente cuando alguien habla y, simultáneamente, mueve sus manos, su cuerpo y sus ojos y cambia su expresión facial. Se dice: "Hablamos con nuestras bocas pero conversamos con todo el cuerpo" (ver capítulo 11).

La simultaneidad también puede verse en la forma en que anticipamos lo que vamos a decir mientras decimos otra cosa. A veces esto nos lleva a cometer errores y decimos, por ejemplo, "el jran jinete" en vez de "el gran jinete", pero habitualmente no suele suceder; como la anticipación siempre está presente. Un ejemplo sencillo mostrará una forma de anticipación: diga la palabra "cruzo"; luego, diga "craso". Puede observar que sus labios ya se están cerrando para formar el sonido "u" mientras pronuncia la "r" o incluso la "c" inicial de "cruzo", mientras que se abren al decir esos mismos sonidos cuando les sigue la "a" de "craso" (Fodor, Bever y Garrett, 1974).[1]

Como uno planifica por adelantado lo que va a decir mientras está diciendo otra cosa, es evidente que existe cierta forma de simultaneidad dentro mismo de diferentes aspectos de la habilidad del lenguaje. Además, naturalmente, la gente puede hablar mientras camina, cocina, maneja o realiza casi cualquier otra actividad.

---

1. Los ejemplos usados en castellano en este capítulo y en otros son equivalentes a los del original en inglés. (N. del T.)

Conocimiento

El último aspecto de la habilidad que se menciona en el capítulo 2 incluye la observación común de que el individuo experto puede traer un ítem de la memoria durante la ejecución de una serie de acciones, pero en otra ocasión bien puede no traerlo. Evidentemente, lo mismo sucede en el caso del habla. A pesar de las vacilaciones y de las raras ocasiones en que no recordamos alguna palabra, el discurso avanza con bastante fluidez y la palabra adecuada se produce en el lugar correcto de la oración en la mayoría de los casos. Pero esto no sucede cuando a uno le piden que diga una palabra exclusivamente a partir de su significado. Mientras escribo esto, mi hija intenta resolver un crucigrama y de vez en cuando me pregunta, por ejemplo: "¿Qué palabra tiene siete letras, significa cansar y empieza con *d*?" Por lo general, no puedo contestarle.

Producir la palabra correcta en el momento adecuado al decir una oración nos exige planificar por adelantado. En el capítulo 2, esto se analizó en términos de un "apilamiento de objetivos". Uno podría ocuparse de elaborar, por ejemplo, el apilamiento de objetivos involucrado en el relato de la historia de Cenicienta.

Hablar es, entonces, una conducta experta no muy distinta de las demás conductas expertas. Se necesita mucho tiempo para adquirir habilidades: se dice que se necesitan unas 10.000 horas de práctica para llegar a ser un experto, ya sea un maestro de ajedrez o un compositor. Pero, después de todo, 10.000 horas es menos de tres horas por día durante 10 años, de modo que al terminar la escuela primaria los niños ya han tenido práctica suficiente como para ser expertos en las habilidades del lenguaje.

El arte de hablar

Hay varios problemas en el estudio del discurso y en particular en la observación de los procesos cognitivos involucrados en la decisión del hablante sobre lo que va a decir. Es evidente que el hablante tiene muchas posibilidades abiertas ante sí: elecciones sobre el tópico, elecciones sobre la selección de puntos relevantes que se quieren destacar, cómo se los ordenará y vinculará para contar, por ejemplo, una historia o una broma, elecciones sobre cómo expresar un punto en particular y cómo afectará al oyente, elecciones de estructuras gramaticales específicas, elecciones de palabras y frases

entre las muchas que pueden transmitir la misma idea, elecciones sobre el tono de voz y el acento adecuados, etc. En el próximo capítulo veremos que los hablantes deben tener en cuenta qué saben y qué creen sus oyentes, deben enmarcar su discurso según las necesidades y propósitos que le atribuyen al oyente y deben intentar hacer que su discurso sea socialmente adecuado (no contar bromas en un funeral, por ejemplo). Pero por el momento nos bastará con observar que las elecciones del hablante no sólo afectan la medida en que el oyente puede comprender lo que se dice sino también la medida en que el oyente estará interesado, le gustará el hablante, la condición social que le atribuirá, etc.

Precisamente porque hay tantas elecciones abiertas a los hablantes y tantos factores que afectan esas elecciones, es extraordinariamente difícil para el psicólogo entender los procesos subyacentes. En este capítulo analizaremos tres técnicas que se han empleado para examinar los procesos cognitivos involucrados cuando un hablante habla.

En la primera técnica, se les da a los individuos alguna tarea: describir sus departamentos, contar una historia o una película, dar instrucciones sobre el camino que se debe seguir para llegar a algún lugar, etc., y se examinan los contenidos de sus discursos. En la segunda de las técnicas, se supone que los procesos involucrados en la toma de decisiones se reflejarán en dudas y pausas en el discurso, de modo que se examinan estas dudas y pausas para descubrir con qué frecuencia y en qué circunstancias se producen. En la tercera técnica, se examinan los errores del habla, con la esperanza de que si se observan los casos en que algo sale mal en el desempeño de alguna acción experta, se pueden hacer deducciones sobre el caso normal en que las cosas salen bien. Estas tres técnicas se ajustan con bastante naturalidad a diferentes niveles de planificación del discurso: el análisis de contenidos es más útil al examinar las elecciones hechas en un nivel global de planificación estratégica, en el que se toman decisiones sobre los puntos que se plantearán y el orden en que se los mencionará; el análisis de las dudas resulta más útil en un nivel intermedio de planificación y el análisis de errores es útil para examinar la planificación puntual en el nivel de la frase o la proposición.

Planificación de largo alcance

Un hablante que se embarca en una descripción es, en cierto sentido, como un explorador, ya que tiene que planificar su ruta por adelantado. En

particular, tiene que pensar en: a) qué puntos debe mencionar; b) en qué orden debe mencionarlos; c) cuál es el nivel de detalle adecuado. El proceso puede ser altamente deliberado y bien estructurado, como en la escritura de un plan para una composición (ver capítulo 12), pero por lo general no es así; el pensamiento involucrado parece ser extremadamente rápido.

Un estudio clásico de la planificación es el de Linde y Labov (1975), en el que se grabaron las respuestas de un grupo de neoyorquinos a la pregunta: "¿Puede contarme cómo es su departamento?". Este estudio es muy atractivo, porque es real: aunque los datos sirvieron para el análisis lingüístico, fueron grabados como si fueran parte de una encuesta sobre la vida en la ciudad de Nueva York.

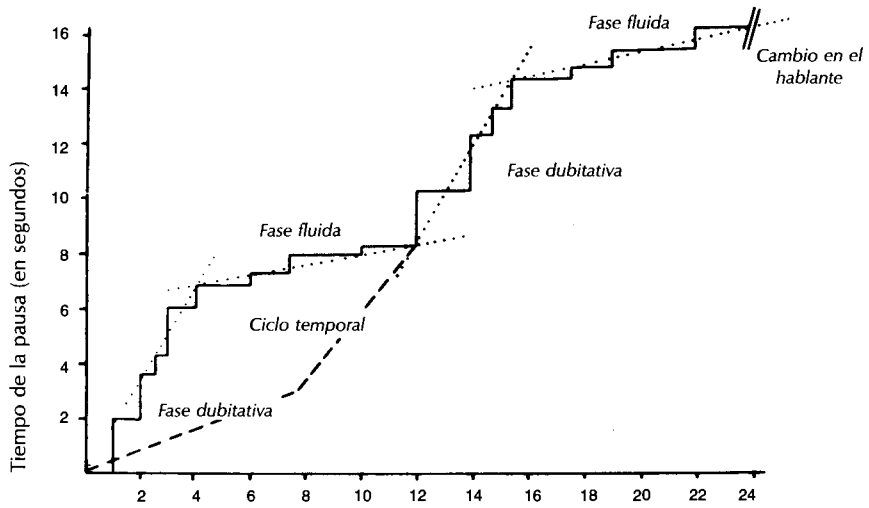
Todos los que respondieron resolvieron los tres problemas antes mencionados de la misma manera. El 97% de los encuestados realizó una recorrida imaginaria por su departamento comenzando por la puerta de entrada y avanzando sistemáticamente por el lugar, recorriendo por turno cada habitación, que sólo cruzaban si había otra al otro lado. Destacaban más las habitaciones grandes que las chicas, a las que veían como accesorias: "Allí derecho hay un dormitorio con un pequeño placard".

Todos los que respondieron dieron por sentado que la pregunta requería un nivel particular de detalle para las habitaciones. Esto determinó en parte el contenido de las descripciones, pero algunas habitaciones eran consideradas más importantes que otras. Finalmente, el problema de ordenar los contenidos se resolvió imaginando una recorrida por el departamento.

Otras descripciones requieren soluciones diferentes, pero los supuestos sobre qué es lo que resulta más comprensible, útil e interesante para el oyente afectan las descripciones de manera tal que, con frecuencia, distintas personas llegan a soluciones similares. Por ejemplo, el relato de una serie de acontecimientos por lo general exige una descripción cuyo orden es el mismo de la serie de eventos (ver, por ejemplo, Levelt, 1981). Esto no es obligatorio y los relatores de cuentos pueden crear efectos peculiares si no observan esta regla.

El nivel estratégico de planificación implica: decisiones sobre los detalles que son adecuados (si alguien pregunta cómo llegar a algún lugar, no es necesario describir todos los negocios por los que pasará); decisiones sobre, por lo menos, algunos de los puntos principales que se deben incluir; decisiones sobre el orden en que se los debe mencionar. Puede haber desviaciones respecto del nivel esperable de detalle, los puntos principales o el orden, pero esas desviaciones tendrán consecuencias en la interpretación del oyen-

te. Es parte del arte del narrador de historias (o, más aún, de quien cuenta bromas) ser capaz de predecir el efecto que tendrán las alteraciones de las expectativas del oyente (ver capítulo 4).



Planificación de alcance intermedio

El desarrollo de un plan general es importante pero, como bien lo sabe cualquiera que escriba composiciones, no resuelve un montón de problemas sobre la ejecución detallada de ese plan.

Al escribir una composición, el paso siguiente después de terminar el plan general es hacer una pausa para pensar; luego, escribir algunas oraciones; luego, hacer otra pausa para pensar, etc. Según Butterworth (por ejemplo, 1980), esto también es válido para el habla, que, según descubrió, tiende a producirse en ciclos, con un período marcado por muchas vacilaciones, seguido por una frase fluida, seguido por otra frase vacilante, etc. Esto puede verse claramente en la figura 9.1. Según Butterworth, los ciclos usualmente "duran alrededor de 18 segundos, pero hay algunos de hasta 30 segundos, lo cual significa que contienen, como promedio, de 5 a 8 proporsiciones; es decir, dos oraciones o más". Sostiene que cada uno de estos ciclos coincide con una "idea" única. Para analizar esto, pidió a ciertas personas que dividieran un discurso espontáneo en "ideas" separadas y encontró que existe una buena correspondencia (aunque no absoluta) entre el comienzo de una etapa dubitativa y el comienzo de una "idea".

La planificación de la expresión de ideas parece requerir tiempo, pero una vez que se desarrolla un plan para expresar la idea, el discurso puede proceder con mayor fluidez.

Figura 9.1. Ciclos temporales en el habla (Según Beattie, 1983).

Las pausas aparecen especialmente entre las cláusulas y antes de las palabras de contenido (Butterworth, 1980; Beattie, 1983).

Una oración puede dividirse en proposiciones, cada una de las cuales debe contener un verbo. Las pausas que aparecen entre proposiciones probablemente tengan tres funciones. En primer lugar, le permiten respirar al hablante; en segundo lugar, pueden ayudar al oyente a dividir el discurso en unidades apropiadas; y, en tercer lugar, probablemente sean importantes en la planificación de la articulación detallada de la proposición. Como las proposiciones son las unidades mayores de una oración, necesitan planificarse como un todo, para que los acentos puedan aparecer en los lugares adecuados. Sin embargo, vale la pena observar que de ninguna manera se producen pausas antes de todas las proposiciones: menos de la mitad de las proposiciones en la fase dubitativa y alrededor de un cuarto en la fase fluida tienen pausas que las anteceden (Beattie, 1983).

Las vacilaciones también aparecen antes de las "palabras de contenido"; es decir, antes de los sustantivos, verbos, adjetivos y adverbios que llevan el sentido de la oración. Tienden a no aparecer antes de las "palabras de función" (preposiciones, conjunciones, artículos, etc.), que indican el marco

gramatical de la oración. Estas pausas a menudo se asocian con gestos que parecen representar el significado de la palabra cuando finalmente aparece (Beattie, 1983). En otras palabras, al hablar, incluso en una fase fluida, a veces tenemos una palabra en la punta de la lengua pero no podemos decirla, aunque manifestamos su significado por medio de un gesto. Fenómenos como éste han sugerido a mucha gente que, cuando planificamos el discurso, planificamos el sentido general de una idea, el marco gramatical de las oraciones y proposiciones y una especificación de las palabras involucradas. Al avanzar por el marco llegamos a un hueco que hay que llenar con una palabra que tiene una especificidad semántica peculiar. Buscamos en nuestra memoria una secuencia de sonidos determinada que se ajuste al significado, pero no podemos hallarla de inmediato, aunque es evidente que conocemos claramente su significado ya que podemos sugerirlo mediante un gesto. Tal vez parezca sorprendente que se pueda establecer el marco de una oración antes de elegir las palabras que la integran, pero en realidad eso es lo que indica la experiencia común; después de todo, es bastante fácil completar con palabras el marco de una rima jocosa:

De la cima de aquel cerro
Venía bajando un .....

Si observamos las vacilaciones, obtenemos evidencias sobre dos aspectos de la planificación del discurso. Primero, sobre la planificación de cómo expresar ideas, lo cual implica planificar unas pocas oraciones por vez; y segundo, el estudio de las vacilaciones empieza a proporcionarnos ciertas indicios sobre cómo se planifican las cláusulas en detalle. Parece que el hablante planifica una cláusula por adelantado, al menos en lo que respecta a la estructura principal, y conoce el significado de las palabras involucradas, pero no siempre sabe precisamente cómo dirá estas palabras.

Sin embargo, para analizar con más detalle algunos de los procesos involucrados en la producción de cláusulas, tenemos que observar los errores que la gente comete al hablar.

Ejecución de corto alcance de los planes de discurso

Hay varias clases de errores de discurso, como se puede observar en la tabla 9.1. Las especulaciones sobre por qué pueden producirse estos erro-

res nos dicen mucho sobre el proceso involucrado en la producción de discurso. En primer lugar, como es esperable, el proceso de búsqueda de palabras provoca errores; a veces se necesita tiempo para encontrar las palabras, lo cual provoca vacilaciones, y a veces se encuentra una palabra equivocada, que puede tener sonido similar al de la palabra que se buscaba, por ejemplo:

1 "No, soy *burdo" (en vez de* "zurdo").

También puede tener un *significado similar,* como:

2 "Fui en bicicleta *a la escuela mañana" (en vez de* "ayer")

En algunas ocasiones, se extraen de la memoria dos palabras al mismo tiempo y se las combina inadvertidamente:

3 "una madera *pulisa" (pulida + lisa)*

4 "Es *torrible" (terrible + horrible)*

Tabla 9.1. Algunos tipos de errores de discurso

1	*Sustitución*
(a)	De palabras con sonido similar
Ejemplo:	No simpatiza
	(en vez de "sintetiza")
(b)	De palabras con significado similar
Ejemplo:	Pregúntame si te parece posible.
	(en vez de "Dime...")
2	*Combinación*
Ejemplo:	¿Alguna vez volejaste de noche?
	(en vez de "volaste" o "manejaste")
3	*Anticipación*
Ejemplo:	Una clección clara
	(en vez de "lección")
4	*Intercambio*
Ejemplos:	
	Abre la casa de tu puerta
	(en vez de "la puerta de tu casa")
	un tejo rocho
	(en vez de "un techo rojo")

Estos errores nos dicen algo sobre los procesos involucrados en el ajuste de palabras en una estructura, y lo que nos dicen es coherente con lo que se desprende de los estudios sobre las vacilaciones: parece que el hablante llega a un lugar de la oración en el que tiene la intención de producir una palabra. Aparentemente, su plan contiene una especificación del significado de esa palabra, como puede observarse en el hecho de que a veces se dice por error una palabra con significado parecido al correcto, y también en el hecho de que en ocasiones se unen dos palabras alternativas.

Sin embargo, en algún punto el hablante tiene que extraer de la memoria una palabra que tenga los sonidos y el significado correctos, y parece que a veces este proceso produce deslices: es como si hubiera un proceso que cumple las especificaciones de sonidos adecuados para una palabra que tiene un significado en particular. Usualmente, esto lleva a la emisión de la palabra correcta, pero a veces otra palabra cumple con los requisitos sonoros bastante bien y se la dice en lugar de la correcta: de ahí los errores de sustitución de palabras por otras con sonido similar (como en el ejemplo 1 de la tabla).

Pero los errores de hallazgo de palabras no nos dicen cómo se planifica la proposición: para eso necesitamos analizar los errores de anticipación y, en especial, los de intercambio.

El estudio de estos errores nos hace comprender que: primero, si anticipamos los sonidos de una palabra cuando estamos diciendo otra y decimos, por ejemplo, "un tino tinto" en vez de "un vino tinto", las especificaciones para la "v" y la "t" deben estar presentes de manera simultánea en nuestras mentes. Del mismo modo, si intercambiamos dos palabras (por ejemplo: "¿Me prestas un cuento de libros?"), ambas palabras deben haber estado presentes a la vez. Por lo tanto, podemos ver una vez más que el habla no procede de a una palabra por vez sino que se planifica por adelantado.

Segundo, si observamos las palabras que se intercambian, podremos tener cierta idea sobre la duración del discurso que se planifica detalladamente. Según Garrett (1980), las palabras suelen intercambiarse dentro de una proposición y sólo un pequeño porcentaje de los errores de intercambio (20%) se produce en extensiones discursivas mayores que la proposición (recordemos que las oraciones pueden tener una o más proposiciones, cada una de las cuales contiene un verbo). Aparentemente, entonces, la proposición constituye una especie de unidad articulatoria. Es, por supuesto, mucho más corta que los ciclos de planificación a plazo intermedio que describió Butterworth, que contenían de 5 a 8 proposiciones. Sin embargo, parece pro-

bable que lo que se planifica a ese nivel sea una especificación bastante abstracta del significado de lo que se va a decir, y que no tiene suficiente nivel de detalle como para articularse realmente. El "programa articulatorio" en sí se ocupa de fragmentos de discurso más breves, y parece involucrar una especificación detallada de cómo decir una proposición en particular.

El tercer punto, y el más interesante, es que el análisis de los errores de intercambio, para varios especialistas (Fromkin, 1973; Garrett, 1980), sugiere que es posible deducir una secuencia de pasos de procesamiento en la formación de un programa articulatorio. Para analizar estas ideas, tenemos que examinar más de cerca los errores de intercambio.

Existen errores de intercambio de tres tipos diferentes:

a) Intercambios de *palabras*
"¿Me prestas un cuento de libros?"
"Abre la casa de tu puerta"

b) Intercambio de *sílabas*
"Justad y liberticia" (justicia y libertad)
"Listas y revibros" (libros y revistas)

c) Intercambio de *sonidos*
"Hay artenes y sollas" (sartenes y ollas)
"Fatos y dotos" (datos y fotos)

Hay tres aspectos de estos intercambios que proporcionan indicadores útiles para dilucidar los procesos que pueden estar involucrados en la producción de una cláusula: obsérvese primero que los ítem intercambiados tienden a ser muy similares entre sí (ya que las palabras se intercambian con otras palabras, las sílabas con otras sílabas y los sonidos con otros sonidos) y los intercambios tienden a involucrar ítem en posiciones similares (por ejemplo, las sílabas intercambiadas se encuentran en la misma posición en sus respectivas palabras).

En segundo lugar, obsérvese que muchos intercambios dejan intacta la estructura gramatical de la proposición:

"Esperar mejora." (Mejor esperar.)
"Tengo que chequear un cobre." (Tengo que cobrar un cheque.)

Observaciones como éstas han sido usadas por Fromkin y Garrett pa-

ra construir sugerencias sobre cómo una sucesión de procesos puede estar involucrada en la articulación de una proposición. Algunas de estas sugerencias pueden resumirse así:

a) *Selección de un significado.* La primera etapa es, presumiblemente, la de decidir la idea que se expresará en la cláusula: por ejemplo, que una persona o un objeto en especial están realizando una acción de alguna clase.

b) La segunda etapa parece ser la de *selección de un marco gramatical.* Como se dijo antes, parece bastante extraño elegir un marco gramatical antes de escoger las palabras que llenarán los huecos en ese marco, pero ésta parece ser la única justificación para algunas de las formas características en que funciona el intercambio: específicamente, que el marco casi siempre permanece intacto. Por ejemplo, cuando alguien quiere decir "Abre la puerta de tu casa" pero dice, en cambio, "Abre la casa de tu puerta", parece que el marco "Abre la _____ de tu _____" ya estaba establecido y luego se ubicaron las palabras en los lugares incorrectos.

c) La tercera etapa es la de *selección de las palabras de contenido* para llenar los huecos. Como vimos antes, esta etapa también puede funcionar mal ya que puede elegirse por equivocación una palabra de sonido similar a la buscada, o una palabra de significado similar, o pueden combinarse dos palabras correctas o, directamente, puede haber dificultades para encontrar la palabra correcta.

d) Finalmente, hay una etapa en la que se especifican los *detalles de pronunciación.* La prueba de que esta etapa es posterior a la que mencionamos antes es que cuando se produce un intercambio, la pronunciación de los plurales, tiempos verbales, etc., es adecuada para las palabras que *realmente* llenan los huecos y no para las que debían llenarlos.

Conclusión

Para un ser humano (y sólo para un ser humano) los años de práctica dan como resultado un individuo experto que puede hablar sin esfuerzo, planificar por adelantado y producir oraciones que nunca ha dicho u oído antes. Se han empleado tres técnicas fundamentales para estudiar esta habilidad extraordinaria: el análisis de las elecciones que hacen los hablantes, el análisis de los puntos en los que los hablantes hacen pausas para el pensamiento, y el análisis de las (sorprendentemente raras) ocasiones en que el habla no funciona bien. Se han usado estas técnicas para empezar a bosquejar detalladamente los procesos involucrados en el habla. Sin embargo, escuchar también es una habilidad y de ella nos ocuparemos en el próximo capítulo. Detallaremos algunas de las formas en que las elecciones de los hablantes afectan a los oyentes y cómo vale la pena considerar todo esto al pensar tanto en el hablar como en el escuchar.

Las habilidades del oyente

Don Rogers

La comprensión del lenguaje

Cuando pensamos en los procesos de comprensión, una teoría muy obvia sobre cómo funcionan nos viene de inmediato a la mente: la comprensión funciona "de abajo hacia arriba". Es decir, oímos y reconocemos sonidos individualmente (o, cuando leemos, reconocemos las letras individualmente); luego, reconocemos que ciertas combinaciones peculiares de esos sonidos o letras son palabras; nuestro conocimiento de la gramática nos permite comprender que ciertas combinaciones de esas palabras forman oraciones; y, finalmente, entendemos que la combinación de oraciones forma una narración, una conversación, etc.

Sin embargo, si bien esta idea es bastante acertada, también parecen existir opiniones según las cuales los procesos de comprensión funcionan "de arriba hacia abajo", ya que comprendemos lo que significan las letras, las palabras y las oraciones según el contexto y de acuerdo con nuestros conocimientos.

Analizaremos este fenómeno en relación con varios niveles lingüísticos, empezando por el más simple, es decir, los sonidos o las letras. Nos ocuparemos de la lectura más que de los sonidos, simplemente porque sus efectos son más fáciles de ilustrar en el papel y la comprensión de los sonidos presenta exactamente las mismas dificultades. Por supuesto, esto relaciona a este capítulo con el análisis de la lectura que se hace en el capítulo 4 de este mismo libro.

El reconocimiento de letras

Si bien las letras son bastante fáciles de reconocer, todos sabemos que a veces (en especial cuando intentamos leer textos manuscritos) puede haber dificultades. Sin embargo, es sorprendente ver con cuánta frecuencia pode-

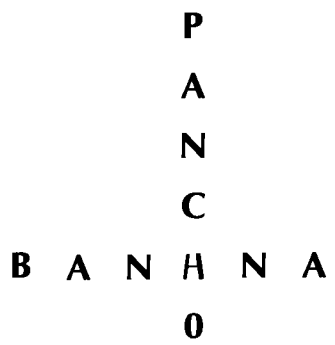
mos leer sin dificultad letras que están muy mal conformadas. Obsérvense los ejemplos de la figura 10.1. Hay muchos casos en los que una letra determinada es muy difícil de reconocer, a menos que uno pueda ver el resto de la palabra en que esa letra se inscribe. También se verán casos en los que se pueden reconocer formas bastante diferentes como ejemplos de la misma letra. En otros casos, la misma forma se ve como letras distintas en diferentes contextos, como lo ilustra la figura 10.2.

En general, entonces, hay ocasiones en las que la decisión sobre cuáles son las letras presentes en una palabra depende de la lectura global de esa palabra. Es decir, el contexto que la precede y la sigue se tiene en cuenta para reconocer las letras. Lo mismo es válido para el reconocimiento de los sonidos que conforman el discurso. Por ejemplo, la misma letra tendrá formas diferentes según la pronunciación y el acento del hablante. Donde esa pronunciación no resulte familiar, la identificación de los sonidos individuales (o, incluso, de palabras enteras) dependerá del contexto.

Figura 10.1. Las letras pueden tener variadas formas físicas. Lo mismo sucede con los sonidos.

La comprensión de palabras y oraciones

Así como las letras son fáciles de reconocer en contexto, éste también facilita mucho la comprensión y el reconocimiento de las palabras. Se pueden hacer varios comentarios al respecto. En primer lugar, como oyentes experimentados del lenguaje, tenemos la impresión de que el discurso se segmenta en palabras, con pausas entre ellas, igual que en la página impresa. Pero esto no es así: como vimos en el capítulo anterior, el patrón de pausas en el discurso es mucho más complejo. Si uno trata de decir una o dos oraciones haciendo pausas entre cada palabra, comprobará que suena muy extraña. La impresión de que existen espacios surge porque comprendemos la oración e imaginamos esos espacios entre las palabras. Es divertido construir oraciones que se puedan dividir en palabras de diferentes maneras, de modo que se puedan cambiar las posiciones de los aparentes espacios entre ellas. Esto sucede en algunas adivinanzas infantiles. Veamos un ejemplo conocido:



A. Tengo 12 huevos metidos en una cesta. Si pongo 3 más, ¿cuántos habrá en ella?

B. Quince.

A. No, cinco.

(En vez de "metidos", la respuesta de A sugiere que lo que había dicho en su primera intervención había sido "metí dos".)

Figura 10.2. El mismo estímulo puede merecer diferentes interpretaciones, según el contexto.

Una segunda función del contexto al nivel de la comprensión de palabras tiene que ver con el hecho de que muchas palabras tienen más de un significado, y en muchos casos hay palabras diferentes que suenan parecido. Para decidir cuál es el significado correcto en cada caso, y cuál es la palabra pertinente, hay que tener en cuenta el significado y la estructura gramatical de toda la oración y, frecuentemente, también de las oraciones anteriores y posteriores. En general, es muy fácil pensar ejemplos de palabras que puedan tener un significado en un contexto y otro muy distinto en otro contexto, sencillamente porque muchas palabras tienen varios significados diferentes. Veamos un caso:

* En el norte argentino hay muchas *llamas*... debido a la abundancia de incendios forestales.

* Si no *llamas* pronto por teléfono a tu hermano, se enojará mucho.

En tercer lugar, cuando escuchamos o leemos, tenemos que decidir las partes del discurso y la función gramatical de cada palabra. Éste no es un procedimiento directo o mecánico, como se puede ver examinando algunas oraciones. Por ejemplo:

La bella llama de las montañas

es superficialmente similar a:

La bella llama desde las montañas.

Pero, evidentemente, en el primer caso, *llama* es un sustantivo y *bella* un adjetivo, en tanto que en el segundo caso *llama* actúa como verbo y bella se sustantiviza.

Estos tres conceptos (el discurso no se divide en palabras separadas por pausas, las palabras pueden tener varios significados diferentes, una palabra dada puede cumplir distintas funciones gramaticales en diferentes oraciones) sugieren que tenemos que usar considerablemente el contexto para determinar la parte del discurso en que se halla incluida una palabra, el significado peculiar que tiene y, en realidad, cuáles son las palabras que están involucradas.

Esto ha llevado a algunos investigadores a pensar que el oyente espera hasta el final de la oración antes de llegar a una decisión sobre su significado. Sin embargo, parece que los procesos "de abajo hacia arriba" y "de arriba hacia abajo" operan simultáneamente. Esto ocurre en parte porque hay que tomar decisiones muy rápidamente. En el discurso normal, escuchamos

unas 2 o 3 palabras por segundo. Marslen-Wilson y Tyler (1981) demostraron que en los experimentos la gente puede repetir un discurso que se está diciendo con una demora de sólo un cuarto de segundo: se pidió a los sujetos que escucharan hablar a alguien y repitieran el mensaje mientras lo oían. Los experimentadores descubrieron que la pronunciación de algunas palabras requería hasta 375 milisegundos pero los sujetos podían empezar a repetirlas sólo 250 milisegundos después del principio. Es decir, comenzaban a repetir la palabra antes de haberla oído entera. Además, había un buen nivel de comprensión del material que se repetía; no era una mera repetición como un eco. La conclusión inevitable es que en esta situación la gente podía decidir correctamente qué palabra estaba oyendo cuando sólo había oído la mitad de ella. Esto demuestra el poderoso efecto del contexto, pero también que no es necesario esperar hasta el final de la oración para comprender las palabras que están incluidas en ella. Por este motivo es bastante fácil engañar al sistema, y en muchos estudios se han usado oraciones que (como dice Aitchison, 1983) inducen a los oyentes al error. Por ejemplo:

¡No seas tonto!... le dije a mi hermano.

Quien escucha esto piensa, al principio, que el "tonto" al que se hace referencia es él mismo; sólo al escuchar la última parte comprende que no es así y que el "tonto" en cuestión es el hermano del hablante.

La comprensión del significado social de las oraciones

Pero aun cuando entiende las palabras y la estructura gramatical de una oración, al oyente le quedan otros problemas. En particular, necesita apreciar las intenciones del hablante para poder responder adecuadamente.

Cuando escuchamos a alguien, no sólo está emitiendo una sucesión de sonidos organizados de forma que podamos entenderlos como oración sino que también está desempeñando una acción social: quizá nos está acusando, advirtiendo o pidiendo algo; a estos se los suele llamar actos de habla. La cuestión es: ¿cómo sabemos qué quiere? (Ver, también, capítulo 13.)

Una forma de saberlo podría ser que nos dijera lo que quiere:

"Te pido algo: sal de mi camino."

Pero, como usuarios del lenguaje, sabemos perfectamente bien que la gente no suele hablar así y que si lo hace es más un desafío que un pedido normal.

En segundo lugar, puede haber estructuras gramaticales específicas

asociadas con actos de habla específicos. Aquí se presentan dos problemas. Primero, como ha señalado Austin (1962), se pueden desempeñar cientos de diferentes actos de habla, y el número de formas gramaticales especiales tendría que ser muy grande. Además, existe de hecho una forma especial para hacer que alguien haga algo. Es el imperativo:

"¡Apártate de mi camino!"
"¡Abre la puerta!"
"¡Préstenme atención!"

Es obvio que el imperativo aparece en contextos en los que hay una diferencia de condición social amplia (y con frecuencia de naturaleza institucional) entre el hablante y el oyente (como, por ejemplo, en el ejército) o resulta extraordinariamente grosero (precisamente porque sugiere la existencia de esa diferencia social).

Por lo tanto, los pedidos suelen hacerse de manera amable, como "pedidos indirectos", y forman parte de los *actos de habla indirectos*. Por ejemplo, podríamos decir:

"¿Podrías lavar los platos?"
"¿No te toca a ti lavar los platos?"
"Hay que lavar los platos."
Etcétera

Es evidente que la forma en que el oyente distingue un pedido indirecto de una pregunta o una afirmación comunes presenta otro problema. El filósofo John Searle tiene un análisis que resulta de mucha utilidad al respecto (Searle, 1975). Señala que para que cualquier expresión pueda ser un pedido, debe cumplir ciertas condiciones. En los ejemplos antes mencionados:

a) debe haber necesidad de la acción (por ejemplo, debe haber necesidad de que se laven los platos).

b) el oyente debe ser capaz de desempeñar la acción y estar dispuesto a hacerlo.

c) el hablante debe ser sincero y querer que el oyente realice la acción.

d) la expresión debe ser un intento de lograr que la acción se realice.

e) el hablante debe tener derecho a pedirle algo al oyente.

Sólo si se cumplen todas estas condiciones puede considerarse que una expresión es un pedido y, con frecuencia, para pedir algo se señala alguna de ellas. Por ejemplo: "¿Podrías lavar los platos?" pregunta al oyente si es-

taría dispuesto a desempeñar la acción. Si se cumplieran todas las demás condiciones (es decir, que hiciera falta que se lavaran los platos, etc.), esto se podría considerar un pedido. Por otra parte, es más factible que algo como "¿Te gustaría ir a la luna?" sea considerado como una pregunta genuina, que espera una respuesta afirmativa o negativa pero ninguna acción posterior (Stubbs, 1983, presenta un análisis más profundo sobre el tema).

Pero para responder a algunos pedidos no basta con evaluar si se nos está pidiendo algo. Con frecuencia, tenemos que ponernos en el lugar del hablante, considerar sus propósitos, sus conocimientos y las características salientes de la situación en general. Veamos un ejemplo simple, como que a alguien se le pregunte dónde queda un lugar:

"¿Sabes dónde queda Harrod's?"

La respuesta que uno dependerá de:

a) Dónde está uno en ese momento. Si uno está en Escocia, la respuesta adecuada podría ser: "En Londres". Si uno está en Londres, podría ser: "En Knightsbridge". Y si uno está en Knightsbridge: "Derecho por esta calle".

b) Su evaluación de por qué el hablante necesita la información. Por ejemplo, si el hablante estuviera mirando un mapa de Londres, la respuesta "Knightsbridge" sería más adecuada que "Londres", incluso si uno estuviera en Escocia en ese momento. Si uno sabe que el hablante es un especulador bursátil y que ha visto que uno está leyendo un informe financiero, la respuesta podría ser: "Tres puntos y medio arriba".

c) Su evaluación de los conocimientos del hablante. Con frecuencia, esto es algo establecido en la conversación antes de elegir la respuesta adecuada:

A: "¿Sabes dónde queda Harrod's?"

B: "¿Conoces Hyde Park?"

A: "No."

B: "Ah, bueno. Si sigues por aquí verás un gran arco. Al otro lado está el parque. Si lo cruzas por el sendero y al llegar al otro lado vuelves a preguntar, llegarás a Harrod's. Pensándolo mejor, ¿por qué no tomas un taxi?"

Más allá de la oración

Las oraciones no aparecen de manera aislada: son parte de textos más amplios (relatos, conversaciones o lo que sea) y también se las puede usar en contextos físicos particulares. Naturalmente, esto ayuda considerablemente

en la interpretación de oraciones: una oración ambigua como "Están comiendo manzanas" tiene menos lecturas alternativas si uno tiene a los comensales delante o si las oraciones anteriores han tenido que ver con manzanas.

Sin embargo, la interpretación de oraciones en contexto también presenta problemas y nos proporciona más evidencias de cuán poderosos, hábiles y activos son los procesos de comprensión.

En un estudio ya clásico, Gordon Bower (1976) les leyó a sus alumnos historias como ésta:

(Nancy) fue a ver al médico. Llegó al consultorio y se presentó ante la secretaria. Fue a ver a la enfermera, que realizó los procedimientos de rutina. Luego, (Nancy) subió a la balanza y la enfermera anotó su peso. El médico entró al consultorio y examinó los resultados. Le sonrió a (Nancy) y dijo: "Bueno, parece que mis expectativas se confirman". Cuando el examen terminó, (Nancy) salió del consultorio.

Estas historias estaban precedidas por una breve descripción, que podía ser, por ejemplo:

> Nancy se despertó sintiéndose mal nuevamente y se preguntó si realmente estaría embarazada. ¿Cómo se lo diría al profesor con el que había estado saliendo? Además, estaba el problema del dinero.

Por otra parte, podía tratarse de una breve descripción de Jack, un joven que está preocupado porque no pesa lo suficiente como para integrar el equipo de luchadores. (Naturalmente, cuando ésta era la descripción que precedía a la historia, los nombres y pronombres cambiaban por "Jack" y "él".)

Veinticuatro horas después, Bower puso a prueba la memoria de los estudiantes. Se descubrió que había muchas distorsiones en sus recuerdos de la historia y que estos variaban según la descripción que la precedía. Por ejemplo, en el relato de "Nancy embarazada" los alumnos recordaron mal la afirmación del médico: "parece que mis expectativas se confirman" y dijeron "Sus temores parecen confirmarse" o simplemente "Ud. está embarazada". En cambio, en la historia de "Jack el luchador", recordaron que el médico le había dicho a Jack que estaba llegando al peso necesario.

A partir de este experimento, pueden hacerse al menos dos comentarios. En primer lugar, demuestra que comprender un relato implica un proceso de inferencia activa (ver capítulos 4 y 13). Se trata, por supuesto, de un fe-

nómeno muy generalizado en la lectura o la audición de historias, y los escritores de novelas policiales como Agatha Christie se valen mucho de esta propensión de sus lectores. Las pistas falsas que el novelista siembra nos confunden sólo porque hacemos inferencias activamente.

En segundo lugar, tanto en el relato de Bower como en las novelas policiales, parece que hacemos inferencias como consecuencia de nuestro intento de ensamblar los fragmentos de información contenidos en la historia. Parece que damos por supuesto que si se ha mencionado algo, debe ser relevante y se lo debe poder ensamblar con las demás cosas que se mencionan en la historia.

Con respecto a esto, el filósofo H.P. Grice (1975) señala que hablante y oyente actúan como si observaran un conjunto de principios co-operativos. Grice encapsula algunos de estos principios en cuatro "máximas":

Cantidad: Sea tan informativo como se necesite: no proporcione información de más ni de menos.
Calidad: Sea sincero.
Relación: Sea relevante.
Modo: Sea claro y ordenado.

Estas máximas no pretenden ser una receta para quienes aspiran a tener una conversación sino más bien un conjunto de principios intuitivos que cualquier conversador hábil y experimentado obedece de manera implícita. Es debido a esto que el lector o el oyente pueden hacer deducciones; precisamente porque damos por sentado que se obedecen las máximas de cantidad (de modo que no se proporciona más información que la necesaria) y de relación (y la información que tenemos es relevante) podemos sacar la conclusión de que la afirmación del médico tiene que ver con el embarazo de Nancy.

La violación de las máximas de Grice produce efectos interesantes. Por ejemplo, como señala él mismo, si después de haber sido tratado abominablemente por otra persona, un hombre dice: "Es un buen amigo", habrá violado la máxima de calidad, diciendo algo que no es cierto. Si su oyente lo sabe, podrá deducir que esa afirmación pretende ser irónica.

Estos temas, en especial la cuestión de la relevancia, son analizados más profundamente por Downes (1984).

Puede hacerse otro comentario sobre la historia de Bower. Damos por sentado que el malestar de Nancy se relaciona con su embarazo. Sin embar-

go, esta deducción tiene que ver con lo que podría denominarse conocimiento "no lingüístico" o "mundano": "sentirse mal" no significa estar embarazada. Entender el lenguaje, por lo tanto, implica un conocimiento no sólo del lenguaje mismo sino también del mundo. Esto puede verse claramente en un experimento bastante extraño realizado por Dooling y Lachman (1971). Este experimento incluye una historia muy difícil de entender hasta que se le da un título:

> Con joyas empeñadas para financiarlo, nuestro héroe desafió valientemente todas las burlas que habían intentado impedir sus planes. Tus ojos mienten, había dicho, un huevo y no una mesa tipifica correctamente este inexplorado planeta. Ahora, tres tenaces hermanas buscaban pruebas, abriéndose camino por los a veces serenos pero con más frecuencia turbulentos picos y valles. Los días se convirtieron en semanas y muchos incrédulos difundieron terribles rumores sobre el abismo. Finalmente, de la nada, bienvenidas criaturas aladas aparecieron, lo cual implicaba un éxito trascendental.

Mucha gente que lee o escucha esta historia puede hallarla incomprensible: entienden las palabras pero no encuentran un marco que haga que todos los datos mencionados resulten relevantes. Pero cuando se les dice que es una historia llamada "Cristóbal Colón descubre América", la relevancia de todos los puntos se hace evidente y pueden interpretarse las ambiciosas metáforas. Las palabras no han cambiado: no hay cambios en el conocimiento lingüístico pero ahora puede articularse el marco de referencia adecuado y el relato se entiende sobre la base de nuestros conocimientos históricos, del mar, los buques a vela, etc.

Mejorar las habilidades del hablante y del oyente

Evidentemente, el oyente enfrenta un gran problema si encuentra dificultades para comprender y recordar los contenidos, por ejemplo, de una conferencia. A diferencia del lector, no puede descansar cuando su concentración flaquea ni puede volver atrás si no alcanza a seguir un argumento: la velocidad a la que tiene que incorporar la información la establece el hablante. Pero, como todos sabemos, es muy difícil mantener la concentración durante toda una conferencia de 50 minutos: del mismo modo que un operador de radar no puede mantener el mismo nivel de vigilancia constantemente, un

alumno no puede prestar la misma atención a cada gloriosa palabra que sale de los labios de su docente. De hecho, según Wilkinson, Stratton y Dudley (1974), "se ha descubierto que los alumnos que oyen conferencias sólo comprenden la mitad (o menos) de la materia básica". Esto es especialmente desafortunado ya que, como señalan más adelante, los estudiantes pasan gran parte del tiempo sólo escuchando; incluso en la escuela primaria se descubrió que los niños sólo escuchaban el 58% de lo dicho en cada día de clase.

Si tenemos en cuenta esto, es evidente que gran parte de la responsabilidad de aliviar la carga del oyente recae sobre el hablante, y hay muchos cursos y libros para ayudar a los oradores públicos a comunicarse con eficacia; por ejemplo, *Lecturing and Explaining*, de George Brown (1978). Naturalmente, hay muchas soluciones diferentes para el problema de la exposición oral eficiente, pero todas tienen que tener en cuenta al oyente. Por ejemplo, muchos de los recursos que emplea el hablante apuntan a superar la incapacidad del oyente para prestar atención todo el tiempo. Así, el docente puede señalar por adelantado los puntos principales que piensa tratar, puede resumir los aspectos principales, puede llamar la atención sobre ellos escribiéndolos en un pizarrón o proporcionar información adicional haciendo referencia al mismo punto mediante su discurso y con ayudas visuales.

Además, debería ser obvio, por lo que ya se ha dicho en este capítulo, que el hablante también tiene que tener en cuenta los conocimientos del oyente, así como sus necesidades y propósitos. Suele ser difícil explicar un tópico nuevo a un grupo de manera tal que todos puedan entenderlo, y quien habla en público tiene que aprender a evaluar correctamente qué sabe su auditorio: si sobreestima sus conocimientos, el auditorio no entenderá, no recordará y ni siquiera se interesará en lo que dice; por otra parte, si subestima los conocimientos de su auditorio, puede aburrirlo.

Si bien el peso principal de la comunicación efectiva recae sobre los hablantes, también parece haber habilidades de comprensión que los oyentes pueden ejercitar con mayor o menor pericia. Pueden discernirse tres tipos de habilidad de comprensión. El primer tipo tiene que ver con la atención y con tener la voluntad de oír al hablante. Se incluyen aquí cosas tales como la decisión del nivel en el que se quiere entender y recordar el material del hablante. Por ejemplo, un ladrón y un dueño de casa podrían extraer diferente información de una charla sobre prevención del crimen. El segundo tipo de habilidad tiene que ver con el desempeño de ciertas operaciones cognitivas, como distinguir entre ideas principales y subordinadas, mantener en la mente detalles relacionados, sacar las conclusiones adecuadas o percibir la es-

tructura lógica de un argumento. En tercer lugar, hay otro conjunto de habilidades involucrado en la identificación de las "pistas" con los que los hablantes señalan la dirección de sus pensamientos. Estos indicios pueden ser verbales ("en primer lugar", "sin embargo", "en síntesis"), pueden incluir énfasis o tonos de voz o pueden ser totalmente no verbales (como los gestos, las posturas y los movimientos corporales en general). Todos ellos pueden proporcionar información sobre la forma en que el hablante considera la organización de lo que está diciendo (ver también el capítulo 11).

En su interesante intento de mejorar las habilidades del oyente, Brown (1968) enseñó a sus alumnos a buscar las pistas verbales (ver tabla 10.1) y no verbales (ver Tabla 10.2) de los conferencistas. Después de practicar con grabaciones de charlas en audio y video, descubrió que la calidad de las notas tomadas por sus alumnos había mejorado. Aparentemente, también los alumnos sentían que se habían beneficiado con el entrenamiento al que se los había sometido.

En general, entonces, un hablante será más eficiente en su discurso si tiene en cuenta las limitaciones y posibilidades cognitivas de sus oyentes. Necesita, particularmente, tomar precauciones contra las consecuencias de las caídas en la atención de parte de sus oyentes; para ello, debe estructurar claramente su discurso, aclarando cuál es la estructura que emplea, señalando sus puntos principales, repitiendo y resumiendo, y proporcionando información adicional por otros medios. Además, tiene que recurrir a las estructuras de conocimiento que el oyente ya posee de manera que lo que diga resulte comprensible para el oyente y pueda aumentar sus conocimientos. Por otra parte, el oyente puede ayudarse a sí mismo a entender, escuchando con mayor atención y buscando las pistas verbales y no verbales que sugieren lo que el hablante pretende decir. La tarea del oyente es recíproca a la del hablante. Tiene que prestar atención a (todos) los mismos puntos que el hablante e intentar deducir su sentido y sus intenciones.

Tabla 10.1 Tipos de discurso de los conferencistas.
(tomado de Brown, 1978, bajo su autorización)

Preámbulos. Murmullos rituales tales como: "Eh... este... buenas tardes. Hoy... estee... vamos a... eeh... analizar... esteee... un punto... eh... muy importante".

Orientación. El marco de la charla. No hace falta decir que algunos conferencistas no lo hacen explícito. En el mejor de los casos, establecen de qué van a hablar y escriben los títulos. Las orientaciones pueden darse al comienzo de una charla o al comenzar cada tópico o subtópico (ver a continuación).

Marcos. El encuadre de los subtópicos de una charla. Suele empezar con expresiones como: "Ahora bien...", "hasta el momento...", "entonces...". A veces, el orador sencillamente hace una pausa y echa una mirada a sus notas. Las "palabras de encuadre" señalan un cambio de tópico. Lo que les sigue suele ser importante (aunque no siempre sea necesariamente así).

Claves. Las afirmaciones clave. Son principios, reglas, hechos, suposiciones o preguntas fundamentales. Cuidado con ellas. Las preguntas que uno ha anotado probablemente alertarán sobre ellas.

Ejemplos. Pueden ser ejemplos de los principios o hechos; o pueden ser metáforas, ilustraciones y analogías. Un breve comentario sobre ellos ayudará a comprender el principio.

Resúmenes. Pueden darse al final de los tópicos o subtópicos o al terminar la charla.

Tabla 10.2 Tipos de conductas de los expositores (tomado de Brown, 1978, bajo su autorización)

El expositor escribe en el pizarrón	(¿siguiente sección o sólo inquietud del expositor?
El expositor da un paso atrás y observa la pizarra	(está verificando)
El expositor se quita los anteojos	(probablemente viene algo importante)
El expositor se quita los anteojos y hace una pausa	(probablemente sea una salvedad o una reserva)
El expositor mira por la ventana	(piensa en lo que va a decir; quizá está pasando una chica bonita)
El expositor levanta un dedo	(viene una salvedad)
El expositor cierra la mano y hace un gesto	(probablemente ahora viene algo importante)
El expositor hace la señal de "alto"	(una salvedad)
El expositor mira sus notas	(viene la siguiente sección o está perdido)
El expositor mira fijamente sus notas	(está perdido)
El expositor revisa sus transparencias	(está perdido)
El expositor levanta la vista de sus notas y deja de leer	(está por explicar un punto; usualmente, es importante)
El expositor se sienta sobre el escritorio y enciende un cigarrillo.	(se avecina la técnica del "¿no soy un buen tipo?" Puede reemplazar a la charla, pero no siempre)

Conclusión

En este capítulo, hemos demostrado que la comprensión no es de ningún modo un proceso pasivo sino que parece ser, a todo nivel, activo y experto. Si utilizamos el contexto y las expectativas podemos comprender formas de letras muy distorsionadas o ambiguas y emplear poderosas rutinas de reconocimiento de palabras; como consecuencia del conocimiento acumulado sobre el mundo social, podemos llegar más allá de las formas de las expresiones, ponernos en el lugar del otro y adivinar sus intenciones; y como consecuencia de nuestro conocimiento general del mundo, podemos encarar la tarea de comprender formas adecuadas de referencia que nos permitan sacar conclusiones que en su mayoría se cruzan correctamente con las que pretenden los hablantes.

Las habilidades sociales

Helen Graham

En *Rosencrantz y Guildenstern han muerto*, el dramaturgo Tom Stoppard (1967) toma sus personajes de Hamlet, la tragedia de Shakespeare. A los dos héroes condenados se les encomienda la poco envidiable misión de descubrir qué aflige a Hamlet, cuyos síntomas incluyen:

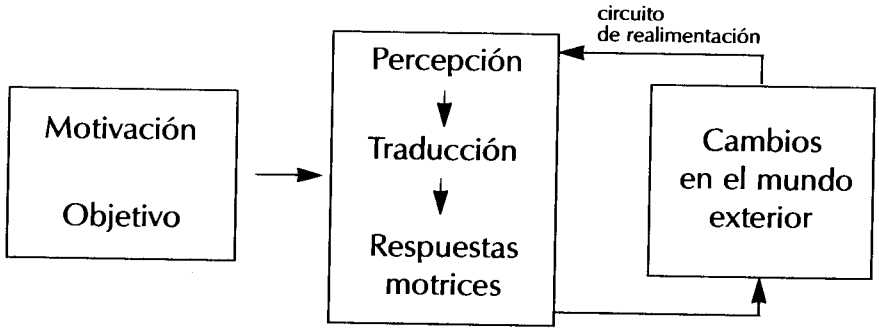
> Réplicas abundantes, alusiones místicas, identidades equivocadas, afirmar que su padre es su madre... cosas así; ideas de suicidio, privaciones, pérdida de la alegría, sensación de claustrofobia (por no decir delirio de encierro), invocaciones a camellos, camaleones, capones, ballenas, comadrejas, halcones, adivinanzas, juegos de palabras y evasivas; amnesia, paranoia, miopía; sueños diurnos, alucinaciones; acuchillamiento de sus mayores, abuso de sus padres, insultos a su amada y apariciones sin la cabeza cubierta en público.

Enfrentados a conductas tan extrañas, Rosencrantz y Guildenstern se sienten terriblemente desubicados. Guildenstern, perplejo, admite: "No sabemos qué está sucediendo ni qué hacer con nosotros mismos. No sabemos cómo actuar". Sobre esta base, un psicólogo podría llegar a la razonable conclusión de que Rosencrantz y Guildenstern son socialmente incompetentes, que sus habilidades sociales son inútiles.

La competencia social como habilidad

Podría decirse que la competencia social consiste en "cómo hacer amigos e influir sobre la gente". Es la capacidad de lograr objetivos personales y profesionales, ya sea formando y manteniendo relaciones con otros o en actividades tales como la docencia, la venta, la entrevista o la psicoterapia. Argyle (1983) sugiere que las interacciones que se realizan en estas conductas sociales utilizan una jerarquía de habilidades cuyos elementos inferiores son automáticos y habituales, mientras que las secuencias superiores se encuentran

bajo control cognitivo. Estas últimas se planifican y están sujetas a control y acción correctiva continuos, a la luz de la retroalimentación.



Argyle (1969) define la habilidad como una actividad organizada y coordinada en relación con un objeto o situación, que involucra toda una cadena de mecanismos perceptuales (sensoriales), cognitivos (centrales) y motrices.

> Una de sus características principales es que el desempeño, o la corriente de acción, se encuentra continuamente bajo el control de la "entrada" sensorial. Esta entrada deriva en parte del objeto o situación hacia el que puede decirse que apunta el desempeño y controla ese desempeño, ya que los resultados de las acciones se ajustan continuamente de acuerdo con cierto criterio de logro o grado de enfoque hacia un objetivo, y el desempeño se adapta consecuentemente. (pág. 180)

Sugiere que durante la interacción social un individuo se involucra en una actividad experta que incluye el ajuste y la modificación de la salida sobre la base de la información disponible. La conducta general es dirigida, adaptada y nada automática, aunque se la puede considerar como formada por elementos que en sí están automatizados.

Los elementos del modelo de habilidad social se representan como diagrama en la figura 11.1.

Figura 11.1 El modelo de la habilidad social (según Argyle, 1969)

El modelo de la habilidad social sigue estrechamente al modelo de las habilidades perceptivo-motrices (capítulos 2 y 3). Tiene cinco etapas:

a) *Los objetivos del desempeño experto.* Pueden incluir la obtención o transmisión de información, el cambio de actitudes o de estado emocional, la supervisión o colaboración. Pueden estar motivados profesionalmente (como sucede en la enseñanza, las entrevistas, la venta o la enfermería) o de un modo puramente social, por necesidades tales como la asociación o la autoridad.

b) *Percepción selectiva de las señales.* La percepción social es altamente selectiva. Quienes participan en las interacciones se tornan altamente sensibles a la información visual, auditiva y, posiblemente, táctil, y aprenden a cuál deben prestarle atención.

c) *Procesos de traducción centrales.* La información obtenida mediante los receptores sensoriales lleva a la formación de planes de acción adecuados. La interacción social depende de las reservas aprendidas de semejantes traducciones, que se construyen durante el proceso de socialización, cuando la persona aprende cuáles son las técnicas sociales que generan en los demás las respuestas deseadas.

d) *Respuestas motrices.* Se pone en acción el plan, pero hace falta práctica para lograr un desempeño fluido y preciso de los patrones de la actividad motriz. Cuando esas habilidades se van perfeccionando, la conciencia alerta se reduce de manera tal que las habilidades sociales complejas (como establecer afinidad o reducir la ansiedad de otra persona) pueden convertirse para algunos en automáticas.

e) *Retroalimentación y acción correctiva.* Por medio del empleo de señales perceptuales, el ejecutante realiza acciones correctivas cuando se hace necesario.

Las habilidades sociales resultan análogas a habilidades motrices como escribir a máquina o conducir un vehículo; son habilidades que, en parte, tienen que aprenderse. Por lo tanto, es esperable que algunas personas las adquieran y desarrollen mejor que otras.

La observación y la experiencia diarias sugieren que esto es efectivamente así. Mucha gente es tímida y le resulta difícil ganar amigos o mantener relaciones. Pueden ser malos conversadores, incapaces de hacerse entender o quizá tengan dificultades para encarar situaciones cotidianas, como relacionarse con miembros del sexo opuesto o con la autoridad, ir a fiestas o decir "no" a los pedidos de los demás. Está claro que la gente difiere notablemen-

te en su habilidad para manejar ese tipo de situaciones, pero las posibles consecuencias de esas diferencias no son tan obvias. Argyle (1984) informa sobre varios estudios que revelan que el ausentismo, la productividad, las quejas y las ventas de un negocio en particular difieren significativamente según los supervisores. Las habilidades sociales incorrectas también pueden tener graves consecuencias y llevar al fracaso en el establecimiento y mantenimiento de relaciones personales, a la imposibilidad de conseguir socios o empleos y, en los casos extremos, al aislamiento social, la enfermedad mental y, quizá, hasta al suicidio.

De hecho, uno de los factores fundamentales para la trágica y temprana muerte de Rosencrantz y Guildenstern en la obra de Stoppard es su incapacidad de apreciar los diferentes matices existentes en las situaciones sociales. Como comprende Guildenstern antes de su ejecución: "Debe haber habido algún momento, al principio, en el que podríamos haber dicho que no. Pero, por algún motivo, no nos dimos cuenta." (pág. 95)

Las habilidades sociales

Las habilidades sociales pueden considerarse bajo varios encabezamientos: habilidades de comunicación, habilidades interpersonales, habilidades de desempeño. Todas ellas tienden a interrelacionarse, y por eso cualquier categorización es, necesariamente, algo arbitraria. Sin embargo, como todas incluyen en alguna medida a la conversación, se puede considerar con justicia que las habilidades conversacionales son de importancia primordial.

Las habilidades conversacionales

La conversación es esencialmente comunicación hablada, que incluye el intercambio verbal entre personas y por lo tanto es de doble sentido, ya que el "habla" o la "conversación" por sí mismas no tendrían significación.

> La conversación es sin duda la piedra basal del mundo social: los seres humanos aprenden a hablar en la conversación, encuentran compañía con la conversación, se socializan a través de la conversación, mejoran su jerarquía social como consecuencia de la conversa-

ción y, se supone, hasta pueden enfermar mentalmente debido a la conversación.

(Beattie, 1983, p. 2)

Sin embargo, como señala Beattie, mientras que la conversación es primordialmente un hecho social, los procesos cognitivos complejos están involucrados en su planificación y generación. (Ver también el capítulo 9.)

En *Rosencrantz y Guildenstern han muerto* podemos ver una amplia planificación de los contenidos de la conversación y su ensayo. Gran parte de la obra de Stoppard trata sobre qué le dirán Rosencrantz y Guildenstern a Hamlet si pueden llegar a hablar con él. Sin embargo, como muchas personas socialmente ineptas, pierden muchas oportunidades para iniciar una conversación. La siguiente escena es un ejemplo:

GUIL.: No se me ocurre cómo podemos empezar la conversación.

(*Hamlet entra en escena y se detiene... Ros. y Guil. lo observan.*)

ROS.: No obstante, supongo que se podría decir que esta era una posibilidad... Uno bien podría abordarlo... Sí, definitivamente me parece que ésta es una oportunidad... Algo así como un acercamiento informal directo... de hombre a hombre... directo desde el hombro... Oye, mira, de qué se trata todo esto... O algo por el estilo. Sí. Sí, parece que hay que aferrarlo con ambas manos, diría yo... si me preguntaran... porque a caballo regalado, etcétera. (*Avanza hacia Hamlet pero sus nervios lo traicionan. Retrocede.*) Estamos intimidados, ése es nuestro problema. Llegado el momento, sucumbimos ante su personalidad... (pág. 55)

Además, cuando Hamlet finalmente les habla, Rosencrantz y Guildenstern son incapaces de mantener la conversación: dan respuestas breves y elementales a sus preguntas y no ofrecen reciprocidad ni ayudan a llevar adelante el diálogo. Se limitan a recibir de manera pasiva las palabras de Hamlet, sin comprometerse activamente en la conversación. Como consecuencia, sólo les quedan las pocas palabras que Hamlet les ha dirigido y lo que los demás han dicho de él; nada de ello resulta particularmente esclarecedor. A Rosencrantz le parece que "La mitad de lo que dijo quería decir otra cosa y la otra mitad no quería decir nada" (pág. 41).

La comunicación no verbal

Gran parte del problema de Rosencrantz y Guildenstern se plantea porque, al tratar de obtener información sobre la condición psíquica de Hamlet, recurren casi exclusivamente a los contenidos verbales de su discurso y el análisis que hacen se centra en los significados precisos de las expresiones de Hamlet. Desalentado, Guildenstern declara: "Palabras, palabras, palabras... Es todo lo que tenemos" (pág. 31).

Los psicólogos, tradicionalmente, también han centrado su atención en las palabras, la estructura de la lengua, la sintaxis y la gramática. Pero, como descubren Rosencrantz y Guildenstern, hablar no es sólo cuestión de palabras. El Intérprete, líder de un grupo de actores o trágicos llamados a representar ante la Corte real, los saca de su error. Dice: "Estamos atados a un idioma que compensa con oscuridad lo que le falta en estilo", y sugiere que es la gestualidad, la "pantomima" (las conductas no verbales que acompañan al lenguaje), lo que hace que la comunicación resulte más o menos comprensible.

Al igual que el personaje del Intérprete de Stoppard, varios teóricos (especialmente Goffman, 1956, y Harre y Secord, 1972) subrayan el parecido entre el teatro y la vida cotidiana, y consideran a la conducta social como una actuación dramática bajo el control continuo de la retroalimentación con su público. El modelo de las habilidades sociales adopta una posición similar. Consecuentemente, muchos psicólogos han centrado su atención, en los últimos tiempos, en la gestualidad, en aspectos no verbales de la comunicación tales como la mirada, la expresión facial, la postura, el gesto y la distancia (la forma en que se percibe, estructura y utiliza el espacio físico), y en rasgos supralingüísticos de la comunicación, como la entonación, la forma de expresión y el tono de voz.

Una de las consecuencias de esta división del interés entre el discurso y la actuación es que, en la literatura psicológica, suelen mantenerse separados los campos de la comunicación verbal y no verbal. Por lo general, se da por sentado que hay dos lenguajes diferentes con dos funciones diferentes: el verbal, para transmitir la información y el no verbal (o "lenguaje del cuerpo") para la actitud y los sentimientos. Pero en la práctica no es posible separar estos dos "canales", y Beattie sostiene que es poco lo que se puede ganar si se lo hace en la teoría. Afirma que ambos se interrelacionan dinámicamente, como los pasos y el estilo en una rutina de baile.

La sincronización del discurso y el movimiento

El análisis de los patrones del discurso ha revelado que existen estrechos vínculos organizativos entre el discurso y la conducta no verbal en el nivel más microscópico, y que esos vínculos son probablemente esenciales para la comunicación eficaz. Además, estos estudios han revelado que la comparación entre la conversación y la danza es especialmente apropiada. Condon y Ogston (1967) demostraron, en su detallado microanálisis de una interacción filmada de tres personas, que "el cuerpo baila al mismo ritmo que el discurso", ya que en el movimiento corporal de un hablante se producen cambios sutiles y pasajeros sincrónicamente con la organización articulada y segmental de su conversación. Además, esta autosincronía (o congruencia) es sólo una de las formas en que se coordinan el discurso y las conductas no verbales.

Condon y Ogston también descubrieron que, durante la conversación, las personas interactuantes comparten con el hablante patrones armónicos de movimientos corporales.

Su estudio sobre un esquizofrénico (1966) sugiere que estos vínculos organizativos pueden ser esenciales para la comunicación exitosa. Los esquizofrénicos suelen ser personas con dificultades de comunicación y se descubrió que, aunque entre el terapeuta y su paciente se mantenía una sincronía interactiva, la autosincronía no funcionaba, y ciertas partes del cuerpo no estaban en sincronía con otras.

Una forma de sincronía interactiva más evidente es la que Scheflen (1964) denominó "congruencia postural", en la que dos o más personas adoptan posturas idénticas o especulares durante la conversación. Por ejemplo, dos o más personas en un pequeño grupo pueden estar sentadas con las piernas cruzadas, los brazos cruzados sobre el pecho y las cabezas inclinadas hacia un mismo lado. Esto no es coincidencia, ya que cuando un miembro de un conjunto congruente cambia su posición, los otros suelen hacer lo mismo rápidamente y así se mantiene la congruencia con los reiterados cambios en la postura corporal. Scheflen sugiere que, en general, la congruencia postural señala semejanza en los puntos de vista o los roles en el grupo, o en la condición social. Cuando la condición social de un miembro de un grupo difiere marcadamente de la de los demás, puede reflejarse en una postura diferente.

El Hamlet de Shakespeare, a pesar de todas sus supuestas aflicciones, reconoce claramente la importancia de los estrechos vínculos organizativos

sultar creíbles. Freud (1905, pág. 94) admite que la información puede transmitirse tanto verbal como no verbalmente y que a veces nuestros cuerpos traicionan a nuestros discursos:

> Si sus labios callan, habla con las yemas de sus dedos; la traición le sale por todos los poros.

Parecería que las acciones hablan más fuerte que las palabras. Ekman y Friesen (1969) sugieren que los "mentirosos" no verbales convincentes (como los actores profesionales, los abogados experimentados, los diplomáticos astutos, los buenos jugadores de poquer y los estafadores exitosos) han fortalecido la conciencia de su conducta no verbal y se han entrenado con la ayuda de retroalimentación externa focalizada (de un entrenador, un director, un público o un cliente) para lograr una mayor efectividad en sus simulaciones.

Mentir es, por lo tanto, una habilidad en sí, y Rosencrantz y Guildenstern no logran dominarla, como observa el propio Hamlet:

> Lo delatáis de tal modo en vuestros semblantes, que vuestra honradez no se da traza para ocultarlos (...)
>
> (*Hamlet*, acto II, escena 2).

Los turnos en la conversación

Otro ejemplo de la forma conjunta en que se organizan las conductas verbales y no verbales es la convención aparentemente universal de los turnos al conversar; generalmente, una persona habla y luego deja que hable otra. Duncan (1972) ha identificado diversas señales que marcan el final de una secuencia discursiva, de modo que una persona sabe cuándo comenzar a hablar. Estas señales suelen incluir cambios en la entonación, el timbre o el volumen, el arrastre de las palabras o el acento en una sílaba final, alguna clase de expresión estereotipada como "¿no es verdad?" o "Ud. me entiende", o un modo tal como la terminación con un gesto o la relajación de una posición tensa de la mano durante el propio turno de conversación.

El desarrollo de los turnos en la conversación se remonta hasta las interacciones básicas entre madres e hijos (Rogers, 1985; Newson, 1978). No obstante, aunque es evidente en los intercambios entre los niños muy pequeños y sus madres, los turnos son una habilidad adquirida y algunas personas los manejan mejor que otras. Esto tiene consecuencias sociales importantes, ya que la violación de los turnos mediante la interrupción o el habla simultánea suele considerarse una grave falta de etiqueta o hasta de respeto.

Mediante nuestra asociación con otros, aprendemos la forma en que utilizan las señales para los turnos, lo cual nos permite juzgar con precisión cuándo están a punto de dejar de hablar o de comenzar a hacerlo. Esa familiaridad se hace muy evidente en los intercambios de Rosencrantz y Guildenstern, cuyos turnos para la conversación son a veces tan ajustados y precisos que da la impresión de que cada uno está completando las oraciones del otro, como en la siguiente conversación sobre Hamlet:

ROS.: Habla solo, lo cual debe significar locura.

GUIL.: Si lo que dijera no tuviera sentido, pero lo tiene.

ROS.: Lo cual sugiere lo contrario.

INTÉRP.: ¿De qué?

GUIL.: Creo que lo tengo. Un hombre que habla cosas sensatas consigo mismo no está más loco que otro que habla sin sentido con otros.

ROS.: O está tan loco como él.

GUIL.: O está tan loco como él.

ROS.: Y él hace ambas cosas.

GUIL.: Así que ahí lo tienes.

ROS.: Sano de remate.

Beattie (1983) informa sobre una cantidad de estudios que sugieren que la conducta de turnos en la conversación está influida por variables sociales como la condición social y la confianza. Parecería que cuanto más confianza sienta una persona por otra, más probable es que la interrumpa; y cuanto más insegura sea en lo social, menos probable es que lo haga. Rosencrantz y Guildenstern interrumpen con frecuencia al Intérprete, que es socialmente inferior a ellos, pero jamás interrumpen a Hamlet que, aunque es su amigo desde la infancia, es heredero de la corona y por lo tanto superior a ellos. Del mismo modo, nunca interrumpen a ningún otro miembro de la Corte real.

Ya que la condición social y la confianza son factores significativos para los turnos en la conversación, podría suponerse que los hombres, cuya condición social suele ser superior a la de las mujeres, podrían interrumpir más que ellas. Algunos estudios sobre la conversación entre adultos (Zimmerman y West, 1975) y entre niños (Esposito, 1979) apoyan esta hipótesis, pero en un estudio sobre las tutorías universitarias, Beattie (1979) no encontró diferencias sexuales en la frecuencia o en el tipo de interrupciones. Sin embargo, la condición social dentro de las universidades puede estar menos determinada sexualmente que en muchos otros contextos, de modo que las convenciones sociales "normales" pueden resultar allí menos evidentes. Los resultados del estudio de Beattie sugieren que la interrupción se ve afectada por el contexto social así como también por otras variables.

Algunas de estas variables fueron aclaradas más en un estudio sobre entrevistas políticas (Beattie, 1982). En un análisis de dos entrevistas televisadas durante 1979, una con el entonces primer ministro británico Callaghan y otra con Margaret Thatcher, que lideraba la oposición, Beattie descubrió que el entrevistador interrumpió a Margaret Thatcher el doble de veces que ella lo interrumpió a él, mientras que Callaghan interrumpió a su entrevistador mucho más de lo que fue interrumpido por él. Sin embargo, cuando se la interrumpía, Margaret Thatcher seguía hablando hasta terminar su idea, sin importar cuánto durara la conversación simultánea. Parecería, por lo tanto, que la insistencia de Margaret Thatcher para hacerse oír es lo que ha originado la difundida idea de que es una mujer estridente y dominante en sus entrevistas, a diferencia de la serena afabilidad de Callaghan. Beattie sugiere que esto no puede explicarse según las diferencias de condición social acordadas a los dos políticos ni a la condición femenina de Margaret Thatcher sino que hay que considerarlo según su respectivo uso de las señales para los turnos en la conversación; es decir, según las diferencias en la habilidad conversa-

cional. Sugiere que Margaret Thatcher ofrece señales de turnos en los lugares incorrectos y que los entrevistadores comprensiblemente malinterpretan esas señales. Es posible que Margaret Thatcher sea interrumpida con frecuencia porque deja caer su tono al final de las oraciones y parece que con ello indica que ha terminado de hablar, cuando en realidad no ha terminado; o porque suele hacer gestos con sus manos después de que la interrupción ha comenzado y no antes.

Sin embargo, en este sentido hay que recordar que Margaret Thatcher es sumamente hábil en la oratoria y el debate públicos. Durante sus discursos, expresa sus puntos de vista de un modo convincente y enérgico. Bien puede ser que adopte una forma similar en las entrevistas: la de hablar a su entrevistador en vez de hablar con él. Ciertamente, cuando es entrevistada, no parece esperar darle la palabra a otro orador, lo cual sugiere que bien puede considerar a la entrevista como una plataforma desde la cual dirigirse a un amplio público y no como una conversación en sí.

Las investigaciones sobre interacción social

Como señala el Intérprete en *Rosencrantz y Guildenstern han muerto*, "hay un diseño en todas las artes" (pág. 59) y le toca al psicólogo descubrir, identificar y describir el diseño existente en la interacción social. Tradicionalmente, esto se ha hecho comparando grupos de ejecutantes eficientes e ineficientes, para determinar dónde radica la diferencia en sus conductas sociales, y luego enseñando las habilidades deseables a aquellos que son deficientes en ese sentido. La psicología social ha realizado en los últimos tiempos muchos aportes al entrenamiento en habilidades sociales. Durante el decenio 1970-1980 se hicieron muchas investigaciones en el campo de la comunicación no verbal, gran parte de las cuales se relacionaba con la codificación de la información interpersonal; es decir, la forma en que las personas intentan comunicar o, en algunos casos, ocultar sus actitudes, emociones, ideas y pensamientos. Los descubrimientos de las primeras investigaciones en este campo (Ruesch & Kees, 1956; Davitz, 1964; Grant, 1969; Mehrabian, 1970) fueron divulgados por Fast (1972). Estas investigaciones se vieron estimuladas por los avances en la grabación en video, que permitían un microanálisis de las conductas faciales y corporales fugaces, y también por la necesidad de muchos políticos y figuras públicas de presentarse efectiva y persuasivamente a través de la televisión.

Fueron los etólogos (como Hinde, 1972) quienes realizaron estudios sobre las conductas faciales y corporales; muchos de ellos se habían sentido impresionados por las notables semejanzas en la conducta expresiva de hombres y primates como los chimpancés. Varios de esos estudios se centraron en niños de menos de 5 años de edad, basándose en la idea de que las conductas no verbales son más fáciles de observar antes de que el lenguaje verbal se haya desarrollado plenamente (Blurton-Jones, 1972; McGrew, 1972). Muchos trabajos se ocuparon de analizar e identificar diferencias interculturales en la expresión facial y la gesticulación (Birdwhistell, 1968; Eibl-Eibesfeldt, 1972; Ingham, 1972; Ekman, 1972; Ekman y Friesen, 1976), y Morris (1977) atrajo la atención popular hacia estas variables, con su éxito editorial *Manwatching*.

La mirada

En los últimos quince años se han hecho muchas investigaciones sobre la mirada, que previamente no había sido tenida en cuenta. La mirada tiene una importancia considerable ya que, si uno no mira en la dirección correcta en el momento apropiado, no recibirá información perceptual. La mirada es también una señal social importante. Las primeras investigaciones en este campo fueron realizadas por Neilson, en Harvard, en 1962, y posteriormente Exline trabajó mucho sobre el tema en América, y Argyle, Kendon y Cook lo hicieron en Inglaterra. Argyle y Cook (1976) afirman que en general las investigaciones realizadas apoyan la idea de que las personas que miran más y sostienen la mirada más tiempo crean una impresión más favorable y son más apreciadas que aquellas que no lo hacen. La gente que observa más tiempo resulta más amistosa y confiada. Por el contrario, quienes miran menos y sostienen la mirada menos tiempo parecen estar a la defensiva, ser evasivos y tienden a sentirse menos cómodos socialmente.

La decodificación del afecto facial

Para responder efectivamente a las comunicaciones de los demás, es esencial la percepción precisa de la información transmitida. Esto se puede considerar como la decodificación de mensajes interpersonales. Rosenthal (1979) ha demostrado que las personas socialmente más hábiles son deco-

dificadores más precisos. Se han hecho varios intentos en la búsqueda de un código comprensivo para la expresión facial de la emoción, o el afecto, para los humanos (Lanzetta y Kleck, 1970; Ekman, Friesen y Tomkins, 1971; y Cuceloglu, 1972). Pero el sistema más comprensivo desarrollado hasta la fecha es el Código de Acción Facial (CAF), desarrollado por Ekman y Friesen (1978). Deriva de un análisis de la base anatómica de los movimientos faciales. Mide el propio rostro en vez de la información que de él puede deducirse, que ha sido el centro de atención clásico en las investigaciones sobre las expresiones faciales desde las obras pioneras de Darwin (1872). Una vez identificadas las diferentes acciones del rostro según los grupos musculares involucrados, Ekman y Friesen proporcionan un manual de auto-enseñanza, de entrenamiento, como referencia para la decodificación de la conducta facial. Comprende material textual que describe cada acción facial de acuerdo con su base muscular y los cambios en la apariencia, información sobre combinaciones de movimientos, ejemplos de fotografías y películas y detalles del desarrollo del CAF, estudios de confiabilidad y validez, experimentos en los que se ha utilizado el código con éxito y áreas de aplicación posibles. El CAF se ha usado para entrenar a diferentes grupos de profesionales en los Estados Unidos y sus autores señalan que se lo ha utilizado para aislar signos faciales entre personas sordas que usan lenguaje de signos y para medir los cambios en niños que han sufrido daño cerebral.

Entrenamiento en las habilidades sociales

Para permitir que la gente interactúe más eficiente y agradablemente y evite las consecuencias indeseables de habilidades sociales deficientes, se han incluido, en el entrenamiento ocupacional de muchos grupos profesionales, los resultados de las investigaciones sobre las habilidades sociales, y se los ha ofrecido en programas y cursos terapéuticos para el público en general. Aquí volvemos a encontrar al psicólogo en su rol de entrenador. Es función de los psicólogos administrar ese entrenamiento en casi todos los ámbitos concebibles, ya sea ocupacionales, clínicos, educativos, sociales o de cuidado. Por ejemplo, en la Universidad de Keele, a los médicos clínicos se les enseña a realizar entrevistas con los pacientes y, en una sociedad crecientemente multirracial, se ha difundido la enseñanza de las diferencias interculturales entre varios grupos profesionales. De este modo, se entrena a la policía esta-

dounidense para que mantenga una cierta distancia física cuando detiene gente de raza negra en la calle (Garratt y otros, 1981), y los hombres de negocios británicos se entrenan en conductas sociales árabes.

El entrenamiento en entrevistas, enseñanza, supervisión y terapia para las habilidades sociales profesionales es una de las principales áreas de interés. Sin embargo, hace tiempo que se admite que los métodos clásicos de educación tales como conferencias, debates y textos resultan insuficentes para afectar las habilidades sociales. Al igual que las habilidades motrices como andar a caballo o nadar, las habilidades sociales no pueden enseñarse de esta manera, y cada vez se enfatiza más la importancia del *role playing* y de varias formas de entrenamiento grupal. La forma más común de entrenamiento en las habilidades sociales es lo que Argyle (1969) denomina "aprendizaje en el trabajo", en el que no se da a la gente entrenamiento específico alguno además de la posibilidad de practicar una habilidad en una situación relevante. Pero, como señala Argyle, esto no garantiza necesariamente una mejora en la habilidad social, ya que, para empezar, mucha gente es socialmente incompetente y sólo persiste en el uso de técnicas sociales deficientes. Para ser eficente, el aprendizaje en el trabajo requiere oportunidades para la práctica de la habilidad, la retroalimentación y la generación de nuevas respuestas. La gente puede adquirir y adquiere habilidades sociales de esta forma pero no necesariamente aprende las formas más eficientes. El método tiene, por lo tanto, sus limitaciones, pero Argyle sugiere que estas se pueden superar parcialmente si, en las situaciones reales, alguien actúa como entrenador.

Role-playing y simulación

A menudo se emplean técnicas teatrales en las que los entrenados actúan la parte que les va a tocar y reciben realimentación inmediata sobre su desempeño, de parte de un entrenador o de sus pares en el entrenamiento. Estas técnicas suelen usarse para el entrenamiento de vendedores y docentes, y han mejorado mucho con los avances en las grabaciones en video.

Grupos de entrenamiento

La idea del entrenamiento grupal se inspiró en el psicólogo de la gestalt Kurt Lewin, que reconoció que el entrenamiento en las habilidades de re-

lación humana había sido sumamente descuidado. Promovió la formación de grupos para el entrenamiento en esas habilidades. El primero de esos grupos se reunió en Maine, en 1947, y poco después se establecieron los *National Training Laboratories* (Laboratorios Nacionales de Entrenamiento). Durante el decenio 1950-1960, muchas comisiones de empleo y escuelas de negocios de los Estados Unidos enviaron sus alumnos a los grupos coordinados por los Laboratorios Nacionales para desarrollar sus habilidades gerenciales y su sensibilidad interpersonal. Inicialmente, los grupos de hasta 12 personas se reunían una vez por semana en un período de varias semanas, para observar la naturaleza del proceso grupal, la interacción social y las relaciones humanas; gradualmente, esta experiencia se fue conociendo como entrenamiento en sensibilidad. El entrenamiento tenía objetivos comprensivos y de largo alcance, que sufrieron un marcado cambio cuando se reconoció que la participación en un grupo de entrenamiento o entrenamiento en sensibilidad solía conducir a fuertes experiencias personales: revelaciones drásticas y conmovedoras, expresiones emotivas catárticas, aumento en la sensación de bienestar y cambio personal. Los efectos parecían similares a los de la psicoterapia, y en el decenio 1960-1970 los grupos de entrenamiento perdieron rápidamente su identidad como grupos de entrenamiento en habilidades sociales y se convirtieron en el Encuentro. Argyle (1969) señala que mientras que entre el 30% y el 40% de los participantes de estos grupos se ha beneficiado con el entrenamiento, muchos otros se han visto gravemente perturbados por la experiencia.

El método de entrenamiento en habilidades sociales más utilizado en la actualidad incluye elementos de trabajo grupal, *role playing* y entrenamiento en la vida real. Estos elementos incluyen explicación y modelado, seguidos de *role playing*, retroalimentación verbal de un entrenador y mediante grabaciones en video y, posteriormente, ensayo. Sin embargo, la generalización a las situaciones reales sigue siendo problemática y por lo tanto suele darse "tarea para el hogar" entre sesiones, y se le requiere al participante que repita ejercicios en ámbitos reales e informe sobre ellos. Aun así, las sesiones de *role playing* pueden ser demasiado ajenas a ciertas situaciones de la vida real como para resultar eficientes, y por lo tanto en algunos entrenamientos profesionales, como en el policial, se ha enfatizado más la práctica en el trabajo.

Se han realizado muchos estudios de evaluación del entrenamiento en las habilidades sociales. Shepherd (1983) revisó 52 de esos estudios y llegó a la conclusión de que el entrenamiento en las habilidades sociales adquiere cierto valor para los que tienen deficiencias sociales y ha resultado bastante

exitoso en los ámbitos ocupacionales. Argyle (1984) es cuidadoso en sus afirmaciones respecto del entrenamiento en las habilidades sociales, pero sugiere que está empezando a satisfacer una inmensa necesidad humana. Aunque no les habría resultado de mucha utilidad a los desfortunados Rosencrantz y Guildenstern, que demasiado tarde reconocieron que "las ruedas se han puesto en movimiento y van a su propio ritmo, al cual nosotros estamos... condenados" (pág. 44).

¿Cómo mejorar las habilidades de aprendizaje?

James Hartley

Este capítulo se divide en dos partes. En la primera, analizaremos cuatro ideas para mejorar las habilidades de aprendizaje, que surgen de las investigaciones de la psicología cognitiva. En la segunda parte, consideraremos las implicaciones de estas ideas para el entrenamiento en las habilidades de estudio.

La psicología cognitiva y el aprendizaje

Si se le preguntara a un grupo de psicólogos cognitivos cuáles serían las consideraciones principales a tener en cuenta en un análisis del aprendizaje, habría muchas respuestas. Pero las más mencionadas serían nociones sobre:

- la organización del material;
- la profundidad de procesamiento;
- el papel del conocimiento previo;
- el conocimiento que tiene la gente sobre sus propias habilidades de aprendizaje.

Este capítulo comienza describiendo experimentos realizados por psicólogos que ilustran cada una de estas cuatro áreas. En algunos casos, se trata de material similar al que ya se ha visto en capítulos anteriores, por lo que se ofrece como una posibilidad para de consolidar las ideas.

¿Cómo ayuda al aprendizaje la organización del material?

Se suele decir que el sello distintivo de la buena enseñanza es su buena organización. ¿Qué significa esto? ¿Pueden demostrarse sus ventajas? Comparemos los siguientes textos:

El zorro se parece al perro. A veces se queda en un agujero. Se alimenta de pequeños animales. Es rojo. Habita en los bosques. También le gusta la fruta. Tiene un gran hocico. Caza aves para alimentarse. Vive entre los arbustos. A veces come pescado. Su cola le cuelga. Duerme en el suelo.

El zorro se parece al perro. Tiene un gran hocico. Es rojo. Su cola le cuelga. Habita en los bosques. Duerme en el suelo. Vive entre los arbustos. A veces se queda en un agujero. Se alimenta de pequeños animales. Caza aves para alimentarse. A veces come pescado. También le gusta la fruta.

El segundo texto presenta la misma información que el primero, pero supongo que nadie dudará de que está mejor organizada. La información se ha agrupado en tres temas principales: cómo es el zorro, dónde vive y qué come. Danner (1976) usó textos como estos para analizar los efectos de la organización en el recuerdo. Demostró que los niños de siete, nueve y once años invariablemente recordaban mejor el segundo fragmento. En varios otros estudios se han hecho descubrimientos similares. (Ver, por ejemplo, Bransford, 1979; Howe, Brainerd y Kingsma, 1985).

Estos estudios se ocupan de la organización de los elementos en el texto. Los autores de libros de texto tratan de ayudar a sus lectores organizando los materiales que presentan. Los libros se dividen en capítulos, los capítulos en secciones, que a su vez se subdividen en parágrafos y estos en oraciones, etc. En cada nivel, la secuencia de elementos es importante si se quiere que la estructura resulte clara para el lector. Recursos tales como los índices, los títulos de los capítulos y los subencabezamientos se utilizan para hacer más evidente la estructura, del mismo modo que los usos más sutiles de la tipografía y el diseño (Hartley, 1985).

Sin recursos de este tipo, gran parte de la organización impuesta por el autor de un libro de texto (o el docente) puede no ser clara para el alumno. Los alumnos, como veremos más adelante, tienen conocimientos previos y expectativas diferentes respecto de lo que se está enseñando, y esto puede influir en la forma en que perciben el material que se les presenta. De hecho, las evidencias existentes sugieren que el aprendizaje mejora más si los alumnos también imponen su propia estructura al material que están aprendiendo.

En un importante estudio, Tulving (1962) presentó a sus alumnos una lista integrada por dieciséis palabras sin relación entre sí, en un orden diferente cada vez, y después de cada presentación les pidió que las recordaran en

cualquier orden. Tulving analizó cada uno de los recuerdos, para ver si sus alumnos empezaban a agrupar las palabras, sin importar el hecho de que cada vez aparecieran en un orden diferente. Y esto fue lo que algunos de sus alumnos hicieron. Además, los que agrupaban ciertas palabras y las aprendían en los agrupamientos subjetivos obtenían mejores resultados que los alumnos que no lo hacían.

Los estudios sobre los alumnos que organizan sus materiales en situaciones de aprendizaje más naturales (por ejemplo, reformulando la información en diagramas y tablas de resumen o usando notas esquemáticas) también sugieren que esos procedimientos organizativos son de considerable valor (Davies y Greene, 1984; Jonassen, 1984).

¿Cómo influye en el aprendizaje la profundidad a la que se procesa el material?

Para considerar esta pregunta, me gustaría presentar antes el siguiente experimento (basado en Howe, 1984). Lea la siguiente lista de palabras y responda mentalmente cada pregunta por turno:

discurso	¿Es una forma de comunicación?
CEPILLO	¿Está escrito con minúsculas?
mejilla	¿Rima con "piso"?
CERCO	¿Rima con "terco"?
LLAMA	¿Es algo caliente?
suelo	¿Es un tipo de casa?
miel	¿Está escrito con minúsculas?
CUCHILLO	¿Rima con cazador?
guante	¿Está escrito con minúsculas?
cobre	¿Rima con "montaña"?
OVEJA	¿Es un mueble?
MONJE	¿Está escrito con mayúsculas?

Volveré a ocuparme de estas palabras en unos pocos minutos (cuando ustedes hayan tenido tiempo suficiente para olvidarlas). Mientras tanto, me ocuparé del tercer tema.

¿Cómo afectan los conocimientos previos al aprendizaje?

Los conocimientos previos pueden tanto ayudar como dificultar el aprendizaje. Rosemary Driver (1983), en *The Pupil as Scientist?* (¿El alumno como científico?) da ejemplos que demuestran que muchos alumnos llegan a las clases de ciencias con ideas ya formadas, que difieren de las teorías que el docente puede querer desarrollar, y que esto puede dificultar el aprendizaje. Estas ideas influyen en las observaciones que hacen los niños en sus experimentos y en las explicaciones que dan sobre ellos. Driver señala que lo que le parece obvio al docente puede no serlo para el alumno y viceversa. Por eso, por ejemplo, los docentes tienen que decirles a sus alumnos que miren por el microscopio y deben ayudarlos a dibujar "líneas de fuerza" cuando bosquejan patrones de limaduras de hierro en torno a un imán.

Un estudio de Morris y otros (1981) demuestra claramente cómo, por otra parte, los conocimientos previos pueden ayudar a la memoria. Morris y sus colegas tomaron a un grupo de alumnos una prueba de 42 puntos sobre su conocimiento del fútbol profesional inglés. (La prueba contenía preguntas como: ¿Quién es el arquero del Manchester? ¿Quiénes juegan en Brisbane Road? ¿Quién es el entrenador del Celtic? ¿Cuál fue el último equipo inglés que ganó la copa UEFA?) Los alumnos completaron la prueba un sábado por la tarde y luego, a las 5 de la tarde, escucharon los resultados de 64 partidos que se habían jugado ese día. Después, se les presentó una lista de los partidos y se les pidió que recordaran los resultados.

Las respuestas demostraron que los alumnos que habían respondido bien en la prueba sobre conocimientos de fútbol recordaban mucho mejor los resultados que aquellos a los que les había ido mal. El promedio de recuerdo para los partidos de primera división (11 partidos) fue de 7,8 para diez alumnos que habían obtenido 25 o más en la prueba sobre conocimientos de fútbol, y de sólo 3,3 para once alumnos que habían obtenido 5 o menos. En general, la correlación entre los conocimientos previos y el recuerdo exitoso fue de 0,81.

Si los conocimientos previos pueden ayudar u obstaculizar el aprendizaje, parece razonable decir que la buena enseñanza debería empezar por lo que los alumnos ya saben. Esto es más fácil de decir que de hacer, pero hay ciertas demostraciones del principio en acción. Wittrock, Marks y Doctorow (1975), por ejemplo, intentaron usar el conocimiento previo de los niños como base para el aprendizaje de vocabulario. Tomaron parte en el estudio cuatro grupos de niños de entre 10 y 11 años. El grupo 1 leyó dos ve-

ces un fragmento que contenía varias palabras difíciles y luego se verificó su comprensión de las palabras. El grupo 2 escuchó el fragmento dos veces y luego se lo sometió a la misma prueba. Los grupos 3 y 4 leyeron y escucharon, respectivamente, el mismo fragmento, y luego se sometieron a la misma prueba, pero en la primera ocasión se reemplazaron las palabras difíciles por sinónimos de las mismas, más sencillos y conocidos. Sólo en la segunda lectura se incluyeron las palabras difíciles. Con todo, los grupos 3 y 4 obtuvieron mucho mejores resultados que los grupos 1 y 2 en la prueba de vocabulario. Su familiaridad previa con las palabras más fáciles les permitió dar significado a las palabras más difíciles.

Profundidad de procesamiento (nueva visita)

Volvamos ahora a la lista de palabras que examinamos hace unos minutos. Observe las 24 palabras que citamos a continuación y vea cuántas puede reconocer de las doce palabras originales. No mire la lista anterior.

BRUJA	CUCHILLO	CONDE
CERCO	LANA	MONJE
BRUTO	LLAMA	CALAVERA
CHARCA	MIEL	CUERPO
MEJILLA	ESPECIA	DISCURSO
ENFERMERA	PINTOR	GUANTE
SUELO	OVEJA	AGUA
ESTRELLA	CEPILLO	COBRE

Con la lista original de doce palabras, se pidió una respuesta a una pregunta sobre cada una. Había tres tipos de preguntas: sobre apariencia visual (mayúsculas o minúsculas), sobre sonidos (qué palabras rimaban con otras) y sobre significados (por ejemplo, si una oveja era un mueble).

Experimentos como éste (con listas mucho más largas) han sugerido que uno recordará mejor algo si tiene que procesarlo o pensar en ello más profundamente (Craik y Tulving, 1975). Por lo tanto, en este experimento, es esperable que el lector recuerde la mayoría de las palabras *discurso, suelo, llama* y *oveja*, porque las preguntas sobre estas palabras se relacionaban con su significado. Es probable que recuerde menos las palabras *cepillo, guante, miel* y *monje*, porque las preguntas sobre estas palabras sólo tenían que ver

con su aspecto. Su puntaje en el grupo de palabras restante (*mejilla, cuchillo, cerco* y *cobre*) probablemente sea intermedio, ya que las preguntas sobre estas palabras implicaban cierto nivel de procesamiento pero no tanto como las preguntas sobre su significado. (No se preocupe si su puntaje individual no es así: sólo quiero sugerir el patrón promedio de resultados obtenidos cuando hay muchos participantes.) Resultados como estos sugieren que la gente recuerda mejor cuando piensa en algo o cuando lo procesa más profundamente. (Ver también el capítulo 5.)

La idea de que cuanto más profundamente se procese la información mejor se recordará es atractiva (aunque a veces es difícil de comprobar). Pero, hasta ahora, sólo hemos considerado breves presentaciones de materiales no relacionados entre sí y su recuerdo. ¿Qué sucede con las situaciones de aprendizaje más naturales? Hay conjuntos de experimentos que sugieren que varias estrategias de procesamiento de la información pueden afectar notablemente el recuerdo de largo plazo.

Estas estrategias (incluidas en la tabla 12.1) pueden considerarse de acuerdo con la profundidad de procesamiento involucrado. Por ejemplo, Jonassen (1984) sugiere que tomar notas pautadas es más eficiente que tomar notas de manera convencional o subrayar, y yo mismo he sugerido antes que la reorganización de la información es una estrategia de aprendizaje más eficaz que la mera repetición.

Otros estudios analizan la forma en que los alumnos leen los textos de enseñanza. Estos estudios distinguen entre los alumnos que adoptan lo que se denomina un "enfoque superficial" para estudiar y los que adoptan un "enfoque profundo" (Marton, Hounsell y Entwistle, 1984).

Los alumnos que adoptan un enfoque superficial para el aprendizaje probablemente aprendan las cosas "como loros", para poder escupirlas en los exámenes, y se concentren en el recuerdo de ejemplos más que en los principios organizativos. En este capítulo, por ejemplo, una persona así podría recordar que tuvo que hacer un experimento que tenía que ver con el procesamiento de palabras pero no recordar que lo que pretendo es *hacer que el lector considere los aportes de la psicología cognitiva al estudio del aprendizaje*. Los alumnos que adoptan un enfoque profundo, en cambio, intentarían buscar los principios organizativos del texto y relacionar las ideas nuevas con los conocimientos previos ganados en los capítulos anteriores. El alumno "superficial" encara la tarea con la intención de memorizar y completar las exigencias de la misma; el alumno "profundo" encara el texto con la intención de comprender.

Hay evidencias que apoyan la idea de que los alumnos "profundos" obtienen mejores resultados en los exámenes, pero es algo contradictoria. Esto puede deberse, en parte, a que:

a) algunos alumnos parecen capaces de cambiar de estrategia (según se trate de material nuevo o no y de por qué se lo esté aprendiendo)

b) muchos exámenes fomentan la memorización y por eso los alumnos pueden aprobarlos con un enfoque superficial. Marton y otros (1984) hacen un análisis muy útil de estos temas.

Tabla 12.1. Estrategias de procesamiento de la información para el aprendizaje

• Estrategias de práctica del material. Por ejemplo: copiar, subrayar, repasar.
• Estrategias de organización del material. Por ejemplo: crear encabezamientos, agrupamientos, resúmenes, mapas.
• Estrategias de integración del material. Por ejemplo: resumir, hacer diagramas, construir tablas de resumen integradoras.
• Estrategias de elaboración de la información. Por ejemplo: usar la imaginación, crear analogías, parafrasear, relacionar la nueva información con la vieja.

Nota: Muchas estrategias (como el repaso) pueden clasificarse de varias formas. Jonassen (1984) comenta algunas de las estrategias menos comunes (como los mapas y las redes).

¿Cómo afecta el aprendizaje nuestro conocimiento sobre nuestras propias habilidades de aprendizaje?

El conocimiento que tenemos sobre nuestras propias habilidades de aprendizaje se denomina metacognición. En el capítulo 6, Angus Gellatly analiza el concepto de metamemoria según lo que los niños saben sobre sus aptitudes memorísticas. El concepto de metacognición es similar pero de alcance más amplio. La metacognición infantil (o la adulta, para el caso) puede analizarse de acuerdo con lo que los niños saben o creen saber sobre sus propios procesos cognitivos (y esto incluiría a su memoria).

El concepto de metacognición es importante por dos motivos. Primero, nos permite explorar el conocimiento que tenemos sobre nuestras propias habilidades de aprendizaje. Segundo, nos permite considerar en qué medida las estrategias que hemos analizado hasta aquí (organización del material, relación entre el material nuevo y el viejo, fomento del procesamiento más profundo) pueden volverse parte de nuestras propias actividades cotidianas cuando estamos aprendiendo.

Consideremos primero cuánto conocimiento podrían tener los adultos sobre sus propios procesos de aprendizaje. En un estudio realizado en 1979, Linda Baker presentó seis textos de unas 250 palabras cada uno a un grupo de quince alumnos. Cada texto contenía tres párrafos, y el párrafo del medio tenía alguna clase de problema, que podía ser: a) incoherencias, b) referencias incorrectas o confusas a lo anterior, c) conectores lógicos incorrectos (por ejemplo, el uso de "sin embargo" en vez de "además"). Primero, se pidió a los alumnos que leyeran los seis textos. Luego, se les pidió que recordaran el párrafo del medio de cada uno de los textos. Finalmente, se les comentaron los tres tipos de problemas y se les preguntó si los habían notado.

Los resultados mostraron que los problemas no afectaron notoriamente el libre recuerdo de los párrafos del medio, aunque los alumnos tuvieron tendencia a recordar menos que un grupo de control que había leído los mismos párrafos pero sin esos problemas. Los alumnos del grupo experimental ignoraron los problemas, los corrigieron o hicieron deducciones correctas o incorrectas al darles sentido a los párrafos.

Los alumnos notaron un 23% de los problemas cuando estaban leyendo y sólo el 38% cuando se les pidió que los buscaran en los textos. La conclusión de Baker fue que algunos alumnos pueden controlar y de hecho controlan su comprensión mientras están leyendo (al menos, en una situación experimental) y que se puede lograr que algunos lo hagan (por ejemplo, si se les pide que busquen los errores) pero que muchos otros no.

La investigación posterior de Baker y Anderson (1982), usando los mismos textos presentados oración por oración en terminales de computadora, demostró más precisamente que los alumnos pasaban más tiempo leyendo las oraciones que tenían problemas y que las revisaban con mayor frecuencia. Pero, incluso en este estudio, sólo el 62% de los alumnos detectó uno o más problemas.

Estudios como estos (con niños y adultos) han alentado a los investigadores a ver si pueden ayudar a los alumnos a evaluar su comprensión mientras leen, para aumentar su procesamiento metacognitivo. Brown y otros

(1983), por ejemplo, desarrollando el concepto de aprendizaje autocontrolado. La idea es que los alumnos controlen, verifiquen y evalúen su progreso en el aprendizaje. En el estudio de un texto, por ejemplo, sugieren que a los lectores se les deben enseñar cinco aptitudes críticas: el resumen (la autorrevisión), la interrogación, la aclaración, la predicción y el control de su comprensión.

Un ejemplo típico de uno de los muchos estudios llevados a cabo por Brown y sus colegas es el siguiente: los investigadores debían ayudar a los alumnos a resumir textos; sobre la base de varios experimentos previos, Brown y Day (1983) aislaron las estrategias que se ilustran en la tabla 12.2, usadas (con diferentes niveles de éxito de parte de alumnos y de expertos) al resumir textos.

Brown, Campione y Day (1981) describen las tendencias evolutivas en el uso correcto de estas estrategias: por ejemplo, los niños de 6 y 7 años se concentran en las estrategias de borrado y los de 15 años sólo usan bien la estrategia de "inventar una oración temática" en el 30% de los casos, a diferencia de los expertos, que lo hacen bien casi siempre. Brown y otros (1981) se interesaron en enseñar a los alumnos a resumir mejor. Para ello, diseñaron un estudio que comparaba tres métodos de enseñanza:

a) *enseñanza "ciega"*: se alentaba a los alumnos de manera general para que hicieran un buen resumen, incluyeran las ideas principales y omitieran las trivialidades y todas las palabras innecesarias, pero no se les daban reglas para lograrlo.

b) *enseñanza informada*: igual que el método anterior, pero se explicaban las reglas para hacerlo y se realizaba ejercitación.

c) *aprendizaje autocontrolado*: igual que (b), pero se proporcionaba entrenamiento explícito en cómo controlar las reglas: es decir, se mostraba a los alumnos cómo asegurarse de que se eliminaran todas las trivialidades y redundancias, de que las listas de ítem fueran reemplazadas por subordinadas, de tener una oración temática para cada párrafo y de saber si necesitaban inventar alguna oración temática.

Los resultados de este estudio demostraron que hubo beneficios para todos los alumnos en su capacidad de escoger e inventar oraciones tópicas con los tres métodos de enseñanza, pero que las técnicas de aprendizaje autocontrolado resultaban especialmente efectivas con los alumnos de menor rendimiento y con las tareas más difíciles.

Los estudios sobre aprendizaje auto-controlado de Brown y sus colegas sugieren que las mejoras en el aprendizaje pueden conseguirse: a) estructurando más la tarea, y b) haciendo más explícito el reconocimiento del éxito. Parece que en todo hay efectos relacionados con la edad y la capacidad, pero que el aprendizaje auto-controlado (donde la responsabilidad de la evaluación del éxito del aprendizaje pasa del docente al alumno) es una poderosa técnica de aprendizaje.

Tabla 12.2. Ejemplos de verbalizaciones de los expertos sobre las reglas del resumen.
(Tomado de Brown y Day, 1983, y reproducido con permiso)

Borrado	"En un resumen de este tipo, los detalles, se eliminan. Se necesitan generalizaciones, no detalles" (trivialidades). "A este texto le sobran oraciones. Hay dos que dicen lo mismo: que los animales del desierto tienen hábitos nocturnos por el calor. Se puede omitir una." (redundancia)
Subordinación	"Una cosa que hice fue eliminar las diferentes clases de plantas. En vez de escribir 'margaritas, amapolas, caléndulas y lirios' sólo puse 'plantas anuales' y nuevamente omití los detalles y sólo hice generalizaciones."
Selección de oración temática	"Esta oración contiene los puntos esenciales del párrafo; especifica el proceso por el cual se conserva la vida de la planta. Hay que incluirla en cualquier resumen."
Invención de oración temática	"El párrafo habla del ciclo de las plantas anuales, que producen semillas, esperan las lluvias, florecen, vuelven a producir semillas, etc. Aunque no lo dice explícitamente, sólo hay que mencionar el ciclo y omitir lo demás."
Combinación entre párrafos	"En los dos primeros párrafos, la única información esencial es lo que dice del calor y la falta de agua en el desierto. Los combinaré en dos oraciones que contengan toda la información que necesito. Una oración es simple; la otra, es compuesta."

Implicaciones para la enseñanza de habilidades de estudio

Los cursos y textos tradicionales sobre las habilidades de estudio se concentran en dar a los alumnos información sobre diversas habilidades, como tomar notas, redactar composiciones y prepararse para exámenes, sin importar la materia (sea Inglés, Matemáticas o Psicología). Esos cursos descuidan los problemas que plantean las diferentes materias y también las diferencias individuales sobre el tema de aprendizaje en las percepciones de los alumnos y, de hecho, cómo estas percepciones pueden ir cambiando con el tiempo (ver Perry, 1981). También descuidan los problemas planteados por las ideas de aprendizaje autocontrolado.

Los cursos y textos modernos sobre habilidades de estudio tienden a centrarse más en todos estos aspectos. Por ejemplo, un curso de esa naturaleza diseñado por Gibbs (1981) considera las actividades de los alumnos dentro de disciplinas específicas. Para tomar notas, por ejemplo, Gibbs les pide primero a los alumnos que tomen notas de un texto en particular, que es parte del tema de enseñanza. Luego les pide que trabajen en equipos de dos y analicen las notas del otro e intenten comprender por qué están escritas como están. Luego, los equipos se unen en grupos de cuatro alumnos y cada uno de ellos debe explicar las notas de su compañero de equipo a los otros tres. Después, se pide a los cuatro alumnos que consideren cuáles son las características que hacen que sus notas sean "buenas", "pobres" o "inútiles" y qué señalen las estrategias útiles y las que es conveniente evitar. Se escriben estas características para después poder leerlas a toda la clase en una sesión plenaria final.

Gibbs adopta un enfoque similar con las habilidades de escritura. Sugiere que se deben proporcionar a los alumnos dos composiciones sobre el mismo tema, escritas por alumnos anteriores, con perspectivas marcadamente diferentes. Los alumnos trabajan primero de manera individual y responden a las siguientes preguntas: ¿Qué composición es mejor? ¿Por qué? ¿En qué difieren? Luego, trabajan en parejas para comparar sus comentarios y elaborar una respuesta conjunta a las mismas preguntas. Después, en grupos de cuatro, se les pide que combinen sus conclusiones y describan lo que piensan que pretendía cada uno de los dos autores de las composiciones. Finalmente, con toda la clase, cada grupo cuenta a los demás sus conclusiones y luego se realiza una discusión general.

Otros cursos modernos de habilidades de estudio se concentran en la enseñanza de habilidades generales y específicas. Habilidad general es la capacidad de elegir, para la tarea que se va a encarar, un conjunto de subhabilidades específicas adecuadas, a partir de una gran variedad de posibilidades. Se enseñan conjuntos de estrategias a los alumnos, que pueden desplegarse de manera diferente en las distintas situaciones de aprendizaje.

Para el análisis de cómo las diferentes estrategias pueden comprometer a los alumnos en un procesamiento más profundo, incluí, en la tabla 12.1, conjuntos de estrategias de procesamiento de la información. A éstas les podemos agregar ahora dos clases más: las estrategias metacognitivas y las de apoyo. Las estrategias metacognitivas, como se analizó antes, se ocupan de las técnicas de control de la propia comprensión (tales como revisión, parafrasis, imágenes, predicción y preguntas para verificar la propia comprensión). Las estrategias de apoyo tienen que ver con las formas de encarar los problemas que provocan las distracciones y la inquietud, y con la organización del propio entorno para el estudio efectivo. Estas estrategias incluyen: tener un lugar especial para estudiar habitualmente, fijar y cumplir fechas, planificar horarios de estudio y hacer ejercicios de relajación para reducir la ansiedad. Weinstein y Mayer (1985) describen cursos de habilidades de estudio en todos los niveles educativos (de primarios a terciarios) que se han centrado en el procesamiento de información particular, las estrategias metacognitivas y las de apoyo. Son escasos los estudios que combinan entrenamiento en varias estrategias de los tres grupos, pero Weinstein y Mayer comentan cuatro ejemplos. Aquí, sólo para ilustración, describiré dos de esos enfoques integradores.

Estudio 1. Dansereau y otros critican a gran parte de los primeros cursos sobre habilidades de estudio porque consideran que son demasiado amplios y no prestan suficiente atención a la psicología cognitiva actual. Desde mediados del decenio 1970-1980, Dansereau y sus colegas han diseñado varios programas de entrenamiento en estrategias de aprendizaje, que buscan remediar estas deficiencias (por ejemplo, Dansereau y otros, 1979; Diekhoff, Brown y Dansereau, 1982; Dansereau y otros, 1983; Dansereau, 1985).

El programa de Dansereau más conocido es el representado por el acrónimo MURDER ("asesinato", en inglés), en el cual:

M = *mood* (establecer el *humor* para el estudio)

U = *understanding* (leer para *entender* las ideas difíciles e importantes)

R = *recalling* (*recordar* el material sin referirse al texto)

D = *digesting* (*digerir* el material, corrigiendo los errores del recuerdo y amplificando y reprocesando el material)

E = *expanding* (*ampliar* el conocimiento por medio de preguntas)

R = *reviewing* (*repasar* los errores y aprender de las evaluaciones).

El acrónimo MURDER describe un conjunto de seis estrategias ejecutivas fundamentales (es decir, qué hacer). Cada estrategia ejecutiva va acompañada de varias subestrategias operativas más detalladas (es decir, cómo hacerlo). Así, establecer el humor para la enseñanza incluye el uso de técnicas de relajación y conversación constructiva con uno mismo (por ejemplo: "Ahora, lo que tengo que hacer... Bien... Listo... Perfecto"). Recordar incluye utilizar subestrategias como la paráfrasis, el uso de imágenes, mapas y el análisis de las ideas cruciales. Además, el control continuo de la propia comprensión es una subestrategia operativa de todas las estrategias ejecutivas.

Para evaluar la eficacia de este esquema, Dansereau y otros (1979) entrenaron a 38 estudiantes de Psicología en el uso de estas subestrategias ejecutivas y operativas, dos horas semanales durante quince semanas. En las comparaciones con los grupos de control, los grupos experimentales evidenciaron mejoras significativamente superiores en las subsiguientes pruebas de comprensión y recuerdo y en los autoinformes sobre las habilidades de aprendizaje.

Estudio 2. Paris, Cross y Lipson (1984) diseñaron un programa de entrenamiento denominado *Estrategias Informadas para el Aprendizaje* (EIA), para ayudar a los niños más pequeños de la escuela a mejorar sus habilidades de lectura. Este programa de entrenamiento en particular duraba catorce semanas e incluía varias características de enseñanza directiva, tales como: a) centrar la atención del niño en el material que se va a enseñar, b) generar altos niveles de compromiso, y c) proporcionar práctica frecuente y retroalimentación inmediata. Además, los módulos de enseñanza del programa contenían una "gran variedad" de actividades diseñadas para ayudar a la comprensión: incluían lecciones sobre la comprensión de los propósitos de la lectura, activar el conocimiento relevante de fondo, destinar atención a la idea principal de cada párrafo, detectar inferencias y controlar la propia comprensión.

El programa EIA fue probado en dos grupos de alumnos de 8-9 años y dos grupos de 10-11 años (cada uno con un grupo de control). Los alumnos de los grupos de EIA obtuvieron mayores beneficios que los de los grupos de control en las pruebas de completamiento de un texto con las palabras faltantes y en las tareas de detección de errores, pero no mostraron mejoría alguna en dos pruebas estandarizadas de comprensión de textos. Sin embargo, Paris y sus colegas sostienen que los grupos de EIA demostraron un mayor conocimiento de las estrategias de lectura.

Estos dos estudios destacan las principales preocupaciones de quienes trabajan en el campo de las estrategias de aprendizaje. Las investigaciones incluyen: a) un análisis detallado de qué implica la realización de tareas específicas, b) el desarrollo de conjuntos de estrategias dentro de un sistema total, para encarar los diferentes aspectos de las distintas tareas, y c) una evaluación del éxito del producto. Los resultados de los estudios de evaluación se usan luego para modificar y mejorar el programa de entrenamiento original.

Conclusiones

En este capítulo, he resumido brevemente algunas de las áreas de la psicología cognitiva que se relacionan con el aprendizaje. Hemos puesto el acento más en los experimentos de laboratorio que en los estudios sobre los efectos del entrenamiento en las habilidades de estudio, fundamentalmente porque hay más experimentos que estudios sobre sus efectos, y son más precisos. Sin embargo, hay dos críticas importantes a los estudios de laboratorio en este contexto:

a) su marcado uso de materiales y condiciones experimentales simplificados.

b) su concentración en el aprendizaje verbal (a expensas de lo práctico, social y afectivo).

Estas deficiencias no han pasado inadvertidas y, sin duda, las futuras investigaciones procurarán remediarlas.

Sección 4

La habilidad y el pensamiento

13

La habilidad en el razonamiento

Angus Gellatly

Algunos lectores conocerán ya la siguiente adivinanza: "Tres indios caminan en fila por un sendero en el bosque. El primero es padre del segundo, pero el segundo es hijo del tercero. ¿Cómo puede ser?"

A muchos, si no han visto antes una adivinanza del mismo tipo, les resultará confusa, al menos por un rato. La dificultad surge del tipo de interpretación que la gente tiende a dar a las oraciones que integran la adivinanza, la tendencia a ir más allá de la información que realmente se proporciona. Naturalmente, la solución es que el tercer indio es la madre del segundo indio, pero si uno inconscientemente ha dado por supuesto que los tres indios eran hombres, puede ser difícil hallarla.

Hay al menos dos factores que pueden fomentar un supuesto, o inferencia, en cuanto al género de los tres indios. En primer lugar, las referencias masculinas de las palabras "hijo" y "padre" pueden crear un ámbito, o expectativa, tendiente a la masculinidad[1]. En segundo lugar, puede estar operando una tendencia a asignar valores naturalmente masculinos cuando no se especifica el género, como en el uso común de pronombres masculinos en los casos en que el género es indefinido. Sea cual fuere la importancia relativa de estos dos factores, la adivinanza funciona aprovechando el hecho (analizado por John Sloboda en el capítulo 4 y por Don Rogers en el capítulo 10) de que la comunicación mediante el lenguaje sólo es posible sobre la base de un conjunto de supuestos compartidos entre hablantes/escritores y oyentes/lectores. Para entender un discurso o texto, el oyente/lector debe hacer todo tipo de inferencias más allá de lo que dice el texto, y la importancia de la adivinanza sobre los indios es que demuestra cuán injustificadas pueden ser esas inferencias.

En este capítulo analizaremos la propensión de la gente a hacer inferencias al razonar sobre cuestiones cotidianas o sobre problemas lógicos, de modo que es necesario que seamos claros respecto del significado de la palabra "inferencia". Se dice que se hace una inferencia cuando, sobre la base de afirmaciones particulares (premisas), sacamos una conclusión que no está

1. En inglés esto es más marcado aún, ya que no existen diferencias de género en los sustantivos en general: Indian es tanto masculino como femenino (N. del T.)

explícitamente contenida en las afirmaciones originales. Para tomar un ejemplo del capítulo 4, si leemos: "Juan iba camino de la escuela; no tenía ganas de dar lección de Matemáticas", podemos inferir que Juan es un alumno al que no le va muy bien en Matemáticas, o que es un docente. Bien o mal, hemos ido más allá de las premisas hacia una conclusión. Hemos hecho inferencias.

Los filósofos distinguen entre dos tipos de inferencia: la deducción y la inducción. Como el tema central de este capítulo es el papel que juegan en el razonamiento humano estos dos tipos de inferencia, debemos analizar más detalladamente la diferencia entre ellos.

Inducción

Además de la comprensión del lenguaje, casi todas las conductas y pensamientos se basan en supuestos e inferencias que no se pueden justificar definitivamente, idea que originalmente destacó el filósofo David Hume en el siglo XVIII. Una inferencia que sólo afirma que la conclusión es probablemente verdadera es una inducción. Por ejemplo, por mi observación de las nubes oscuras que hay hoy en el cielo y mi conocimiento de que habitualmente llueve cuando hay nubes oscuras, inductivamente infiero que hoy va a llover, tomando esta conclusión sólo como algo probable. Mi conclusión puede expresarse verbalmente o mediante una acción: en el caso del cielo nublado, tomo mi impermeable antes de salir de casa. La vida (y el lenguaje) sería imposible si no nos permitiéramos hacer inferencias que no es seguro que sean correctas. Muchos de nuestros mejores empeños se basan en inferencias de conclusiones probables, y parte de la destreza depende de juzgar con precisión los grados de probabilidad. Sin embargo, desde que Aristóteles descubrió (o, según el punto de vista, inventó) el razonamiento deductivo, el pensamiento occidental reverencia de manera especial las inferencias que se consideran concluyentes y no meramente probables.

Deducción

Una inferencia en la que las premisas garantizan la conclusión es una deducción, y puede cobrar la forma de un silogismo. Un ejemplo famoso de silogismo válido es:

(1) Todos los hombres son mortales.
Sócrates es hombre.
Por lo tanto, Sócrates es mortal.

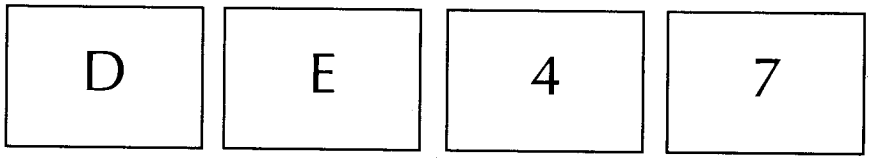
Al leer este silogismo uno comprende que la conclusión sigue naturalmente a las premisas. Si Sócrates no fuera mortal, podríamos asegurar con confianza que una o las dos premisas deben haber sido falsas. Esta confianza surge de nuestro sentido intuitivo de que el silogismo tiene una forma válida, y la forma de un argumento válido es aquella en la cual las premisas verdaderas deben siempre llevar a una conclusión verdadera.

Desde Aristóteles, las deducciones han sido algo impresionante para la gente. El conocimiento al que se llega deductivamente, como en las matemáticas, parece especialmente satisfactorio. Por ejemplo, Euclides pudo establecer un pequeño número de premisas (o postulados, como él los llamó) y deducir a partir de ellas toda su geometría. Al hacerlo, fijó un ideal deductivo-matemático con el que tienden a medirse los métodos de todas las otras ramas del conocimiento.

Deducción y razonamiento

Una consecuencia de la estima en que se llegó a tener a la deducción fueron los interrogantes que se plantearon acerca de su relación con la racionalidad y el razonamiento humano. ¿La racionalidad es la capacidad de razonar de acuerdo con una lógica deductiva? Si esto es así, ¿todos los humanos pueden ser considerados racionales? ¿O sólo algunos? ¿O ninguno? Una posición que se puede adoptar en este tema (y la han adoptado, entre otros, los filósofos Kant y Boole) es que las reglas de la lógica deductiva son descriptivas del pensamiento humano, y el pensamiento cumple sus reglas. Esas reglas son como en el siguiente par:

Modus Ponens	*Modus Tollens*
Si p implica q	Si p implica q
p	No q
ergo q	ergo no p



En vez de concebir al razonamiento como algo guiado por una lógica mental, se lo puede considerar una habilidad, tal como todas las otras formas de cognición de las que se ocupa este libro. Los desempeños expertos tienen que entenderse en sus propios términos. No recurrimos a lógicas subyacentes para explicarlos sino a evidencias de los rasgos característicos de la habilidad, como el agrupamiento de entrada y salida, la mejora con la práctica, la fluidez y rapidez de las respuestas, la automaticidad y demás (capítulo 2). De modo que si el razonamiento es una habilidad, debemos poder analizarlo sin recurrir a la lógica mental. De hecho, el debate sobre si el razonamiento se puede entender mejor en términos de habilidad o de lógica mental, o en términos compatibles con alguno de los dos enfoques, es complejo (Johnson-Laird, 1982, 1983; Gellatly, 1986). En el resto de este capítulo, analizaremos algunas de las evidencias a favor y en contra de ambos puntos de vista sin pretender acabar con la discusión en un sentido o en otro. Para empezar nuestra investigación sobre el razonamiento, podemos ver un problema diseñado por Peter Wason (1966).

El problema de Wason

El problema de Wason se refiere a cuatro tarjetas, que se ilustran en la figura 13.1. Sólo se ve un lado de esas tarjetas, que muestran los símbolos D, E, 4 y 7, respectivamente. Se nos dice que cada tarjeta tiene una letra de un lado y un dígito del otro, y no se duda de que esto sea así. Luego, se nos da la siguiente regla: "Si una tarjeta tiene una D de un lado, tendrá un 4 del otro lado". El problema consiste en decir qué tarjetas hace falta dar vuelta (y cuáles, por lo tanto, no es necesario dar vuelta) para comprobar si esa regla es cierta.

No hay trampas en este problema, aunque puede ser de ayuda subrayar que la regla no es reversible, de modo que la inversa no es aplicable. Intente averiguar la respuesta usted mismo antes de seguir leyendo.

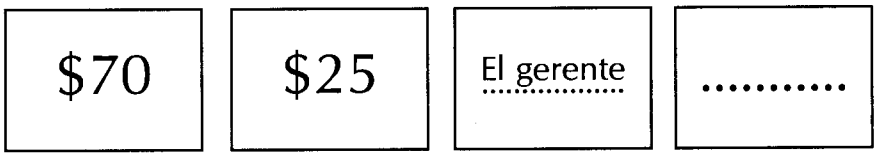


Figura 13.1 El problema de selección de tarjetas de Wason

El problema de D'Andrade

Antes de revelar la solución correcta al problema de Wason, veamos un segundo problema, originalmente creado por Roy D'Andrade (ver Rumelhart y Norman, 1981). Imagine que usted es empleado de una gran tienda y supervisa los recibos de ventas. La empresa tiene una norma: "Si una compra excede los $50.-, el recibo de venta debe estar firmado al dorso por el gerente". Le muestran cuatro recibos como los de la figura 13.2: uno es por $70, otro es por $25; uno está firmado al dorso y el otro no está firmado. El problema consiste en decir qué recibos hace falta dar vuelta (y cuáles no) para comprobar si se ha respetado la norma. Una vez más, intente resolver usted mismo este problema.

Figura 13.2.La versión de D'Andrade del problema de selección

Los experimentos han demostrado que la mayoría de la gente da la solución correcta al problema de D'Andrade. Eligen dar vuelta el recibo de $70 y el que no está firmado. Es bastante evidente que la norma se viola sólo si el recibo que supera los $50 no está firmado (contraviniendo el *modus ponens*) o si el recibo no firmado resulta ser por una cifra superior a los $50 (contraviniendo el *modus tollens*). Fácil, ¿no?

Volvamos ahora al problema de Wason. Mucha menos gente (el 10% o menos de los estudiantes universitarios) pueden conseguir la respuesta correcta aquí. La solución consiste en dar vuelta la tarjeta que tiene una D y la que tiene un 7. El problema es decidir si la regla dada es verdadera o falsa. Si la combinación de símbolos en cualquiera de las cuatro tarjetas rompe la regla, la regla es falsa. De lo contrario, es verdadera. La regla dice que "si una tarjeta tiene una D de un lado, tendrá un 4 del otro lado". Sólo si la tarjeta con la D no tiene un 4 del otro lado se violará la regla, o también si la tarjeta que no tiene un 4 (y por lo tanto tiene un 7) tiene una D al dorso. Sin embargo, lo más frecuente es que la gente elija dar vuelta la tarjeta con la D y

la tarjeta con el 4, en vez de las tarjetas con la D y el 7. Es decir, dan vuelta las tarjetas que muestran los símbolos mencionados en la regla. En vez de resolver el problema, simplemente "adaptan" sus respuestas a los símbolos mencionados. La adaptación no suele ser un proceso consciente y a veces los sujetos experimentales sostienen acaloradamente que la solución correcta es "D y 4" y no "D y 7" (Wason, 1983).

El razonamiento y la memoria

Lo interesante de esta diferencia en el desempeño en los dos problemas es que se trata de dos versiones del mismo problema; tienen exactamente la misma estructura lógica. De hecho, el objetivo de D'Andrade, al crear su problema, fue precisamente encontrar una versión más fácil del problema de Wason, y si a alguien le resulta difícil aceptar la solución correcta en el de Wason puede comprender claramente su forma elaborándolo en paralelo con la versión de D'Andrade. Los problemas con la misma estructura lógica pueden ser fáciles o difíciles, según el contenido que los rellene. No se trata simplemente de que los contenidos abstractos sean más difíciles que los concretos o realistas, ya que algunas versiones concretas y realistas del problema de Wason son tan difíciles como su versión abstracta.

¿Por qué, entonces, la gente responde bien a la versión de D'Andrade del problema? No hace falta haber sido empleado de una tienda; la experiencia o la comprensión de tipos de relación análogos alcanza. Griggs (1983) sostiene que la gente no resuelve en realidad la versión de D'Andrade sino que recuerda un problema análogo que alguna vez enfrentó antes y del cual ya sabe la solución. Esto sugiere que la gente tenderá a resolver un problema novedoso sólo si reconoce su semejanza con un problema familiar para el cual ya tiene la solución o un procedimiento para solucionarlo.

Para decirlo de una forma levemente distinta, pero que enfatiza igualmente el papel de la memoria: desde el capítulo 5 sabemos que los problemas que imponen una pesada carga a la MCP, o memoria a corto plazo operativa, son difíciles de resolver. Una forma de reducir la carga de la MCP es el agrupamiento de los datos que se ingresan siguiendo esquemas almacenados en la MLP. De este modo, será más fácil interpretar ("tener en mente") un problema que se presenta de una forma que se ajusta a uno o más esquemas (o modelos) de la MLP que un problema que no se ajusta a ningún esquema almacenado en la MLP. Uno de los modelos de la MLP (de los que

ya se habló en el capítulo 5) es el que se denomina libreto. La versión de D'Andrade extrae de la MLP el libreto sobre cómo actúan en las tiendas los gerentes y los vendedores, y el problema puede así interpretarse razonablemente. Pero la versión original de Wason no se ajusta a ningún esquema familiar. Hay que interpretarlo más o menos palabra por palabra en la memoria operativa. Esto supera la capacidad de la MCP y el resultado es que la mayoría de la gente no llega a comprender bien el problema.

Según lo que acabamos de ver, el papel del razonamiento es raramente (si alguna vez lo es) el de tomar la información dada sobre un problema y deducir directamente una conclusión. Es más probable que el razonamiento actúe retrospectivamente para justificar una solución a la que se ha llegado por otros medios. Ese punto de vista sobre la forma en que se resuelven los problemas es coherente con la idea de la regla de producción *"si... entonces..."* presentada en el capítulo 2. La *acción* de revisar superficialmente un procedimiento de solución sólo se realiza si el problema está configurado de una forma que satisfaga las *condiciones* para esa *acción*. La secuencia de *acción* puede dispararse automáticamente y ofrecerá una solución que luego puede justificarse mediante el razonamiento. Aprender a configurar los problemas nuevos para que se asemejen a los conocidos es el proceso por el cual se mediatiza, o transfiere, la generalización (ver capítulo 8).

Los estudios realizados sobre las diferencias entre novatos y expertos resolviendo problemas de física apoyan la idea de que la resolución deductiva de problemas depende de la activación de las producciones almacenadas en la memoria de largo plazo y que la generalización se puede hacer aprendiendo a configurar los problemas de la manera adecuada. Los físicos profesionales reconocen (configuran) tipos de problemas más rápidamente y responden a ellos con procedimientos de solución más amplios y automáticos. Sus soluciones se ejecutan en unos pocos cálculos (a veces en uno solo), en vez de en una serie de pasos más pequeños. Incluso cuando los novatos son capaces de ejecutar la acción de un procedimiento de solución, suelen tener dificultades para reconocer las condiciones en las que resulta adecuado. Larkin, McDermott, Simon y Simon (1980) sugieren que puede entenderse a la intuición matemática como este reconocimiento de esquemas altamente desarrollado sobre las condiciones a partir de las cuales una acción asociada surge automáticamente.

El razonamiento y las acciones

Hemos visto que la familiaridad con el contenido de los problemas verbales influye en el éxito con el que se los puede enfrentar. Se ha descubierto que lo mismo sucede con los problemas no verbales que se deben resolver más con acciones que con palabras.

Kendler y Kendler (1963) hicieron una prueba con niños en un aparato que comprendía tres paneles: A, B y C. Primero, se presentaba el panel A y se enseñaba a los niños que si apretaban un botón obtenían una bolita. Luego, se reemplazaba al panel A por el B, en el que si apretaban un botón conseguían un rodamiento. A continuación, se presentaba el panel C junto con una pila de bolitas y rodamientos, cualquiera de los cuales podía entrar en una ranura del panel. Los niños aprendían que si insertaban una bolita en la ranura conseguían una recompensa, que podía ser un juguete o una golosina, pero que si insertaban un rodamiento no conseguían nada. Finalmente, se les presentaban los tres paneles a los niños y se los invitaba a obtener una recompensa. Kendler y Kendler encontraron que hasta los 10 años los niños tenían dificultades para unir las dos acciones: apretar un botón del panel A para obtener una bolita y luego insertarla en el panel C para conseguir la recompensa. Combinar las dos cosas en una "inferencia de acción" era muy difícil para los niños más pequeños.

Cole, Gay, Glick y Sharp (1971) repitieron este experimento en Liberia y hallaron que los adultos Kpelle iletrados tenían un rendimiento pobre, y sólo alrededor del 8% alcanzaba la solución. ¿Los Kpelle eran incapaces de hacer la inferencia? Cole y sus colegas consideraron que la compleja maquinaria del aparato (que funcionaba según los principios de una máquina tragamonedas) podía resultar inhibitoria para los Kpelle. Transformaron la tarea en otra, con llaves y cerraduras, objetos que resultaban conocidos para los Kpelle. Reemplazaron los paneles A y B por dos cajas de fósforos diferentes e identificables que contenían, respectivamente, una llave roja y una negra. El panel C fue reemplazado por una caja cerrada que se podía abrir con una de las llaves para obtener una recompensa. Como antes, los sujetos aprendían primero qué llave había en cada caja y luego, separadamente, qué llave encajaba en la caja cerrada. Cuando se les presentó la tarea completa, más del 70% de los Kpelle lograron obtener la recompensa. El contenido del problema (en este caso, la naturaleza del aparato) influía en la tasa de solución. Cole y sus colegas pensaron que esto se debía a que la falta de familiaridad con el aparato inhibía a los sujetos y no les permitía pensar en el procedimiento

de solución. Su hallazgo no resultará soprendente, quizá, para quienes no se lleven bien con los equipos mecánicos.

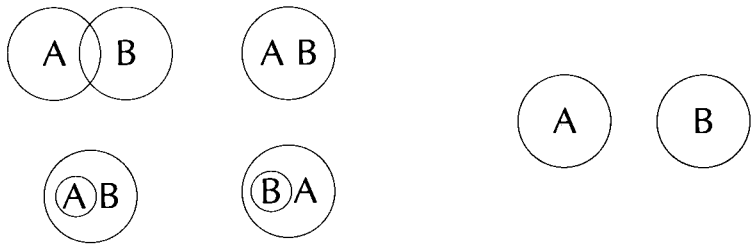
El razonamiento y la lógica

No resulta nada novedoso el hecho de que el éxito con un problema sea una función de su contenido así como también de su forma lógica. Ya Aristóteles era consciente de que la facilidad con la que se puede juzgar la validez de un silogismo varía según su contenido. Por ejemplo, veamos el siguiente silogismo:

2) Algunos miembros del Partido Laborista son autodidactas.
Ningún valón pertenece al Partido Laborista.
Por lo tanto, al menos algunos valones no son autodidactas.

Begg y Denny (1969) hallaron que el 55% de los alumnos juzgaron erróneamente que un silogismo similar al 2) era válido. A veces la gente defiende acaloradamente la validez de un silogismo de este tipo aun cuando se les dice que no es válido. Sin embargo, un cambio en los contenidos puede revelar de inmediato que la forma del silogismo es defectuosa. Por ejemplo, 3) tiene la misma forma que 2) pero muy poca gente lo considera válido.

3) Algunos mamíferos saben nadar.
Los peces no son mamíferos.
Por lo tanto, algunos peces no saben nadar.



El hecho de que el contenido de los problemas tenga tanta relación con la capacidad de la gente para razonar correctamente sobre ellos podría tomarse como una negación de la doctrina de la lógica mental. Se podría afirmar que si hubiera una lógica mental, su eficiencia operativa debería depender sólo de la forma y no de los contenidos. Además, la posición alternativa (que el razonamiento es una habilidad) se ve apoyada por muchas evidencias. Sabemos que cuanto más tiempo pase alguien practicando la resolución de problemas matemáticos o de ajedrez, mejor será en ese tipo de problemas. Del mismo modo, la capacidad de evaluar categorías silogísticas puede mejorarse si se enseña la técnica de los círculos de Euler. Esta técnica emplea círculos para representar las categorías de las entidades mencionadas en el silogismo, como se muestra en la figura 13.3, lo cual también demuestra que una premisa dada puede tener más de una representación posible. Es com-

prensible que la mayoría de la gente tienda a cometer más errores cuando hay varias formas de representar un par de premisas que cuando sólo hay una representación posible (Johnson-Laird, 1983). En el caso anterior, simplemente hay más para pensar y por lo tanto hay más posibilidad de error. No obstante, sigue siendo cierto que la práctica y la adquisición de estrategias, o técnicas, lleva a mejoras en el desempeño, y éste es uno de los puntos claves de la habilidad.

Quienes defienden la lógica mental, sin embargo, no aceptan que la existencia en el razonamiento humano de errores que dependen de los contenidos haga insostenible su planteo. Una defensa común, recientemente esbozada por Henle (1962, 1978), consiste en afirmar que la razón misma nunca está en falta pero que a veces se la aplica a información distorsionada o mal percibida. En el caso de los silogismos, puede olvidarse una de las premisas, incorporarse al problema una premisa extra que deriva del conocimiento fáctico o malinterpretarse una premisa. Por ejemplo, se puede pensar que si se dice que "Todos los A son B", también significa que "Todos los B son A". Henle sugiere que cuando se realiza el esfuerzo de reconstruir el razonamiento real aplicado a un problema, se comprueba que la gente siempre razona de manera válida pero a veces es el problema lo que está equivocado. Alternativamente, se puede no intentar resolver el problema sino tratar de adivinar la respuesta, o evaluar la verdad de una conclusión en vez de la validez del argumento del cual se deriva. Sea cual fuere el caso, podría afirmarse que el razonamiento mismo no equivoca el camino.

Una de las dificultades de la propuesta de Henle es que no parece estar abierta a la refutación. Sea cual fuere la respuesta a un problema, siempre será posible hacer una reconstrucción que la haga parecer racional, siempre que se suponga un adecuado malentendido de las premisas. Por otra parte, no hay duda de que los malentendidos ofrecen una explicación plausible de muchos errores manifiestos en las tareas de razonamiento. Podemos ver esto muy claramente en relación con los estudios interculturales de la cognición.

Algunos A son B

(b)
Ningún A es B

Lógica, cultura y lenguaje

En la cultura occidental siempre nos hemos preguntado si la gente de otras culturas tiene los mismos procesos mentales que nosotros. Frecuentemente, se ha afirmado que las culturas llamadas tradicionales se parecen a los niños occidentales en sus procesos psíquicos, y que ambos grupos difieren de los adultos occidentales (por ejemplo, Piaget, 1974). Este tipo de comparaciones demuestra, en la práctica, graves dificultades conceptuales (Gellatly, 1986). No obstante, los estudios interculturales han tenido resultados estimulantes.

Se han hecho varios estudios en los que se ha pedido a gente iletrada, sin escolarización, con frecuencia habitantes de pequeñas aldeas de diversos lugares del mundo, que razonara con silogismos. Scribner (1977) observa que cuando se les pide que repitan las premisas que se les acaban de leer, con frecuencia no pueden hacerlo. Omiten premisas o las sustituyen por conocimientos personales. De manera similar, cuando se les presentaba el siguiente silogismo:

4) Todas las mujeres que viven en Monrovia están casadas.
Kemu no está casada.
¿Kemu vive en Monrovia?

Una respuesta típica era: "Monrovia no es para una clase de personas solamente, y Kemu fue a vivir allí". Se ignora la condición hipotética del silogismo en favor de la información práctica relativa al tema de conversación

que se ha introducido; en este caso, la residencia en Monrovia. Como consecuencia de este hábito, los tipos de distorsión descritos por Henle se observan abundantemente. Y, como Henle, Scribner sostiene que la gente no alfabetizada siempre razona de manera lógica sobre sus propias interpretaciones de un problema, si es que razona sobre él.

Esta última aclaración es necesaria, porque a veces la gente iletrada rechaza por completo las tareas de razonamiento propuestas por los psicólogos. En el decenio 1930-1940, Luria (1976) presentó el siguiente problema ante un grupo de campesinos de Uzbek, en Asia Central:

5) En el norte todos los osos son blancos.
Novaya Zemlya queda en el norte.
¿De qué color son los osos allí?

Entre las respuestas que obtuvo, algunas decían: "Habría que preguntárselo a la gente que ha estado allí y los ha visto", y "Siempre hablamos exclusivamente de lo que vemos; no hablamos de lo que no vemos". Estas personas simplemente no estaban preparadas para jugar al juego de preguntas y respuestas de Luria, y su rechazo nos lleva a comprender que efectivamente se trata de un juego. Scribner (1977) dice que el juego depende de la comprensión de un tipo peculiar de discurso y lo que se hace evidente es que un juego (o un tipo de discurso) y sus reglas pueden darse por sentadas en una cultura pero resultar extraños para otra. El juego del silogismo (el tipo de discurso en el que se funda) resulta extraño en las sociedades iletradas no escolarizadas.

Las reglas y el discurso

Ya hemos visto que la comprensión del lenguaje involucra al oyente en todo tipo de inferencias lingüísticas relativas al tema de conversación. Pero esto no es todo. Como ya se dijo en el capítulo 10, los oyentes también deben inferir las intenciones del hablante, lo que se puede denominar "sentido implícito" de una expresión (Clarke, 1977). Si alguien pregunta: "¿Sabe dónde queda la estación?", y uno responde: "Sí", uno no ha inferido correctamente las intenciones del otro o ha decidido ser hostil, irónico o algo por el estilo. Para inferir las intenciones del hablante (el sentido implícito) hace falta comprender a qué tipo de discurso pertenece su expresión. Los diferentes tipos de discurso tienen sus propios conjuntos de reglas (que se superpo-

nen) para guiar a hablantes y oyentes. Las reglas que rigen el discurso conversacional en castellano incluyen que la expresión "¿Sabe dónde queda la estación?" se interprete como: (a) un pedido de información y no un interrogatorio sobre los conocimientos geográficos del oyente, y (b) que requiere, en caso de ser afirmativa la respuesta, información sobre la forma de llegar a dicha estación. En el discurso conversacional de otras culturas, es posible que se mantenga la regla (a) pero en lugar de la regla (b) quizá los buenos modales exijan que el oyente intente ofrecer la información solicitada aun cuando no tenga idea de dónde está la estación. Esto puede ser desconcertante para el turista que le pregunta a algún residente local sin tener en cuenta la divergencia entre sus respectivas reglas de discurso.

Debería ser evidente la importancia de este análisis para el desempeño en los silogismos. Al preguntar si Kemu vive en Monrovia o de qué color son los osos de Novaya Zemlya, el psicólogo recurre a un conjunto de reglas del discurso que incluyen una regla que indica que los oyentes deben ignorar sus conocimientos personales, o su falta de esos conocimientos, y responder sólo a la información dada en las premisas, que bien puede ser falsa. En la conversación, ésta es una exigencia muy poco común (Gellatly, 1987) porque, como hemos visto, en general se espera que los oyentes aporten sus conocimientos sobre un tema en vez de omitirlos. De hecho, tan extraño resulta el pedido que los miembros de culturas iletradas no lo reconocen. Se aferran a sus reglas habituales de conversación y responden a la pregunta recurriendo a sus conocimientos personales. O, como en el caso de Luria, pueden llegar a increpar al psicólogo por violar las reglas con una pregunta que los lleva más allá de sus conocimientos personales.

El razonamiento como habilidad

Cumplir las reglas del discurso es, de por sí, una habilidad, como lo analiza Don Rogers en el capítulo 10. Esto se plantea notoriamente cuando uno entra a un grupo social en el que se comparte cierta forma idiosincrática de sentido del humor, por ejemplo. Uno bien puede sentirse incapaz de interpretar rápidamente el sentido implícito de las expresiones de los hablantes, de distinguir los insultos en broma de los verdaderos insultos o las emociones reales de las fingidas. Pero si uno pasa en este grupo el tiempo suficiente, esos problemas se resolverán solos. Mediante la aplicación de las habilidades sociales que posee (capítulo 11), uno aprende a decodificar los

mensajes que se transmiten e ingresa en la forma de pensar y hablar del grupo. Esto nos dice, entre otras cosas, que hay más de un nivel de habilidad en el razonamiento deductivo. Ya hemos visto que la resolución de problemas deductivos es una actividad que implica habilidad, la cual puede, como en otros casos, estar representada en términos de sistemas de producción. El éxito en los problemas deductivos mejora con la práctica, que lleva a que los problemas se configuren en agrupamientos mayores, que activan automáticamente unidades más amplias de procedimientos de solución. Ahora vemos que también hay involucrada una forma previa de habilidad. Antes de poder involucrarse en la resolución de problemas deductivos, hay que dominar las reglas del discurso que rigen a esa forma de cognición. Esto consiste en hacer inferencias lingüísticas-discursivas que no son en sí deductivamente seguras; pueden resultar falsas. Así, la deducción, ese ideal del conocimiento seguro, se construye sobre los cimientos de la inferencia inductiva. Lejos de trascenderla, la deducción resulta ser dependiente de la capacidad de hacer inferencias inductivas.

Esto no significa que lo antedicho deba leerse como una desvalorización de la deducción. La configuración de argumentos de manera deductiva es, cuando resulta aplicable, un método de suma importancia para garantizar la fuerza y el rigor de nuestro pensamiento. En la ciencia, así como en muchos otros campos de la vida cotidiana, procedemos planteando una hipótesis y luego verificándola para ver qué consecuencias se pueden deducir válidamente de ella, y luego verificando esas consecuencias. También en las matemáticas el modelo euclideano de establecer postulados seguidos de deducciones sigue teniendo vigencia. En este capítulo hemos intentado demostrar que el éxito en los problemas de naturaleza deductiva es una cuestión de aprendizaje cultural, de habilidad cognitiva. La resolución de los problemas deductivos no difiere, en principio, de la resolución general de problemas, que es el tema del próximo capítulo.

La resolución de problemas

Angus Gellatly

Al empezar este capítulo, presentamos dos problemas para que el lector intente resolverlos.

> a) Una mañana, al amanecer, un monje budista empieza a escalar una montaña por un sendero estrecho que serpentea en torno a ella. Asciende a un ritmo regular de 4,5 km por hora.
>
> Después de 12 horas llega a la cima, donde hay un templo, y se queda allí meditando durante varios días hasta que, un amanecer, empieza el descenso por el mismo sendero, a un ritmo regular de 7,5 km por hora.
>
> Demuestre que el monje pasa por algún punto del camino a la misma hora del día a la ida y a la vuelta.
>
> (Basado en un problema creado por Duncker.)

> b) Usted está organizando un torneo de tenis por eliminación simple y tiene 111 inscriptos. Para cada partido se necesita un juego de pelotas nuevo. ¿Cuántos juegos de pelotas harán falta?
>
> (Basado en un problema creado por De Bono.)

Veremos las soluciones a estos problemas unas páginas más adelante. Por el momento, ya habrán cumplido su objetivo si han hecho pensar al lector en qué es lo que implica la resolución de problemas, por qué a veces es una tarea difícil y cómo se puede mejorar. Estos son los temas de los que se ocupa este capítulo. Examinaremos los procesos que constituyen la resolución de problemas y la cuestión de si se puede entrenar a la gente para que mejore su eficiencia en la resolución de problemas.

Pero, para empezar, se necesitan algunos comentarios generales sobre la naturaleza de los problemas y sus soluciones.

La naturaleza de la resolución de problemas

Puede parecer extraño que este libro contenga un capítulo dedicado específicamente a la resolución de problemas. Después de todo, los capítulos anteriores también se han ocupado de las soluciones a los problemas relativos a la memoria, la comunicación y el estudio. ¿En qué sentido, entonces, este capítulo tiene más que ver con la resolución de problemas que los anteriores?

Eso depende de qué sentido le demos a la palabra *problema*. Newell y Simon (1972) definen un problema de la siguiente forma: "Una persona se enfrenta a un problema cuando desea algo y no sabe de inmediato qué serie de acciones puede desempeñar para conseguirlo". En esta definición, un problema se relaciona con las aptitudes del individuo. Para un niño de 4 años, recordar una lista de palabras que incluya dos animales, dos frutas y dos colores puede ser un problema, pero para el adulto alfabetizado ya no es un problema, porque da los pasos adecuados (la práctica categorizada) de manera automática. Del mismo modo, leer o conducir un automóvil plantean al novato toda clase de problemas que sencillamente no existen para el experto. Muchos de los problemas mencionados en los capítulos anteriores (aunque no todos) han sido de este tipo. Es decir, son problemas para los que se adquieren los procedimientos de solución en el curso de la evolución social y cognitiva normal, o como consecuencia del entrenamiento especial, y por lo tanto (según la definición de Newell y Simon) dejan de ser problemas.

Evidentemente, la gente puede aprender (y aprende) habilidades para eliminar todo tipo de problemas culturalmente identificados, desde el dominio de la gramática de la lengua hasta la navegación sin instrumentos, pasando por el juicio sobre la validez de un silogismo. Algunas de estas habilidades, como el control de la comprensión, tienen una amplia gama de aplicaciones, en tanto que otras sólo resultan útiles en circunstancias muy específicas. Sin embargo, pese a todas estas habilidades adquiridas, la vida cotidiana nos presenta permanentemente nuevos problemas para los que no tenemos una solución preparada. Esto nos lleva a la pregunta sobre si es posible (o no) aprender un conjunto muy general de habilidades, o principios, para resolver todo tipo de problemas. En otras palabras, además de adquirir habilidad en el uso de procedimientos de solución para problemas específicos, como en el ejemplo de los físicos planteado en el capítulo 13, ¿es posible adquirir habilidad para resolver problemas en general? El resto de este capítulo se ocupará de este tema. Analizaremos los procesos (como el de representación) involucra-

dos en la resolución de problemas y luego ofreceremos una evaluación de los intentos de mejorar la eficacia con la que se ejecutan.

La representación de problemas

Ya hemos visto, en la selección de tareas de Wason (capítulo 13), que se puede encarar el mismo problema lógico con mayor o menor facilidad, según los contenidos que lo informan. Este es un ejemplo de la influencia de la representación. ¿Pero de qué otro modo, además del contenido, pueden diferir las representaciones? Bueno, un camino es el modo de representación.

Las representaciones verbales y las imágenes visuales

Un buen ejemplo de diferencia en la forma de representación de los problemas es la existente entre la codificación verbal y la codificación en imágenes. En la práctica, ésta es una cuestión de grado ya que una formulación verbal puede provocar al menos algunas imágenes visuales y una imagen probablemente esté asociada con determinadas palabras. De todas maneras, un problema puede representarse predominantemente en palabras o predominantemente en imágenes, y la forma elegida puede tener consecuencias importantes. El problema del monje budista de Duncker, planteado al comienzo de este capítulo, está presentado verbalmente y de manera tal que estimula los intentos de resolverlo de manera matemático-verbal. Pero esta forma de representar el problema no resulta nada conveniente. Por el contrario, la solución se hace sencilla cuando representamos el problema en imágenes. Para hacerlo, imaginen un monje trepando una montaña durante un día. Imaginen también un segundo monje, descendiendo por la misma montaña durante un día. Superpongan ahora las dos imágenes, como si los dos viajes se hicieran el mismo día. Evidentemente, en algún momento del día los dos monjes deben cruzarse, y por lo tanto estarán en el mismo lugar al mismo tiempo. Esto es igual para el caso de un monje solo que haga los dos viajes en días separados.

En el problema de los monjes, la representación visual es superior a la verbal. Pero esto no siempre es así. El problema del campeonato de tenis que plantea De Bono es mucho más difícil si uno empieza con una hoja con el diagrama de un torneo por eliminación: una forma de pirámide caída hacia

un costado. Esto nos lleva a empezar agregando un partido final a dos semifinales, a cuatro cuartos de final, y así hasta llegar a la primera ronda, donde alguno no tendrá que jugar, ya que 111 no es múltiplo de 2, como 64 o 128. Si uno representa el problema de manera verbal la solución es mucho más sencilla: el número de participantes es 111; todos ellos perderán una vez, excepto el ganador del torneo; por lo tanto, habrá 110 partidos y ésa es la cantidad de juegos de pelotas que se necesitan.

Estos dos ejemplos demuestran la importancia de probar las diferentes representaciones de un problema y evaluar su potencial relativo para ofrecer una solución. Desafortunadamente, varios factores se unen para hacer que la representación flexible sea difícil de lograr en la práctica; nos ocuparemos ahora del análisis de algunos de esos factores.

Configuraciones mentales

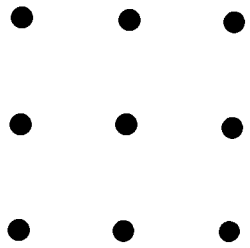
Las experiencias pasadas influyen sobre nuestra conducta presente de muchas maneras, y si no tuviéramos la capacidad de aprender de ellas estaríamos realmente muy mal. De todos modos, los viejos hábitos no siempre se adecuan a las exigencias de las nuevas situaciones. Podemos quedarnos demasiado inmóviles en algunos sentidos. Thomas Kuhn, el notable historiador de la ciencia, sostiene que los hábitos de pensamiento son un importante factor en la determinación de los compromisos teóricos en la ciencia. Cuando se propone una nueva teoría, que desafía a otra establecida, raramente hay evidencias concluyentes para decidir entre ellas. La vieja teoría gradualmente se va abandonando porque la generación que creía en ella (y había aprendido a pensar según ella) desaparece. Los científicos más viejos encuentran a las teorías novedosas, que introducen conceptos no conocidos y postulan la existencia de nuevas entidades, difíciles de aceptar. Como han aprendido a construir el mundo según una teoría previa, no hacen la transformación hacia una perspectiva moderna de inmediato. Kuhn (1970) ilustra el tema con un relato sobre el "descubrimiento" del oxígeno. En 1774, Priestley aisló una muestra de lo que ahora llamamos "oxígeno" pero que él pensó que era óxido nitroso o "aire deflogisticado". En 1777, Lavoisier propuso que el gas era uno de los dos constituyentes mayores del aire y desarrolló la base de la concepción moderna del elemento oxígeno. Priestley jamás pudo aceptar la teoría de Lavoisier y siguió conceptualizando al nuevo gas según la antigua teoría "flogística", con la que estaba familiarizado. Así, si bien Priestley fue el pri-

mero de los dos en aislar el gas ahora denominado oxígeno, no puede considerarse su descubridor. En realidad, la idea de "descubrimiento" es un concepto bastante difícil.

El ejemplo de Kuhn se refiere a los efectos de largo plazo de la experiencia, con hábitos mentales acumulados en años de aprendizaje, pero la configuración psíquica también puede solidificarse en el corto plazo. Esto queda demostrado con el famoso experimento de Luchins y Luchins (1950) con las jarras de agua, que se ilustra en la tabla 14.1. Dadas tres jarras de diversas medidas y una cantidad de agua ilimitada, hay que obtener cantidades específicas de agua. Se presentan varios problemas: el primero es bastante fácil. Los problemas 2 a 6 pueden resolverse de la misma manera (b - a - 2c). El problema 7 puede resolverse de la misma manera, pero tiene también una solución más fácil. Luchins y Luchins descubrieron que la gente que había realizado los problemas del 2 al 6 tendía a no ver la solución más sencilla del problema 7. Como se había creado una configuración mental solidificada, el problema 7 se representaba como si fuera uno más de una serie de problemas idénticos.

Las configuraciones mentales de corto plazo son fáciles de romper si uno toma conciencia sobre ellas. Pero las configuraciones mentales de largo plazo pueden resultar totalmente inevitables, o hay que estar constantemente cuidándose de ellas. Las configuraciones de largo plazo son parte del estilo de pensamiento de una persona.

Tabla 14.1 Ilustración de los problemas de las jarras de Luchins



Problemas	Capacidad jarra A	Capacidad jarra B	Capacidad jarra C	Cantidad deseada

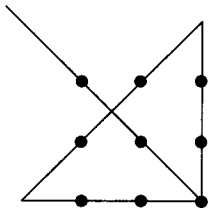
Inmutabilidad funcional

No sólo es importante la representación general de un problema. La representación de sus elementos individuales también puede influir en la probabilidad de éxito en su resolución. Tendemos a representarnos los objetos según sus funciones, y si bien esto suele ser correcto, a veces puede ser excesivamente limitativo. La inmutabilidad funcional, como se denomina a este hábito, fue investigada por Maier (1931), quien planteó un problema en el que había que atar dos cuerdas que colgaban del techo de una habitación. Las cuerdas estaban tan separadas que no era posible sostener una y estirarse, al mismo tiempo, para alcanzar la otra. En el suelo de la habitación había varios objetos, incluyendo unas pinzas. Una solución posible consistía en atar las pinzas a la primera cuerda, hacerla balancearse, tomar la segunda cuerda y estirarse para alcanzar la primera cuando se acercara por el balanceo. Maier descubrió que la gente tendía a pensar en las pinzas sólo según su función usual. A menos que se hicieran sugerencias al respecto, era difícil percibir su potencial como plomada de un péndulo.

La historia de la tecnología es una abundante fuente de ejemplos de inmutabilidad funcional y de repentinos escapes de esa inmutabilidad. La innovación técnica con frecuencia consiste en la apreciación de cómo se puede adaptar una máquina ya existente a la resolución de problemas muy ajenos a sus actuales posibilidades de aplicación. Weizenbaum (1984) recuerda que la máquina de vapor había sido usada durante cien años para bombear agua de las minas antes de que Trevithik percibiera por primera vez su potencial como fuente de potencia de locomoción. Trevithik puso una máquina de vapor en un carruaje, que a su vez colocó sobre unas vías ya existentes, y ofreció así una novedosa solución al perenne problema del transporte. Weizenbaum señala que una inmutabilidad funcional similar dominaba también el uso inicial de las computadoras, que a menudo se consideraban meras máquinas de calcular o tabular con rapidez. Pasó bastante tiempo hasta que se reconoció su versatilidad como manipuladoras de símbolos en general (ver capítulo 16).

Figura 14.1. El problema de los nueve puntos

Contrabando de supuestos



Tanto las configuraciones psíquicas solidificadas como la inmutabilidad funcional son casos especiales de un factor general que puede inhibir la flexibilidad en la representación de los problemas. Este factor es el contrabando de supuestos. En el capítulo 13 vimos que todo el pensamiento se basa en supuestos implícitos e inferencias, y que éstas no siempre son correctas. Un conocido ejemplo de contrabando de supuestos se da en el problema de los 9 puntos, en el que hay que unir los nueve puntos de la figura 14.1 usando cuatro líneas rectas o menos, y sin levantar el lápiz del papel. Adams (1979) analiza el problema detalladamente y ofrece varias soluciones posibles. A la mayoría de la gente le resulta difícil hallar alguna solución; Adams dice que esto se debe a que contrabandean en sus representaciones del problema varios supuestos limitativos. Por ejemplo, la mayoría de la gente supone que las líneas no pueden extenderse fuera del cuadrado marcado por los puntos. Esto no les permite ver la posibilidad de la solución mostrada en la figura 14.2. Mucha gente también elimina la posibilidad de dibujar una sola línea muy gruesa que abarque todos los puntos de un trazo.

Otro ejemplo de dificultad provocada por contrabando de supuestos se da en el problema de los seis fósforos (Catona, 1940), en el que hay que formar cuatro triángulos equiláteros idénticos, todos con lados de un fósforo de largo, utilizando sólo seis fósforos. La gente tiende a suponer que el problema exige una solución en dos dimensiones. Esto no les permite ver la solución de contruir una pirámide triangular.

En los dos ejemplos que acabamos de comentar, el contrabando de supuestos nos impone una limitación innecesaria a lo que Newell y Simon (1972) denominaron "dimensión del problema del problema", metáfora lite-

ral satisfactoria para ambos casos. Lo que ya debería estar claro es que la forma en que se representa un problema influye notoriamente en la probabilidad de solución. Es necesario tener en cuenta el modo de representación y el omnipresente peligro de configuraciones psíquicas e inmutabilidad funcional. A veces, como sucede en el ejemplo del monje budista, una representación correcta del problema es equivalente a su solución. Pero, con más frecuencia, la representación es sólo la primera etapa y a ella le debe seguir la búsqueda de una solución. Ahora nos ocuparemos de la etapa de solución en la resolución de problemas.

Figura 14.2. Una solución elegante al problema de los 9 puntos

El uso de heurísticas

Para algunos problemas existen procedimientos de solución conocidos que, si se ejecutan bien, garantizan respuestas correctas. Esos procedimientos se conocen con el nombre de *algoritmos* (ver capítulo 16). Pero la mayoría de los problemas no se puede encarar algorítmicamente o, si existe un algoritmo que ayude a resolverlos, puede ser extenso o difícil de operar. En esos casos solemos avanzar a tientas hacia la solución, recurriendo a varias reglas empíricas denominadas *heurísticas*. Las heurísticas son guías para la acción que se han adquirido con la experiencia. Sus ventajas incluyen la simplicidad y la familiaridad y su desventaja es que nunca podemos saber por anticipado si nos llevará en la dirección correcta.

Análisis de medios-fines

John Sloboda proporciona un ejemplo de análisis de medios-fines en el capítulo 2 de este mismo libro, cuando introduce la idea de una "pila" de objetivos. El problema consistía en llegar del campo a Londres. Un análisis de medios-fines nos lleva a la pregunta: ¿cuál es la diferencia entre su situación presente y la del objetivo deseado? Es una cuestión de distancia. ¿Qué reduce la distancia? Un tren. ¿Dónde hay un tren? En la estación. ¿Cómo se llega a la estación? Busque un mapa. O pregúntele el camino a alguien del lugar. (Y ojalá que las convenciones discursivas locales se ajusten a las suyas. Ver capítulo 13.) Y así sucesivamente.

En este tipo de análisis, quien resuelve el problema oscila entre varios fines (objetivos y subobjetivos) por un lado y diferentes medios de lograrlos por el otro. La táctica predominante consiste en trabajar hacia atrás, desde la solución final, y eliminar las diferencias percibidas entre la situación presente y algún nivel de la situación del objetivo, repitiendo el proceso en cada nivel.

El análisis de medios-fines constituye la base del programa de computación tan ampliamente aplicable, el *General Problem Solver* (Newell y Simon, 1972). Es un método que básicamente utiliza el sentido común, pero su aplicación sistemática es un poderoso medio para resolver problemas, desde los más simples hasta aquellos relativos al ajedrez de alto nivel.

El uso del análisis de medios-fines fue explícito en los registros de "pensamiento en voz alta" de los sujetos del experimento de Duncker (1975), con el "problema de la radiación". Se refiere a un paciente con un tumor de estómago inoperable, y los rayos destruyen tejidos a la intensidad suficiente. El problema consiste en llegar a un procedimiento por el cual se pueda destruir el tumor sin dañar los tejidos sanos que lo rodean, como sucedería con el sencillo enfoque de dirigir un haz de rayos directamente hacia el tumor. Los sujetos tendían a trabajar hacia atrás, empezando por el objetivo general y siguiendo por subobjetivos, como irradiar el tumor mientras evitaban el tejido sano. Una solución posible era fijarse el subobjetivo de reducir la intensidad de los rayos mientras pasaban por el tejido sano. Este subobjetivo llevó a las ideas de enfocar, o hacer converger, rayos débiles en el lugar del tumor.

El análisis de medios-fines incluye una serie de procesos componentes como la reducción del problema, el trabajo hacia atrás y la evaluación de las semejanzas entre la situación presente y la del objetivo. Cada uno de estos puntos merecería un capítulo entero (ver Gilhooly, 1982).

Disponibilidad

Al abrir juicio respecto de un problema tenemos que basarnos en la información que tenemos a nuestra disposición. Pero esa información puede no retratar con precisión la situación. Esto suele darse en casos en que nuestra exposición a la información está determinada por criterios que resultan irrelevantes para el problema que nos ocupa. Por ejemplo, si uno quiere decidir cuál es el medio de transporte de larga distancia más seguro, la información que proporcione la prensa no resultará útil. La cobertura que realizan los medios depende fundamentalmente del criterio de "noticia": destaca los desastres y no la seguridad.

Tversky y Kahneman (1973) hicieron una ilustración experimental de la influencia de la disponibilidad de la información. Le preguntaron a angloparlantes si las letras K, L, N, R y V aparecían, en inglés, con más frecuencia en la primera o la tercera posición en las palabras del idioma. Los resultados dieron que la gente pensaba que las cinco letras aparecían más en la primera posición, aunque en realidad todas son más frecuentes en la tercera. Presumiblemente, la gente comete este error porque es mucho más fácil pensar en palabras que empiecen con una letra en particular que en otras que lleven la misma letra en tercer lugar, y no se tienen en cuenta los efectos distorsionantes de esta desviación.

La disponibilidad es una heurística útil en la resolución de problemas pero sólo cuando la frecuencia objetiva de un tipo de acontecimientos se correlaciona con la disponibilidad subjetiva de ejemplos de esa clase. Pero esto no suele suceder. Además de la exposición irregular de la información en los medios de prensa, todos tendemos a buscar la información que confirma nuestros propios prejuicios. Flavell (1985) sugiere que la razón por la que es tan difícil no ver las cosas desde nuestro propio punto de vista es que nuestro propio punto de vista está inmediatamente disponible. Las interpretaciones que más practicamos son las nuestras propias, y se han automatizado. Es necesario mucho esfuerzo consciente para adquirir eficiencia en adoptar el punto de vista de otro.

Representatividad

Lea la siguiente descripción:

> Linda tiene 31 años, es soltera, sincera y brillante. Se graduó en filosofía. Cuando era estudiante, le preocupaban los problemas de la discriminación y la justicia social, y participó en demostraciones antinucleares.

Elija ahora cuál de las siguientes alternativas le resulta más factible:

1. Linda es cajera de banco.
2. Linda es cajera de banco y militante feminista.

Tversky y Kahneman (1982) hallaron que el 87% de los entrevistados elegía la segunda alternativa como más factible que la primera. Sin embargo, un momento de reflexión nos señalará que esto no puede ser así. La probabilidad de conjunción de dos acontecimientos (o características) no puede ser mayor que la probabilidad de uno de ellos por sí mismo. Por ejemplo, si es improbable que usted gane un premio Nobel y también es improbable que gane una medalla de oro olímpica, difícilmente sea más probable que usted logre ambas cosas en vez de una sola de ellas. Sin embargo, incluso aquellos entrenados en estadísticas y teoría de las probabilidades cometen el error de considerar a la segunda alternativa como la más probable. Parece que la gente responde según lo que Tversky y Kahneman llaman "representatividad". La descripción de Linda se construyó para que fuera representativa de una feminista activa pero no de una cajera de banco, y la gente parece basar su juicio en esta representatividad, o semejanza, más que en las probabilidades objetivas.

En los problemas para los que hay poca información disponible sobre las probabilidades objetivas, lo cual es muy frecuente, la representatividad puede ser un recurso heurístico razonable. Pero en ciertas circunstancias puede desencaminar marcadamente nuestros pensamientos. Por ejemplo, unos pocos casos bien publicitados de abusos en el sistema de bienestar social pueden, si se supone que son representativos, desviar las evaluaciones del nivel de abuso entre la población total de beneficiarios del bienestar social.

Anclaje

Tversky y Kahneman (1974) analizan otra fuente de error en el pensamiento humano: la influencia que puede tener un punto de partida en el desempeño en las tareas de evaluación. Esto quedó claramente demostrado al hacer que dos grupos evaluaran, en 5 segundos, el resultado de un cálculo numérico escrito en la pizarra. Un grupo vio el siguiente cálculo: 8 x 7 x 6 x 5 x 4 x 3 x 2 x 1, y dio una estimación media de 2.250. El otro grupo vio: 1 x 2 x 3 x 4 x 5 x 6 x 7 x 8, y dio un resultado promedio de 512. La respuesta correcta es 40.320, por lo que ambos grupos estuvieron muy por debajo de lo correcto, pero la subestimación fue mucho mayor en aquellos que, presumiblemente, tuvieron tiempo de multiplicar algunas de las cifras más pequeñas que en aquellos que pudieron multiplicar las mayores. El punto de partida actuó como anclaje.

Fiske y Taylor (1984) señalan que los efectos del anclaje pueden darse siempre que alguien tenga que evaluar la frecuencia de aparición de alguna característica en la población en general o la probabilidad de alguna forma específica de conducta. En la mayoría de los casos, la gente comienza sus deliberaciones de acuerdo con su propia actitud ante el tema, y esto les ofrece un punto de anclaje. Es probable que una persona muy honesta sobreestime el peso de la honestidad en la población ("¿Cómo podrían...?") y que una persona deshonesta sobreestime el peso de la deshonestidad ("Te apuesto a que tú, en realidad..."). De manera similar, aunque podemos dudar de lo que dice un publicista a favor de un producto, la mera exposición a avisos favorables bien puede proporcionar el anclaje a partir del cual haremos nuestra evaluación real. La consecuencia puede ser una evaluación ventajosa para el fabricante del producto.

El entrenamiento en las habilidades de resolución de problemas

En las últimas dos secciones analizamos varios procesos relacionados con la representación de problemas y la búsqueda y ejecución de procedimientos de solución. En el curso normal de los acontecimientos, estos importantes procesos operan, fundamentalmente, de manera inconsciente. La conducta común sería imposible si no detectáramos automáticamente las seme-

janzas entre el pasado y el presente, si no simplificáramos los problemas complejos y extrapoláramos a partir de datos incorrectos. Nada de lo que se ha dicho debe tomarse como crítica de la utilidad de estos hábitos cognitivos. Sólo cuando se encuentran dificultades, cuando la conducta resulta ineficaz o los problemas resultan extraños para los enfoques habituales, nuestros procedimientos irreflexivos deben convertirse en objeto de estudio. De alguna manera hay que llevarlos a la conciencia.

Hábitos y conciencia

En los últimos años se han hecho esfuerzos combinados, especialmente en los Estados Unidos, para desarrollar planes de entrenamiento para las habilidades de resolución de problemas generales (Hunt, 1982; Mayer, 1983). En todos estos programas hay un énfasis común en el "conocimiento consciente aumentado".

Como la vida cotidiana está llena de problemas que todos debemos enfrentar, es evidente que debemos tener mucha experiencia en la resolución de problemas. La experiencia es indudablemente buena pero puede llevar a la formación de malos hábitos y ciertamente da como resultado diversas formas de falta de atención a los procesos de resolución de problemas. El entrenamiento apunta a hacer conscientes esos procesos, a que la gente conozca sus propios hábitos de pensamiento y esto le permita ejercer mayor control sobre sus actividades de resolución de problemas. Como en los grupos de encuentro y otras formas de entrenamiento de la sensibilidad, los orígenes de este enfoque derivan de la psicología de la gestalt, surgida en la Alemania de comienzos de siglo (capítulo 11).

Mientras que la tradición conductista siempre ha subrayado la importancia del aprendizaje mediante ensayo y error para la resolución de problemas, que hace que las soluciones exitosas se vuelvan habituales, los psicólogos gestálticos destacan fundamentalmente el papel de lo que denominan *insight*. Se refiere a la comprensión de las relaciones involucradas en un problema. Los psicólogos gestálticos sostienen que la forma en que se percibe (o configura) un problema es de vital importancia para el diseño de una solución y que las soluciones suelen estar precedidas de *insights* en los que repentinamente se ve al problema según una nueva organización. Ejemplo de ello sería el problema de los 6 fósforos antes mencionado. La comprensión de que la solución puede estar en tres dimensiones (la pirámide triangular) puede ex-

perimentarse como un *insight* en la naturaleza del problema. La noción de *insight* y los procesos cognitivos de la representación de los problemas se consideran análogos a los de la percepción visual. La reorganización abrupta del problema se asemeja a la reestructuración perceptual de una figura ambigua, como cuando se percibe la figura 5.2 del capítulo 5 como dos paralelogramos en vez de como un par de soportes para huevo duro. El entrenamiento en resolución de problemas que deriva de los principios de la gestalt se centra en hacer que la gente tome conciencia de la importancia de la representación, de la necesidad de probar diferentes formas de conceptualizar un problema y de las restricciones que actúan contra la reconceptualización. Si se aumenta la conciencia en los factores involucrados en la representación de problemas, es esperable que su pensamiento se torne más flexible.

La pregunta es, entonces, ¿sirve el entrenamiento?

Evaluación del entrenamiento

Suele afirmarse que las habilidades de resolución de problemas generales pueden mejorarse mediante el entrenamiento. Se escriben libros sobre el tema y se organizan cursos universitarios y comerciales por los que los participantes (o sus compañías auspiciantes) pagan grandes sumas. Si uno debiera juzgar exclusivamente a partir de los informes subjetivos sobre si la gente siente que se ha beneficiado con un curso en particular, tendría que llegar a la conclusión de que al menos algunas personas mejoran su habilidad en la resolución de problemas como consecuencia del entrenamiento. Hay un considerable grado de satisfacción entre los consumidores.

Pero los informes subjetivos no son necesariamente confiables. Mayer (1983) analiza varios intentos de evaluación objetiva de los cursos de entrenamiento y llega a una conclusión menos optimista. Sugiere que aunque se puede demostrar que el entrenamiento mejora la capacidad de resolución de problemas en áreas específicas tales como las matemáticas y la ingeniería, las evidencias sobre la adquisición de habilidades generales que se transfieren a otros tipos de temas siguen siendo dudosas. Los estudios menores (en los que tanto entrenadores como estudiantes pueden ser conscientes de que toman parte en un estudio de evaluación y en los que la motivación puede ser consecuentemente alta) suelen tener resultados positivos. Los estudios a gran escala, por otra parte, frecuentemente muestran que los efectos del entrenamiento son escasos (cuando tienen algún efecto).

La demostración concluyente de resultados positivos es una dificultad común a todos los intentos de entrenamiento en las habilidades cognitivas de nivel superior (ver capítulos 8, 11, 12 y 15). Es indiscutiblemente difícil encontrar evidencias firmes del éxito en el entrenamiento en habilidades de resolución de problemas generales, pero parte de la dificultad puede radicar en la naturaleza de la propia evaluación. ¿Las pruebas de laboratorio son los mejores indicadores de la mejora en una habilidad? Es posible que la gente se esfuerce más y use mejor su entrenamiento en los ámbitos naturales. Pero, quizá, el obstáculo principal para una buena evaluación del entrenamiento en estas habilidades se relacione con la práctica. Se ha dicho reiteradamente que el desarrollo de la habilidad exige mucha práctica. Naturalmente, más de la que se puede proporcionar durante un curso de resolución de problemas que dura apenas unas semanas. Se pueden enseñar técnicas y enfoques sistemáticos pero la práctica depende finalmente de cada individuo. Puede ser por esto que sólo en los estudios de evaluación de menor escala, con sus niveles de motivación concomitantemente más altos, se observen resultados positivos constantes.

De todos modos, el tema del entrenamiento para la resolución de problemas volverá a plantearse en el próximo capítulo, esta vez en el contexto del entrenamiento en creatividad.

La creatividad y las habilidades cognitivas

Alan Branthwaite

En los capítulos 13 y 14 se sostiene que los procedimientos relativos a la resolución de problemas pueden volverse rutinarios dentro de campos específicos y que se pueden aprender ciertas habilidades y enfoques para ayudar a la resolución de una amplia variedad de problemas. Pero las ideas brillantes no aparecen por un simple pedido. Algunos problemas son insolubles durante muchos años y algunas ideas son tan novedosas que quienes las tuvieron sólo alcanzan el reconocimiento póstumo. Estos son casos de pensamiento creativo; algunos de ellos se describirán en este capítulo, mientras exploramos el papel que pueden jugar las habilidades cognitivas en la creatividad.

La naturaleza del pensamiento creativo

No siempre resulta fácil reconocer las ideas creativas, ya que no hay un estándar claro para medirlas. La creatividad, como el genio, es esquiva, y sólo el consenso social decidirá si una idea se considera creativa e innovadora. Esto es especialmente así en el campo del arte, pero también en la ciencia y la tecnología, donde algunas ideas o descubrimientos han estado dormidos durante generaciones porque su valor creativo no era reconocido en su tiempo (por ejemplo, las leyes de la herencia de Mendel).

La historia ofrece muchos ejemplos célebres de soluciones a problemas difíciles e importantes que ganaron reconocimiento y aceptación públicos como innovaciones creativas. Al observar algunos ejemplos, prestaremos especial atención a la forma en que aparecieron las soluciones para ver qué luz arroja esto sobre el proceso creativo.

Arquímedes

Es famosa la exclamación de Arquímedes cuando encontró la solución a su problema: "¡Eureka!" La historia fue así: Arquímedes tenía que averiguar

si parte del oro de una corona que habían fabricado unos artesanos había sido sustituido por plata. La corona pesaba lo mismo que el oro que les habían dado a los artesanos para hacerla. Arquímedes razonó que, como la plata tiene más volumen que el oro para el mismo peso, una corona adulterada sería más grande que una de oro puro. El problema de Arquímedes consistía en medir el volumen de la corona, que tenía una forma irregular. Como todos sabemos, la solución se le ocurrió en un contexto diferente, ya que casualmente Arquímedes observó, mientras visitaba los baños públicos, que cuanto más se sumergía más agua desbordaba. La creatividad de Arquímedes consistió en aplicar las implicaciones de esta observación común al problema de medir el volumen de la corona. De repente, descubrió la solución: sumergiendo la corona en el agua pudo medir su volumen por la cantidad de agua que desplazaba. La leyenda termina con Arquímedes corriendo desnudo por las calles de Siracusa mientras gritaba, excitado, "¡eureka!", que significa "lo encontré". Por coincidencia, una actividad no relacionada le proporcionó la pista para resolver el problema que lo preocupaba, aunque probablemente no estaba pensando en él cuando se le ocurrió la solución. Ah... parte del oro, efectivamente, había sido reemplazado por plata.

Darwin

Darwin tenía libretas en las que registraba sus ideas y pensamientos; estas libretas ofrecen un informe más preciso y detallado sobre su creatividad que la leyenda de Arquímedes. Las libretas de Darwin muestran cómo desarrolló su explicación para el proceso de la evolución (Gruber, 1974). Le llevó 15 meses, durante los cuales probó diversas explicaciones que resultaron insatisfactorias y, por lo tanto, tuvo que liberar a su mente de ellas. Lentamente, Darwin fue acumulando un conjunto de ideas que le parecían relevantes y en torno a las cuales fue trabajosamente amasando un considerable cuerpo de evidencia de apoyo. Un avance especialmente importante fue el de la idea de la selección natural. En su libreta, Darwin escribió: "En octubre de 1838, es decir, quince meses después de empezar mi investigación sistemática, leí casualmente, sólo por diversión, *Malthus y la población*, y al estar bien preparado para apreciar la lucha por la existencia que se da en todas partes, a partir de mi larga e ininterrumpida observación de los hábitos de plantas y animales, *de inmediato se me ocurrió* que en estas circunstancias las variaciones favorables tenderían a preservarse y las no favorables a destruirse." (Dar-

win, 1911, p. 68; las bastardillas son nuestras.) Darwin se sintió inmediatamente impresionado por esta nueva idea pero siguió trabajando en otros pensamientos, y quizá no se haya dado cuenta por entonces de que este proceso de selección natural iba a convertirse en la piedra fundamental de su explicación de la evolución. Habría que recordar, al examinar otros relatos sobre creatividad, que es muy fácil destacar un punto en particular como el momento de inspiración después de los hechos, cuando toda la solución ha quedado ya bien clara, sin tener en cuenta todo el trabajo realizado antes y después. De hecho, Darwin pasó otros 20 años analizando la teoría y buscando evidencias que la sustentaran.

Kekule

El "descubrimiento" de que las moléculas de benceno tienen átomos ordenados en un anillo cerrado en vez de tenerlos en forma de cadena, se le ocurrió a Kekule, según su propio relato, del siguiente modo (citado por Koestler, 1964): "Volví mi sillón hacia el fuego y me eché a dormitar. Una vez más, los átomos bailaban ante mis ojos. Esta vez, los grupos más pequeños se mantenían humildemente atrás. Mi ojo mental, agudizado por reiteradas visiones de este tipo, podía ahora distinguir estructuras mayores, de conformación múltiple; largas filas, a veces más estrechamente unidas, que se retorcían en un movimiento de serpiente. Pero de pronto... ¿Qué fue eso? Una de las serpientes se atrapó su propia cola y la forma remolineó burlona ante mis ojos. Como sobresaltado por un relámpago, desperté... Aprendamos a soñar, caballeros."

Babbage

Otro ejemplo similar de creatividad surgida en parte gracias a la lógica sistemática y en parte a debido a los sueños imaginativos fue la invención de la Máquina Analítica de Babbage, precursora de las computadoras modernas (citado por Cohen, 1970, p. 65): "La primera idea que puedo rastrear en mi propia memoria acerca de realizar cálculos aritméticos mediante máquinas surgió de esta forma: una tarde yo estaba sentado en los salones de la Sociedad Analítica de Cambridge, con mi cabeza inclinada hacia adelante sobre la mesa en una especie de ensoñación y con una tabla de logaritmos

abierta ante mis ojos. Otro miembro de la sociedad entró al salón, me vio medio dormido y dijo: '¿Qué estás soñando, Babbage?'. Y yo respondí: 'Estoy pensando que todas estas tablas (señalando los logaritmos) podrían calcularse mediante máquinas'".

Koestler, 1964, hace otras descripciones sobre la forma en que surgieron muchas ideas creativas trascendentales. Pero es importante comprender que la creatividad no se limita a los casos famosos que transformaron la comprensión del mundo. Estos ejemplos de creatividad son célebres por la seriedad de los problemas que resolvieron y la utilidad de las soluciones y no porque implicaran ideas especialmente imaginativas o inventivas. Pero la creatividad también se encuentra en la soluciones inventivas e imaginativas a los problemas cotidianos de un individuo o también en el niño que "descubre" por sí mismo el principio de Arquímedes, aunque es improbable que la historia registre tales logros. Después de todo, Darwin sólo hizo públicas sus ideas cuando otro (Alfred Wallace) concibió la misma idea independientemente, proporcionándole apoyo y aliento para que superara sus dudas y temores. Eso no hace menos creativa a la idea de Darwin o a la de Wallace, aunque la creatividad de este último es mucho menos conocida. Al analizar qué es la creatividad debemos tener en cuenta no sólo la importancia social de los resultados sino también la resistencia del problema a la solución y la dificultad que supera un individuo para alcanzar una resolución satisfactoria.

El proceso creativo

¿Qué nos dicen estos relatos sobre algunas ideas creativas acerca de los procesos cognitivos involucrados? Los ejemplos dados ofrecen ciertos informes introspectivos en cuanto a la forma en que surgieron esas ideas. En otros capítulos hemos visto algunas de las limitaciones de los informes introspectivos como medio para aclarar los procesos psíquicos. Esto es especialmente cierto cuando el informe se escribe después de los hechos que describe (en lugar de hacerlo mientras suceden), ya que la memoria reconstructiva es selectiva y parcial (ver capítulo 5). Algunos investigadores (por ejemplo, Perkins, 1981) han combinado los informes biográficos sobre creatividad natural con observaciones sobre la creatividad en el laboratorio, cuando se pide a los individuos que vayan contando en voz alta cómo resuelven los problemas o componen poesías (procedimiento que tiene sus propias limitacio-

nes). Sobre la base de estas evidencias, parece haber cuatro procesos involucrados, que Wallas (1926) fue el primero en denominar *Preparación*, *Incubación*, *Iluminación* y *Verificación*. Esta descripción de la creatividad ha sido confirmada por autores posteriores, aunque ahora estos procesos no se consideran etapas discernibles sino parte de un interjuego dinámico que se da durante la creatividad.

1) Preparación

La preparación incluye la definición y exploración de las características de la tarea o problema, y es afín a la cuestión de la representación del mismo, analizada en el capítulo 14. Los procesos involucrados en la preparación se ilustran en algunos de los ejemplos de creatividad descritos: las deducciones de Arquímedes sobre el hecho de que la plata tiene más volumen que el mismo peso en oro; las observaciones de Darwin de las manifestaciones de la evolución y los componentes sobre los cuales podría operar el proceso, tales como la variabilidad dentro de cada especie y la adaptación al medio. Durante la preparación, se consideran las soluciones posibles y se las prueba lógicamente para ver si funcionan. En muchos problemas, con esto basta para llegar a una solución (ver capítulo 14). Sólo con los problemas más difíciles e intransigentes hace falta mayor creatividad. Sin embargo, este proceso preparatorio de exploración del problema es precursor esencial de las soluciones más creativas e imaginativas. En este proceso, surge una conciencia sobre las propiedades de una solución satisfactoria que es importante más tarde para poder reconocer la solución cuando aparece. La preparación también aumenta la relación con el problema, que probablemente resulte beneficiosa para aumentar la motivación y la atención a soluciones posibles cuando surgen. Pero este aumento del compromiso también puede resultar contraproducente, ya que provoca configuraciones psíquicas solidificadas y pensamientos rígidos sobre las mismas soluciones posibles que se repiten una y otra vez.

Algunos psicólogos han descrito el proceso de preparación como un sistema de pensamiento cerrado que se centra en las posibilidades lógicas y corre sistemáticamente por carriles familiares, usando enfoques que se han aprendido por la experiencia pasada en lo que parecen ser problemas similares. Pero, durante la preparación, los pensadores creativos "sondean" un problema, como si exploraran un rompecabezas para familiarizarse con la forma

de la pieza faltante, como en el caso de Kekule, que sabía muy bien cuáles eran los criterios que debía satisfacer la solución del problema del ordenamiento de los átomos en el anillo de benceno. De manera similar, durante mucho tiempo Darwin tuvo una clara noción de lo que habría que obtener mediante el mecanismo de la evolución que estaba buscando.

2) Incubación

La incubación se refiere a los procesos aparentemente inconscientes que tienen lugar cuando un problema no está siendo considerado de manera activa pero a partir de los cuales surge, de todos modos, una solución imaginativa y exitosa. Esto ocurrió claramente en los sueños diurnos de Kekule y Babbage. La esencia de la incubación es que durante la meditación serena (o a veces desasosegada) del problema se generan nuevas posibilidades y combinaciones de ideas. Éstas surgen del libre juego de la imaginación, de la intuición y del pensamiento abierto y fluido que trae nuevas perspectivas para encarar el problema. Bruner (1962) afirma que la intuición "produce interesantes combinaciones de ideas antes de que se sepa su validez. Precede a la prueba; de hecho, es lo que estudian y comprueban las técnicas de análisis y verificación" (pág. 102). Estas características son muy evidentes en la descripción que hace Poincaré de la forma en que estableció una prueba matemática después de un período de preparación:

> "Todos los días me sentaba ante mi mesa de trabajo, me quedaba una o dos horas, probaba varias combinaciones y no llegaba a ningún resultado. Una noche, contra mi costumbre, bebí café y no me podía dormir. Las ideas surgieron en grandes cantidades; las sentía chocar entre sí hasta que se formaban pares que, por así decirlo, constituían una combinación estable. A la mañana siguiente, ya había establecido la existencia de una clase de funciones fuchsianas, las que vienen de las series hipergeométricas; sólo tenía que escribir los resultados, lo cual no me llevó más que unas horas."
>
> (Ghiselin, 1952, pág. 37)

Durante la incubación, la mente parece volver a formas de operación más primitivas (como en los sueños) y recurrir a la fantasía, la asociación, las analogías y las metáforas. Piaget (1926) lo denominó pensamiento autista (en oposición al pensamiento inteligente lógico). No se adapta a la realidad sino

que crea por sí mismo un mundo de ensueño de la imaginación, que es estrictamente individual e incomunicable mediante el lenguaje y que funciona mediante imágenes y símbolos.

Perkins (1981) ha sugerido una visión alternativa de la incubación. Se pregunta si la incubación incluye un tipo especial de pensamiento inconsciente que genere nuevas alternativas como soluciones posibles a un problema. Subraya el papel de los procesos cognitivos más comunes: el olvido fructífero de las posibilidades apreciadas pero fracasadas; el refresco físico y psíquico; la observación de nuevas pistas en experiencias no relacionadas (como en el caso de Arquímedes), que exige un alto nivel de interés, alerta y atención no focalizada; el reconocimiento contrario, que incluye el reconocimiento de cosas no sólo por lo que son sino también por lo que podrían simbolizar (por ejemplo, ver animales en la forma de las papas). Sin embargo, el proceso de reconocimiento contrario presenta grandes semejanzas con el pensamiento autista y las ensoñaciones que se describen más arriba.

No veo razón alguna por la cual los procesos cognitivos comunes sugeridos por Perkins, así como las formas de pensamiento más primitivas, no puedan estar incluidos en la incubación (ver más abajo). La función principal de la incubación es aumentar la gama de soluciones posibles y la habilidad para generar ideas alternativas fácilmente y sin esfuerzo es característica de la gente creativa. Cohen (1970) observa que Norbert Weiner, el creador de la cibernética, "atesoraba en sí mismo lo que sentía que era una imaginación caleidoscópica de libre fluir, que por sí misma revelaba las posibilidades de una situación complicada" (pág. 57) y Picasso afirmaba, tajante: "Yo no busco, encuentro", con lo que quería decir que las ideas se le ocurrían sin necesidad de pensar en ellas deliberada o laboriosamente. Es posible que la práctica pueda llevar a un aumento en la habilidad de generar ideas; éste es un supuesto subyacente en las técnicas de entrenamiento de la creatividad que se verán más adelante. Pero, además, no debemos subestimar el papel de las ocurrencias casuales al estimular las soluciones alternativas y de la atención alerta ante tales hallazgos casuales.

3) Iluminación

La iluminación es el momento de *insight* o comprensión repentina de que una idea se ajusta a un problema y ofrece una solución. Queda ilustrada con claridad en la historia de Arquímedes, cuando comprendió la importan-

cia del agua desbordando en el baño, o en la experiencia de Darwin, cuando de pronto se le ocurrió la idea de la selección natural (aunque siguió trabajando en otras ideas mientras buscaba verificar esta 'iluminación'). Lo importante aquí es el "salto psíquico" por el cual algo aparentemente irrelevante se relaciona con las características del problema. Esto requiere alerta y vigilancia mientras no se presta atención consciente al problema, y se da si uno está profundamente comprometido con la tarea. Por este motivo es importante, en el proceso de preparación, una clara comprensión de la naturaleza y las características (la "forma") de una solución.

En la creación artística, la iluminación surge cuando una idea posible le da al artista la sensación de que se ha logrado una expresión más satisfactoria y valiosa, que enriquece el significado de su obra. Tiene una fuerte cualidad emocional, como la experimentada por Arquímedes, que acompaña a la convicción de que la nueva idea completará el problema. Con la iluminapéensaimiento logico y sistematico para verificar si las soluciones potenciales se ajustan a las características del problema. Se trabaja y elabora la inspiración creativa. Este proceso queda claramente ejemplificado en el caso de Darwin, pero también en los de Babbage y Poincaré. Se aducen evidencias y argumentos a favor para poder comunicar la solución a los demás de una manera racional y coherente. Se utilizan los conocimientos y habilidades previamente adquiridos para comprobar la sensatez y coherencia de la idea iluminadora. Desafortunadamente, algunas de estas ideas que parecían satisfacer los requisitos del problema resultan erróneas en el análisis posterior, de modo que el proceso de verificación se convierte en apenas uno más de los procesos de preparación.

Los procesos creativos y el funcionamiento de los dos hemisferios

Los cuatro procesos que acabamos de describir incluyen dos tipos contrastantes de habilidad psíquica:

a) el análisis consciente, racional, lógico y sistemático (importante en la preparación y la verificación).

b) la intuición consciente, las analogías simbólicas, las metáforas y las asociaciones que crean nuevas perspectivas y diferentes posibilidades de solución (en la incubación e iluminación).

La existencia de dos formas de pensamiento contrastantes ha sido reconocida en muchos aspectos de la psicología (Bogen, 1977). Por ejemplo:

racional	versus	metafórico	(Bruner)
realista	versus	impulsivo	(Hilgard)
diferencial	versus	existencial	(William James)
positivo	versus	místico	(Lévi-Strauss)
racional	versus	intuitivo	(Maslow)
secuencial	versus	múltiple	(Neisser)
dirigido	versus	autista	(Piaget)

Recientemente, se identificó una posible base para estos diferentes modos de pensamiento en las diferentes funciones de los dos hemisferios cerebrales. (Por un resumen de las evidencias, ver Trueman, 1985; Springer y Deutsch, 1985). Se sugiere que los dos hemisferios se especializan en diferentes formas de actividad psíquica.

Hemisferio izquierdo	*Hemisferio derecho*
* pensamiento secuencial, analítico	* holístico, simultáneo, integrador
* verbal	* manipulación espacial, imagen y orientación corporal en el espacio
* lógico	* intuitivo
* procesamiento serial	* procesamiento en paralelo
* modo lineal de operación, temporal	* procesa la información difusamente
* intelectual (consciente)	* relacional, asociativo
* convergente	* divergente

La evidencia de que ambos hemisferios se relacionan diferenciadamente con aspectos del proceso creativo no es concluyente pero es decididamente sugerente (Katz, 1978; Torrence, 1982). El hemisferio derecho parece estar involucrado en aquellos aspectos de la creatividad que dependen de la imaginación, la analogía, la flexibilidad cognitiva y el pensamiento divergente, característicos de la incubación y la iluminación. Naturalmente, resulta prácticamente demasiado simplista decir que el hemisferio derecho se especializa en la creatividad. Casi todo el pensamiento sofisticado involucra aspectos de la actividad de ambos hemisferios y la interacción entre ellos, y esto también sucede con la creatividad. En particular, hay un continuo interjuego entre la imaginación verbal y la no verbal en nuestro pensamiento. Sin embargo, esta comparación entre procesos que durante mucho tiempo se han considerado importantes en la creatividad y las formas especializadas de trabajo en los dos hemisferios ayuda a clarificar la naturaleza de los procesos involucrados. Amplía nuestra comprensión de los aspectos misteriosos, primitivos y no verbales de la incubación y la iluminación. Esta explicación sitúa la descripción de la creatividad en un contexto más amplio del actualmente conocido sobre las funciones cognitivas y explica por qué la gente creativa suele sentir la solución antes de poder articularla. Además, sugiere que se podría mejorar la creatividad aprovechando las habilidades de cada hemisferio en las diferentes etapas del proceso creativo. Pero esta idea no es nueva, como puede verse en la respuesta de Schiller a un amigo que se quejaba de su falta de creatividad:

> "Creo que el motivo de tu queja radica en las restricciones que tu intelecto impone a tu imaginación... Aparentemente, no es bueno (y, de hecho, obstaculiza la creatividad de tu mente) que el intelecto examine de muy cerca las ideas que ya están llegando en forma abundante, por así decirlo, a la salida. Considerada aisladamente, una idea puede ser insignificante y en extremo aventurada, pero puede adquirir importancia por una idea que le sigue; quizá, en determinada ubicación junto a otras ideas, que pueden parecer igualmente absurdas, pueda ser capaz de ofrecer una vinculación beneficiosa... En el caso de una mente creativa, me parece, el intelecto ha retirado a sus vigías de las puertas y las ideas fluyen tumultuosamente, y recién entonces el intelecto se ocupa de revisar e inspeccionar a la multitud. Ustedes, los críticos de valía, o como quiera que se llamen a sí mismos, se avergüenzan o le temen a la locura momentánea y pasajera que se encuentra en todos los creadores... De ahí sus quejas por la falta de frutos, ya que rechazan demasiado pronto y discriminan con excesiva severidad."
>
> (Brill, 1938, pág. 193)

El argumento de Schiller recibe nueva fuerza y apoyo cuando se lo ve de acuerdo con la operación de los dos modos de la conciencia en los hemisferios cerebrales.

El conocimiento de la existencia de dos tipos complementarios de habilidad psíquica involucrados en la creatividad sugiere dos estrategias amplias para mejorarla. Cuando revisamos los diversos métodos que se han planteado para aumentar la creatividad, encontramos que entran en dos categorías amplias que buscan mejorar lo que podemos llamar, por conveniencia, modos de pensamiento del hemisferio izquierdo y derecho. El desarrollo de habilidades creativas involucra la búsqueda de mejores estrategias para producir soluciones posibles; en el resto de este capítulo analizaremos algunas de las técnicas que se han sugerido. Estas técnicas comparten dos propiedades con muchas de las habilidades cognitivas que examinamos en el resto del libro. En primer lugar, son heurísticas (ver capítulo 16), ya que ninguna de ellas garantiza la solución de un problema en particular pero muchas pueden ayudar en la búsqueda estimulando ideas. En segundo lugar, su aplicación mejora con la práctica (ver capítulo 3). Al principio, muchas de las técnicas parecerán extrañas y difíciles de llevar a cabo. Sólo se convierten en realmente efectivas tras una aplicación persistente. No ofrecerán creatividad instantánea al primer intento.

El desarrollo de las habilidades del "hemisferio izquierdo"

Estas técnicas fomentan un análisis más exhaustivo, sistemático, lógico y racional del problema. Algunas de las tácticas usadas para lograrlo son:

- reformule el problema en sus propias palabras;
- formule preguntas sobre el problema;
- aclare mentalmente todos los datos del problema;
- haga anotaciones;
- haga una lista incluyendo todos los objetos/aspectos importantes del problema y piense cuidadosamente en cada uno de ellos;
- busque las cosas raras o confusas de un problema y concéntrese en intentar explicarlas;
- cuando haya varias cosas confusas en un problema, intente explicarlas con una sola idea que las conecte a todas.

Algunas técnicas buscan crear nuevas ideas identificando las omisiones y creando nuevos cambios a partir de las características existentes. Las técnicas suelen incluir listas de verificación, para fomentar el análisis más completo y exhaustivo del problema. Los siguientes ejemplos proceden fundamentalmente del campo del desarrollo de productos (Whiting, 1958):

1) Revisión sistemática

Revise todos los aspectos de un producto existente y sus mercados de manera sistemática, usando la siguiente lista de verificación. Escriba todas las posibilidades que se le ocurrran. No sea negativo: convénzase de que puede haber mejores soluciones.

PRODUCTO	Considerar cambios	• características físicas • envoltorio • método de fabricación
	Analizar	• posición frente a la competencia • posibilidades técnicas
CONSUMIDOR	Considerar cambios	• método de uso • propósito del uso • posición percibida • actitudes
	Analizar	• compradores alternativos • estilos y tendencias de compra
PROMOCIÓN	Considerar cambios	• publicidad, promoción
	Analizar	• precios • actividad competitiva

2) Análisis morfológico

Esta técnica incluye la división de un problema en sus dimensiones constituyentes. Cada dimensión se subdivide a su vez en sus posibles valores o formas y las varias combinaciones resultantes son examinadas para verificar la utilidad de las soluciones que ofrecen. Consideremos, por ejemplo, el problema del desarrollo de un nuevo tipo de envase para leche. El envase tiene tres dimensiones: tamaño, forma y material. La dimensión del tamaño se subdivide en varias unidades (1 l, 750 cl, etc.); la forma se subdivide en las formas posibles (cubo, cilindro, tetraedro, etc.) y lo mismo sucede con los materiales (vidrio, cartón, metal, etc.). Se examinan sistemáticamente las combinaciones de estas categorías para averiguar su utilidad potencial como soluciones. Éste es un procedimiento mecánico y quizá el uso de computadoras podría simplificar la tarea.

3) Listado de atributos

Se hace una lista con los principales atributos de un producto o de un servicio (o de otro problema). Luego, se consideran las formas de cambiar o mejorar cada uno de ellos en todas las maneras imaginables, sin abrir juicios de valor. Concentrarse en los atributos peculiares de un producto ha resultado productivo para el desarrollo de nuevos productos, ya que se trata de sus características más significativas. El lector podría tratar de diseñar un nuevo cepillo de dientes, por ejemplo, usando este enfoque.

El desarrollo de las habilidades del "hemisferio derecho"

Estas técnicas mejoran la creatividad estimulando asociaciones novedosas y a menudo excéntricas respecto de un problema. No buscan soluciones directas sino alentar el pensamiento lateral para generar analogías y metáforas, que casi parecen agregar confusión pero que pueden producir enfoques totalmente nuevos de un problema.

La esencia de estas técnicas radica en el uso de metáforas por las cuales se transportan diferentes perspectivas de un campo de referencia a otro. Schon (1979) ha enfatizado que los conceptos y el lenguaje que usamos pa-

ra representar un problema guían nuestro pensamiento hacia ciertos tipos de solución. Bajo el hechizo de la metáfora espontánea e implícita que usamos para plantear un problema, somos propensos a cierto tipo de soluciones más que a otras. Usando diferentes metáforas podemos cambiar las connotaciones del problema y el marco de referencia para una solución. Esto se conoce como "reestructuración del marco" y es un fenómeno psíquico importante y muy difundido involucrado en la percepción, las ilusiones, la memoria e incluso en la capacidad de apreciar las bromas. Este proceso queda claro en el siguiente ejemplo, tomado de Schon.

Un grupo de investigadores de desarrollo de productos intentaba mejorar el rendimiento de un pincel de cerda sintética. Habían probado varias soluciones para hacer que las cerdas sintéticas parecieran reales; habían, incluso, llegado a cambiar el diámetro de las cerdas y les habían hecho puntas divididas. Pero su pensamiento estaba limitado por la palabra "pincel", y eso los hacía buscar una solución que incluyera cambios en las cerdas. Cuando alguien del grupo observó que un pincel era una especie de bomba que propulsaba la pintura a través del espacio entre las cerdas, se produjo un gran avance. Esta analogía cambió la perspectiva del problema y se convirtió en una nueva metáfora que alteró el contexto, y se empezó a buscar entonces otra solución, cambiando el flujo de pintura entre las cerdas.

Las siguientes técnicas pretenden desarrollar habilidades en la creación de metáforas, analogías y asociaciones. (En Stein, 1975, pueden hallarse más detalles sobre las técnicas que se describen a continuación.)

1) Sinéctica

La sinéctica se basa en la unión de elementos diferentes y aparentemente irrelevantes (Gordon, 1961). El objetivo es hacer familiar lo extraño y viceversa, para cambiar de perspectiva. Hay muchos recursos para hacer esto, generando analogías y metáforas:

• *Analogías personales.* Una persona trata de imaginarse a sí misma como el objeto con el que está trabajando; primero, describiendo las propiedades y características del objeto; luego, imaginando los sentimientos y emociones del objeto; finalmente, identificándose con el objeto para experimentar lo que podría sentir si fuese eso. Fácilmente puede imaginarse la analogía del pincel-bomba, que acabamos de mencionar, surgiendo de este tipo de análisis íntimo de cómo sería uno si fuera un pincel.

• *Analogías directas.* Se buscan metáforas del problema pertenecientes a otro campo. Con frecuencia, se recurre a analogías para los problemas inorgánicos haciendo referencia a la forma en que operan los seres vivos. Por ejemplo, Brunel resolvió el problema de la construcción de túneles bajo el agua mediante una analogía directa con la forma en que una polilla excavaba en la madera; y, para inventar el teléfono, Bell encontró una forma de convertir la voz en energía mecánica y eléctrica mediante comparaciones con el mecanismo del oído humano.
• *Analogías simbólicas.* Se recurre a metáforas poéticas o simbólicas para caracterizar la esencia del problema. Se exploran las asociaciones no verbales tratando de encontrar formas, colores, texturas, olores, etc., que caractericen los conceptos del problema. El objetivo es lograr que los problemas abstractos resulten más concretos y viceversa.
• *Analogías fantasiosas.* El problema se plantea pensando en formas en que podría resolverse de manera simple y rápida en un mundo ideal en el que todo fuera posible. Al diseñar un cierre hermético para trajes espaciales, un grupo que utilizaba esta técnica soñó con una línea de insectos que cerrara sus garras en respuesta a una orden, para cerrar herméticamente los trajes. Esto llevó a otras ideas que proporcionaron una solución factible (Gordon, 1951).

La técnica de usar analogías aleja al pensamiento del problema por varios desvíos. Luego, hay que regresar al problema desde el lugar al que se ha llegado.

2) Tormenta de ideas

La tormenta de ideas suele realizarse con un grupo de personas, pero eso no es esencial. Se hace un listado de las ideas relacionadas con el problema como cadena de asociaciones, a menudo en forma de fluir de la conciencia. Hay cuatro reglas básicas para los torbellinos de ideas:

• Se eliminan las críticas. Deben generarse ideas sin pensar en su valor, su factibilidad o su importancia.
• Se fomenta la "conversación libre", para que pueda plantearse cualquier idea, no importa cuán absurda o intrascendente parezca. La intención es otra vez la de eliminar la selección y la censura y promover la libertad en las sugerencias.

• Se busca la cantidad: se intenta generar el mayor número posible de ideas. Suele suponerse que el énfasis en la cantidad da como resultado una mejor calidad, pero esto no ha quedado siempre demostrado en los estudios de investigación. Sin embargo, el énfasis en la cantidad ayuda a suspender la crítica y el juicio de valor.
• Se recurre a la combinación y la mejora de ideas y se da prioridad a las que se basen constructivamente sobre sugerencias previas. Esta regla fomenta el desarrollo de ideas y busca eliminar, a la vez, la vergüenza o la incomodidad al usar ideas de otros.

La superación de los bloqueos en el pensamiento creativo

Las técnicas descritas para facilitar la creatividad sólo tienen éxito si se tiene la actitud mental correcta. Los bloqueos obedecen a razones cognitivas y sociales, aunque esos dos tipos de motivos no están, de ninguna manera, separados. El clima social en el que se realiza el trabajo creativo puede servir de ayuda o de obstáculo. Cuando las recompensas o premios dependen de la creatividad y hay supervisión externa y controles extrínsecos, la creatividad se reduce (Amabile, 1983). Esas condiciones limitan los riesgos que la gente se atreve a correr en su búsqueda de alternativas imaginativas, enfatizando el valor social que se podría poner en sus excursiones creativas. Es más probable que la gente sea creativa cuando está motivada intrínsecamente, cuando un problema le importa realmente. La creatividad exige una perspectiva positiva y confiada y la seguridad de ser no conformista y de cuestionar el status quo. El proceso creativo exige individualidad y singularidad, que se consiguen mejor en un medio que sea socialmente poco amenazante, tranquilo y seguro.

Los bloqueos en la creatividad suelen ser dificultades en el paso del análisis sistemático y racional del problema (pensamiento del hemisferio izquierdo) al uso de la imaginación y la libre asociación para crear nuevas perspectivas (pensamiento del hemisferio derecho). Esto no es sorprendente, ya que muchas instituciones (la escuela, el trabajo) le otorgan mayor valor y prestigio al análisis lógico y racional que a las asociaciones libres "infantiles" y a las analogías fantasiosas. Sin embargo, debemos recordar el consejo de Schiller de no permitir que el intelecto limite la imaginación. Para lograrlo, hay ciertas ideas que vale la pena recordar:

- Elija condiciones de trabajo conducentes y apropiadas, que eviten las distracciones y alienten la satisfacción, la atención relajada y la diversión.
- Tenga a mano objetos relacionados con el problema, cámbielos de posición y juegue con ellos; preste atención a la búsqueda de los objetos y la observación de sus características; use la imaginación visual de manera similar para estudiar las propiedades de las cosas.
- No intente retener las ideas mentalmente; tome notas y haga listas; esto ayuda a evitar la sobrecarga de aptitudes cognitivas y también libera al pensamiento para permitir que surjan otras ideas.
- Intente, deliberadamente, ser original, creativo y osado.

Conclusión

La creatividad como la de Arquímedes, Darwin o Picasso empieza con la búsqueda de una solución a un problema con el que el individuo creativo está profundamente comprometido. La búsqueda de una solución pone en actividad muchas habilidades cognitivas, incluyendo el análisis, el razonamiento, el recuerdo, la observación, el reconocimiento, la asociación y la creación de analogías y metáforas cambiantes. Hace mucho que se piensa que la creatividad tiene procesos conscientes y procesos inconscientes. Se ha dicho que la mística peculiar y la fuerza de la creatividad radica en la incubación inconsciente y el *insight* en el problema. Sin embargo, una forma alternativa de observar los procesos involucrados es que la creatividad aprovecha aptitudes complementarias en las que se especializan los hemisferios cerebrales derecho e izquierdo. La esencia de la creatividad radica en la capacidad de generar alternativas en la búsqueda de una solución, tanto a través del razonamiento lógico (hemisferio izquierdo) como mediante la asociación y las metáforas, que crean nuevas perspectivas o marcos de referencia para el problema (hemisferio derecho). Cuanto mayor sea la gama de alternativas consideradas, más probable es que surja una solución creativa a un problema nuevo y difícil. Para ser creativos, entonces, debemos concentrarnos en habilidades para generar una gama de alternativas nuevas, mejores y más amplias en nuestro pensamiento. Pero en el análisis final debemos recordar el papel de la casualidad y la suerte para tropezar con la alternativa profunda, para tener en cuenta el incidente importante pero inadvertido o para vivir la experiencia correcta en el momento preciso. Quizá lo máximo que pueden hacer las personas es fomentar la aparición de esas casualidades y volverse receptivos a las que se cruzan en su camino.

Las computadoras y la cognición

John Sloboda

Como dice Angus Gellatly en el capítulo 1, hemos intentado evitar el uso excesivo de la metáfora de la computadora en nuestro análisis de los diversos aspectos de la cognición. Una razón fundamental para hacerlo es que la mayoría de las personas no entiende muy bien a las computadoras y no tiene mucho sentido intentar explicar el funcionamiento de la mente según algo que en general no se conoce. Sin embargo, ignorar por completo el papel de la computadora en la psicología cognitiva moderna sería un grave perjuicio.

Este capítulo se ocupa de dos usos específicos de las computadoras, que se han convertido en el sello distintivo de una disciplina llamada ciencia cognitiva, lugar de encuentro de psicólogos, filósofos, lingüistas y científicos computacionales (Norman, 1981). El primero de estos usos es el de la metáfora de la computadora como medio para precisar nuestra comprensión de qué es o no es la mente. Esta es una empresa que involucra a los exponentes más filosófica y conceptualmente representativos de la ciencia cognitiva. La segunda, aunque estrechamente vinculada, es la escritura de programas de computación que imitan algún aspecto del funcionamiento humano. Esto se denomina *simulación por computadora* y es una rama de la disciplina conocida como inteligencia artificial. Requiere cierto grado de dominio de la programación y comprensión de las posibilidades y límites de las computadoras como herramientas prácticas. En un libro de este tipo, es más fácil disfrutar del primer aspecto, conceptual, que escribir sobre el segundo, más práctico. Aunque me referiré a ambos, dedicaré proporcionalmente más espacio al primero. Quienes deseen profundizar en los detalles de la simulación deben consultar las sugerencias de lecturas adicionales, al final del capítulo.

¿Qué es una computadora?

Una computadora es una máquina. Las máquinas realizan funciones físicas específicas y repetibles, según ciertas ordenes, llamadas, en inglés, *inputs*. Por ejemplo, mi máquina de escribir es una máquina. Cuando le doy una orden específica (*input*) presionando una tecla, responde moviendo un martillo determinado. El mismo martillo se mueve cada vez que presiono esa tecla. Las máquinas generalmente actúan trasnformando la energía de alguna forma. Una máquina de escribir transforma la presión hacia abajo de mis dedos en los golpes horizontales de los martillos sobre el papel. Un automóvil transforma la fuerza explosiva de la ignición de combustible y los movimientos de manos y pies de su conductor en movimientos rápidos pero controlados. Las formas de la energía involucrada pueden ser diversas: mecánicas, eléctricas, electromagnéticas o atómicas.

Una de las características principales de la mayoría de las máquinas es que sus funciones están rígidamente limitadas. La configuración física de sus partes las restringe a una tarea en particular. No se puede convertir una máquina de escribir en otra cosa sin desarmar sus partes y reconstruirlas. Podemos decir que la configuración física fija de una máquina es su *hardware*. En la mayoría de las máquinas, entonces, el *hardware* determina la función.

En cierto sentido, todo esto también es cierto respecto de las computadoras. Una computadora específica toma los impulsos eléctricos como *inputs*, los mueve por dentro de ella en sentidos totalmente determinados por su configuración física y produce salidas (*outputs*) eléctricas transformadas. Si uno alimenta la misma computadora con los mismos *inputs*, siempre obtendrá los mismos *outputs* (siempre y cuando la configuración física no funcione mal). Pero cuando observamos la función de una computadora, aparece una inmensa diferencia. No podemos definir una función específica de una computadora de la misma forma que podemos hacerlo con una máquina de escribir. Más estrictamente, podemos decir que la función de una computadora consiste en manipular símbolos. Si esto no resulta suficiente, podemos aclararlo diciendo que, en principio, se puede hacer que una computadora imite a cualquier otra máquina, sin alterar su configuración física. Esto se hace dividiendo el *input* en dos conjuntos: un conjunto de *inputs* es llamado el programa, y este determina cómo se manejará el segundo conjunto (los datos).

Regresemos un momento a mi máquina de escribir. Funciona como

funciona porque tiene un conjunto de varillas y palancas que conectan determinadas teclas con determinados martillos. Es fácil observar el funcionamiento de estas palancas levantando la tapa. Pero supongamos que tuviéramos que sellar la tapa y ya no pudiéramos mirar el interior; supongamos, además, que tuviéramos que reemplazar la conexión mecánica entre teclas y martillos por conexiones eléctricas que se dirigieran mediante una computadora. Si programáramos correctamente la computadora, no podríamos decir (con sólo escribir en la máquina) que las conexiones no son mecánicas. De hecho, la computadora hace que mi máquina de escribir sea mucho más versátil. Puedo reprogramarla para que cualquier presión sobre una tecla dé como resultado el golpe de martillo que se me ocurra. Incluso puedo hacer que la presión sobre una sola tecla se convierta en una palabra o en una oración entera.

El programa de computación hace esto básicamente informando a la computadora qué *outputs* corresponden a determinados *inputs* o combinaciones de *inputs*. Si identificamos cada *input* de las diferentes teclas de la máquina de escribir con un número arbitrario y cada *output* de los martillos con otro número, parte del programa podría decir:

SI EL *INPUT* ES 27, QUE EL *OUPUT* SEA 36

o bien

SI EL *INPUT* ES 13, QUE EL *OUPUT* SEA 11, LUEGO 3, LUEGO 15 Y LUEGO 19

Lo crucial consiste en advertir que la computadora no tiene idea de qué significan estos *inputs* y *outputs* en la realidad. No tiene forma de saber que, en este caso en particular, el *input* 27 significa que alguien está presionando la tecla W, o que el *output* 36 activa el martillo W. Para la computadora, sólo se trata de símbolos abstractos que conecta según las reglas de su programa. Estos símbolos podrían ordenar conducir un automóvil, calcular un salario o comenzar la tercera guerra mundial.

Por lo tanto, se puede pensar en un programa de computación como un conjunto de instrucciones para que una computadora manipule símbolos de determinada manera al recibir determinados *inputs*. La computadora es una *máquina de uso general* que un programa convierte, cuando está cargado, en una máquina *específica* para realizar una tarea específica.

Para nuestros propósitos, no es necesario conocer en detalle cómo la configuración física de una computadora nos permite almacenar programas y datos. Se la puede imaginar como un conjunto de muchos miles de células

eléctricas conectadas de una manera específica, donde cada célula puede encenderse o apagarse mediante la aplicación de corrientes eléctricas a un número relativamente pequeño de células de *input*. Un programa determina la secuencia o la lógica de los pasajes de impulsos a través de la configuración física. El diseño de la configuración física de las computadoras ha cambiado mucho en los últimos 30 años. Donde antes había válvulas, ahora hay chips microelectrónicos. Sin embargo, uno puede hacer funcionar programas escritos hace 30 años en las computadoras actuales y obtener los mismos resultados. Así como las computadoras pueden imitar a otras máquinas, también pueden imitarse entre sí. Los avances en las configuraciones físicas no han alterado en esencia el tipo de programas que se pueden hacer funcionar; antes bien, han hecho que las computadoras sean más baratas, más rápidas, más confiables y capaces de manejar programas mayores y grandes cantidades de datos.

La metáfora de la computadora para la mente

Como se señala en el capítulo 1, muchos investigadores se han sentido impresionados por las semejanzas entre las computadoras y el cerebro humano, y esto ha planteado nuevas posibilidades para comprender los procesos mentales. Veamos algunas de las principales semejanzas que se han propuesto:

a) Tanto las computadoras como los cerebros pueden considerarse procesadores de información. Es decir, reciben *inputs* de diversas fuentes, los transforman y manipulan y producen *outputs*.

b) Se puede decir que ambos logran sus diversos resultados mediante la combinación de muchos elementos similares que desempeñan funciones simples. En las computadoras, las células eléctricas se encienden y apagan. En los cerebros, las células nerviosas se excitan o inhiben.

c) Tanto las computadoras como los cerebros pueden considerarse dispositivos de uso general. Pueden realizar muchas operaciones diferentes con la misma configuración física.

d) Ambos pueden almacenar y utilizar grandes cantidades de información.

e) Se podría decir que ambos siguen planes de acción organizados (programas).

Estas similitudes se relacionan con algunas conclusiones generalmente aceptadas y no controvertidas. En primer lugar, que las computadoras pueden imitar exitosamente algunos aspectos de la conducta humana. Para tomar sólo un ejemplo, Siegler (1986) ha escrito un programa de computación que simula el desempeño de los niños en los problemas de resta (por ejemplo, "seis menos cuatro"). Es decir, que cuando se lo hace funcionar en una computadora, el programa comete el mismo tipo de errores que los niños. También le lleva el mismo tiempo que a los niños resolver los problemas. Del mismo modo, mejora con la experiencia, igual que los niños. Como Siegler escribió el programa, puede describir su lógica subyacente y proponerla como modelo hipotético de la forma en que los niños realmente encaran la tarea de restar números. Si los niños usan esta lógica, tendrán exactamente el mismo patrón de errores y tiempos que, de hecho, tienen. (Sin embargo, debemos recordar que es posible que haya otros sistemas que puedan producir los mismos resultados.)

En segundo lugar, la mayoría de los científicos acepta que la disciplina intelectual necesaria para producir un programa que realmente funcione es una valiosa ayuda para teorizar mejor sobre el funcionamiento humano. Como a una computadora hay que decirle exactamente lo que debe hacer, no hay lugar para el pensamiento confuso o impreciso. La computadora también demuestra las incoherencias ocultas en el pensamiento de una forma muy clara. Si hay contradicciones internas, el programa sencillamente no funcionará o dará resultados extraños. Por esta razón, muchos educadores (por ejemplo, Papert, 1972) ven a la computadora como un valioso "gimnasio intelectual". Hay algunos aspectos del control de una computadora que pueden resultar casi necesariamente útiles (ver también Weizenbaum, 1984) y así los niños adquieren la habilidad como subproducto incidental de "hacer que el maldito aparato funcione".

Pero más allá de esos puntos generalmente aceptados, hay un gran debate en torno a lo que a veces se denomina "ardiente defensa" de la inteligencia artificial, que sostiene que cuando ciertos tipos de programas están operando en una computadora, ésta no se limita a imitar la conducta humana sino que realmente puede decirse que "piensa", "sabe" o "entiende".

¿Las computadoras piensan?

El advenimiento de las computadoras planteó de inmediato en la conciencia popular profundas preguntas sobre la naturaleza última de la concien-

cia y la personalidad. Muchas de estas preguntas han sido obsesivamente trajinadas en la ciencia ficción, particularmente en lo que tiene que ver con los "androides", robots de carne y piel sintética que los hacen parecer humanos. Algunas de esas preguntas tienen implicaciones morales. Por ejemplo: ¿debe tratarse a los androides como a seres humanos con derechos? Los relatos en los que las computadoras esclavas enloquecen y se vuelven contra sus amos expresan el profundo temor (ya desde la historia de Frankenstein) de que los científicos estén abriendo una caja de Pandora.

El desarrollo, en la ficción popular, de nuestra fascinación con las computadoras no debería disminuir la profundidad de los temas planteados. De hecho, la obsesión popular puede considerarse una medida de su profundidad. Estos temas siguen acosando y polarizando a la comunidad intelectual. Me gustaría esbozar las opiniones de dos claros y convincentes defensores de puntos de vista opuestos sobre las computadoras: Alan Turing y John Searle. Nunca se conocieron personalmente. Turing murió hace unos años y Searle mantiene su debate con los discípulos intelectuales de Turing. Las ideas de Turing están bella e inteligentemente expresadas en un artículo publicado en 1950 y las de Searle muestran el mismo aplomo en un ensayo de 1980. Hofstadter y Dennett (1981) han reimpreso extractos de lo más relevante de ambos autores.

El test de Turing

Turing empieza preguntándose cuál podría ser un test adecuado para comprobar si una computadora piensa. Rechaza con justicia la idea de que debamos ocuparnos de la apariencia de la computadora (es decir, si podemos hacerla parecer humana) y nos pide que imaginemos una situación en la que un interrogador se sienta en una habitación frente a dos teletipos. Estas máquinas le permiten enviar mensajes a otras personas ubicadas en otro lugar y recibir mensajes enviados por ellas. En el test de Turing, una de las "personas" es un ser humano y la otra es una computadora. La tarea del interrogador es tratar de determinar, preguntando lo que se le ocurra, cuál de sus teletipos lo comunica con el ser humano y cuál con la computadora. Si quien interroga no puede tomar una decisión segura después de un extenso interrogatorio, podremos decir que la computadora ha pasado el test de Turing. Turing sostiene que si una computadora puede pasar una prueba así, no nos quedará más remedio que aceptar que piensa.

Esta es la formulación clásica de la "ardiente defensa" de la inteligencia artificial. En su ensayo, Turing menciona luego algunas objeciones posibles. Veamos apenas dos de las principales y las respuestas que él mismo da:

OBJECIÓN 1: Aunque una computadora actúe como si pensara, no se puede concluir que dentro de ella suceda algo afín a lo que llamaríamos *experiencia consciente*.

RESPUESTA: El único ser del cual uno puede saber con certeza que tiene esas experiencias es uno mismo. Uno no sabe si los demás seres humanos también tienen conciencia pero supone que la tienen. ¿Por qué no, entonces, las computadoras?

OBJECIÓN 2: Aunque las computadoras pueden *simular* algunos aspectos de la conducta humana, jamás podrán enamorarse, hacer algo realmente creativo, etc.

RESPUESTA: Acepto que no hay programa de computación existente que pueda aprobar todavía el test de Turing. Pero esta no es razón suficiente para suponer que no podemos seguir creando programas que cubran cada vez más aspectos de la conducta humana y que algún día no tendremos éxito. Habría que ofrecer alguna razón fundamentada que demostrara que ciertas cosas son imposibles de programar.

Nos ocuparemos ahora de Searle, quien, como Turing, nos pide que juguemos con él un juego del pensamiento, para demostrar su posición.

El "salón chino" de Searle

El juego imaginario de Searle se denomina "Test del salón chino". Se basa en un programa de computación descrito por Schank y Abelson (1977) que, según sostienen algunos, "entiende" historias. El programa simula la operación del tipo de conocimientos que hemos visto que los lectores usan para interpretar historias o discurso (capítulos 4 y 10). Las palabras de Searle son tan claras y convincentes que dejaré que hablen por sí mismas:

En resumen, y sin mencionar los detalles, puede describirse así al programa de Schank: el objetivo del programa es simular la capacidad humana

para entender historias. Es característico de la capacidad de comprensión de historias de los seres humanos el poder responder preguntas sobre la historia, aun cuando la información pedida no esté explícitamente mencionada en la historia. Así, por ejemplo, supongamos que a uno se le cuenta la siguiente historia: "Un hombre entra a un restaurante y pide una hamburguesa. Cuando se la traen, está dura como una piedra. El hombre sale del restaurante enojado, sin pagar la hamburguesa ni dejar propina." Ahora bien, si a uno le preguntan si el hombre se comió la hamburguesa, probablemente responda que no. Del mismo modo, veamos la siguiente historia: "Un hombre entra a un restaurante y pide una hamburguesa. Cuando se la traen, el hombre piensa que tiene un aspecto apetitoso. Cuando se va del restaurante, le deja a la camarera una buena propina después de pagar su cuenta." Si esta vez nos preguntan si el hombre comió la hamburguesa, probablemente responderemos que sí. Las máquinas de Schank pueden responder preguntas sobre restaurantes de una forma parecida. Para hacerlo, tienen una "representación" del tipo de información que los seres humanos poseen sobre los restaurantes, lo cual les permite contestar preguntas como las planteadas ante historias de este tipo. Cuando a la máquina se le da la historia y luego se le hace la pregunta, imprimirá respuestas semejantes a las que serían esperables en una persona si se le contara una historia así. Los defensores de la inteligencia artificial sostienen que en esta secuencia de preguntas y respuestas, la máquina no sólo está simulando una capacidad humana sino también: 1) que se puede decir que la máquina literalmente entiende la historia y responde las preguntas, y 2) que lo que hacen la máquina y su programa *explica* la capacidad humana de entender la historia y responder preguntas sobre ella.

Me parece que el trabajo de Schank no ofrece sustento a ninguna de las dos afirmaciones, e intentaré demostrarlo a continuación.

Una forma de verificar cualquier hipótesis sobre la mente es preguntarse cómo sería si mi mente realmente funcionara según los principios que, de acuerdo con la teoría, rigen el funcionamiento de todas las mentes. Apliquemos esta prueba al problema de Schank con el siguiente *Gedankenexperiment* (experimento del pensamiento). Supongamos que estoy encerrado en una habitación con una gran carpeta con escritura china. Supongamos, además, que no sé nada de chino, oral o escrito (como sucede en la realidad), y que no creo poder reconocer la diferencia entre la escritura china y, por ejemplo, la japonesa o meros garabatos sin sentido. Para mí, la escritura china son muchos garabatos sin sentido. Supongamos también que después de

esta primera carpeta con escritura china me dan una segunda carpeta con escritura china junto con un conjunto de reglas para correlacionar la segunda carpeta con la primera. Las reglas están en inglés y yo las entiendo como las entendería cualquier otro angloparlante. Me permiten correlacionar un conjunto de símbolos formales con otro. "Formales" significa, en este caso, que puedo identificar los símbolos por sus formas. Supongamos también que me dan una tercera carpeta de símbolos chinos junto con instrucciones, nuevamente en inglés, que me permiten correlacionar elementos de esta tercera carpeta con las dos primeras, y estas reglas me enseñan a darles ciertos tipos de formas a ciertos símbolos chinos, en respuesta a ciertos tipos de formas que hay en la tercera carpeta. Quienes me dan todos estos símbolos, desconocidos para mí, llaman "libreto" a la primera carpeta, "historia" a la segunda y "preguntas" a la tercera. Además, a los símbolos que les doy en respuesta a la tercera carpeta los llaman "respuestas a la pregunta", y denominan "programa" al conjunto de reglas en inglés que me han dado. Para complicar un poco la cosa, imaginen que esta gente también me da historias en inglés, que comprendo, y luego me hacen preguntas en inglés sobre estas historias, y yo les respondo en inglés. Supongamos también que después de un tiempo llego a ser tan bueno siguiendo las instrucciones para manipular los símbolos chinos y los programadores llegan a ser tan buenos escribiendo los programas que, desde un punto de vista exterior (es decir, desde el punto de vista de alguien que esté fuera de la habitación en la que estoy encerrado), mis respuestas a las preguntas son absolutamente imposibles de diferenciar de las respuestas de los chinos nativos. Nadie puede decir, viendo mis respuestas, que no sé una sola palabra de chino. Supongamos también que mis respuestas a las preguntas en inglés son (como seguramente serían) imposibles de diferenciar de las de otros hablantes nativos de inglés, por la simple razón de que yo mismo soy un hablante nativo de inglés. Desde el punto de vista exterior (desde el punto de vista de alguien que lee mis "respuestas"), las respuestas a las preguntas en chino y a las preguntas en inglés son igualmente buenas. Pero, en el caso del chino (a diferencia del inglés), produzco las respuestas manipulando símbolos formales no interpretados. En lo que respecta al chino, me comporto simplemente como una computadora; realizo operaciones computacionales con elementos formalmente especificados. Para el chino, soy simplemente una ejemplificación del programa de computación.

Los defensores de la inteligencia artificial sostienen que la computadora programada entiende las historias y que el programa en alguna medida ex-

plica la comprensión humana. Pero ahora estamos en condiciones de examinar estos argumentos a la luz de nuestro experimento del pensamiento.

1. En lo que respecta a la primera afirmación, me parece más que evidente, por el ejemplo, que no entiendo una sola palabra de las historias chinas. Tengo *inputs* y *outputs* imposibles de distinguir de los de un hablante de chino y puedo tener cualquier programa formal, pero sigo sin entender nada. Por las mismas razones, la computadora de Schank no entiende nada de ninguna historia (escrita en chino, inglés o en cualquier otro idioma), ya que en el ejemplo chino la computadora soy yo, y cuando la computadora no soy yo, ella no tiene más de lo que yo tengo en el caso en que no entiendo nada.

2. En lo que respecta a la segunda afirmación, que el programa explica la comprensión humana, podemos ver que la computadora y su programa no proporcionan las condiciones de comprensión suficientes ya que, aunque ambos están funcionando, no hay comprensión.

Si aceptamos los argumentos de Searle (y son muchos los que han intentado demolerlos), debemos preguntarnos qué es lo que hace tan especiales a los seres humanos. En esto, Searle no es tan preciso. En síntesis, considera que atributos intencionales tales como el pensamiento, el saber y la comprensión tienen que ver con el hecho de que la computadora humana se manifiesta en nervios, carne y hueso.

Lo que importa de las operaciones cerebrales no es la representación formal de las secuencias sinápticas sino más bien las propiedades reales de las secuencias. Todos los argumentos que he visto en defensa de la inteligencia artificial insisten en trazar un perfil en torno a las imágenes que produce la cognición y luego afirman que esas imágenes son la realidad.

En este punto, dejemos descansar al debate. Si se resuelve (y cuando se resuelva) nos acercará a la esencia de lo humano. Por ahora, debemos seguir viviendo en la incertidumbre.

Programas y simulaciones

Durante muchos años, los expertos en computación han estado creando programas de ajedrez, buscando producir alguno que ningún ser humano pueda derrotar. El ajedrez representa un desafío estimulante pára los programadores

porque sus reglas básicas son muy simples y bien definidas y sin embargo casi no hay límites para el refinamiento en el dominio del juego. En 1957, Herbert Simon predijo que en diez años habría un programa de computación al que nadie podría vencer. Treinta años después su predicción sigue sin cumplirse, aunque hay un par de sistemas de origen estadounidense (en especial el "Belle", de Bell Laboratories, Nueva Jersey) que pueden derrotar al 99,5% de los jugadores.

Algoritmos

Como ya se comentó en el capítulo 14, hay básicamente dos enfoques para encarar un problema de cálculo. Uno es intentar descubrir un *algoritmo* eficiente para la tarea; el otro consiste en desarrollar un sistema *heurístico* funcional. Un algoritmo es un procedimiento que garantiza una solución para problemas de determinado tipo. Por ejemplo, la mayoría de nosotros aprendimos algoritmos para resolver multiplicaciones largas cuando estábamos en la escuela. Si se siguen todos los pasos en el orden correcto y no se cometen errores de cálculo, siempre se llegará a la solución correcta.

¿Existe un algoritmo para el ajedrez? En teoría, sí. Incluye el análisis de cada movimiento posible, luego el de cada respuesta posible del rival, luego el de cada respuesta propia posible, y así sucesivamente hasta haber explorado las consecuencias de todos los movimientos posibles hasta el momento en que alguno de los jugadores gana. Luego, uno elige el movimiento asociado con la mayor cantidad de resultados ganadores.

Por desgracia, un algoritmo así es impracticable. Se ha calculado que hay más partidas de ajedrez posibles que átomos en el universo. Si uno quisiera analizar apenas cinco movimientos por adelantado, tendría que considerar hasta 50.000.000 de diferentes combinaciones de movimientos. Probablemente a la computadora más veloz del mundo (que contara con una capacidad de almacenamiento de información ilimitada) le llevaría varios millones de años jugar una partida de ajedrez usando semejante algoritmo.

Heurística

Para "reducir el campo de búsqueda" en los problemas de este tipo, hacen falta las heurísticas. Son reglas empíricas que tienen una probabilidad razonable de producir resultados aceptables. Es bastante evidente que la resolu-

ción de problemas en el ser humano normalmente se realiza con una gran provisión heurística (ver capítulos 13 y 14) y que esas heurísticas conforman el caudal con el que cuentan la mayoría de los entrenadores. Así, casi todos los manuales de ajedrez aconsejan a los jugadores elegir movimientos tendientes a ganar el control del centro del tablero. Otra heurística consiste en comer las piezas del adversario cada vez que se presenta la oportunidad. Cada heurística tiene sus propias limitaciones. En el ajedrez, un jugador puede hacer un "sacrificio" mediante el cual gana una ventaja mayor si su adversario se siente tentado por la recompensa menor de comer una de sus piezas.

Pero en general las ventajas de las heurísticas son mucho mayores que sus limitaciones. Muchos problemas humanos están demasiado mal definidos como para poder aplicar algoritmos. A menudo, no tenemos conciencia de todas las posibilidades disponibles y por lo tanto no podemos evaluar todos los cursos de acción posibles. Incluso cuando podemos hacerlo, puede requerir demasiado tiempo o exigir demasiado esfuerzo psíquico. Las heurísticas ofrecen la perspectiva de respuestas rápidas a diversas situaciones. En la vida real, uno no suele contar con tiempo ilimitado para tomar una decisión. Las heurísticas simples también han demostrado tener muy amplia aplicabilidad en computación. Los trabajos pioneros de Simon y sus colegas (Newell y Simon, 1972) dieron como resultado un programa llamado *General Problem Solver* (Solucionador General de Problemas, SGP), basado en un conjunto de heurísticas, una de las cuales ha sido denominada "heurística de medios-fines" (ver capítulo 14). En pocas palabras, dice que si uno quiere pasar de una condición inicial A a una condición final Z y hay algún estadio intermedio M que de alguna forma está más cerca de Z que A, lo que hay que hacer es intentar llegar a M. Este es el enfoque subyacente en el problema de "llegar a Londres" que se plantea en el capítulo 2.

Newell y Simon demostraron que heurísticas como ésta pueden formularse e implementarse con rigor en un programa de computación que sea capaz de encarar coherentemente una gran variedad de problemas (por ejemplo, encontrar pruebas de las afirmaciones matemáticas). También se puede considerar a las reglas de producción descritas en el capítulo 2 como corporizaciones de heurísticas (relacionadas con la heurística de medios-fines, pero de una naturaleza bastante más específica). Un sistema como el SGP puede implementarse fácilmente como sistema de producción de computación, y ya existen programas que pueden aprender, a partir de heurísticas bastante generales que se dan como supuestos, reglas específicas adaptadas a situaciones individuales (Anderson, 1982).

Los programadores de ajedrez deben recurrir a las heurísticas porque es la única forma que tienen para lograr que alguna vez las computadoras jueguen al ajedrez bien y rápido. En general, no se preocupan por imitar el desempeño humano. Su objetivo es superarlo, hacer el mejor trabajo posible. Como ellos, muchos trabajadores en inteligencia artificial están preocupados fundamentalmente por proporcionar buenas soluciones a los problemas existentes. Siempre que haya algoritmos posibles preferirán usarlos porque aumentan la confiabilidad. También aprovechan la increíble velocidad con que las computadoras pueden realizar operaciones reiterativas. La velocidad y la confiabilidad son las principales razones por las que las computadoras han reemplazado al ser humano en muchos de los campos laborales más mecánicos. Una computadora puede encargarse de los salarios del personal con mucha mayor eficiencia que una persona, si está programada para hacerlo. Pero para aquellos que están interesados fundamentalmente en usar las computadoras como vinculadores, y así entender mejor el funcionamiento humano, no es importante tener el mejor programa. Precisamente el programa que resulta de mayor interés psicológico es aquel que comete errores "humanos" y muestra la capacidad humana para ir más allá de los datos que se proporcionan (como en el programa de "comprensión del relato" de Schank).

Es posible que en niveles bastante periféricos del funcionamiento sensorial y motriz (ver, por ejemplo, Marr, 1983) el cerebro actúe según principios algorítmicos. El cálculo de la profundidad visual a partir de una imagen estereoscópica parece estar basado en un algoritmo. Pero tan pronto como entramos en pleno territorio cognitivo, las heurísticas parecen abundar. Desde la percepción de la forma visual hasta la creación de una obra de arte, la característica humana de la imperfección parece conferirnos una ventaja peculiar. Aunque las computadoras están llegando lentamente a poder imitar algunas de estas cualidades de flexibilidad e ilimitación que caracterizan a la mente humana, no es para nada evidente que el enfoque de la computadora haya explicado o vaya a explicar todos los misterios no resueltos. Como todas las metáforas, realza las semejanzas y aclara las ideas, pero la comprensión que ofrece sólo es parcial.

Estrategias de aula

Esta obra se estructura en torno al tema de las habilidades humanas, analizando sus naturalezas, las formas en que se adquieren y las técnicas que pueden contribuir a mejorarlas.

El acento está puesto fundamentalmente en habilidades cognitivas comunes como *hablar*, *recordar* y *razonar*, que suelen darse por sentadas y pueden parecer irrelevantes; pero que, como demuestra este libro, son tan extraordinarias y complejas como las habilidades no comunes.

La inteligencia hábil sostiene que la cognición se entiende mejor en términos de *habilidad*; que las habilidades deben ser analizadas en su contexto social, y que pueden mejorarse por medio del entrenamiento.

Angus Gellatly es profesor del Departamento de Psicología de la Universidad de Keele (U.S.A.). Las investigaciones sobre la memoria, el razonamiento y la percepción que presenta en este libro constituyen un aporte significativo a la búsqueda de estrategias para desarrollar y mejorar las habilidades de aprendizaje.

OXFORD PSYCHOLOGY SERIES

1. The neuropsychology of anxiety: an inquiry into the functions of the septo-hippocampal system *Jeffrey A. Gray*
2. Elements of episodic memory *Endel Tulving*
3. Conditioning and associative learning *N. J. Mackintosh*
4. Visual masking: an integrative approach *Bruno G. Breitmeyer*
5. The musical mind: the cognitive psychology of music *John A. Sloboda*
6. Elements of psychophysical theory *Jean-Claude Falmagne*
7. Animal intelligence: *Edited by L. Weiskrantz* Proceedings of a Royal Society Discussion Meeting
8. Response times: their role in inferring elementary mental organization *R. Duncan Luce*
9. Mental representations: a dual coding approach *Allan Paivio*
10. Memory, imprinting, and the brain: an enquiry into mechanisms *Gabriel Horn*
11. Working memory *Alan Baddeley*
12. Blindsight: a case study and implications *L. Weiskrantz*
13. Profile analysis *David M. Green*
14. Spatial vision *Russell L. DeValois and Karen K. DeValois*
15. The neural and behavioural organization of goal-directed movements *Marc Jeannerod*
16. Visual pattern analyzers *Norma V. S. Graham*
17. Cognitive foundations of musical pitch *Carol L. Krumhansl*
18. Perceptual and associative learning *Geoffrey Hall*
19. Implicit learning and tacit knowledge *A. S. Reber*
20. Neuropsychology of communicative behavior *D. Kimura*
21. The frontal lobes and voluntary action *R. E. Passingham*

Preface

When it was first suggested that I should write a book on the cognitive psychology of music, I had no clear conception of what sort of book might be the outcome. As I began to take stock of the existing literature, it became clear that there was a gap that needed to be filled. On one side of this gap could be placed the vast majority of the psychological research on music. On the other side was the experience and insight of the musician, as expressed both through his practices and through the rigorous disciplines of musicology, music theory, and analysis. It seemed, to me at least, that the psychology of music related rather little to what musicians actually did, and so was failing to tackle questions of central musical importance.

There are several reasons why this state of affairs might have arisen. One is that many psychologists studying music have not had the good fortune to receive extended musical training, and so have had a limited range of musical insights and intuitions to guide their work. The difficulties caused by this are akin to the difficulties that might be experienced by someone attempting to carry out psycholinguistic research on a language that he did not know at all well, and without a thorough grounding in linguistics. Even psychologists *with* musical expertise have often seemed to detach their scientific work from their musical knowledge.

Another reason is that theoretical developments in the psychology of music have been slow. Experimentalists have tended to construct micro-theories to account for their own results so that research from different sources cannot easily be synthesized. Only in the last few years have people well-grounded in both psychology and music begun to construct psychologically interesting theories of musical functioning which might be capable of unifying and giving direction to a wide range of research endeavours.

A third reason is that psychological research has been dominated by the view that one must understand the most peripheral and simple aspects of intellectual functioning as a prelude to the study of more central and complex aspects. Although this view is now accepted to be largely misconceived, a vast amount of so-called 'music' research has concentrated on the processes involved in the perception of single tones. Topics such as the representation of large-scale musical structure, performance, and composition, have received comparatively little attention. Yet these are the topics which are of most direct relevance to musicians.

A fourth and related reason is that psychologists have, rightly, wished to conduct their research with rigorous control and measurement. It is much

easier to construct brief auditory stimuli to exact specifications whilst constraining subjects to simple yes/no responses, than it is to to allow subjects the freedom to indulge in some complex but musically interesting behaviour in response to complex musically structured conditions. Yet the latter *can* be done with rigour, and is beginning to be done with increasing frequency.

Fifth, and finally, writers on the psychology of music have tended to address themselves exclusively either to the professional psychologist or to the music educator and educational researcher. There has been little fruitful dialogue between psychologists and practising or academic musicians. This may not be entirely the fault of psychologists, but few psychologists seem to have been really concerned to break the interdisciplinary barrier.

I have written with this barrier very much in mind, and have tried to offer something to both the psychologist and the musician. The psychologist will, I hope, find a coherent account of the important research carried out in this area. He will also be exposed to some of the questions and issues which have not yet stimulated a great deal of research. These questions arise as I critically examine the field through the eyes of a musician, but also through the eyes of a cognitive psychologist who finds psychologists of music slow to accept the wider perspectives which cognitive science has brought to other branches of psychology in the last decade. I have assumed a moderate degree of musical literacy in my readers. To have done otherwise would have made my task impossibly slow. Likewise, an acquaintance is assumed with the broad range of topics and methods embraced by scientific psychology, although I have attempted to write in such a way that detailed knowledge in specific areas is not required. I have made liberal reference to suitable introductory reading where the general reader might wish to seek further information.

Musicians will, I hope, find that cognitive psychology has something to offer in helping them understand the mental bases of their skills. I have not, however, set out to provide a 'recipe book' of psychological aids to specific musical problems. Rather, I have tried to highlight and elucidate some basic characteristics of musical skills and the cognitive mechanisms which serve them. An understanding of these underlying factors will, hopefully, allow musicians to formulate better solutions to some of their problems.

I am very much aware that the subject I present abounds with loose ends and unsolved problems. I have not tried to give the field more substantiality than it has. What I hope to have done is to describe the main achievements in this rapidly growing area up to the end of 1982 or thereabouts, and map out some important topics and questions which need more attention than they have received.

My own approach to the cognitive psychology of music has been most greatly influenced by the writings of Christopher Longuet-Higgins who, in the early 1970s, was asking and answering important questions about the psychological representation of extended tonal music at a time when many

others were hooked on peripheral questions. I gratefully acknowledge his encouragement and support, which has been directly instrumental in getting this book finished. I am also grateful to several people for putting me on the track of material that I otherwise would have discovered much later or not at all. Alan Mosley first told me about the work of Heinrich Schenker; Michael Durand first showed me the fascinating story revealed by ink changes in Mozart's operatic autographs; and Ian Hunter introduced me to David Sudnow's unique account of his own improvisatory development, as well as opening my eyes to the profound contrasts between skills of literate and non-literate people.

Several people deserve special mention in connection with the immediate preparation of this book. I am grateful to Stephen Banfield, Ian Hunter, Pamela Liebeck, George Pratt, Henry Shaffer, Ursula Sharma, my wife Judith, and anonymous reviewers for the Oxford University Press, for reading portions of the first draft and offering useful comments. My late father also made detailed comments on the earlier portion of the book which much improved its intelligibility, and I dedicate this book to his memory. I am particularly grateful to the Senate of the University of Keele for the award of a Keele Research Fellowship in 1982 which allowed me the uninterrupted time required to complete the first draft. I gratefully acknowledge the secretarial help of Dorothy Masters and Margaret Woodward, and technical assistance from John Coleman and the Keele University Computer Centre.

The psychology of music is a rapidly growing subject, and it is exciting to be directly involved in that growth. I have enjoyed writing this book, but I am also aware that the field has leapt forward even in the two years I have taken out of the laboratory to complete it. I am now anxious to return to the laboratory. My principal hope is that psychologists who enjoy reading this book will also be stimulated to repair to the laboratory and render some of my critical comments obsolete.

J. A. S.

July 1983

Preface to the 1999 reprinting

The text of *The Musical Mind* was completed in 1983. Fifteen years have now passed since then, and a new printing makes it timely for me to say something about the progress of music psychology since 1983. In effect, I need to justify why any reader should turn to this book, given the substantial progress in the field since that time. Fifteen years is a long time in science, and anyone wishing to enter the field of music research as an active participant cannot do so without concentrating their attention on materials published in the last five years or so. However, it seems that *The Musical Mind* has served a variety of constituencies outside the research laboratory. Musicians, students, and interested lay-people have been kind enough to say that they have found something of more lasting value in the book. This pleases me, for it was never my intention to provide a comprehensive textbook, of the kind that could be straightforwardly updated by the addition of new sections every few years. I wanted, as I hope I expressed in the Preface to the first printing, to address the field from a critical perspective (in which I saw psychologists as insufficiently interested in making their research relevant to the interests and concerns of musicians) and highlight areas of investigation which I felt to be important, regardless of the quantity of research that had been published in those areas.

This Preface is not in any sense, an exhaustive summary of where the cognitive psychology of music has got to since 1893. That would require another book. Rather, it is a brief evaluation of the development of some of the key themes that I identified. It therefore is probably best read *after* consulting the relevant chapters, rather than before, and I have therefore referenced all my comments to the numbered sections and page numbers of the chapters. I have tried to be selective in my citation of more recent research, favouring books and review articles over specific empirical studies unless these latter are of foundational significance. In this way, interested readers will gain the fastest access to recent surveys of specific areas of research.

Music, language, and meaning

My organizing principle for discussing links between language and music was the tripartite distinction between phonology, syntax, and semantics (2.3(h) ff. pp. 22–65). In so far as music could be mapped on to this distinction, it seemed appropriate to think of music and language as overlapping

(both functionally and conceptually). In 1983 my broad conclusion was that evidence for equivalence at the phonological and syntactic level was rather impressive, but that musical and linguistic semantics operated in rather different ways, in so far as the scanty research literature in music allowed any definite conclusions at all.

About phonology (2.4, pp. 23–32) I wish to add rather little. The ability to make categorical distinctions between musical elements is a foundational aspect of music perception and performance. My treatment concentrated on pitch and duration. More recent research has widened the range of dimensions about which we have knowledge. Of these, timbre is undoubtedly the most significant (Hajda, Kendall, Carterette, and Harchberger 1997).

The study of psychological aspects of musical syntax (2.5, pp. 32–57) has seen phenomenal growth since 1983. To me, the most interesting feature of this growth is that it has been largely driven organically by developments within experimental psychology, rather than developments within musicology. Our understanding of pitch relations has deepened largely through the application of traditional psychophysical techniques to long-established cultural conceptualizations of tonality (e.g. Krumhansl 1990) rather than in response to new theory, even when that theory is explicitly psychologically oriented (e.g. Lerdahl and Jackendoff 1983: Narmour 1989, 1992). Earlier (Sloboda 1986) I predicted that Lerdahl and Jackendoff's *Generative Theory of Tonal Music* (1983) would give the kind of new impetus to music psychology research that Chomsky (1965) gave to psycholinguistics. With a few brave exceptions (e.g. Deliege 1987) I have been proved entirely wrong about that. More fruitful growth points have been at the junctions between psychology and neuroscience, partly as a result of the rise of connectionism and neural-net modelling (see Bharucha 1991), but also as a result of a range of new techniques which allow direct measurement of the overlap of brain activity between language and music processing (e.g. Besson 1997; Patel and Peretz 1997). One possible reason for the slowness for psychology to take on new musicological theorizing is that such work attempts to grapple with sytactical issues at the global as well as the local level (i.e. pertaining to entire movements and not just single phrases). Our methods for studying global cognition are still in their infancy, and psychology is still best suited to studying our interactions with materials lasting seconds rather than minutes.

Interest in musical semantics (2.6, pp. 57–65) has increased considerably since 1983. A particularly acute philosophical contribution has been made by Raffman (1993) who pointed out that the phrase 'music has meaning'. can mean both 'music has semantics', and 'music has personal significance' (as in 'music means a lot to me'). Much conceptual confusion has been created by previous unclarity on this point. The psychology of musical semantics is concerned with the mapping and explanation of relationships,

between musical elements and their non-musical connotations, which are often emotional (e.g. Juslin 1997), but by no mans always need be so (e.g. Watt and Ash 1998). Over and above semantics, music can be used to achieve valued psychological states, including emotional states, and an explanation of these effects requires an understanding, not only of cognitive psychology, but also social psychology (Hargreaves and North 1997), therapy (Bunt 1994), and the psychology of motivation (Sloboda and Davidson 1995). Cognition remains central to this aspect, however, since there is now some evidence to support Meyer's (1973) contention (2.6, pp. 64–5) that violations of structural expectancy (describable in syntactic terms) contribute in a very direct way to the intensity of experienced emotion, if not its content (Krumhansl 1998; Sloboda 1991).

Music performance

My treatment of performance (3) was also based round three issues, sight-reading, rehearsal, and expert performance. A great deal of new work has been done in the latter two areas, almost nothing in the first.

The emphasis on sight-reading in 1983 (3.2, pp. 68–90) largely reflected my own research interests, in which reading was a dominant theme at that time. Despite the fact that notational competence remains central to much musical skill and development, there is little more known about it than in 1983. Waters and Underwood (1998) report a study on eye movements which summarizes the small recent literature.

The study of rehearsal (3.3, pp. 90–3) has seen a recent renaissance as a result of the rise of a branch of cognitive psychology known as 'expertise studies' (see Ericsson and Smith 1991). This area was foreshadowed by seminal work on problem-solving (1 p. 8) begun by Simon and colleagues, and has led to detailed investigations of the conditions under which skilled individuals improve their skills. Not only do we understand much more about the details of effective musical practice (e.g. Ericsson, Krampe, and Tesch-Romer 1993; Jorgensen and Lehmann 1997), but we have a much clearer idea of the social, motivational, and emotional factors which allow unusually high levels of musical achievement to develop (Manturszewska 1990; Davidson, Howe, and Sloboda 1997). This work is entirely in keeping with the 'demystification' of talent and genius, which characterized my approach in 1983 (see 1 pp, 3–6), and which has been a central theme in the cognitive psychology of creativity and achievement ever since (e.g. Howe, Davidson, and Sloboda 1998; Weisberg 1993)

The section on expert musical performance was, in 1983, largely conceptual (3.4, pp. 93–101), and driven by the hope that psychologists would begin to study it. This hope has been fulfilled beyond all expectations. Work begun in Europe by Shaffer (pp. 98–9) and Gabrielsson (p. 30), built on by their students (Clarke 1995; Juslin 1997; Todd 1985), and taken up enthusi-

astically in the US (e.g. Palmer 1996, 1997, Repp 1990, 1997) has confirmed my hypotheses that expert performance depends upon the flexible deployment of structural knowledge. One reason why this area of work progressed much faster than I expected was the development of MIDI (Musical Instrument Digital Interface) technology, which allowed for easy storage and manipulation of performances through commercially available industry-standard equipment. This now allows the achievement in days of what it took Shaffer years to develop. A notable feature of much of this research is its use of entire pieces of music performed in naturalistic contexts, thus meeting demands of ecological validity, and forming one of the really productive meeting points between psychologists and practising musicians, for whom 'performance studies' is now an established subdiscipline, sharing many of the technologies and methodologies developed in psychology (e.g. Rink 1995). These developments recently allowed the opportunity to revisit the question of fingering strategies (Sloboda, Clarke, Parncutt, and Raekallio 1998), and do the research suggested in 1983 (3.4, pp. 96–7), a source of some personal satisfaction.

Composition and improvization

Despite a considerable general interest in creativity and the products of creative individuals (e.g. Simonton 1996), the amount of new work on cognitive processes in composition and improvisation since 1983 has been small. A collection of preliminary studies in this area (Sloboda 1998) has not led to major subsequent developments. In general, what little work there is focuses on detailed analyses of improvisations (e.g. Jarvinen 1995). The only study of composition published in a major music psychology journal this decade is a small expert–novice comparison on a classroom composition exercise (Colley, Banton, Down, and Pither, 1992). It is hard to understand why so little attention has been paid to these areas. Admittedly, they pose methodological problems; but it is possible that their neglect also reflects the general neglect of musical creativity in the arena of the high art or 'classical' tradition which dominates schools, colleges, and universities. Whatever the reason, it means that my 1983 chapter remains as pertinent today as it did then.

Listening to music

The notion that music listening draws on general auditory mechanisms designed for a range of detection tasks in the natural world (5.2, pp. 154–66) has now motivated an active research area called 'Auditory Scene Analysis' of which Bregman's (1990) contribution is the defining work (see also McAdams and Bigand 1993). The most impressive application of this work to music is undoubtedly the series of studies by Huron (e.g. 1991, 1993)

which show, through computer-based analyses of very large corpuses of classical compositions, that composers have intuitively conformed to many of the perceptual principles that allow, for instance, separate musical voices to be heard as separate perceptual objects. A natural consequence of this line of work is the demonstration that, at many levels, what experts and novices extract from their hearing of music is remarkably similar, despite the effects of training. Significant evidence of these commonalities has been provided by in a series of studies on cue-abstraction while listening to complete compositions (Deliege and Melen 1997). This work has also been supported by the strong theoretical claim (Lerdahl 1998) that certain structural features (intended by, for instance, some avant-garde composers) are simply incapable of being detected by natural hearing mechanisms, and this accounts for their difficulty and relative unpopularity among listeners.

Given that memorizing music is such a central and ecologically pertinent aspect of musical cognition, I tried to give significant coverage to memory for extended musical sequences in my treatment of listening (5.4, pp. 174–93). A number of books treating music perception and cognition have been published since (chronologically: Howell, Cross, and West 1995; Dowling and Bartlett 1996; Riess-Jones and Holleran 1990; Butler 1992; Aiello 1994; Deliege and Sloboda 1997). It is surprising how little explicit attention is given to memorization (although the role of memory is implied in studies of recognition and other forms of judgment). The most comprehensive coverage of memory is given by Dowling and Harwood (1986) although it reviews almost the same materials as I did. Only two other chapters focus primarily on memory and recall (Sloboda and Parker 1985; Krumhansl 1990). Curiously, the most extended examination of the memorization process since 1983 has been provided through the study of anomalous cognition displayed by autistic musical savants (Miller 1989). It would be fair to say that the predominant strand in recent research on music listening has been to further our understanding of the experience of pitch, within the context of western tonal music (e.g. Cuddy 1997; Cross 1997; Krumhansl 1991; Sloboda 1992). Since memorization requires integration of information across all relevant domains, pitch, rhythm, melody, and large-scale structure, it is perhaps unsurprising that our understanding of it has not progressed as fast as one would have liked. More integrative syntheses in other areas of the kind attempted by Parncutt (1994) for rhythm and metre are required.

Learning and development

Since 1983, substantial progress has been made in our understanding of the development of musical awareness from birth to school age (Deliege and Sloboda 1995; Trehub, Schellenberg, and Hill 1997). One of the most interesting new findings relating to the first year of life (6.2.1, pp. 198–202) is that

infants have musical preferences which seem to be informed by an appreciation of such high-level musical features as phrase structure (e.g. Jusczyk and Krumhansl 1993). The scaffolding for early musical development provided by parent–child interaction is now much better understood (Papousek 1995).

In middle childhood two research strands have developed. On the one side is research into autonomous or naturalistic musical behaviour, such as song singing (Davidson 1994), or spontaneous notations (Bamberger 1991), following in the tradition of Moog and Gardner (6.2.2, pp. 202–5). On the other are experimental studies, using paridigms developed for the study of adult cognition and which allow direct comparison between different age groups on the same materials, (e.g. Drake 1993; Lamont 1998). However, it would be fair to say that adult cognition still accounts for the vast majority of work in music cognition, and there is still much to be understood about the development of musical cognition.

Perhaps as a result of the slowness of the developmental literature to progress, there have been a few successful applications of cognitive psychology to musical education and training. My enthusiasm for production systems as a theoretical tool (6.3, pp. 215–29) proved to be overstated. The rise of connectionism as an alternative theoretical framework both rendered production-system theorizing unfashionable, and at the same time seemed to disable or inhibit experimental work which might apply this theorizing to concrete musical learning situations (Morrongiello 1992). Instead, the predominant interest of the last few years has been in ways in which involvement with music might aid developmental progress in other areas of cognition (Sharp, Benefield, and Kendall 1998). This may reflect pressures on music within the school curriculum in many countries.

Work on the assessment of musical ability (6.4, pp. 233–8) has not been a major concern of recent research within the cognitive tradition. By and large there is too little clarity concerning what precise cognitive skills are being tapped by many ability tests, and predictive validity is generally low. Individual researchers seem to devise their own tests to suit their particular research question (e.g. Macpherson 1995), with the consequent loss of generality.

Culture and biology

Cross-cultural issues have continued to be a neglected aspect of the study of musical cognition. Comparisons of oral and literate cultures are almost non-existent, notable and pioneering exceptions being the work of Arom and colleagues on perception of scales and tuning in Central Africa and Indonesia (Arom, Leothaud, and Voisin 1997) and that of Kessler and colleagues on perception of tonality in Bali (Kessler, Hansen, and Shepard 1984). Indeed, even studies of western music show a worrying narrowness,

concentrating on perception and performance of high-art classical music to the near exclusion of other forms.

In relation to biology, on the other hand, new techniques such as Magnetic Resonance Imaging (MRI) and Positron Emission Tomography (PET) have revolutionized the amount and quality of information available concerning brain activity during music engagement. Most of the work in music is in the somewhat better-established area of Event-Related Potentials (ERPs) (see Besson 1997). Much of this has focused on the measuring of musical expectancy as a function of manipulations of structure. There are also some excellent case studies on individuals with brain damage which add to our knowledge of functional dissociation (see Patel and Peretz 1997).

The scientific milieu

It is not possible to conclude this brief update without reference to the very changed intellectual climate for the study of music psychology. In 1983, researchers in this topic had only just begun to co-ordinate their activities intentionally. Fifteen years later the activities of the field are co-ordinated by major national and international scholarly bodies, including the Society for Music Perception and Cognition (SMPC), the European Society for the Cognitive Sciences of Music (ESCOM), as well as the Deutsche Gesellscahft fur Musikpsychologie (DGM), Japanese Society for Music Perception and Cognition (JSMPC), and the Society for Research in Psychology of Music and Music Education (SRPMME). A major international conference, the International Conference on Music Perception and Cognition (ICMPC) is held every two years in a different part of the world. When the conference was last held in Europe, in 1994, there were over 200 papers presented. The major journals in the field, *Music perception* and *Psychology of music* go from strength to strength.

Despite the great advances made, challenges remain. The relationship between music cognition and more traditional academic disciplines remains problematical. I see music cognition as primarily a science, with most of its roots in psychology, but with important inputs from linguistics, computer science, and philosophy. However, the subject matter, music, is traditionally studied from within faculties of fine arts. Attempts to locate music cognition teachers and researchers within arts contexts has never proved easy. The assumptions of scientists and artists about how to approach the subject matter are usually too different. This means that the dialogue between scientists and musicians has been and remains problematical.

Another challenge relates to the lack of cohesion within the discipline of music cognition itself. Understanding the phenomenon of music requires inputs from many disciplines, and even from many parts of the discipline of psychology. For instance, the areas covered in this book touch social psychology, developmental psychology, educational psychology, neuro-

psychology, as well as cognitive psychology. Each of these has its own theories, nethdologies, and preoccupations. To become truly expert in any one of them could take a lifetime. Music psychology is, thus, not a coherent discipline, but a loose confederation of disciplines converging around the same object of study. It is hard, therefore, to agree on what the important problems are, or how they should be addressed. International funded research collaborations, such as those found in medicine or physics, are absent from music psychology, with the result that the discipline grows by accretion, each researcher or group making their own idiosyncratic contribution. Governments and other funding agencies are, in general, not interested enough to impose discipline through national or international research policies.

Finally, both psychology and music are undergoing rapid changes as disciplines. Both are entering 'post-modern' phases where some of the earlier certainties are evaporating. In psychology, the hope for a unified theory of mind, possibly in the form of some computational model has faded. In music, activities such as historical musicology, which were once considered the unshakable foundations of the discipline, are being supplanted by a range of interdisciplinary approaches within what is sometimes characterized as 'the new musicology' that relativize, and to a certain extend, undermine the central focus of tranditional musicology, on the historical canon of 'masterworks' which universities study, and music academies prepare young musicians to perform.

These interesting problems form, in themselves, part of my justification for not attempting a thoroughgoing revision of this book. The *Musical mind* was written from within a point of some stability and self confidence in the historical development of cognitive psychology. To reflect the feel of today's intellectual climate, and to foresee some important questions for the next millenium, would require an altogether different approach from a refocused perspective. And two things are very clear to me about that approach: (1) it would need to take much more account of the messy world of emotion and motivation, to balance the precisions and tidinesses of cognition; (2) it would need to encompass a far greater range of the world's musics, cultures, and sub-cultures than the classical art tradition that has moulded the discipline up to this point.

1. Music as a cognitive skill

The reason that most of us take part in musical activity, be it composing, performing, or listening, is that music is capable of arousing in us deep and significant emotions. These emotions can range from the 'pure' aesthetic delight in a sound construction, through emotions like joy or sorrow which music sometimes evokes or enhances, to the simple relief from monotony, boredom or depression which everyday musical experiences can provide.

If someone from a civilization without music were to ask us why our civilisation supported so much musical activity, our answer would surely point to this capacity of music to heighten emotional life. Of course there are other reasons for individuals or societies to make use of music. Because much musical activity is also social activity it can come to have many social meanings, offering a variety of social rewards to those who participate in it. For instance, knowledge about certain types of music is a prerequisite for full membership of particular subcultures. The adoption of music for use in formally defined social situations allows people to earn a living through music. Aspects of musical training, such as the need for discipline and co-operation, may be held to be generally worth while. And so on. However, we may label these social motivations as secondary, if only because they are so closely tied to particular cultures. The emotional factor is, however, transcultural. It seems unlikely that music could have penetrated to the core of so many different cultures unless there were some fundamental human attraction to organized sound which transcended cultural boundaries.

If emotional factors are fundamental to the existence of music, then the fundamental question for a psychological investigation into music is *how* music is able to affect people. Seen with the cold eye of physics a musical event is just a collection of sounds with various pitches, durations, and other measurable qualities. Somehow the human mind endows these sounds with significance. They become symbols for something other than pure sound, something which enables us to laugh or cry, like or dislike, be moved or be indifferent.

There are two reasons why this issue leads us straight into the realms of cognitive psychology. The first is that most of our responses to music are learned. This is not to deny the possibility of some primitive responses to music shared by the whole species. For instance, loud fast music is arousing, whilst soft, slow music is soothing. Certain pitch ranges and timbres seem particularly attractive to infants, as do simple repetitive rhythms. But these primitive tendencies cannot account for the subtle and multidimensional

nature of the adult response to music, nor can they account for the many significant cultural differences in response. I can still recall the surprise I felt when, after hearing a rather jolly sounding Greek folk song, my Greek companion indicated that this was a desperately sad piece of music. No doubt, an understanding of the words was partly responsible for her different view of the music; but I realized that my own response was determined by the major key, the simple and open harmonies, and the general rhythmic impetus. These qualities are, in fact, common to most Greek folk music. More subtle differences, undetected by me, are responsible for the communication of affect.

A second pointer to the cognitive component of our emotional responses is the fact that they are not to be explained simply in terms of 'conditioning'. Conditioning theory (amusingly called the 'Darling, They're Playing Our Tune' theory by Davies 1978) supposes that a piece of music acquires the emotional significance of the circumstances in which it happened to be heard. On this theory, the form and content of the music is irrelevant to its acquired emotional character. Only its context is important. Although this type of conditioning may occur in certain circumstances, and may help explain particular idiosyncrasies of musical taste, there are several observations which show that it is inadequate as a complete explanation for emotional responses:

1. Listeners within a musical culture generally agree on the emotional character of a given piece of music, even though they may have never heard it before (Hevner, 1936). Conditioning theory, in contrast, would predict wide individual differences according to circumstances of hearing.

2. The emotional character of a piece of music is not unitary and unchanging. On the contrary, experienced listeners to some types of music are able to identify a web of differing emotions which are evoked by the detailed sequence of events, and which become more finely differentiatied the better the music is known. Conditioning theory, in contrast, would lead one to expect that a piece of music would always be dominated by a single generalized emotional tone acquired from the conditioning context.

3. Our emotional response to the very same music can vary considerably from hearing to hearing. For instance, there have been occasions when the last movement of Tchaikovsky's Sixth Symphony has moved me to tears of grief, and others on which it has left me completely unmoved. What remained the same about my mental state on the different occasions was my *knowledge* that this was music *expressing* extreme grief, regardless of my emotional response to it.

An analogy which I find helpful is that between music and humour. When hearing a joke the listener must first understand it; he must perceive and identify the constituent words, recognise them as sentences, form a mental representation of the propositions that the sentences assert, and then determine the nature of the incongruity, double meaning, or whatever that makes the joke. Thus, to 'get the joke' involves a large set of cognitive

processes, drawing upon knowledge of language and the world. After this the listener may, depending on his mood and taste, experience an emotional reaction involving laughter. So there is both a cognitive and an affective stage to his response. The cognitive stage is a necessary precursor of the affective stage; a listener cannot find a joke funny unless he understands it. However, the affective stage does not *necessarily* follow the cognitive stage. A person may understand a joke perfectly well without being moved to laughter by it. So it is with music. A person may understand the music he hears without being moved by it. If he *is* moved by it then he must have passed through the cognitive stage, which involves forming an abstract or symbolic *internal representation* of the music. The nature of this internal representation, and the things it allows a person to do with music, is the central subject matter of the cognitive psychology of music.

The way in which people represent music to themselves determines how well they can remember and perform it. Composition and improvisation require the generation of such representations, and perception involves the listener constructing them. These representations, and the processes which create them, are not directly observable. We have to infer their existence and nature from observations of the way in which people listen to, memorize, perform, create, and react to music.

Because such activities are learned, they may be viewed as skilled behaviours. Although composing and performing are universally acknowledged to be skills of some complexity, one must also remember that more commonplace activities, such as the ability to whistle a familiar melody, or to detect a 'wrong sounding' note in an unfamiliar melody, are also complex skills which are capable of shedding light on the nature of internal representations in music. What makes the composer or performer special is his rarity rather than anything *fundamentally* different about his mental equipment.

To illustrate this point, let us take two contrasting examples of musical skill and see what a cognitive psychologist might make of them. The first is the much quoted incident in the life of the young Mozart who, denied access to the score of Allegri's *Miserere*, listened to two church performances and then wrote it out from memory. The primary source for the authenticity of this incident is a letter from Mozart's father dated 14 April 1770 (Anderson, 1966). Such an accomplishment, although by no means unique, is well beyond the capacity of most people, and has become one of a handful of legends about the apparently superhuman powers of great musicians. In discussing this example the psychologist Farnsworth (1969) claims that Mozart's 'eidetic' memory was responsible for his ability. Eidetic memory is a peculiarly vivid, almost hallucinatory, recall which is alleged to be present in some children. On this view, the unusual accomplishment is the result of possessing unusual mental powers, since most people do not possess eidetic memory.

An alternative explanation is that Mozart was more adept, through

experience, at doing something we all do when trying to memorize complex material; that is, to identify patterns in the material, thereby remembering groups as single units or 'chunks'. It is difficult to decide between these two alternatives with respect to Mozart's memory, since we cannot test him further. There is, however, contemporary evidence which tends to favour the latter explanation. For instance, there has been much recent interest in the abilities of game players with various levels of expertise to remember game positions. Chase and Simon (1973) asked chess players of varying standards to examine boards taken from actual games for five seconds and then attempt to reproduce the boards from memory. Players in the category of chess master were able to reproduce the boards almost perfectly, whereas novices did very poorly. This is, perhaps, unsurprising, and similar results have been obtained when musicians and non-musicians are asked to reproduce the positions of a few notes displayed briefly on a stave (Halpern and Bower 1982; Sloboda 1976a). The really important result is that when chess players were asked to reproduce random boards which could not have occured in any rational game, the masters and novices performed equally, and very poorly. This shows that masters do not have better visual (eidetic) memory than novices. They are superior *only* when the material to be remembered makes some sense, and can be grouped into strategic 'chunks' (e.g. a pawn chain, a fork, a concealed check). This is confirmed by detailed observation of the way masters carry out the reproduction task. They tend to recall all the members of a chunk together, with pauses between separate chunks.

For a chess master, the mental representation of a chess position is not a copy of the physical board. It is a more abstract *structural* description of the meaningful relationships between groups of pieces. Through many years of experience he has acquired automatic perceptual mechanisms which rapidly pick out frequently occuring strategic patterns from the input. It has been estimated that the master must be able to recognise several thousands of patterns in this way.

Most musical material has just as much patterning and structure as a chess position. Within particular idioms there are many regularly occuring patterns (e.g. chords, scales and arpeggios) and someone exposed to an idiom will rapidly become familiar with them. Patterning also occurs on a larger scale. Thematic repetition is a cornerstone of most music, certain harmonic progressions are ubiquitous, and so on. The master can make use of all this patterning when building up a representation of a piece of music.

My second example is commonplace. Nearly everybody is capable of identifying well known melodies, or of recalling them if given the title (e.g. 'Yankee Doodle', 'Frère Jacques', 'God Save the Queen'). What makes this observation particularly important in the current context is that a precise pitch, speed, or medium is not crucial for identification, nor will a person necessarily reproduce a melody at a pitch he has ever heard before. For instance, Attneave and Olson (1971) asked people to sing the NBC chimes

from various given starting notes. The chimes are broadcast several times each day as a station identifier for the American National Broadcasting Corporation, but they are always played at the same pitch. The experimental subjects were able to transpose the chimes to any starting note within their range instantly and effortlessly. This is one of several demonstrations that people do not remember simple melodies in terms of precise pitches and durations but in terms of patterns and relationships. The NBC chimes remain identifiably the same so long as the pitch and duration *ratios* between the notes remain constant. This simple demonstration of musical memory already demonstrates how it is a *abstraction* from the physical stimulus. Sequential structure also influences untrained musicians. For instance, music which conforms to the rules of diatonic tonal harmony is much easier for Western listeners to remember than is music which breaks these rules. Some of the most important demonstrations of this are reviewed in Chapter 5, which examines the processes involved in listening to music. Here I wish to stress the closeness of the analogy to the chess experiments. Music which does not contain familiar patterns and structures cannot easily be represented in a listener's memory.

If expert and commonplace musical achievements are to be explained in the same sort of way, how are we to account for the *differences* between experts and novices? The most important factor is probably the *number* and *complexity* of the structural features in terms of which the listener is capable of representing music. The 'ordinary' listener is probably aware only of the musical 'foreground', noticing small patterns which are made up from a few adjacent notes. The Mozarts of the world probably share this level of representation, but have overlaid it with higher-order grouping processes which form single 'background' units from groups of 'foreground' units. The same process could be repeated on the new units to form even larger units, building up a hierarchical schema which could span a piece of music lasting several minutes.

A second difference between trained and untrained musical memories may lie in the degree of awareness that the memorizer has of the structures he is using. Commonly, musical training involves acquiring the vocabulary in terms of which to describe the structure of music. Elements of this vocabulary (e.g. cadential sequence, tonic chord, passing note) often function as means for extending memory capacity. A musician can be consciously looking out for instances of such structures. This does not imply that such structures are not available to untrained people. The evidence suggests, rather, that untrained musicians have implicit knowledge of that which musicians can talk about explicitly. In this respect, music is similar to language. Ordinary people speak their natural language according to the same grammatical rules as professional linguists even though they may have very limited conscious knowledge of those rules.

The 'representation of musical structure' is a unifying concept for the

various topics treated in this book; and it may be helpful at this point to give a brief sketch of the topics to be covered, and the approach I shall be taking to them.

One of the key features of any cognitive skill is speed. A process such as reading or listening is useless if it cannot keep up with the inflow of new material. Mozart had not only to notice structural relationships in the piece he memorized, he also had to perform all the necessary mental operations quickly enough to keep abreast of the music. Skilled performance must also be rapid and fluent. This has led psychologists to think that performance is controlled by the same sort of hierarchical structures as seem to account for input skill. Here, highly automated procedures control detailed performance while the performer is free to attend to higher-order aspects. For instance, the experienced sight reader confronted with a familiar scale passage will not need to make conscious decisions about which fingers to use for which notes. His hand will automatically take up the right configuration, while his attention may be on expressive factors, or on mentally preparing the following phrase. When we hear the phenomenal speed of a virtuoso performance, we can render it explicable, although no less of an achievement, by recalling that what strikes the ear as 20 separate notes may well be, for the performer, a single integrated and automated unit. What makes the achievement impressive is the many hundreds of hours' practice which may be needed to develop the degree of automation required. In examining psychological investigations of music performance (Chapter 3) we shall find considerable evidence for abstract high-level structures governing all aspects of skilled performance.

When we turn to the creation of music through composition or improvisation (Chapter 4), we shall find that the same notions of structured representation and rapid deployment of structural units are helpful in understanding these skills. Succesful composition relies on the ability to be sensitive to very large-scale structures, so that detailed working out can be governed by a conception of the overall framework. This applies to any large creative endeavour, such as writing a book. Without some unifying conception the author will find it hard to co-ordinate and shape the many sub-sections. Success in improvisation relies on structural grasp too, but also on the ability to rapidly choose appropriate, yet novel, elements to fill the slots in a basic script. Improvisers achieve their best results when working within a highly constrained form (e.g. jazz blues, fugue), whereas composers are more likely to achieve successful innovation of forms.

Since a basic premise of this book is that we *learn* the structures that we use to represent music, an examination of the learning process itself is central to our concerns (Chapter 6). This process can be seen as having two phases. The first is developmental enculturation. This is the learning that takes place as a result of our exposure to the normal musical products of our culture in childhood, together with the acquisition of simple skills like the ability to

reproduce short songs. The knowledge acquired at this stage is not, on the whole, the result of self-conscious learning or teaching effort. Rather, children simply acquire the knowledge through their everyday social experiences. In consequence such knowledge tends to be universal in a culture, and is the ground on which more specialized skills may be built. The second phase is, then, the acquisition of specialized skills through training. These skills are not universal within a culture, and are what turn ordinary citizens into 'musicians'. Our treatment of enculturation can be only descriptive. The treatment of specialized skills should arguably be prescriptive as well. Musicians have some right to expect that cognitive psychologists should be particularly well qualified to advise teachers and students on the self-conscious acquisition of skill.

Because musical skills are culturally transmitted, it follows that they may vary significantly between cultures. Many writers on the psychology of music talk about Western tonal music as if it were the only type of music. Whilst ignorance prevents me from dwelling on music from other cultures at any length, Chapter 7 contains an attempt to evaluate just how far some of the cognitive principles which underlie Western musical skill are relevant to other forms of music.

Most contemporary thought in cognitive psychology is functional, in that it attempts to discover the *principles* of structure and operation which would allow an information handling system to behave in the way we observe humans to behave. We have to keep in mind, however, that these principles are *in fact*, in our case, realized in the structures and functions of the *brain*, and that it is worthwhile finding out what we can about the brain in relation to the skills we examine. Studies reviewed in Chapter 7 reveal that, as with other cognitive skills, components of musical skill appear to have specific brain localization. The functional organization of the brain is modular, with specific portions doing specific jobs.

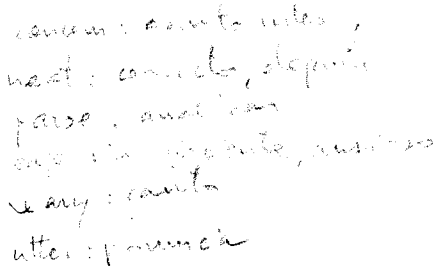
I began this chapter with reference to what is, humanly, the most important psychological fact about music; that it carries emotional significance or meaning for us. To say this prompts the thought that music is, in some respects, like a language. Although many writers on music have used this analogy in a loosely metaphorical way, there is now a growing body of theory and data which make a more rigorous assessment possible. Chapter 2 attempts such an assessment. It is possibly the most technical of the chapters, but is central to the book in that it provides a source of ideas about the nature of cognitive representations in music. These ideas are put to work elsewhere in attempting to understand specific musical skills. I hope, though, that the selective reader will be able to read the other chapters in isolation, and still obtain a broad idea of how music is represented in the mind, and why an understanding of these representations is so central to an understanding of all the skills discussed.

Before going further, I must say something about the term 'cognitive

psychology' itself and its role in this book. Cognitive psychology is a fairly new branch of psychology. It is also a rapidly changing discipline, and a generally acceptable definition of its aims and boundaries would be hard to produce. The emergence of an identifiable discipline coincided approximately with the publication of Broadbent's seminal *Perception and Communication* (1958). It marked the advent of a cautious experimental mentalism, which showed that it was possible to subject processes such as attention and recognition to rigorous laboratory investigation. Subjects were not required to introspect on these processes but to perform tasks from whose accuracy or speed of execution could be inferred something about the internal structure of the system controlling these tasks. It was another nine years before Neisser's influential *Cognitive Psychology* (1967) gave the discipline its name, but during the years spanned by these two books the preoccupations of researchers in this field remained quite narrowly defined. The research concentrated on 'input' skills, including the recognition of letters, words, and other simple stimuli, in artificially simplified laboratory surroundings. Major theoretical disputes centred on questions of capacity: how many items could be held in memory at once? were cognitive operations on incoming stimuli performed in series or in parallel? The 1970s saw a broadening of the field in several directions. One development was a greater interest in higher cognitive processes and the control of complex behaviour, and an allied interest in the organization of knowledge and its deployment in cognitive skills. Several influences were important here. One was a renewal of interest in problem-solving behaviour, much neglected since the 1930s. Newell and Simon's *Human Problem Solving* (1972) is arguably the most important contribution to this branch of the subject, and is also a prime example of another very important influence on cognitive psychology—the growth of the science of artificial intelligence. The opportunity to embody theories in working computer programs has stimulated concern with theories of cognitive functioning which are specific enough to predict actual instances of behaviour, but which are broad enough to account for a wide range of cognitive achievements.

The second major development of recent years has been the attempt to study cognitive skills in situations more closely resembling those in which people would normally employ them outside the laboratory. Thus, concern has focused on how people deal with extended and meaningful material rather than on fragmented, meaningless stimuli. This movement has brought in its train an increased interest in developmental aspects of cognition, and cultural variance; and a greater commitment to finding practical applications for cognitive research. Neisser's second book, *Cognition and Reality* (1976) has been a rallying point for this approach, and some of the first fruits of research in this vein are exemplified by collections such as Gruneberg, Morris, and Sykes' *Practical Aspects of Memory* (1978).

Luckily for the beginning student there are now many excellent introductions to the subject available (e.g. Anderson 1980; Solso 1980), although



they sometimes tend to exaggerate the stability and unity of the subject. Claxton (1980) provides some more candid and critical assessments, although some of the arguments will be difficult for beginners to follow. In this book I identify, although fairly loosely, with what I perceive as the mainstream of current cognitive research outlined above. The focus is on empirical study of what people *do* with music, rather than what they *say* they do, and, where possible, I address myself to the real-life behaviour of musicians, rather than to their behaviour in artificially constricted laboratory situations. I try to give as much prominence to output skill (e.g. performing) and higher cognitive functioning (e.g. composition) as I do to input skill (e.g. listening). Finally, my criterion for selecting empirical studies to describe is that they should have a particular theoretical or practical importance. I make no claim to provide a complete survey of the literature.

The cognitive psychology of music is still a very young discipline and there are several areas of enquiry which have not yet received detailed empirical attention. I have felt it important to identify some of these areas, and say something about the kinds of questions which need to be asked. In this respect the book looks forward to the future, and is not simply a statement of the current position. I have freely used my experiences and intuitions as a practising musician to augment and complement experimental findings; indeed the section on composition would hardly have been possible without them. Here, as elsewhere, my aim has been to stimulate scientific thinking and experiment. If some of the ideas in this book are proved wrong through new research no-one will be more pleased than I.

The last purpose of this chapter is to place this book in the context of other writing on the psychology of music, and to suggest some further general reading in the area. Some aspects of the psychology of music fall outside the concerns of this book. I make little mention of musical taste or preference, and the reader is referred to Farnsworth (1969) for an introduction to this area. I do not deal with social applications of music (e.g. to industry or therapy). Farnsworth is quite useful here, and Priestley (1975) and Alvin (1975) are two of several introductions to music therapy. There is also a *Journal of Music Therapy*. Purely educational research falls outside the scope of this book. Two main journals in this area are the *Journal of Research into Music Education* and *Psychology of Music*. Sensory psychology and psychoacoustics are not covered in any detail. The *Journal of the Acoustical Society of America* is a prime source of research in this area. Plomp (1977) offers a recent synthesis, and Moore (1982) provides a sensible introduction to the area. Research on music reported in the main perceptual journals tends to be of this sort. My last area of exclusion concerns psychometric approaches to musical ability. Shuter-Dyson and Gabriel (1981) provide a useful summary of research in this tradition.

General collections of papers by Critchley and Henson (1977), Clynes (1982) and Deutsch (1982a) are useful source books for the whole subject. A

recent book by Davies (1978) approaches nearest to the orientation of this book, although his emphasis, and that of a new journal *Music Perception*, is on the processes involved in listening. Finally, the journal *Psychomusicology* has recently been founded with an editorial policy which closely fits the aims of this book. The name, although new and unwieldy, is perhaps the best single-word description for the subject which this book explores.

2. Music, language, and meaning

2.1. Introduction

This chapter begins by looking at two influential theorists, the linguist Chomsky and the musicologist Schenker. Their theories have some striking similarities. They both argue, for their own subject matter, that human behaviour *must* be supported by the ability to form abstract underlying representations. Two of man's highest and most complex products seem to display something central about his intellect.

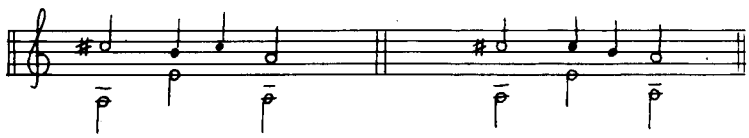
Chomsky and Schenker gained their principal insights from examining the *structure* of language and music rather than from examining linguistic and musical *behaviour*. Recent empirical work has shown that music and language share behavioural as well as formal features; and so the chapter moves on to review this work. The major portion of the chapter is organized around the subdivision of language and music into three components: phonology, syntax, and semantics. Phonology concerns the way in which a potentially infinite variety of sounds are 'parcelled up' into a finite number of discrete sound categories which constitute the basic communicative units. Syntax concerns the way in which these units are combined into sequences. A major concern of those studying syntax has been the discovery of rules which reliably produce legal sequences and eliminate illegal ones. Semantics concerns the way in which meaning is carried by the sequences so constructed. Particular fixed combinations of phonological units can have fixed meanings, but it is a characteristic of both language and music that meaning is also carried by the ordering and combination of elements in longer sequences.

The concern of this chapter is not only to describe linguistic and musical rules or categories, but also to examine the degree to which psychological evidence confirms their reality. A linguist searches for the neatest and most economical way of describing a language's structure. A *psycholinguist* seeks the description which most closely resembles the psychological processes by which language is produced and understood. And so it must be for the psychomusicologist.

2.2. Chomsky and Schenker

The cognitive psychology of language almost owes its very existence to the linguist Noam Chomsky. His radical approach to the problem of describing language structure (Chomsky 1957, 1965, 1968) was the main impetus to the formation of the discipline of psycholinguistics, and the impact of his work

still reverberates around the psychological laboratories of the world. As is the case with all seminal thinkers his work has attracted as much cogent opposition as it has support, but it is doubtful if any current approach to language owes nothing to him.



One of Chomsky's main claims has been that, at a deep level, all natural languages have the same structure, and that this structure tells us something universal about the human intellect. Many writers on music have been attracted to the idea that there are musical universals; maybe that there is something particularly natural about tonality. Could it be that Chomsky's theses receive independent support from music? A few writers seem to think so. For instance, Leonard Bernstein has recently celebrated his discovery of the 'Chomsky connection' with characteristic exuberance (Bernstein 1976). Sundberg and Lindblom (1976) have written a 'Chomskyan' grammar for a set of Swedish folk-songs; and researchers in artificial intelligence have written programs for parsing music which share formal properties with language programs. For the most part, however, psychologists investigating music have not been eager to pursue this path, preferring to treat music as a totally independent phenomenon.

There are, of course, good scientific reasons for approaching the study of music without too many presuppositions, but my own attitude to this issue has been profoundly affected by the writings of the German musicologist Heinrich Schenker (1868–1935) which have been gaining influence in contemporary analytic thought (e.g. Schenker, 1935). There are some striking parallels between Schenker's views on music and Chomsky's on language. For instance, Schenker would wish to claim that, at a deep level, all good musical compositions have the same type of structure, and that this structure reveals to us something about the nature of musical intuition. There is no evidence to suggest that Chomsky knew of Schenker's work at the time of formulating his theories of language. It appears, therefore, that similar ways of viewing language and music arose quite independently in two creative intellects steeped in their own subject matter.

My view is that the linguistic analogy in music deserves serious attention; although I would make three qualifying remarks. Firstly, it would be foolish to claim that music is simply another natural language. There are many fundamental differences which cannot be overlooked, the most obvious being that we use language to make assertions or ask questions about the real world and the objects and relationships in it. If music has any subject matter at all, then it is certainly not the same as that of normal language. Secondly, this analogy can clearly be exploited in metaphorical, poetic ways, of which scientists are right to be wary (e.g. 'music is the language of the emotions'). However, this does not exclude the possibility of a more rigorous use of the analogy. Indeed, it is arguable that the most productive scientific analogies are those which fire the imagination as much as they fuel empirical and theoretical endeavours. Thirdly, it is an open question just how far the

analogy can be pursued, and its application is subject to the weighing of empirical evidence and argument that characterizes any scientific endeavour. In other words, the analogy is something to be evaluated, not assumed.

What, then, are the main similarities between Chomsky and Schenker? Perhaps the most fundamental similarity concerns the differentiation between *surface* and *deep* structure. Surface structure is, roughly, the form taken by a linguistic (or musical) sequence as it is uttered (or written). The two sentences 'John phoned up Mary' and 'John phoned Mary up' have different surface structures; and so do the two musical sequences given in Example 2.1. Nevertheless, in both cases we would wish to say that there is a particular closeness between the two sequences, which is not simply a result of their containing the same elements in a different order (e.g. the closeness would not be shared by 'Phoned John up Mary'). In the language example we would wish to say, at the least, that the two sentences *mean* the same thing. Chomsky proposed that we could capture the closeness of such sentences within a grammar, if we assigned them to the same deep structure. This deep structure is an abstract entity, not itself a sentence, from which both surface structures can be derived by the application of *transformation* rules.

Example 2.1.

In order to represent the deep structure of a sentence it is useful to employ an 'immediate constituent tree' notation as shown in Figs. 2.1–2.3. Each tree has a single *node* at its head; S for sentence. This node can be decomposed into two or more nodes at the next lower level. The rules governing the decomposition of nodes are called the generative (or rewrite) rules of the grammar. One generative rule allows S to be rewritten as NP + VP (noun phrase + verb phrase). Other rules allow further rewriting (e.g. VP goes to V + NP). At the lowest level, individual words can be specified. For many simple sentences, immediate constituent analysis of this kind gives a satisfactory account of their structure because words connected to a single node are next to one another. Grammatical relation is signalled by sequential adjacency. In Fig. 2.1 'The' has a closer grammatical relation to 'girl' than any other word in the sentence. An informal way of testing the grammatical relation of two words is to see whether they could be replaced by a single word to form a new meaningful sentence. Thus, 'The girl' could be replaced by 'Mary', and 'hit the ball' by 'sang'; but 'girl hit the' cannot be so replaced.

There are, however, many sentences where an immediate constituent analysis does not capture our intuitions about the grammatical relation of words. In Fig. 2.2 we find that the constituent tree links 'up' to 'Mary', whereas one

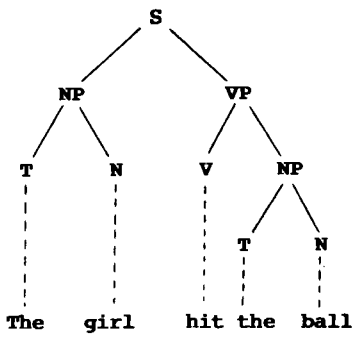


Fig. 2.1

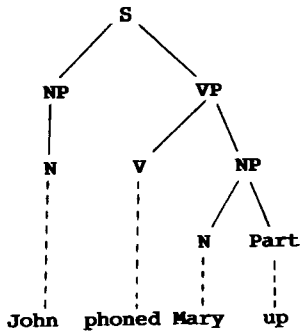

Fig. 2.2

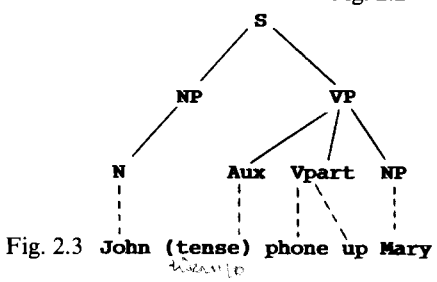

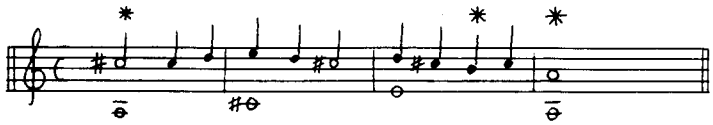

Fig. 2.3

Fig. 2.1–2.3. Examples of immediate constituent trees for English sentences. Key: S = sentence, NP = noun phrase, VP = verb phrase, T = article, N = noun, V = verb.

may feel that 'up' is, in fact, more related to 'phoned'. What is more, we can introduce longer sequences between 'phoned' and 'up' without destroying this relation. For instance, 'John phoned the brown eyed girl he met for the first time yesterday up' is an acceptable sentence. Chomsky's solution to this problem is to propose that the deep structure is a tree in which words having close grammatical relationship are governed by the same node. So 'John phoned up Mary' and 'John phoned Mary up' are given the *same* deep structure, shown in Fig. 2.3. Note that the symbols in the bottom row (the terminal string) do not constitute a sentence. There are some obligatory transformations that must be performed (in this case the inflection of the verb form to indicate tense). Other transformations are optional, such as the moving of 'up' to the end of the noun phrase governed by the verb phrase. These transformations generate the various different surface structures that a single deep structure may exhibit.

Turning now to the music sequences in Example 2.1, although Schenker analysis would rarely be applied to such trivial excerpts, we can note some interesting parallels to the language examples. Schenker would give both excerpts the same deep structure (*Ursatz*). This deep structure always has two components: a fundamental melodic line (*Urlinie*) which, in this case, is the progression 3–2–1 in the scale of A major, and a bass arpeggiation

(*Bassbrechung*) which, in this case, is the progression I–V–I in the same key. In each excerpt the melodic C receives no explicit representation in the deep structure. Rather, it is an interpolation between the notes of the *Urlinie*which results in expansion or *prolongation* of the material. However, no amount of appropriate prolongation destroys the integrity of the *Ursatz* or the fundamental interdependence of its elements. For instance, Example 2.2 possesses precisely the same deep structure as both sequences in Example 2.1. The asterisked notes show the *Ursatz*. The relation of the melodic B to the preceding C is not weakened by the intervening notes, just as the relationship of 'phoned' to 'up' is not weakened by intervening words.

Example 2.2.

The source of the *Ursatz* (the top node in a hypothetical constituent structure tree) is the chord of the tonic triad. It must, however, be admitted that neither Schenker nor any of his followers have produced anything approaching a formal generative grammar for deriving *Ursatze* from triads, or for transforming an *Ursatz* into an acceptable composition through prolongation. What they have shown is that *Ursatze* are discoverable in a very large body of tonal compositions. One aim of modern linguists is to produce a set of generative and transformational rules which generates all and *only* acceptable sentences of a language like English. While Schenkerians might claim that all good compositions are built upon *Ursatze*, they would not claim to be in possession of rules which would generate *only* good music. Schenker's method is, in essence, analytic, not generative.

There are three significant contrasts between Schenkerian and Chomskyan structures which we should note before proceeding. Firstly, the *Ursatz* is, in itself, a legal although trivial piece of music. It obeys rules of counterpoint and harmonic progression just as do the 'surface' elements. Schenker analysis proceeds by a recursive 'reduction' of a finished composition, eliminating subsidiary prolongations to reveal a harmonic and contrapuntal 'skeleton'. This skeleton is then further reduced by the very same methods over and again until the simplest and most fundamental structure is revealed. In contrast, as we have already noticed, Chomskyan deep structures are not, in themselves, acceptable sentences.

Secondly, the transformations applied to an *Ursatz* result in a lengthening and complexifying of the music. Very long movements containing hundreds of notes may be subsumed under a single *Ursatz*. To demonstrate this was one of Schenker's major achievments. In contrast, Chomskyan deep structures govern only single sentences, which are typically short, and a common effect

of applying transformations is condensation rather than expansion. For instance the sentence 'John likes Mary and John likes Jane' mirrors rather closely the deep structure which would normally be transformed and shortened to 'John likes Mary and Jane.'

Thirdly, differentiation between pieces of music is achieved at the surface level rather than at the level of deep structure. According to Schenker there are very few different types of *Ursatz*. If the *Ursatz* determined the significance of music, then there would be very little for composers to say. Much of the 'meaning' of any piece of music is given to it through the actual surface details. In language it is different. The significance of a sentence, in practical discourse, lies almost entirely in its deep structure. There are an indefinite number of deep structures, corresponding to all the different propositions thata language can express. Transformations of these deep structures often *reduce* differentiation because, for instance, different deep structures can be transformed into identical surface structures—as in 'Bill shot the man with a gun'. This is ambiguous: one possible deep structure would have Bill doing the shooting with a gun; the other would have the man possessing a gun.

The demonstration that events quite far apart in both linguistic and musical sequences can have a close structural relationship has two major consequences. The first is that whatever grammars are eventually shown to be fully adequate for language and music, they must be more powerful than 'finite state' grammars. Chomsky (1957) provided the classic proof that this type of grammar is inadequate for a natural langauge. In such a grammar, words are generated one at a time, each word determining the set from which the next word may be chosen. The rules are thus 'context independent'. It does not matter in which context a word is found; exactly the same set of consecutive words is permissible in each case. In a finite state grammar, for instance, the word 'washes' must allow both 'himself' and 'herself' to follow, since 'the boy washes himself' and 'the girl washes herself' are both correct English sentences. Yet such a grammar would allow 'the boy washes herself', which is unacceptable. To improve on a finite-state grammar we must introduce 'context sensitive' rules which take into account more than the immediately preceding word. The same arguments apply by analogy to music.

The second consequence is more directly psychological. If music and language have properties which demand grammars of a certain complexity, then humans must have the psychological resources to represent such grammars. This claim is hardly controversial nowadays, but it is incompatible with the radical behaviourism of Skinner (1957) and others which dominated many branches of psychology at the time of Chomsky's early work. Their basic claim was that behavioural sequences were brought about by simple causal chains in which a given response was triggered by an immediately preceding stimulus (which could, in verbal behaviour, be internal feedback from the preceding word uttered). Today, Lashley's (1951) classic argument for hierarchical models of sequential behaviour, in which the whole sequence is,

in crucial respects, mapped out in the mind before any behaviour is initiated, is the basis of standard theory (see, for instance, Martin 1972, and Shaffer 1976). A speaker is able to produce grammatical sentences precisely because he is able to represent each sentence as a unified structure in which the parts have the kinds of relationships between them which are exemplified in a deep-structure tree. Similarly, as Schenker would claim, a composer is able to produce a masterwork precisely because he has an intuition of the *Ursatz* underlying it, which guides and unifies the process of generating the individual notes.

As this chapter progresses I shall return to Chomsky and Schenker on several occasions. I will not, however, be able to provide a detailed analysis or critique of either transformational grammar or Schenker analysis. To do so would require lengthy excursions into linguistics and musicology. For a useful introduction to Chomsky's work the reader is referred to Lyons (1970). Greene (1972) and Fodor, Bever, and Garrett (1974) provide psychological assessments of transformational grammar. A criticism of Chomskyan linguistics may be found in Robinson (1975).

A difficulty with approaching the work of Schenker is that good English translations of all his major writings are not yet available. The major English-speaking musicologists to employ Schenkerian concepts are Salzer (1952) and Forte (1962). Yeston (1977) has made a collection of articles on Schenker, and a recent critical approach is provided by Narmour (1977). It is worth emphasizing that Schenker's work does not occupy the central position in musicological thought that Chomsky's work does in linguistics. Schenker did not present his ideas with the formal precision of Chomsky, and their application to anything other than mainstream classical compositions is problematical.

2.3. Other comparisons between language and music

Although the Chomsky–Schenker parallel seems one of the most striking links between language and music, it is not, of course, the only one. Before reviewing selected research in detail I would like to list, and comment upon, some of the other major similarities between language and music.

(*a*) Both language and music are characteristics of the human species that seem to be *universal* to all humans and *specific* to humans. To say that language and music are universal is to say that humans have a general capacity to acquire linguistic and musical competence. There may, of course, be special reasons why particular individuals do not acquire competence (e.g. brain damage, lack of appropriate experience). The claim that language is *specific* to humans has been the subject of psychological controversy. Clearly, there seems to be no other species whose natural communication shares all the features of human language, but attempts to teach chimpanzees a modified human language (Gardner and Gardner 1969) have met with enough

success to sustain lengthy argument in the psychological literature. On balance, most psychologists would conclude that such studies, whilst possibly forcing us to reassess our ideas about chimpanzees' mental capacities, do not seriously challenge the specificity hypothesis. Although chimpanzees have learned modest vocabularies of sign-language words, they use and combine them in ways which do not go significantly beyond the capacities of a normal two-year-old human child, and the human effort required to produce and sustain this behaviour is prodigious.

The specificity hypothesis for music has not been subject to the degree of psychological assessment that has been devoted to language. However, it is clear that the functions of music for man find no parallel in the animal world; many of the most highly patterned sound behaviours (e.g. bird song) are relatively rigid intra-specific signals of territory, aggression, warning, etc. I shall discuss more fully in Chapter 7 the question of whether non-human primates display capacities in virtue of which man's musical origins could be explained. Certainly, no serious scientific effort has been made to exploit such capacities. For now, a quote from Williams (1980) will suffice to typify the generally accepted conclusion about non-human music. 'In the vocalising of apes we do not find the elements, nor even the beginnings of the chant and dance ritual of primitive man.'

(*b*) Both language and music are capable of generating an unlimited number of novel sequences. People can produce sentences they have never heard before, and composers can write melodies which nobody has ever produced before. Animal 'languages' in contrast usually contain a finite (and small) set of utterances which exhaust the communicative repertoire.

(*c*) Children seem to have a natural ability to learn the rules of language and music through exposure to examples. Spontaneous speech and spontaneous singing are first exhibited at around the same age (between one and two years). Language development proceeds through intermediate forms to model adult grammar at about the age of five. The studies reviewed in Chapter 6 show an analogous progression for music.

(*d*) The natural medium for both language and music is auditory-vocal. That is, both language and music are primarily received as sequences of sounds and produced as sequences of vocal movements which create sounds. Thus, many of the neural mechanisms for analysing input and producing output must be shared. The most universal of all musical forms is the song, where words and music are intimately combined.

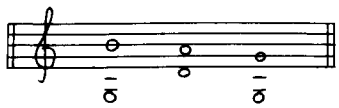
(*e*) Although the auditory-vocal mode is primary, many cultures have developed ways of writing down music. In such notational systems the writer expresses the sequence he wishes to communicate as a set of written symbols, and the receiver retrieves the message by decoding the visual symbols. Although most people acquire the ability to understand and use spoken language without specific tuition, reading and writing has usually to be taught *after* a person is a competent user of spoken language. Many cultures have

no notational systems for their language or music, and many individuals in literate cultures have difficulty in acquiring literacy. Adult illiteracy is acknowledged to be a major social problem in nearly all literate cultures, and inability to sight read bedevils a great number of music performers (see Chapter 3). The inability to deal with notation is all the more striking when, as is the case with standard Western notations, the grammatical structure is actually made more explicit in the notated form than in the spoken form. For instance, English orthography marks each word with a gap, and each major segment with a punctuation mark; whereas in speech words and clauses run together with no explicit marker. In standard musical notation key, metre, phrasing, and other structural information is explicitly signalled by notational elements; whereas in the auditory mode the listener must frequently work this out from the note sequence itself (see this chapter, section 5, and Chapter 5).

Although literacy is hard to acquire, its acquisition can profoundly alter cognitive functioning. Activities such as the accurate memorisation of long passages, or extended composition, would be impossible without it. In Chapter 7, I shall be exploring some of the ways in which literate and non-literate musical activity differ.

(*f*) Receptive skills precede productive skills in development. Children can understand sentences using certain constructions before they can invent sentences using those same constructions. In music, children are able to respond to musical devices before they can use these devices to make their own music. Generally, most adults retain a severe production deficiency in music. Although they may be able to learn to reproduce specific musical sequences, and although they may develop complex analytic listening abilities, they can be totally incapable of producing novel musical sequences of a style and complexity similar to those they are competent to deal with receptively. So, for instance, a listener may have a deep knowledge of Mozart's symphonies, as evidenced by his ability to recall, describe and classify them, or to analyse their structure, yet he may be totally unable to generate a theme, let alone a whole work, which is original yet 'Mozartian'.

(*g*) The forms taken by natural language and natural music differ across cultures, but some universal features constrain these forms. The fact that there are different forms has the consequence that people familiar with a particular form are often unable to deal appropriately with other forms. Thus, a native English speaker is unable to understand Chinese. Similarly, someone whose musical culture has consisted of English nursery rhymes is unlikely to be able to understand Tibetan chant. In both language and music, there are varying degrees of formal difference. For instance, spoken Slovakian is quite similar to spoken Polish, and so a native Pole will have partial success in understanding a Slovak speaker. Similarly, Mozart has more in common with nursery rhymes than Tibetan chant, so someone familiar with nursery rhymes will have partial success in understanding



Mozart. Formal differences arise because there is a certain degree of arbitrariness about the precise sounds used to realize linguistic and musical forms. In language, any pronounceable set of sounds will do as a word, provided that all users know its function. Similarly, there are many ways of signalling grammatical dependency, from word ordering to inflection.

Given the diversity in linguistic and musical forms, it seems initially puzzling that one should wish to claim that there are universal features nonetheless. One form of the argument for linguistic universals runs something as follows. The role of language is to express thought. The form of human thought is innate and common to all humans. The deep structure of an utterance is closely related to the thought it represents (whether or not is is identical *to* the thought need not concern us here). In order to represent a thought faithfully, the deep structure is constrained in certain ways. In other words, because all human prelinguistic thoughts have the same type of form, then all linguistic deep structures which represent them must have the same kind of form. In order to turn the deep structure into a sentence, the speaker must transform it into a linear sound sequence which supplies the necessary information to a listener. These transformations are thus doubly constrained; by the nature of the vocal apparatus shared by all humans (which determines the general surface appearance of an utterance); and by the deep structure which they must carry through to the surface. This argument draws in many complex issues in philosophy, linguistics, and cognitive psychology. For instance, if language expresses propositions, does this imply that human thought is propositional? If so, what role does imagery play in thought (Pylyshyn 1973, Kosslyn and Pomerantz 1977)? Rather than pursue these issues, our purpose here is to see what a similar argument might look like for music.

The first question we must ask is whether there is any entity which bears the same relationship to a musical sequence as a thought bears to a linguistic sequence. A thought is not, in itself, a linguistic sequence on the argument we have outlined. It exists independently of language and could be entertained by a non-linguistic or pre-linguistic human. Is there any form of mental activity which could take place in a mind without musical knowledge that could be somehow *expressed* by a musical sequence? Such activity would be, precisely, one which could find musical expression in such natural but diverse forms as a Tibetan chant or a nursery rhyme. One suggestion is that the mental substrate of music is something like that which underlies certain types of story. In these stories a starting position of equilibrium or rest is specified. Then some disturbance is introduced into the situation, producing various problems and tensions which must be resolved. The story ends with a return to equilibrium. The underlying representation for music could be seen as a highly abstracted blueprint for such stories, retaining only the features they all have in common. The learning of a musical language could then be seen as the acquisition of a way of representing these features in sound. Maybe,

therefore, we should look more closely at Schenker's *Ursatz* for insight into the possible nature of universals; for, as a deep structure, it is likely to have a close resemblance to the underlying thought representation of music.

The *Ursatz* is derived from a tonic triad. The tonic triad is a fundamental musical structure built on the natural harmonic series. Leaving aside octaves, which we may hold to be harmonically equivalent, the triad is the chord which results from combining the three lowest distinct harmonics of a note (the second, third, and fifth harmonics). If the fundamental note is C then these harmonics are C, G, and E, respectively (the fourth harmonic is a further C). For Schenker, this tonic triad represents the ultimate resting place in music, the place from which it starts and to which it returns. It has this function precisely because it is present in many natural periodic sounds (*Klang in die Natur*). When an elastic medium of any sort is set in periodic motion, it will produce sound waves corresponding to twice, three times, four times, the lowest (fundamental) frequency of vibration, and so on (see Jeans 1937, for an introduction to the physics of sound in relation to music). These sounds constitute the harmonic series, although higher harmonics are usually very faint compared to the fundamental and lower harmonics. The tonic triad is 'natural' in a very real sense because it is audibly present in most natural sounds.

Example 2.3. An *Ursatz*, the fundamental Schenkerian structure.

If we examine an *Ursatz* such as that given in Example 2.3, we find that all its notes are contained in the tonic triad (of G major in this case) except the middle note of the upper line (the *Urlinie*). At the midpoint of the *Urlinie* we thus find a departure from the resting position which is established at either end of the *Ursatz*. Tension and discord have been introduced; but it is *motivated* tension. One may argue that in good stories neither the tensions nor their resolutions are arbitrary. We find it unsatisfactory when the author introduces some *deus ex machina* to extricate the hero from a seemingly impossible situation. We prefer it when the kernel of the solution is somehow implicit in what has gone before. For instance, the villain's evil designs have within them them the seeds of their own destruction; the internal dynamics of a relationship lead the partners to the brink of breakdown and also provide the final resources to save it; and so on. Similarly, the *Ursatz* satisfies because it is not just *any* note (say F) which introduces tension. It is, in this case, an A which has two highly important pivotal functions. Firstly, it creates a linear progression in the *Urlinie*, B–A–G. The line has its own logic or pattern (two consecutive linear descents of one scale step) so that, in one sense, the A becomes an inevitable consequence of travelling from the B to the G.

Secondly, it creates, together with its accompanying bass note, the elements of a new triad based on D (A is the third harmonic of D). The tension-inducing element thus operates by attempting to set up a 'rival' triad. In the final chord of the *Ursatz* we witness the 'defeat' of this rival system. Let us, then, hypothesize that one appropriate 'deep' universal for musical thought is to be summarized in the phrases 'creation and resolution of motivated tension'. This notion has a family resemblance to the 'implicative' theory of L. B. Meyer (see this chapter, section 2.5).

What, if anything, can we say about the universal features of music brought about by 'surface' constraints, i.e. the constraints dictated by the fact that music is primarily vocal, and thus melodic? Firstly, since the deep structure has discrete phases, then the surface constituents must display discreteness or discontinuity, whether at the level of 'episode' or 'note'. At the very least, music must contain two discrete aspects of a sound event which begin 'in unity' with one another, move to a state of 'disunity' and then return to unity.

Second, there must be sound dimensions along which distance can be measured. The tension-inducing elements must be more distant from the initial elements along one of these dimension than the final elements. So, clearly, linear time cannot be this dimension, because the middle tension-inducing elements will always be closer in time to the beginning of the music than will the resolving terminal elements.

Third, sounds must be capable of being classified along a *second* independent dimension of sound representing distance. This is so that *motivated* tension can be introduced. As we have seen, motivated tension is achieved when an element is discrepant on one dimension (e.g. harmony) but unified on another (e.g. scale), thus displaying ambiguity. The system of tonality may be seen as one particularly satisfactory solution to the problem of representation that is consistent with these constraints. Within the tonal system there are two ways of representing the closeness of two notes with definite pitch. One is scalar: notes are close if their pitches are as near to one another as the scale allows. The other is harmonic: notes are close when their pitch *ratios* are those between low harmonics in the harmonic series. Thus, a given note can be close to another on the scalar dimension whilst being distant on the harmonic dimension, and *vice versa*. It is possible that one reason for tonality's success is that its dimensions of closeness are ones which it is easy for people to work with. We return to this issue in greater detail in Chapter 7.

(*h*) It is common to consider a human language as comprising three components: phonology—a way of characterising the basic sound units of a language; syntax—the rules governing the way in which sound units are combined; and semantics—the way in which meaning is assigned to sound sequences. Music seems to break down quite naturally into the same three

components, and the following sections take a more detailed look at research on these three aspects of language and music.

2.4. Musical phonology

All utterances of a natural human language like English can be analysed into a small set of basic speech-sound classes called 'phonemes'. The characterization of a phoneme is somewhat technical, but many phonemes correspond directly to letters. Thus, the word 'cat' has three phonemes, one for each letter. Each phoneme can be thought of as a certain sound pattern, having certain frequency and duration parameters, typically produced by a characteristic combination of lip, tongue, and vocal chord motion. The continuing debate about the extent to which phoneme characteristics are invariant in different sound environments need not concern us here (Cole and Scott 1974; Liberman, Cooper, Shankweiler, and Studdert-Kennedy 1967). Two points about phonemes are of special significance. One is that most phonemes are characterized by a *range* of sounds along particular dimensions rather than totally specific values. The other is that different languages divide up the sound continuum in different ways. Thus, two sounds which are distinct phonemes in one language may be heard as the same phoneme in a different language. Hence the well documented difficulty encountered by people trying to learn a language having substantially different phonology to their own. They simply fail to hear important distinctions. The human tendency to perceive speech *categorically* provides much of the explanation for these phenomena.

Categorical perception is best described by means of a specific example. It appears that the principal determiner of whether one hears a consonant as voiced (e.g., /d/) or unvoiced (e.g., /t/) is the time relationship between the onset of two components of the sound known as the first and second formants (f_1 and f_2). Formants are bursts of sound occupying discrete frequency bands. A typical speech sound will have four such bands. The first formant is the name for the lowest frequency band present, the second for the next highest, and so on. Such sounds can be synthesized by machine, and it appears that the optimal /d/ is heard when the onsets of f_1 and f_2 are simultaneous. In contrast, the optimal /t/ is heard when f_1 commences about 60 ms after f_2. With a machine it is possible to synthesize sounds with onset delays intermediate between 0 and 60 ms, and then discover how listeners classify them. If we generalize from other perceptual studies where one dimension is varied between two extreme values, our expectation would be that as onset delay increased from 0 to 30 ms, listeners would hear a sound less and less like /d/. When the midpoint was reached we would expect to hear an ambiguous sound, and then, as the delay approached 60 ms, the sound would become more and more like /t/.

The actual result of such an experiment is very different (Liberman, Harris, Kinney, and Lane 1961). Up to about 20 ms delay there is almost no change in the perceived sound. Subjects identified nearly all the sounds as absolutely clear /d/s, indiscriminable from the case where the delay was zero. Then over a very small range of delay (about 10 ms) perception 'flipped over' to /t/. Further increases in delay produced no perceptible change, all sounds beyond this boundary being indiscriminable from the case where the delay was a full 60 ms.

It has been found that this type of effect is demonstrable for nearly all phonemic distinctions, and this shows that the level of analysis of which we are habitually aware has discarded much of the specific information present in the sound. From sounds which vary continuously on a number of dimensions we extract a few categories into which all normal speech sounds are assigned. These are the categories which feed onto higher level syntactic and semantic analyses.

It appears that we acquire the categories of our native language very early in life. A set of studies by Eimas and his colleagues (Eimas 1975; Eimas, Siqueland, Jusczyck, and Vigorito 1971) has demonstrated that three-day-old infants already categorize sounds in the same way as adults. This precocious ability strongly suggests the existence of special learning mechanisms for speech patterns, since—of course—infants categorize differently according to the language they are exposed to in the first few days of life.

These features of language seem to have some rather close musical parallels. The basic 'phoneme' of music is a 'note'. Like a phoneme a note is characterized by frequency and duration parameters. Within a particular musical culture, all music is composed from a small set of these notes, chosen from an indefinitely large set of possibilities. Different cultures, however, choose different subsets of possible notes for their music. The selection takes place along two dimensions of sound: frequency and duration; these merit separate discussion.

2.4.1. *Categorical perception of frequency*

The perceived pitch of a musical sound is, in most naturally occurring instances, determined by its fundamental frequency of vibration. The exceptions to this will not concern us here. Furthermore, we will assume that octaves are musically equivalent in the context of this discussion. The 'phonology' of pitch thus concerns the way in which the octave is subdivided. The subset(s) of pitches chosen by a musical culture constitutes the musical scale(s) of that culture.

There is some evidence that people brought up within one musical culture have difficulty in perceiving and reproducing scales of another culture. It is hard to find convincing contemporary evidence for this since the Western diatonic scale has infiltrated most cultures through the broadcasting media. There is, however, some ethnomusicological data which shows how tunes

which have migrated from one culture to another have been adapted to the new scale (Cohen and Cohen 1973). Hodeir (1956) has put forward the interesting hypothesis that the 'blue notes' in the jazz scale came about through the efforts of African musicians (from a culture using a pentatonic scale) to assimilate the diatonic scale of the North American culture. If we represent the diatonic scale as a sequence of note names (e.g. C, D, E, F, G, A, B) then the proposed pentatonic scale would use only C, D, F, G, and A. Users of the pentatonic scale would have no normal representation for the diatonic E and B of this example. When attempting to reproduce a Western melody using these notes, Africans would have heard them as 'mistuned' notes falling somewhere between D and F or A and C. Accordingly they would 'fish' for these notes when playing or singing, producing something which would sound unstable and mistuned to Western ears. Gradually this accidental feature would become formalized as part of the jazz style—the flattened third and seventh. One must emphasize that this is an unproven hypothesis and does not receive universal acceptance (Virden and Wishart 1977).

The psychological principle underlying such examples appears to be the categorical nature of pitch perception. It has been demonstrated in laboratory conditions by Locke and Kellar (1973). They presented listeners with triads in which the tuning of the middle note (the third of the chord) was systematically varied from major to minor, passing through several intermediate pitches. The outside pitches were always 440 Hz (A) and 659 Hz (E). The middle note varied between 554 Hz (C sharp) and 523 Hz (C natural). There were two experimental tests. In one, subjects heard a single chord (the standard) and then, after a short delay, were required to say whether each of a sequence of chords was the same as, or different from, the standard. In the other test, subjects heard pairs of chords in which the middle notes differed by a few Hz at most. They were required to say whether the chords were the same or different. In both tests, musician subjects showed clear evidence of categorical perception. Fig. 2.4 shows the mean responses for 15 musicians. The hatched line shows the result of the first test when the standard was 554 Hz (A major chord). Almost all chords with middle notes above 546 Hz were heard as A major. Almost all chords with middle notes belowo 540 Hz were heard as A minor. The evidence suggests a category boundary at about 542 Hz.

The data from the second test (full lines) corroborates this picture. The four lines are for different degrees of separation of the test pitches. In each case there is a clear peak in discrimination at the category boundary. That is, when members of the pair of chords straddle the boundary, discrimination is good. When they are both on the same side of the boundary, discrimination is poor.

Interestingly, non-musicians did not show such clear evidence of categorical perception. The discrimination functions have peaks at around

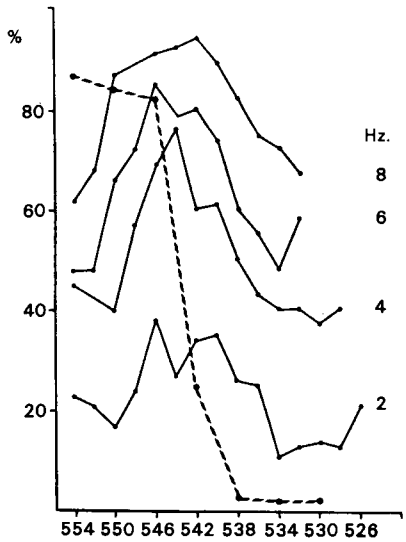


Fig. 2.4. Categorical perception in musicians (from Locke and Kellar, 1973).

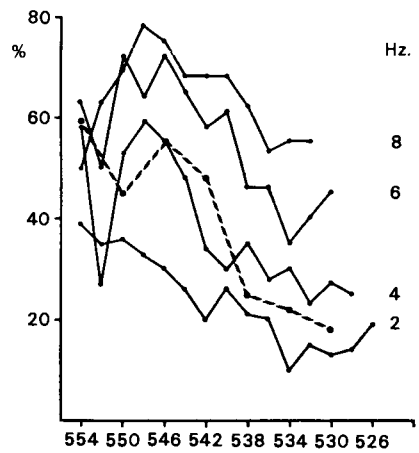

Fig. 2.5. Categorical perception in non-musicians (from Locke and Kellar, 1973).

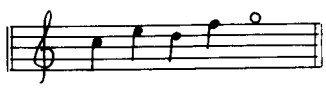
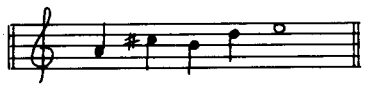
Figs. 2.4. and 2.5. Key: the dashed line gives the data from the categorization test; the full lines give the data from the discrimination test at various pitch separations; the abscissa represents the frequency of the middle note of the chord; the ordinate represents percent correct judgement.

546 Hz, but the comparisons to a standard show a more smoothly declining function: the greater the pitch difference, the less likely a 'same' judgement (see Fig. 2.5).



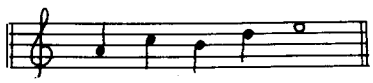
This study raises several issues. Firstly, there is the question of the accessibility to listeners of the *uncategorized* frequency information. In the speech studies it would appear that this information is not normally available to conscious perception. In music, however, this information certainly *can* be made available to consciousness. If it were not so, then no chord could ever sound badly tuned—the assimilation to categories would 'complete' the perceptual experience. The music listener, we must conclude, has some ability to operate both within and outside the categorical mode.

A second question is, therefore, what perceptual contexts encourage categorical perception? For most listeners the likely answer is that the context must be one which provides a framework for the construction of a musical scale. This framework will supply, at the very least, two simultaneous (or closely consequent) notes, such that one can act as a 'tonic' for the other. The notes of a musical scale are defined not absolutely but relatively, so that a scale can be constructed on any pitch using a characteristic set of frequency ratios to generate the notes. Thus, what music listeners carry in their memories are not the absolute pitches of any particular scale, but procedures for generating a scale from any given tonic. In Locke and Kellar's study this framework was supplied by the invariant outer notes of the chord which maintained a 3:2 frequency ratio throughout. This identified them, within diatonic tonality, as the tonic (first step) and dominant (fifth step) of a diatonic scale. This framework imposed a categorization on the middle note as the submediant (third step) of either a major or a minor diatonic scale. Had the experiment been carried out using only a single variable note without chordal context, then it is unlikely that any categorization would have taken place. Data from normal psychophysical studies support this assertion. There is no evidence of discontinuity in the discrimination functions for single frequencies.



A third question concerns the genesis of categorization within the individual. The music data suggest that, unlike language, mere exposure to tonal music is insufficient to bring about categorical perception. Some aspect of musical training heightens the tendency to categorize. For instance, most musical training involves learning note names and scale terminology. It is possible that possessing verbal labels increases the likelihood of categorical information being extracted and stored. Another possibility is that, for some musicians, each category becomes associated with a prototypical 'absolute' frequency band. This is possible, at least in Western cultures, because there are generally agreed conventions about the precise frequencies to which instruments should be tuned. Concert A is defined as 440 Hz. Such frequencies could come to represent the 'central' positions of scale categories for listeners, with deviant pitches being assigned to the nearest prototype.

There is considerable evidence for an ability that could support such behaviour. It is called 'absolute pitch' or 'perfect pitch' and is possessed by a significant minority of trained musicians. This is an accurate long-term memory for prototypical pitches and their associated scale names; and I shall discuss it more fully in Chapter 5. We do not know, unfortunately, how many of Locke and Kellar's 'musician' subjects possessed absolute pitch.



A different type of evidence for assimilation of music to scale categories is provided by Dowling (1978). In this study subjects were required to judge pairs of brief melodies as the same or different. In some cases the second melody (which was always at a different pitch from the first) was an exact transposition of the first melody. In other cases, the second melody was a 'tonal answer' to the first; that is, the melodic contour was transposed up or down *within the same key*. This has the consequence that the exact intervals of the original melody are not preserved. Example 2.4 is an illustration of the type of melodic stimulus used by Dowling. Example 2.5 is an exact transposition of it. Example 2.6 is a tonal answer starting on the same note as 2.5. Dowling found that his subjects could not consistently discriminate exact transpositions from tonal answers. One plausible explanation for this finding is that, at least for unfamiliar melodies, subjects code melodies as contours in which the *number* of scale steps between adjacent notes is represented, but not the precise pitch distance.

2.4.2. *Categorical perception of duration*

One of the most well researched areas in this field concerns the perception of plucked and bowed string notes (Blechner, Day, and Cutting 1976; Cutting and Rosner 1974; Cutting, Rosner, and Foard 1976). In a carefully designed series of experiments, Cutting and his colleagues have demonstrated that variations in rise time (the time from sound onset until the time when waveform amplitude reaches its peak) are responsible for the perception of this quality, rise times of 30 ms or less giving rise to 'plucked' sounds, and those of 60 ms or more producing 'bowed' sounds. The discrimination function shows a peak at the category boundary (around 40 ms) and troughs within each category. The interest of this phenomenon is threefold. First, it exactly matches the functions for the categorical perception of a phonetic distinction

in speech; the one displayed between the words 'chop' and 'shop'. This also depends on rise times and shows a category boundary at about 40 msec (Cutting and Rosner 1974). Secondly, adaptation to a sound well within one category shifts the category boundary towards the unadapted category. This exactly matches speech perception data (Eimas and Corbit 1973). Thirdly, infants as young as two months demonstrate categorical perception for these sounds (Jusczyck, Rosner, Cutting, Foard, and Smith 1977), just as they do for many speech sounds (Eimas 1974; Eimas *et al.* 1971).

These findings have been used to dispute the view that speech perception involves unique psychological processes and mechanisms. Cutting *et al.* (1976) state that 'it is evident that the arsenal of empirical findings which once distinguished speech perception as a unique type of auditory perception is being steadily depleted.' It seems, in fact, that we possess some perceptual mechanisms which are present from an early age and are deployed in both speech and music perception to produce categorical perception. The reason why the same physical attribute (rise time) gives rise to different perceptual experience in speech and music is probably that the acoustic contexts are different. There is evidence that the nature of the immediately following vowel/note affects the way in which the rise portion is heard. For instance, the sound patterns for stop consonants (like /t/ and /p/) are heard as chirps when presented in isolation (Mattingley, Liberman, Syrdal, and Halwes 1971). They require a subsequent vowel in order to be heard as speech sounds. Similarly, Cutting *et al.* (1976) show that synthetic musical sounds must persist for at least 250 ms after the initial rise in order to be heard as plucked or bowed.

The issue of context also assumes central importance in the second major aspect of musical duration that I wish to discuss. This is the perception of the duration of a note. The results of standard psychophysical tests tell us that when two successive isolated tones are presented for discrimination of duration (i.e. subjects must say which is longer), then the longer the sounds are, the greater must be the difference between them if it is to be reliably detected (Woodrow 1951). In music, however, absolute durations are less important than the rhythmic implications which notes acquire through their immediate context. Fundamental to most Western music is the concept of a *beat*, a musical pulse which underlies any melody. In general, notes will either begin on the beat or at some simple subdivision of the beat (half, third, and quarter being common). This fact is reflected in musical terminology and notation, where there exists a limited set of categories for describing durations of notes. These categories are, for the most part, divisions of a longer category into two equal halves. Thus, there are two crotchets (quarter notes) to every minim (half note); two quavers (eighth notes) to every crotchet, and so on. In a particular performing situation, one of these symbols may be defined as having a particular duration (for instance, 'crotchet = 120' is a standard way of indicating that there should be 120 crotchet beats per minute). Thus,

all the other symbols acquire a defined duration which is exactly double, or half that of the standard. None the less, in any human performance it is certain that there will be significant deviations from these defined durations.

In all empirical studies which have measured times between the beginnings of successive notes, such deviations have been found in abundance (Michon 1974; Seashore 1938; Shaffer 1981b; Sloboda 1983), even when the performer has been asked to produce absolutely strict rhythms (Gabrielsson 1974). None the less, identification of intended rhythm is a commonplace accomplishment for listeners, who are continually faced with the potentially confusing phenomena of *rubato* and gradual changes in speed. In contrast, accurate perception of deviations from metricality is difficult, and requires much specific training. It is almost impossible for one performer to imitate another *exactly*. All this strongly suggests that listeners achieve a categorization of the durations of the notes they hear into crotchets, quavers, etc.

In the light of these considerations it becomes a little easier to understand some puzzling data provided by Sternberg, Knoll, and Zukofsky (1982) who showed that three highly trained professional musicians, including Pierre Boulez, were unable to reproduce non-standard subdivisions of a beat accurately. In the experiments subjects heard a series of regular beats at one second intervals, one of which was followed by a click at a delay ranging from one eighth to seven eighths of a beat. They were then required to place an equivalent click after a subsequent beat. The reproduction of the shorter subdivisions (less than one third of a beat) were systematically in error, all being overestimates. In contrast, reproduction was very accurate when the subdivision was half, three quarters, five sixths, or seven eighths of a beat. A similar pattern of results was obtained when the subjects were asked to *estimate* the delay of a click by giving a verbal categorization (e.g. 'between one eighth and one seventh of a beat'), except that in this situation the errors were *under*estimates. Why were these subjects so poor? Maybe accurately reproduced and estimated delays correspond to frequently occuring rhythmic patterns in music, which are readily categorized. In Fig. 2.6 I have written out the experimental stimuli in musical notation. The first, second, and fourth notes in each example correspond to the regular beats, and the third note corresponds to the click. The lower half dozen notational forms will be familiar to most performing musicians. It is hard to think of well-known examples of the upper four. These are precisely the ones that caused difficulty for the subjects used by Sternberg *et al.* Perhaps they are particularly hard to perceive as examples of distinct rhythmic categories.

Just as in the discussion of categorical perception of pitch, one would not wish to claim that categorical perception of duration makes finer temporal discriminations impossible. We *can* hear rhythmic imprecision and *rubato* with appropriate training, but fine differences in timing are more often experienced not as such, but as differences in the quality (the 'life' or 'swing')

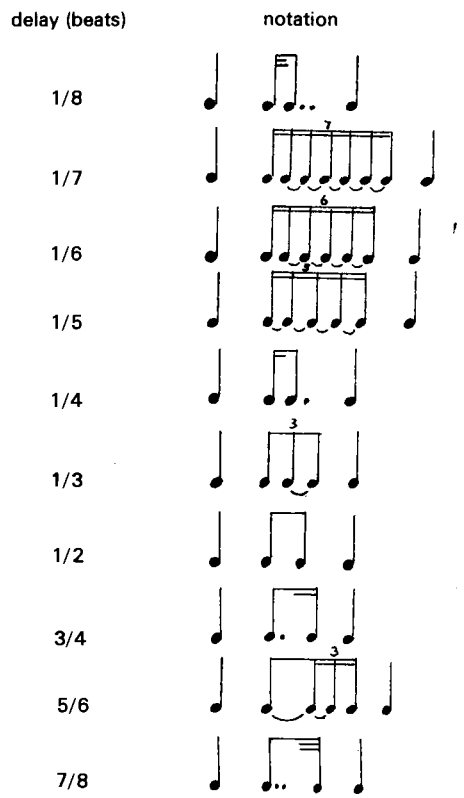

Fig. 2.6. Stimuli used by Sternberg, Knoll, and Zukofsky (1982), expressed in conventional rhythmic notation.

of a performance. This accounts in part for the intangibility of performance style (see Chapter 3). Differences in style are due to real differences in performance, but many of them cannot be consciously categorized by most listeners. Most of us have only global and imprecise means of capturing our experience of style difference.

My discussion of musical phonology has been designed to illustrate one fundamental feature of music behaviour. That is, we tend to categorize our musical experience along the available dimensions of sound, giving importance to differences between categories at the expense of differences within categories. The notions of scale and metre are the fundamental concepts underlying musical phonology (although timbre and intensity are arguably additional dimensions). The similarities between language and music in this respect are striking, although categorical perception in music is neither as complete nor as universal as it appears to be in language. To understand the musical significance of categorization we must now turn to the way notes are combined with one another. This is the subject matter of musical syntax.

2.5. Musical syntax

2.5.1. *The psychological reality of grammar*

The attempt to construct formal descriptions of musical structures is a central concern of musicology (see, for example, Bent 1980). Schenker is only one of many people who have attempted to characterize the sequential regularities of music in terms of rule systems. Since music, like language, is a human product, we can legitimately suppose that the observed structure of music tells us something about the nature of the human mind that produces it. But what? An extreme view would be that the rules of a musical (or linguistic) grammar are the very psychological procedures that someone uses to generate music (or language). This view has been strongly criticized on a number of grounds, both for music (Laske 1975) and for language (Olson and Clark 1976). One of the strongest arguments is that there is no such thing as a unique grammar for any body of data. Different rules, applied in different orders, can produce exactly the same set of sentences or musical sequences. The mere discovery of a single workable grammar is, therefore, no guarantee that *this* grammar is the one that best describes psychological processes of generation. Another argument derives from the observation that humans can (and deliberately do) violate the rules which seem to account for some of their behaviour. Thus, people *do* speak ungrammatically, and composers *do* violate the formal conventions within which they work. A formal syntax or grammar is a closed system whose sole purpose is to generate the set of sequences stipulated as 'grammatical'. The psychological generation of language is, in contrast, a process whose purposes are wider. The intention to communicate a particular meaningful proposition is the psychological motivation behind most utterances, and if a speaker has good reasons to suppose that he will be understood even without correct grammar, then he may disregard grammatical conventions. In music, the intention to violate a listener's expectancies may lead to a comparable freedom with the grammar.

The modest view supported by more psychologists is that some features of grammars have implications for the general way in which we think about psychological processes. One implication of the generative approach exemplified by Chomsky's work is that we decide what to say by the application of a finite set of rules (or procedures) to some unspoken proposition we wish to utter, rather than by having to recall, by association, the correct utterance for each separate proposition. On an associationist view, it is impossible to know how to express the proposition that, say, John loves Mary until one has learned the verbal formula 'John loves Mary' and is able to recall it when required. On the generative view, a speaker may never have heard or uttered the sentence 'John loves Mary' yet still be capable of producing it to express the appropriate proposition. This is done in the following way. A person's knowledge that John loves Mary is to be characterized, roughly, as know-

ledge that a certain person, John, is the agent of some activity, loving, this activity being directed towards a recipient, Mary. The person then *constructs* the appropriate sentence by reference to rules which stipulate how general relationships between agents and objects are expressed. One form of expression is given by the formula, agent + active verb + recipient. In simple three element propositions the conditions for this formula to be applied are satisfied, so, with appropriate knowledge of the vocabulary items 'loves', 'Mary', and 'John', the speaker can utter them in the correct order. Because the number of acceptable sentences in a language like English is indefinitely large, and because we are all capable of generating acceptable sentences that we may not have heard before, it seems inevitable to conclude that we store rules for constructing sentences rather than (or at least in addition to) storing sentences themselves.

A second, and related, implication is that listeners will be able to sort utterances they hear into acceptable and unacceptable categories. Thus, most people can tell that a novel utterance is ungrammatical, even though they judge another equally novel utterance to be acceptable. Since neither utterance has prior associative meaning, it seems incontrovertible that the utterances are being assessed in virtue of their conformation to a set of rules of construction. Hard questions arise, however, when we try to specify exactly what rules are invoked. Is a generative grammar, as such, the principal mental tool? If so, then a listener would have to judge a quasi-sentence like 'John the apple ate' ungrammatical by somehow running the grammar 'in reverse' and failing to condense the sentence to a single node. Alternatively, he might try generating sentences according to the grammar and fail to come up with a match. The trouble is that either of these processes may involve an indefinite number of steps. If one used the second process one could not, strictly speaking, be certain that a sentence was ungrammatical until one had generated all possible sentences, and noted the absence of the sentence in question. Since we may argue that the number of English sentences is indefinitely large, this is clearly a very implausible psychological mechanism. More plausibly, people have 'metaknowledge' about the grammatical systems they work with. For instance, someone may know that, in English, a sentence never starts with a verb in the indicative mood. This is not itself a rule of the generative grammar (although statements of this sort are sometimes confusingly referred to as grammatical rules). It is a generalization about the *products* of the grammar. Or again, it seems likely that people use non-syntactic considerations in judging sentences. Given 'John the apple ate', a listener might attempt to work out a plausible proposition including all the elements mentioned (which would presumably entail the apple being eaten by John) and then discovering how he or she would naturally express the proposition, rejecting the given utterance if it did not match his or her own.

A third implication, and one that I wish to examine in some detail, since it relates to comparable experimental data in language and music, is that,

regardless of our conclusions about the equivalence of generative grammars to psychological processes, the *structures* embodied in such grammars have psychological reality. Briefly, this claim is that elements of an utterance which are closely linked to one another in the grammar are closely linked psychologically, in whatever form of cognitive representation a speaker or listener may make of a sentence or melody. If the structure of a sequence is best represented in a grammar as a tree of the sort shown in Figs. 2.1–2.3, then the claim would be that adjacent items governed by the same node are closer in 'psychological space' than are adjacent items governed by different nodes. Figure 2.7 shows an idealized constituent tree which might equally well be a proposed structural tree for a linguistic or a musical sequence containing eight elements. The nodes are indicated by letters, the terminal elements that constitute the actual sequence are indicated with numbers. Taking, as an example, elements 3 and 4, we see that they are very closely linked in the structure. They are both subsumed under node E, and more remotely by node B. In constrast, elements 4 and 5, whilst also being adjacent members of the sequence, are not closely linked in the structure. Element 4 is 'governed' by node B, whilst element 5 is 'governed' by node C.

An experimental technique developed to investigate this claim involves subjects listening to short well-formed sequences of language or music over which an audible click has been superimposed, at a particular point. Subjects are asked to indicate exactly when they hear the click to occur by reporting the syllable or note which seemed to be simultaneous with it. The initial results of applying this technique have been reported for language by Fodor and Bever (1965) and Ladefoged and Broadbent (1960); and for music by Gregory (1978) and Sloboda and Gregory (1980). The basic findings in both domains are easily summarized. Firstly, click location is quite inaccurate. Secondly, clicks appear to migrate perceptually to boundaries between structural groupings. For instance, in the sentence 'That he was happy was evident from the way he smiled', a click occurring during the fourth word tended to

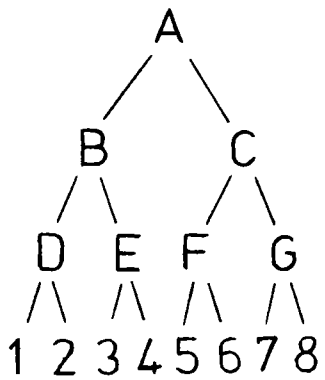

Fig. 2.7. An idealized constituent tree structure.

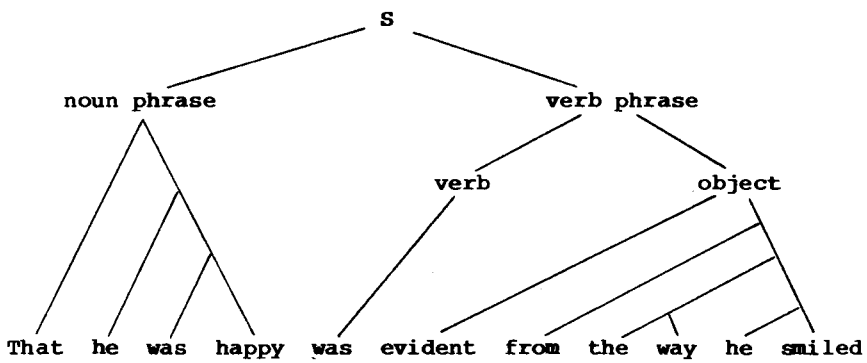

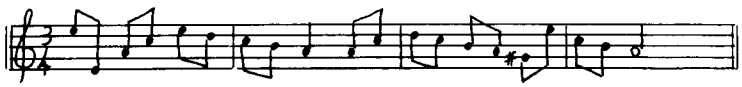

Fig. 2.8. Constituent tree analysis of a sentence used in Fodor and Bever's (1965) study.

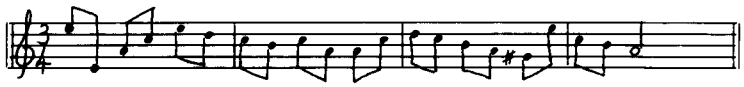
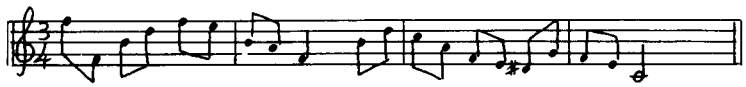
be heard as coming later than its actual time of occurrence. If the click occurred during the fifth word, it was heard early. A constituent analysis of the sentence (Fig. 2.8) assigns the first four words to the major node NP (noun phrase) while the rest of the sentence makes up VP (the verb phrase). In structural terms, therefore, words 3 and 4 are close, as are words 5 and 6. Words 4 and 5, though, are not structurally close. The experimental results show that these structural relations *are* represented psychologically. It seems that there is a tendency to represent closely related elements as 'uninterrupted', so that an extraneous event (the click) gets pushed towards a point where the structural links are weak.

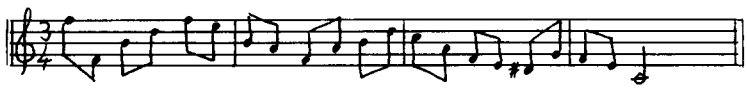


A pictorial analogy of the process may be obtained if one imagines the words (or notes) of a sequence to be laid out in a line on a surface. Each major structural grouping is covered by a smooth hemispheric dome. The click can then be envisaged as a small pellet dropped on to the surface from a position vertically above its real location in the sentence. When it hits the surface of the dome its final position will be determined by the slope of the dome at that point. Pellets falling near the apex of the dome are likely to be displaced rather little; pellets falling near the edge are likely to roll off into the space between.

The music results are to be explained in a similar way to the language results. Here, the main structural unit is the musical phrase. In Sloboda and Gregory's (1980) experiment, each melody contained two metrically equal phrases, and, in one condition, equal durations for all the notes. Example 2.8 shows one such melody. Musicians generally agree that the first phrase ends on the fourth note of the second bar. In this experiment the notes were computer-generated and exactly equal in all respects other than pitch. In physical terms, therefore, notes 4 and 5 of the second bar are as close to one another as notes 5 and 6 (arguably even closer since they are at the same pitch). Structurally, however, notes 4 and 5 are distant. A click placed on note 5 had a higher tendency to 'migrate' backwards than any other placement of



the click, confirming that listeners were representing the phrase boundary in a special way. The migration tendency was enhanced by melodies which marked the phrase boundary with a long note (see Example 2.7) but reduced by melodies which did not have a 'normal' harmonic structure (Examples 2.9 and 2.10).



Ex. 2.7.

Ex. 2.8.

Ex. 2.9.

Ex. 2.10.

Examples 2.7–2.10. Examples of stimuli used by Sloboda and Gregory (1980).

The precise interpretation of such 'click' experiments has been the subject of some controversy in the literature (Olson and Clark 1976). For instance, Reber and Anderson (1970) presented subjects with sentences over which *no* click had been superimposed, but told their subjects that very faint clicks were present. Subjects were asked to detect the location of the 'clicks'. They tended to locate clicks at phrase boundaries. Thus, argue Reber and Anderson, the earlier results are explicable by a bias subjects display to place their responses at phrase boundaries rather than by a perceptual migration. However, it may be argued that a tendency to organise *any* aspect of cognitive behaviour, be it perceptual or response-orientated, on the basis of phrase structure is good evidence for the psychological reality of grammatical structures. More worrying, perhaps, are studies like those of Bond (1971) and Lehiste (1972) who found that non-grammatical cues, like pauses and stresses, were more important than syntax in determining the nature of the migration. In Sloboda and Gregory's study pauses (long notes) were also found to elicit click migration. However, in both these cases, no harm is done to the general thrust of our argument if it is acknowledge that pausal and stress patterns in speech and music can be generated by a grammar along with the word ordering (see Chomsky and Halle 1968, for langauge; and Martin 1972, and Sundberg and Lindblom 1976, for music). In other words,

it may be *because* they occur in a systematic syntax-related fashion that stresses and pauses become psychological 'magnets' for clicks in individuals with long experience of a particular grammar.

'Clickology' is not the only way that the psychological reality of grammatical structures can be demonstrated. For instance, if phrases are psychological units, then one might expect processing within a single phrase to proceed more rapidly or effectively than processing which requires integration of information from two phrases. This prediction has been confirmed by Green and Mitchell (1978) who showed that language readers' pauses are longest after fixations which complete major grammatical units. Also, Levin and Kaplan (1970) have shown that the eye-voice span in language reading tends to extend to a phrase boundary, and Sloboda (1974, 1977a) has shown the same for music reading. Span, here, is defined as the number of words (or notes) that a reader can produce after the text has suddenly and unexpectedly been removed. It is a measure of how much has been taken in ahead of what is actually being said (or played). The findings suggest that readers take in material up to the boundary of the current phrase quite soon after starting to read it, but then 'mark time' until the execution of that phrase is almost complete before sweeping rapidly on to the next boundary.

In the discussion so far I have been deliberately vague about musical syntax and its nature. I wished, for purposes of exposition, to let it be assumed that grammars of roughly equivalent power and sophistication had been discovered for both language and music, so that some central psychological findings could be introduced. I have now to confess that, to my knowledge, there have been very few attempts to produce full-blown generative grammars for any significant corpus of music, even in outline. In what follows I shall discuss the most significant psychologically oriented work in this area in order to help us understand what kind of structures we use to mentally represent music. This will bring to light some similarities with language, but significant differences too.

2.5.2. *Syntactical structures in music*

In attempting to produce a musical syntax, an important question to be answered is '*what* body of music do we wish the syntax to account for'? The answer to this question is not as clear cut as the same questions asked of language. Most people have only one language at their disposal, whose grammar is fairly stable over long periods of time. The English language is delimited as containing all utterances which the majority of English inhabitants judge to be acceptable and meaningful. In contrast, the forms and styles of music with which a given person may be familiar can be very diverse. Musical forms change rapidly, and there is heated discussion within our culture about what does and does not count as acceptable music. It is interesting to speculate on the reasons for this difference. One possible reason

is that the communicative functions of language favour unity and stability. Syntax is a vehicle for communicating knowledge about the world, and given that the world remains the same sort of place and human concerns remain the same, there seems little to gain and much to lose by diversity and rapid evolution of syntax. Art music, in contrast, has no such clearly defined function. Syntax becomes, in itself, an object of aesthetic awareness, and the pressures for novelty invite diversity and change. It is arguable that music shows the greatest stability in cultural contexts where it is the vehicle for some non-musical activity (the recounting of verse, ritual, etc.).

The most cautious approach to musical syntax would be to start from a particular small sub-area in music, say the works of a single composer, and attempt to discover a grammar adequate for this corpus. The next step might be to extend the domain of the grammar by discovering if other compositions or other composers conformed to it. In this one might be guided by historical and social factors (looking at composers who lived at the same time and were subject to the same sort of influences) and also by the subjective judgements of experienced listeners (judgements of which types of music sound most similar). On the other hand, it is commonly claimed that very large bodies of music share certain aspects of syntax. If this is so, such aspects should be given the greatest prominence. A piecemeal approach to small areas of music can, arguably, obscure wider patterns (e.g. basic features of harmonic, melodic, and rhythmic construction which are common to the vast bulk of tonal music). I shall begin with some work which takes the former, cautious approach, and then move to wider consideration about tonal music as a whole.

Sundberg and Lindblom (1976) have written a complete generative grammar for eight-bar melodies which all bear a family resemblance to a set of Swedish nursery tunes written in the late nineteenth century by Alice Tegner. These tunes are familiar to, and sung by, most Swedish children today. The outline of this grammar is given in Fig. 2.9. It resembles the generative phonology of Chomsky and Halle (1968) in two respects. Firstly, the basic grammatical structure is an hierarchical tree. Secondly, integral to the tree is a 'prominence contour'. In speech, such a contour is used to assign stress, timing, and intonation to a sentence. In this music grammar, the contour is used to generate appropriate chords and durations.

The structure of the constituent tree is given in Fig. 2.10. It is completely symmetrical and composed by binary subdivisions of each node. So, each phrase divides into two equal sub-phrases; each sub-phrase divides into two equal bars; and so on. It is noteworthy that the structure is *metrically* based (in contrast to Schenker analysis where the fundamental structure is *harmonically* based).

The prominence contour is derived from the tree by assigning left elements priority within each foot, but right elements priority within larger sub-units. The contour derived by Sundberg and Lindblom is given at the bottom of

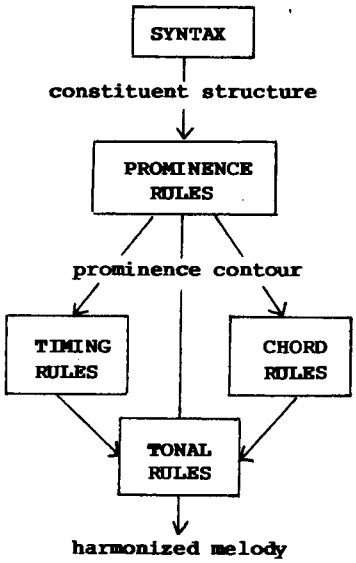


Fig. 2.9. Outline of Sundberg and Lindblom's (1976) grammar for nursery tunes.

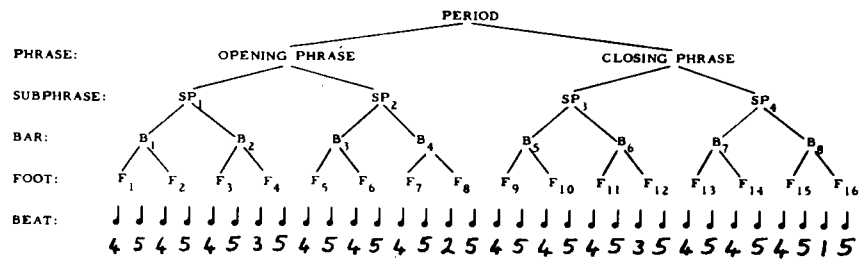
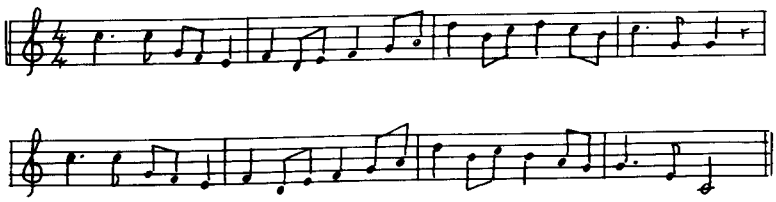
Fig. 2.10. The numeral 1 indicates an element with the highest prominence. Elements with equal numbers have equal prominence.

The next step is to generate separately a rhythmic pattern and a chordal progression from the prominence contour. Rhythm is generated by a set of obligatory and optional rules. The most important of the obligatory rules is that no note may begin on an element *following* an element of the highest prominence. In this example, the very last element cannot contain a new note; and the penultimate element will carry the last note of the melody. Then there are other optional deletion and addition rules, with certain repetition restrictions (e.g. the second four bars must repeat the rhythm of the first four bars).

The chordal derivation rests on two main principles. Only notes with prominence of 4 or greater (i.e. 4, 3, 2, or 1) may introduce new chords; and





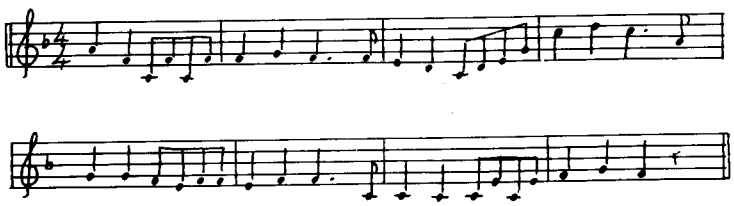


Fig 2.10. Constituent structure of tunes generated by Sundberg and Lindblom's (1976) grammar.

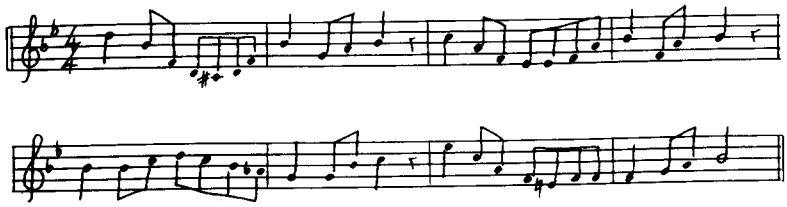
certain sequences of chords are obligatory at certain points (e.g. the final chord must be a tonic and must be preceded by a dominant).



The actual notes of the melody are then generated. Notes at points of high prominence must be chosen from the chord specified at that point. Elsewhere, passing notes and suspensions may be introduced. Examples 2.11–2.16 show six melodies. One was written by Tegner. The other five were produced by the grammar, the choice among the optional alternatives being made at random on each occassion. The reader is invited to try and spot the 'real' Tegner melody before reading on.

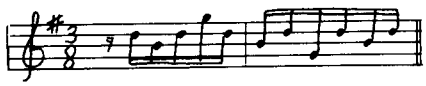
Ex. 2.14.

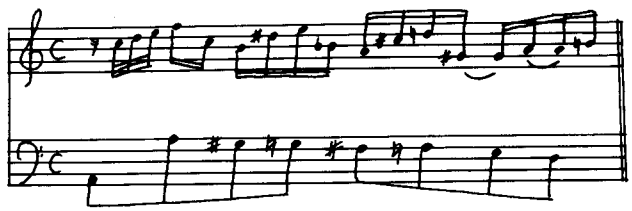
Examples 2.11–2.16.
Tunes produced by Alice Tegner or Sundberg and Lindblom's grammar (1976).

It is Sundberg and Lindblom's claim for the melodies generated by their grammar that 'the general reaction of Swedes listening to these melodies informally is that they are similar in style to those by Tegner.' Whilst this is hardly a rigorous proof of the adequacy of the grammar, the work demonstrates that music with a definite style can be generated from a small set of completely definite grammatical rules. The rules could, no doubt, be improved. For instance, I find it hard to believe that the repetitions of the same pitch in Example 2.12, or the intervallic leap between the second and third bars of Example 2.11, are characteristic of the idiom. However, there seems no principled reason why further restrictive rules could not eliminate such occurrences. The important feature of any such grammar is that major decisions are context-determined. They are governed by an overall structure represented in the constituent tree and the prominence contour derived from it. The psychological implication is *not* that Tegner composed her tunes by running through these precise steps in her mind. Rather we would wish to say that her compositional procedures incorporated the structures and restrictions inherent in this grammar *in some way*.



Of the examples given only 2.15 is, in fact, genuine Tegner. The structure of Sundberg and Lindblom's grammar affords no easy answer to the question of which rules characterize Tegner's music alone, and which are characteristic of wider bodies of music. Perhaps the best way to tackle this question is to consider each of the three traditional features of music—harmony, rhythm, and melody, in turn.

2.5.3. *Harmony and tonality*



If one consults any standard textbook on harmony, one finds that it contains a large set of prescriptions for the sequences of chords that are or are not

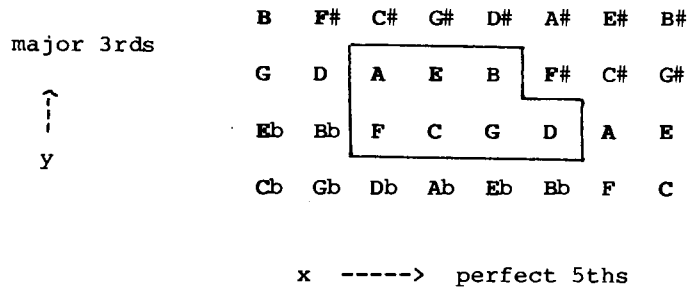
permissible in tonal music. These are not generative rules; rather they allow one to check whether a given sequence conforms to them. The rules specify, not actual notes, but chords within a key. Thus, for instance, it might be stated that a piece of music must terminate with a tonic chord. In order to check out whether this type of rule is being obeyed by a particular sequence it is, therefore, necessary to determine what key the music is in. A key is specified by a particular scale (e.g. G major; containing the notes G, A, B, C, D, E, and F sharp) and an assignation of functional names (tonic, dominant, etc.) to the members of that scale. The notion of a key also contains the idea that the *tonic* is the fundamental or central note in relation to which all other notes are characterized.

The concept of a key raises two psychological questions. First, in virtue of what is the note C in the set (C D E F G A B) heard or understood as central? Why is it not E or F that has this centrality? Although there exist simple rules for assigning a tonic to a scale (e.g. it is the note preceded by three whole tone and one half tone scale steps when the notes of the scale are arranged in asending order) such rules do not *explain* the psychological centrality of the tonic. Secondly, how does a listener determine which note is the tonic of a musical sequence on first hearing? One possible procedure would be to examine the opening measures to enumerate all the different notes contained there, putting these notes in scalar order to discover what scale was present, and so determining the tonic by the application of a rule like the one given above. Unfortunately there is much music where we can easily hear a tonic, but where there are too few different notes in the opening measures to specify a single scale uniquely, or where the measures contain a set of notes that does not come from any single scale. Two examples from Bach's *Well-Tempered Clavier* demonstrate this point well. Example 2.17 shows the opening two bars of Fugue 15 (Book 2). Only three notes are present (excluding octaves), but most listeners will easily identify the fourth note (G) as the tonic (and not the D or B). Example 2.18 shows the opening bar of Prelude 20 (Book 2). It contains all 12 notes of the chromatic scale yet listeners will identify the key as A minor without difficulty.

Example 2.17. From J. S. Bach, *Well-Tempered Clavier*, Fugue 15, book 2.

Example 2.18. From J. S. Bach, *Well-Tempered Clavier*, Prelude 20, Book 2.

A theoretical framework in the context of which such problems may be elucidated has been provided by Longuet-Higgins (1972, 1976, 1978). In this theory every note of a composition is assigned a coordinate in a three-dimensional psychological space by a listener. In the first dimension (x) a move of $+1$ raises the pitch of a note by a perfect fifth (pitch ratio 3:2). In the second dimension (y) such a move raises the pitch by a major third (5:4). In the third dimension the octave (2:1) is the unit. For expositional purposes we may ignore the third dimension under the principle of octave equivalence and represent tonal space in a two dimensional form (see Fig. 2.11). The third dimension can be thought of as extending out of and below the page, all notes with the same name in the various octaves being 'stacked' above or below the note shown. Within this space a key is a bounded sub-space. In Fig. 2.11 the space of C major is bounded by the solid line.



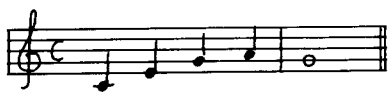


Fig. 2.11. A representational matrix for tonal music. From Longuet-Higgins (1978).

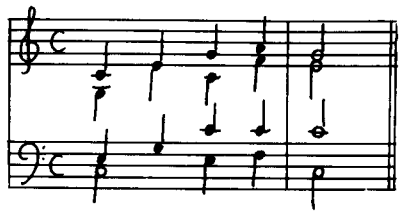
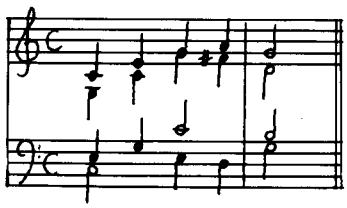
It is of note that, taking C as the origin, all other notes in the scale can be reached in a maximum of two moves (either one move of a fifth and one of a major third, or, in the case of C–D, two moves of a fifth. If we take any other note as the origin the number of moves increases (e.g. it takes four moves to get from A to D). So, a mental representation of this sort accounts in a direct way for the *centrality* of the tonic. It has the closest average distance from its fellow scale members than any other note.

Another feature of note is that the fundamental chord of tonal music, the major triad, can be obtained by taking any note together with its next highest neighbours in the x and y dimensions. The triad thus comes out as a compact L-shaped representation in the space. Whenever chords of this kind are encountered they are strongly suggestive of particular tonalities. The C–E–G triad is to be found within three keys only, and these keys can be visualized by sliding the key 'box' to the left or the right by one step (giving either F major or G major). Some chords are even less ambiguous than this. The dominant seventh chord (G–B–D–F) can be accommodated only within C major. If the key frame is shifted in any direction, one or more of the notes falls outside it. This reflects the fact that, in traditional tonal harmony, the dominant seventh has very strong key implications. In contrast there are



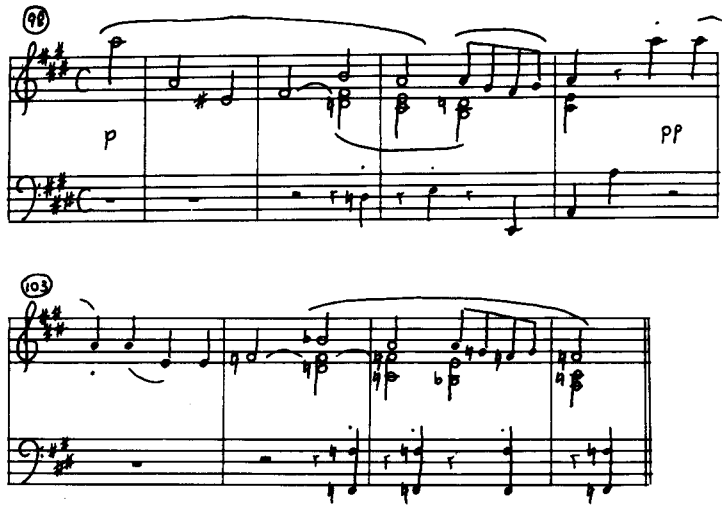
some chords which cannot be fitted into any key 'box' (e.g. C–E–G sharp, the augmented fifth; or C–E flat–F sharp–A, the diminished seventh). This is reflected in the fact that these chords do not have key implications, at least in isolation.

A further feature is that notes get multiple representation in the space. For instance, as well as the A in the C key-frame, there is another A just to the right of it. This feature reflects the musical insight that the same note can fulfil different tonal functions in different contexts. Consider the phrase in Example 2.19. Here, given a starting key of C, the A could be *either* part of an implied subdominant chord (F–A–C) in the key of C leading, via a plagal cadence, back to the tonic C, *or* part of an implied dominant chord of G major (D–F sharp–A) leading to a modulatory perfect cadence into the key of G. Longuet-Higgins' claim is that, in listening to an excerpt like this, we have to decide which tonal interpretation to give the A before we can represent the excerpt in tonal memory (or at least acknowledge the ambiguity and hold both readings until further information allows us to choose one of them). The use of equal temperament tuning on many instruments increases the possibility for ambiguity, for then C natural, D double flat, B sharp etc. are all represented by the same sound. Any note played on the piano has multiple ambiguity (in isolation). Listeners generally decide on a single tonal interpretation for a note by taking into account the context in which it appears, i.e. the ordering of the musical elements. This is equivalent to saying that the listener is sensitive to syntactical considerations.

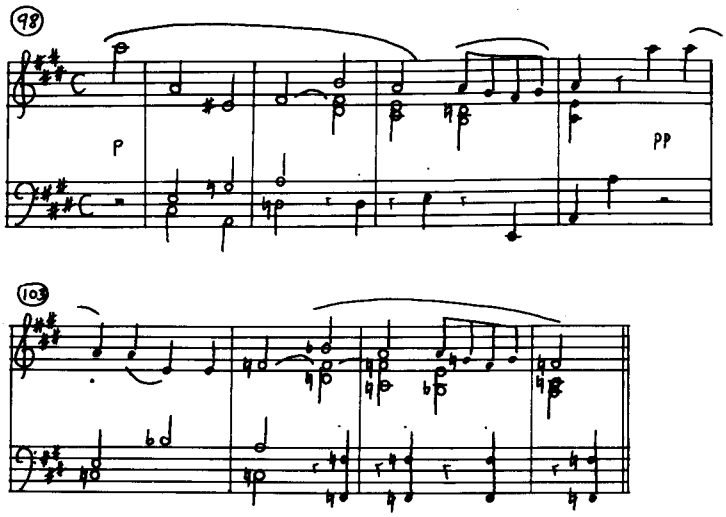


Example 2.19.

Some of these considerations may be quite simple. For instance, all other things being equal, a listener will choose a tonal interpretation for a note which places it close to preceding notes in tonal space. In other words, he operates within a restricted 'window' of tonality which changes position only slowly. Another principle could be to choose an intepretation which preserves the current key frame rather than one which shifts it. Most listeners will hear Example 2.19 as remaining in C major, rather than modulating to G. They choose the intepretation of A which preserves the initial key. If, however, we write out two alternative chordal accompaniments (Examples 2.20 and 2.21) we can disambiguate the phrase. The appearance of an F sharp in Example 2.21 'forces' the listener to shift the key frame to G major. In general, the fuller the accompaniment to a melody, the less possibility for tonal ambiguity there is. This does not mean, however, that composers are advised to 'flesh out' implied harmonies all the time. Ambiguity is, in itself, a very important compositional device. I cannot systematically describe the myriad types of



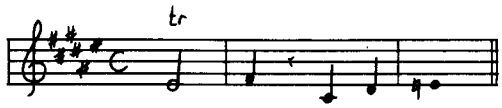
Example 2.20.



Example 2.21.

harmonic ambiguity found even in classical compositions, but here is one simple and beautiful example from Beethoven's Piano Sonata (Op. 14 No. 1). Example 2.22 gives bars 98 to 106 of the last movement. The music is firmly in A major at this point. Taken in isolation, the four-note figure which opens the excerpt (and which recurs in repeated crotchets four bars later) is harmonically ambiguous. The context will, however, suggest to many listeners a move from the chord of A to the chord of D (via an augmented fifth on A). This interpretation in confirmed by the chord in bar 100. This creates a strong expectation that the harmonic pattern will be repeated in bars 103 to 104. The first note of 104 will be heard as an E sharp awaiting resolution upwards to F sharp as before. But then comes the chord of B flat (!), taking the music firmly into the key of F major and forcing interpretation of the preceding two notes as intiating a movement into F. Both the original tendency to interpret as E sharp and the surprise which causes the reinterpretation as F are part of Beethoven's intention. The passage would lose all its dramatic power if an accompaniment such as that in Example 2.23 had been provided. This would have prepared the listener for a transition to F major, and the crucial moment of surprise would have been lost.

In this, and all other examples of musical ambiguity, there is no single syntactical structure. Rather, we have two possible structures, each of which the composer intends to be construed by the listener at different times. The rules for the introduction of ambiguity, if rules there are, lie outside the set of rules which describe legal moves within tonality. When psychologists and others talk of a musical syntax they are usually talking of rules for the construction of music which is intended to be *un*ambiguous (such as Tegner's nursery rhymes). We return, therefore, with caution to our earlier question—how to determine the key of compositions from their opening measures (Examples 2.17 and 2.18). A composer may not always wish for us to solve

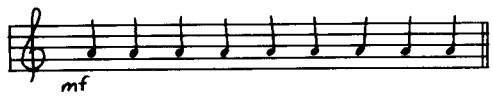


Example 2.22. From Beethoven, Piano Sonata Op. 14 No. 2, last movement.

Example 2.23. Alternative harmonization for Example 2.22.

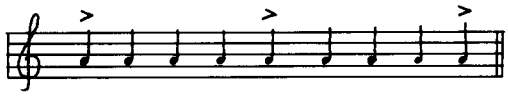
this particular problem easily. Although it would be generally true to say that tonal melodies tend to start on a note of the tonic chord, and therefore a listener would be trying to 'fit' a tonic harmony at the soonest opportunity, there is no guarantee that melodies will not be written which start on other notes. In Example 2.17 the rapid establishment and maintenance of a G major chord strongly suggests G major, and in Example 2.18 the emphatic bass line establishes A as the tonic immediately, although the chromatic writing then does its best to dissuade the listener from his certainty. But what

of the F sharp major Fugue of Book 2 (Example 2.24)? This starts resolutely on an E sharp, which is no part of the F sharp major chord. Arguably, what allows such a strong sense of F sharp major here is the trill on the first note. This evokes the leading-note to tonic trill which characterizes the final cadence of many pieces of the period. So Bach may have been relying on listeners' ability to recognise this very distinctive figure to determine the tonality.



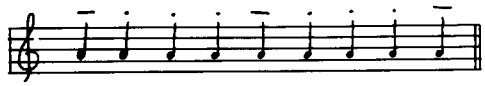
Example 2.24. From J. S. Bach, *Well-Tempered Clavier*, Fugue 13, Book 2.

How may we sum up this brief discussion of harmony in tonality? Generative grammars, such as Sundberg and Lindblom's (1976), written for a small corpus of tunes, allow further tunes in the same idiom to be produced. What they lack is reference to any principles in virtue of which the rules may be understood. The purpose of theorists such as Longuet-Higgins is to make general postulates about the way in which listeners represent large bodies of music. They can explain why it is that much music seems to operate within certain constraints, but they also help us understand the effect of music which strikes the ear as tonally ambiguous.



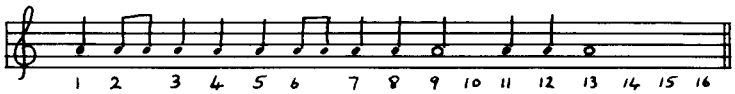
2.5.4. *Rhythm and metre*

The structure underlying the rhythm of a piece of music is often a metrical tree of the sort depicted in Fig. 2.10. The simplest type of structure involves a regular pulse, so marked that every *n*th occurrence (usually 2, 3, 4, or some simple multiple of these) is stressed. A stress marks the beginning of a metrical unit, which is notated in much music by the use of bar lines. Sometimes the tree has several nested levels (as in Fig. 2.10) but I will concentrate here on the rules which prescribe possible rhythmic structures *within* a single bar. As with harmony, the most fruitful discussions of rhythmic syntax have occurred in the context of the problems facing a listener trying to identify rhythmic stress from a sound pattern. How does he work out which notes are principal stresses? If a listener is presented with a set of equally spaced, equally loud notes of equal pitch (Example 2.25) there is no way in which any rhythm may be said to be present (although the listener may *impose* some rhythmic grouping of his own (Woodrow 1951). To communicate an intended rhythmic interpretation, the primary stresses must be marked in some way. One method of doing this involves variations in intensity. In the absence of other information a stressed note should be louder than its neighbours. Thus, Example 2.26 gives a strong indication of a quadruple metre, each loud note marking the start of a new bar. On instruments where dynamic change from note to note is not possible (e.g. organ) analogous ways of indicating stress

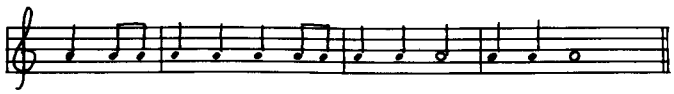


are available through articulation and phrasing. For instance, the first note may be held for the full length of its duration (tenuto) whereas the other notes are released early (staccato), as in Example 2.27.

Example 2.25.

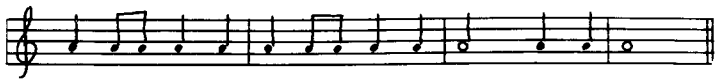


Example 2.26.



Example 2.27.

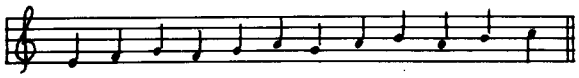
This general class of marking procedures I shall call 'performance markers' because they rely on the way the notes are played rather than on their specified pitches and durations. I shall discuss them further in Chapter 3 (particularly section 3.2.3). They are analogous to stress and intonation in speech.



A different type of marker is illustrated in Example 2.28. Here the note durations are varied by subdividing the beat or by making a note last for more than one beat. Observation of much tonal music supports certain generalizations about the distribution of note values. For instance, the stressed beat is not usually subdivided, and does not occur within a long note other than at its beginning. Thus, in Example 2.28 we can eliminate beats 2, 6, 10, 14, 15, and 16 as primary stresses, leaving a quadruple metre stressing notes 1, 5, and 9 as the only regular interpretation. In this example, however, some possible barrings cannot be eliminated without reference to the 'empty' beats 14 to 16. This seems rather a long time for a listener to wait before the rhythm can be determined, to say nothing of the memory load imposed by holding so many notes whilst various rhythmic interpretations are tried out. Are there other features of the structure which could be used to make an earlier judgement? One possible strategy is to look for repeating patterns, on the assumption that a rhythmic pattern will fall at the same position within a bar on its two occurrences. The distance between two patterns will then be a whole bar or a simple multiple of one bar. On this principle, the repetition of the crotchet + quaver + quaver pattern in Example 2.28 limits us to a duple or quadruple metre because a triple metre would inevitably involve the pattern falling at a different position within the bar on its two consecutive occurrences. Even this strategy, however, does not help the listener decide

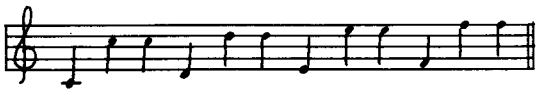
Example 2.28.

Example 2.29.



Example 2.30.

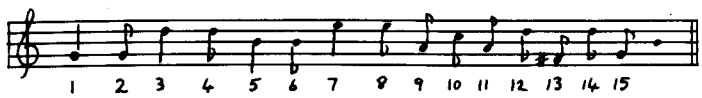
between the two quadruple barrings given in Examples 2.29 and 2.30. Here, it is only the absence of a new note at beat 14 which is decisive in favour of 2.29.



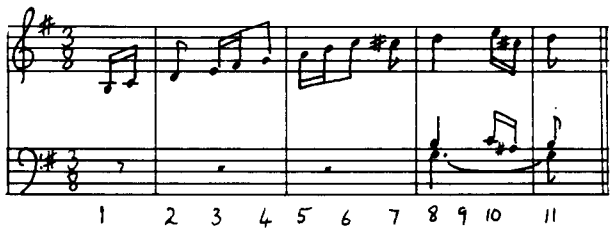
Another strategy which allows an earlier decision involves the search for dactylic groupings. A dactyl is a figure where one note is followed by two of half its duration (e.g. crotchet followed by two quavers). A recursive parsing based on this grouping can sometimes yield an appropriate barring quite early. Applied to Example 2.28 the procedure would search for the first dactyl to be encountered, duly identifying the first three notes as such. This dactyl would then be considered as a unit (effectively by replacing the three notes with a single note of their summed durations, a minim). The sequence is thene searched again from the beginning for a dactyl, and the procedure identifies the initial minim together with the following two crotchets as a superordinate dactyl. Once again, the dactyl is replaced by a single note, a semibreve. At this point, the procedure can find no further dactyl involving the first beat, and moves on to consider the fifth beat. Acting on the assumption that the beginning of a dactyl marks a stressed beat, this procedure identifies beats 1 and 5 as primary stresses.

Of course, very little music contains passages which remain at a single pitch for any length of time, and a further possibility for determining rhythm rests on the tendency of much music to contain repeating pitch patterns. Although the notes of Example 2.31 are all of the same duration the listener experiences a sense of triple metre because the pitch pattern repeats itself in transposition after every three notes. This effect can be heightened by emphasising the pitch separation of the first note in each group as in Example 2.32. For a fuller discussion of these and other strategies of rhythm recognition, see Steedman (1977) and Longuet-Higgins and Lee (1982).

The difficulty with proceeding from plausible strategies like these to a grammar of rhythm is that composers arguably use their knowledge of listeners' likely strategies to support music which is neutral with respect to,

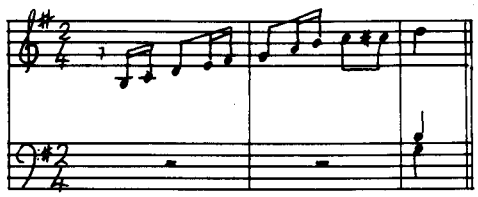


Example 2.31.

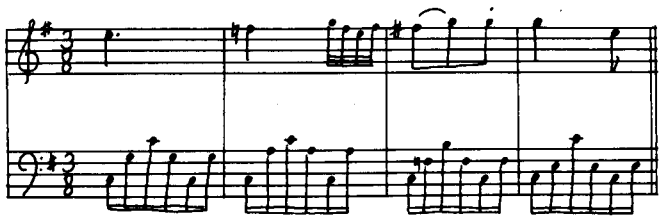


Example 2.32.

or even violates, the rules which the strategies imply. For instance, one may postulate a principle of consistency with regard to the way in which listeners ascribe metre to a piece of music. If a sequence begins with strong cues to a certain metre, the listener is likely to maintain that metre as an interpretational aid for some time, even in the absence of further strong cues. Thus, the composer may write music which would be 'without metre' if heard in isolation, but which acquires a particular interpretation in a listener's mind by extrapolation of the preceding metre. A good example of this is provided by Bach's Organ Fugue commonly known as the 'Gigue Fugue'. It gets its nickname from the unmistakeable triple metre strongly implied by the first eight notes of the theme (Example 2.33). Then follows a string of quavers. There are certainly no durational cues to metre here, and indeed, the repetition of note 9 by note 11 might be taken as a counter-suggestion of duple metre. Nonetheless one experiences a strong sense of triplet grouping 'carried over' from the opening. Elsewhere, the use of syncopation takes this idea one step further by placing an apparent stress in a place where the previous metre would not predict it. If the syncopation is to be heard as a syncopation (and not as a change of metre) then we must look to the listener's reluctance to alter the inferred metre (and the composer's exploitation of this reluctance) rather than to rules for generating sequences from a rhythmic 'tree.'



Example 2.33. Adapted from J. S. Bach, Gigue Fugue for organ.



As with harmony, one must acknowledge that it is often the composer's intention to thwart or puzzle the listener with rhythmic ambiguities. Take, for instance, the opening of the last movement of Beethoven's Piano Sonata in G (Op. 14 No. 2) given in Example 2.34. Despite the barring, the effect of this sequence, up to beat 9, is to suggest the duple metre shown in Example 2.35. This grouping is suggested by the dactyl groups, particularly the superordinate dactyl formed by beats 4, 6, and 7, but the interpretation runs into trouble at beat 10 (where a subdivision of the beat is not expected) and is strongly challenged by the absence of a new note on the supposed primary

Example 2.34. From Beethoven, Piano Sonata in G, Op. 14 No. 2, Last movement.

Example 2.35.

Example 2.36. From Beethoven, Piano Sonata in G, Op. 14 No. 2, Last movement.

stress at beat 12. In this case the listener has no real way of settling for one particular interpretation of the rhythm, but it would destroy the point of the music for the pianist to thump out an accent on the first beat of each bar. The uncertainty is all part of a mischievous 'catch me if you can' first subject, full of abrupt stops and sudden flurries of activity. All manner of uncertainties are only resolved finally in the serene and rhythmically unambiguous second subject (Example 2.36).

These considerations lead us to some fundamental restrictions on the way we postulate a grammar of music to be *used*. In language we can usually assert that both speaker and listener *abide* by the grammar, and that the speaker's intention is normally to provide unambiguous utterances which the listener will interpret as the speaker intends. In music the composer abides by grammar in a much looser sense. He may certainly know of its existence, and how to write unambiguous music using it, but he also stands outside the grammar in a way that the listener may not. He anticipates the strategies that a listener in his culture will use to structure his or her experience, and seeks to thwart these strategies in interesting ways. Thus, any shared grammar does not *generate* the compositions. Rather, its existence is a major

consideration in determining the nature and degree of freedom the composer can exercise to transform and extend musical style. Put simply, if a composition is totally generated by a grammar it is likely to be dull; if it breaks rules in an unmotivated way it is likely to be unintelligible.

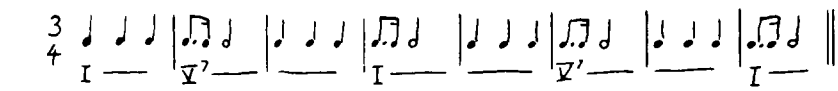
The best linguistic analogy for musical composition is not so much the utterance of a novel sentence as the utterance of a non-sentence (as in a poem) which, by virtue of the utterer's appreciation of his listener's linguistic apparatus, has significance for the listener.

2.5.5. *Melody*

Many of the constraints on melody are dictated by the requirement that the melody be capable of communicating harmonic and rhythmic structure to a listener. This is the reason why Sundberg and Lindblom's grammar generates the melody *after* the harmony and rhythm have been determined. It would be oversimplistic, however, to suppose that composers conceived harmony and rhythm prior to melody in all cases. Although a composer may sometimes be constrained by harmony and rhythm (e.g. 'I need to get from D major to A major in four bars') there are times when he may well allow harmony and rhythm to be derived from a melodic idea. The claim that rhythm and harmony are syntactically prior to melody does not rest on observations about the composing process (of which more in Chapter 4). It rests rather on observations about the musical *product* and its effect on listeners. Firstly, the number of different melodies within an idiom is much greater than the number of harmonic and rhythmic sequences common within the idiom. There are many cases where very different melodies are supported by identical harmonic progressions, but rather few cases where very different harmonies support identical melodies. Secondly, it makes some sense to talk of harmony without melody, or rhythm without melody, but very little sense, at least within the tonal idiom, of talking about melody without harmony or rhythm. When listeners hear a melody, their processing of it normally involves the attempt to retrieve implicit harmonic and rhythmic structure. Representing the melody to themselves *means* recovering this structure. In contrast, a chord sequence can be heard without any attempt to recover an 'implicit melody'.

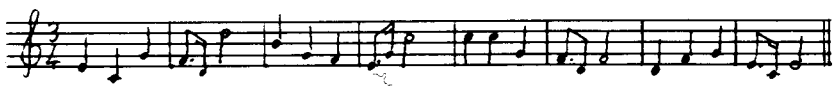
Melody, thus, represents the level of the greatest differentiation in music, the level at which our evaluative and critical faculties are most immediately engaged. It is the aspect of music which is nearest to the 'surface', and that which, for most listeners, most immediately characterizes the music. Our appreciation of a 'great' melody rests partly on our appreciation that a composer has a great many options when generating a melody even if harmony and rhythm are determined. His choice becomes memorable when it is sufficiently different from anything we might have thought of, or heard before, and when we appreciate some particular rightness or fittingness about the choice. A syntax for melody should not aspire to formalize greatness.

What it can do, perhaps, is specify the permissible options in a way which makes clear just how formidable the composer's task is to select from among them.



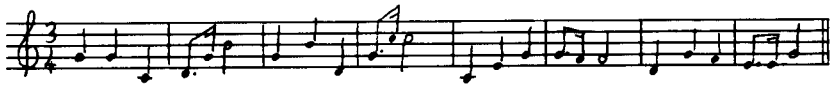
Let us, then, take a very simple harmonic and rhythmic framework as an example, and examine the kind of rules which would allow us to derive acceptable melodies from it. Example 2.37 gives the rhythm and harmony that our melody must 'carry'. We may imagine this to have been generated by the application of a context-sensitive set of rules such as those of Sundberg and Lindblom discussed in section 5.2 of this chapter. A first rule of melodic construction which we might wish to consider is:

1. A note may be chosen from the chord of the implied harmony at that point.



If we suppose that we are in the key of C major, then this rule allows any note in the first and fourth bars to be C, E, or G, and any note in the second and third bars to be G, B, D, or F (dominant seventh chord). Even if the choice of notes is confined to a single octave this rule allows 2 985 984 distinct melodies. Examples 2.38 and 2.39 are just two of such melodies. Examination of published melodies rapidly demonstrates, however, that Rule 1 is too restrictive for many melodies, because they contain notes outside the harmony at a given point. Consider, for example, Verdi's famous 'La donna è mobile' from his opera *Rigoletto* in which the precise pattern of Example 2.37 is repeated twice (see Example 2.40). There are five notes (asterisked) which Rule 1 does not allow. To accommodate these notes we need at least two more rules:

2. A note may be inserted between two adjacent notes of a given chord if it forms a scale step with one or both notes (passing note).
3. Two occurrences of the same note may be replaced by a pair comprising that note preceded by one a single scale step higher (*appogiatura*).



The derivation of the melody from these rules can be illustrated in stages. Example 2.41 shows a melody derived by Rule 1 alone. Example 2.42 shows the modifications introduced through Rule 2, and Example 2.43 the form achieved after selective application of Rule 3. Notice that there is still one note (asterisked) which does not conform to the Verdi melody. Is there yet another rule which we should introduce to account for this? Maybe there is; but we should also allow for the possibility that Verdi deliberately breaks formal rules for some particular reason. In this case such a reason is not hard to find. The melody breaks down quite naturally into two-bar segments (each with identical rhythm). The second segment (bars 3–4) is an exact repetition of the first segment transposed down a scale step. Clearly Verdi has it in mind that the fourth segment (bars 7–8) should be a similarly transposed version of bars 5–6. If. however, the transposition were to be *exact*, we would get Example 2.44 which leaves the three final notes

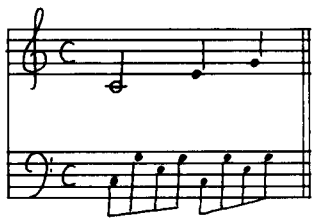
unaccounted for under the three rules we have so far. Verdi's 'compromise' is to slip the last four notes down by a tone. This preserves the contour (i.e. the 'up', 'down', or 'same' relationship of adjacent notes) of the previous segment, and, additionally, imitates in bar 7 the melodic shape of bars 2 and 4. This mixture of imitation and slight deviation from exact repetition, together with the mild discord of the 'discrepant' last note of bar 7, gives the melody

interest. A less imaginative composer might have provided a stricter, more 'correct' solution (e.g. Example 2.45).



If there are simple rules of melodic construction of the sort outlined above, then I believe we must conclude two things about them. Firstly, we will find composers breaking these rules from time to time when they consider some other organizational principle to take precedence. Secondly, these rules allow such a vast number of options that the art of composition consists in developing motivated ways of restricting the options. Because the 'search space' is so large, and because there are so many relevant musical properties which could influence compositional choice, composition seems normally to involve the establishment of provisional goals and the application of heuristic procedures for attempting to achieve them. Such procedures do not formally resemble the steps of a generative grammar, and we shall examine their nature in Chapter 4.

2.5.6. *Pattern and structure*

Although rules of harmony, rhythm, and melody provide much in the way of detailed moment-to-moment restrictions on musical sequences, they do not account for many larger-scale aspects of musical structure which arguably fall within the realm of musical syntax. The most general of such aspects is probably *repetition*. Exact repetition can occur on many levels. The same melodic fragment can be repeated (Bach's French Suite No. 5 in G, last movement, Example 2.46), as can an accompanying figure (Alberti bass as in Mozart's Piano Sonata in C, K. 545, 1st movement, Example 2.47). On a

Example 2.46. From J. S. Bach, French Suite No. 5, last movement.

Example 2.47. From Mozart, Piano Sonata in C (K. 545), first movement.

larger scale, the same phrase may be repeated (e.g. the typical A–A–B–A song form) or a whole large-scale portion (e.g. the exposition of a classical sonata form movement). Equally often, however, the repetition is not exact. Pitch transposition of melodic material is common. Other forms of repetition with change include inversion, augmentation, contraction, segmentation, and

retrogression. Sonata form and many later compositional forms make multiple use of such transformations to extend and develop thematic material. Simon and Sumner (1968) have shown that many important characteristics of musical patterning can be captured by simple formalisms involving the operators SAME and NEXT applied to the major dimensions of musical sound. They take, as their example, the Gavotte from Bach's French Suite No. 5, and show how the first four bars can be almost completely described in terms of repetitions of elements contained within the first bar.

Whilst accepting that such patterning is integral to music, I believe that it is necessary to claim that it cannot, on its own, give a full account of the structure of a musical composition. I can, perhaps, illustrate this point by two analogies. The first is an architectural one. A curved masonry arch, such as might be found in an old church, contains several examples of patterning. For instance, the curvature of each brick may be slightly greater than that of its neighbour, whilst retaining enough similarity of shape to appear a fitting next member of the sequence. Repetition and transformation are there, but when we ask why *that* transformation is chosen, and how much transformation is required, we cannot answer the question by recourse to a formalism which describes each transformed element in terms of its predecessors. Rather, we must see what the overall function of the *set* of transformations is: to provide a self-supporting bridge of a certain shape. There is, of course, the possibility that some aspects of pattern (say, decorative carving on the masonry) are irrelevant to this level of structure, but typically, such decoration will, in some way, be *governed* by the structure (e.g. the decoration maintains a constant relation to the line of the arch).

A second analogy comes from graphic art,as exemplified by the work of M. C. Escher. In many of his drawings, a basic technique of patterning is easily discernible. Escher uses ordered series of shapes, each one of which is slightly different from its neighbour, so that as one's eye moves across the picture, subtle and disturbing metamorphoses are experienced. And yet, what makes these pictures compelling is not so much the transformational technique as the end-points which Escher uses these transformations to travel between. A drawing describes a journey with a beginning and an end, and structurally the outer destinations *control* the inner transformations. We are engaged at two levels; the technique fascinates, but a major cause of the fascination is the way the technique is used to arrive at the various significant forms.

And so it is, I believe, with music. Music uses patterning to achieve structural goals; it also uses patterning to engage the listener with decorative detail, but the structural coherence of a piece of music is not to be found solely *within* the principles of patterning. These principles do not have starting points and goals built into them. They can be applied over and over again to any musical idea whatever, so that an indefinitely long piece of music could be produced (just as, using Escher's techniques, an indefinitely large drawing

could be produced). Schenkerian concepts offer one possible basis for goal-directed structure, with the concept of a harmonic journey from the tonic which returns back there in the end, but clearly, any fully adequate characterization of goal structure is going to be complex and multidimensional. The fact that it is relatively easy to understand and characterize the small-scale techniques of repetition and transformation which operate within short musical segments, whilst it is extremely difficult to characterize the factors which give a work an integrated and directed form, probably explains Schenker's belief that it takes a genius to produce an extended piece of music with a unified and motivated structure.

A common implication of several aspects of musical syntax we have dealt with is that they are best understood as relating to propensities of *listeners* to infer particular underlying structures from note sequences rather than to the generative processes of *composers*. Recently, Lerdahl and Jackendoff (1983; also Jackendoff and Lerdahl 1982) have extensively followed through the implications of this observation by offering a set of grammatical rules which attempt to account systematically for the way in which listeners assign structural prominence to the various elements in a musical composition. They have, in effect, proposed a formal system for *analysing* a given musical sequence. Their rules can 'cope' with ambiguity because they incorporate a set of independent strategies for grouping musical elements. The final interpretation assigned by a listener will depend on the weight he or she gives to the various strategies, and on whether their effects are to reinforce or contradict one another. Their theory is too recently published to evaluate in detail here, but it promises to be a major contribution to this topic.

2.6. Musical semantics

It is a significant fact about language behaviour that people almost never remember what they read or hear in *verbatim* fashion. Not only does recall paraphrase the original, but it also contains many inferences about information not present in the original. Take, for instance, the following short story:

> Jill was invited to Jack's birthday party.
> She wondered if he would like a kite.
> She went to her room and shook her piggy bank.
> It made no sound.

A typical recall might produce something like the following:

> Jill was going to Jack's birthday party.
> She wanted to buy him a kite.
> She went up to her room and shook her piggy bank.
> There was no money in it.

Such a recall, although we might wish to call it accurate, is heavily laden with inference. For instance, it is possible that the reason why Jill's piggy bank made no sound was that it was full of bank notes. It is also possible that Jill's wondering about Jack's wants was a passing thought, and that she had no intention of buying him anything. These alternatives do not normally occur to us, because we bring knowledge to bear on what we hear; knowledge about birthday parties, the financial circumstances of little girls, and much else. The thrust of recent evidence (see, for instance, Sandford and Garrod 1980) is to suggest that people make these inferences during reception of the message, and that their aim in doing so is to build up an internal model of the portion of the world referred to in the message. Although it is possible that given information can be marked as such and held separate from inferred information, the evidence suggests that it is remarkably difficult to do this. When it is possible to check the verbatim record of some real-life conversation, it is found that even people claiming to have excellent memories for what other people say, and testifying under oath, deviate grossly but systematically from what was actually said (see Neisser's analysis of John Dean's 'Watergate' testimony, 1981).

The implication of this type of evidence is that people recode linguistic information into semantic information. The 'meaning' of a sentence for a listener is, roughly, what he adds to his model of the situation being described as a result of hearing the sentence. This addition allows him to do a number of things. One of these *may* be to reproduce what he received, but this is by no means a necessary, or even important, consequence (we can imitate speech that has *no* meaning for us). Other things may include taking some appropriate action (as in response to 'you have left your car headlights on'), representing the information presented in some other mode (as in drawing a picture of 'the red brick is beneath the green brick'), or experiencing some significant emotion (as to 'your grandmother died today'). From a psychological point of view language is, in some sense, a substitute for sensory experience. We respond to being told that our headlights are on in the same kind of way as we would if we saw them to be on. Contemporary theorists account for this equivalence by saying that the two inputs have equivalent effects on our mental representation of the world.

The principal issue in musical semantics is whether we can establish analogous equivalences between music and some essentially non-musical phenomenon. Does music cause psychological effects which can be caused by other means, and does it do this in a systematic way?

The first position we might consider is that music simply has no semantics. On this view, music is psychologically self-contained, a separate species of psychological activity for which unique modes of representation have been developed. The suggestion, discussed earlier, that people represent music in a tonal space such that notes are assigned harmonic functions within keys, is

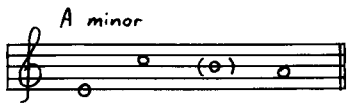
certainly different from any suggestion psychologists have made about cognitive representation in other spheres.

Clearly, there is much in musical behaviour which can be accounted for by considering musical representation to be a closed sub-system with no essential links to other cognitive domains. This system merits study, is the principal topic of discussion in this book, and is the subject of the most prominent research initiatives in the area. However, I believe that the available evidence forces us to accept that there is some 'leakage'. Musical experience *is* translated into other representational modes. Consider, for example, the case of someone who has just listened to a performance of a long and complex symphonic work. It is quite possible that he or she cannot recall a single theme from the work (I have often been in this situation myself), yet he or she certainly remembers *something* about the work, and can make some appropriate response to it. When this response is expressed in words it characteristically contains remarks about the substance of the music which are neither descriptive ('it was loud') nor reactive ('I liked it') but embody an attempt to *characterize* the music through metaphor ('It had the feeling of a long heroic struggle triumphantly resolved'). It seems less significant that people often disagree about their characterizations than that they nearly always have *some* comment to offer. This is not an arbitrary reaction, but a genuine attempt to describe some real thing or experience. For a great number of us, then, music has extra-musical meaning, however intangible.

What is it that makes music have meaning for us? One possibility is that it *mimics* the sounds which occur in extra-musical contexts. There is a great deal of music which employs mimicry to considerable effect (woodwind 'birdsong' to suggest a pastoral scene, glissandi violins to suggest the howling wind of a storm, and so on). Our recognition of these meanings requires only the knowledge of the appropriate extra-musical sounds. Other music employs *symbolic* reference to an extra-musical event. In opera, for instance, if a particular theme is associated with each appearance of the hero, then it might be used to signify that, in his absence, the heroine is thinking of him. Sometimes music can be *programmatic*, aiming to illustrate a given story. In Dukas' *Sorcerer's Apprentice* there is a bizarre moment when the music suddenly stops; then out of the silence bass instruments take up the first few notes of the main theme one after another, haltingly at first, but gradually increasing in speed and intensity. This corresponds to the moment in the story when the desperate apprentice, unable to undo his spell, chops the relentless water-carrying broom into small fragments. For a moment he thinks he has solved his problem, but then, to his horror, each fragment rises, one after another, to continue its task, compounding his folly.

In all the above cases the composer has set out to depict a definite set of world events through music, and it is easy to understand how it is done.

Unfortunately, very little music has such explicit extra-musical reference, and even in that which does, its reference does not exhaust its significance. If the sole aim of such music were reference, one might as well have a sound recording of the event referred to. Musicial reference is special because the music 'makes sense' even if the reference is *not* appreciated by a listener. A referential passage nearly always serves a double function: it points to an external event, but it also forms part of the thematic structure of the piece as a whole. It is a well-formed segment of the music quite independently of its reference, and one of art of composition consists precisely in finding passages which are capable of serving this double function.



What, then, of the vast bulk of music, which does not have meaning in the specific sense outlined above? One of the most popular suggestions is that musical sequences somehow denote, or stand for, certain emotional states. Deryck Cooke (1959) has presented one of the most fully worked out versions of this thesis. He argues that the intervals of the diatonic scale suggest different emotional qualities (e.g. major third—pleasure, fifths and octaves—neutral) and goes on to isolate several basic melodic combinations of these intervals which seem to recur throughout tonal music. For instance, there are many melodies which start on the dominant of a minor scale, then rise over the tonic to the third of the scale, before falling, possibly via the super-

TABLE 2.1

Composer	Approximate date	Words (English translation)
Dowland	1612	When the poor cripple by the pool did lie
Bach	1722	Flow my tears in floods of weeping
Bach	1729	Have mercy on me, O Lord
Bach	1731	I am weary of this world
Mozart	1791	Day of bitter lamentation
Verdi	1873	Day of bitter lamentation
Schubert	1823	Life flows away like the waters of a river
Schubert	1827	(The jilted lover bids farewell to his faithless sweetheart)
Verdi	1852	Farewell to the past, to the fair smiling dreams
Wagner	1853	(He who wishes for the power of the Ring must renounce love)
Mahler	1883	The unhappiest day of my life
Mahler	1884	Goodbye to all I ever loved
Britten	1944	We planned that their lives should have a good start

tonic, to rest on the tonic (Example 2.48). Of this motif Cooke says: it 'conveys the feeling of a passionate outburst of painful emotion, which does not protest further, but falls back into acceptance—a flow and ebb grief. Being neither complete protest nor complete acceptance, it has an effect of restless sorrow'. In support of this, and his other analysis, Cooke collects together an impressive array of supportive examples from all periods of tonal music. The most telling of these are, perhaps, taken from vocal music, where we have some independent evidence from the words concerning the emotional mood. For Example 2.48 Cooke gives fourteen examples, all from vocal music, summarized in Table 2.1.

The ubiquity and stability of such motifs is impressive, even if it is all too easy to accuse Cooke of picking his examples to support his case. Counter-examples are not immediately damaging to the thesis, because melody is only one of the dimensions along which composers may signify emotion. Rhythm, tempo, orchestration, and dynamics are all capable of modifying the meaning. It is quite clear that Example 2.48 would have different emotional connotation when entoned fortissimo by the entire brass section of a symphony orchestra than when played liltingly by a solo violin. It is not coincidental that most of Cooke's examples of this theme are quiet and slow. I believe that Cooke has identified a real and important component of musical meaning with his melodic analyses. As psychologists, however, we need to ask what psychological mechanisms allows these meanings to be comprehended by a listener.

Example 2.48. One of Cooke's (1959) thematic motifs.

One possibility is that the motifs are intrinsically neutral with respect to the emotions and that people acquire their meanings through association with exactly the kind of words that seem to habitually accompany the motifs. Whilst this does not explain why composers should have begun to pair emotions with melodic motifs in the first place, it does seem the simplest explanation for the listener brought up within the existing musical culture. On this argument a listener would have no added difficulty in learning some different pairing of melody and emotion. For instance, it might have been that the emotion paired with Example 2.48 in our culture were paired with, say, a rising major triad in some alternative tonal culture. This is by analogy with the arbitrariness of word-meaning pairings in natural language. We believe that a language like English, where the meanings of 'cat' and 'dog' had been exchanged, would be just as easy to learn and use as the language we actually have. There is nothing about the sound 'cat' as such which makes it particularly suitable to stand for the small feline domestic mammal as opposed to anything else.

Cooke, however, invites us to reject the notion of instrinsic neutrality for music. He argues that certain motifs are more suitable than others for suggesting particular emotions by virtue of the tonal relationships that hold between their members. For instance, positive emotions are suggested by major sequences, especially those involving triads, because such sequences are directly derived from the early members of the harmonic series. Similarly, movements away from the tonic, particularly upwards, are suitable for expressing outgoing emotions, whilst movements towards the tonic signify rest or repose. This is because the tonic occupies a central or 'home' position in tonal harmony. What is suggested, therefore, is that the tonal system, as such, offers analogies for the way in which people represent emotions in some 'semantic space', and that these analogies allow a partial mapping of tonal relations onto emotions (Makeig 1982).

The psychological implications of this view are twofold. Firstly, the discovery of analogical relationships between music and emotion should be discoverable, in principle, by anyone who is capable of appreciating the tonal relationships in music and who has a normal understanding of the emotions. Thus, an explicit word–music association is not necessary to come to appreciate emotional meanings in music (although it may, of course, assist the process of acquisition). This helps to explain how so many composers, working in different times and places, seem to have hit upon the same types of melodic forms for the explicit expression of textual emotion. Secondly, it follows that pairings of melodies with emotions *other* than the ones we now have would not be as easy to learn, since they would be working against the 'ready made' analogical relationships inherent in tonality.

Although Cooke's thesis is empirical, it is not easy to know how it could be practically demonstrated. The 'ideal' demonstration would be given by someone who had never been exposed to any word–music associations (through song, etc.) showing culturally 'normal' appreciation of the emotional connotations of music. Such a person would, of course, have to have received otherwise normal musical and linguistic experience. It is unlikely that the conditions for this demonstration could ever be set up.

The research of Gabriel (1978) illustrates the considerable difficulties besetting the psychologist wishing to conduct empirical investigations into the mechanisms whereby emotional meanings in music are transmitted. He played each of Cooke's basic motifs to musically untrained subjects twice. On one occasion the motif was paired with Cooke's emotional characterization of it, on the other by a randomly chosen description from Cooke's set. Subjects were asked to rate the appropriateness of each motif–description pair. Gabriel argued that if subjects were aware of the supposed emotional connotation of each motif, then they should rate Cooke's designated description as more appropriate than the randomly chosen one. The results showed that subjects did not, in fact, distinguish between descriptions in this way. The 'random' description was equally often chosen as more appropriate. Here,

then, is an apparent failure to demonstrate any relationship between tonal pattern and emotional connotation. Gabriel's tentative conclusion is that more primitive features of melodies (such as contour) are the principal carriers of musical meaning. Before accepting this conclusion, however, it is worth questioning whether Gabriel's experiment was maximally *conducive* to the discovery of Cooke's melody–emotion links. There are three issues which seem to require consideration.

First comes the question of subjects. It is natural to suppose that, as one becomes increasingly sophisticated musically, one becomes attuned to finer emotional nuance. A hierarchy of emotional cues seems likely, with primitive cues (such as speed and loudness) available at all levels of musical sophistication, and with more subtle cues (such as aspects of tonal relations) available only to those with deeper analytic powers with respect to the music. A common experience among many music lovers (including myself) is a belated appreciation of the emotional diversity and subtlety in the music of a composer such as Mozart. The inexperienced listener may find Mozart pale, insipid, and all vaguely 'jolly', especially when set beside the kalaeidosocopic turbulence of the romantic composers. Closer knowledge of Mozart (and maybe of the emotional world) results in his music becoming richly and sublimely expressive. The ability to 'read' the emotional language of music is an acquired skill, and we should, perhaps, not be too surprised that a group of 'ordinary' subjects do not show much awareness of the finer details of this language.

Second is the consideration of the nature of the experimental stimuli. In Gabriel's study the motifs were presented in musically 'disembodied' form. Each stimulus was a series of equally loud and equally long sine waves following the minimal tonal context of a tonic chord. The justification for this is the wish to hold all factors other than melody constant. There is no real music where melody is the *only* dimension on which two excerpts differ, and so it is impossible to tell which of several differences between two pieces of music is responsible for a difference in emotional connotation. In Gabriel's experiment, any difference in emotional meaning *must* be due to a difference in melodic shape, since nothing else varies. The major criticism of Gabriel's design is that it may have destroyed the conditions under which it is possible for a listener to activate the cognitive mechanisms which mediate between music and emotion. For instance, one may argue that the ascription of emotional meaning depends upon exposure to an extended context in which the crucial melody is embedded. By analogy, in recognition of facial expression we use information from the area of the eyes, but if we see *only* the eyes without the rest of the face, our ability to use this information is diminished. We may need to know where an excerpt comes in the structure of the music before we can interpret it emotionally; or we may need to give it some metrical reading. It would be difficult even for Cooke to hold that *every* occurence of a melodic motif has emotional significance. More likely, it is

the portion of a sequence that is highlighted through its position in the musical structure, or its scoring, that carries the brunt of the emotional burden. For these, and other reasons, Gabriel's task is an unreal one. The future task is to find more realistic listening situations which nevertheless allow for the degree of control over the various dimensions of sound which is an undoubted prerequisite of the experimental investigation of response to music.

Third we must consider the nature of the response that subjects are asked to make. The judgement of the emotional meaning of a piece of music is not necessarily an instantaneous thing. It may be only gradually that one comes to the best characterization of the extra-musical themes that seem to be given metaphorical expression through the music. The analogy from language, where we hear a word or phrase and then can instantly access some central aspect of its meaning, is not necessarily the best one for understanding what goes on in music listening. A better analogy would perhaps be the ill-defined process by which we come to appreciate that a particular turn of phrase in a poem has implications which contribute to the meaning of the poem in a way that some putative 'synonymous expression' would not do. To come to this appreciation may require extended mental work during which we give the object of attention detailed and repeated scrutiny. Gabriel's subjects were required to come to a rapid unmeditated judgement about the meaning of short musical excerpts. Although music can have immediate emotional impact, there is nothing in Cooke's thesis which demands that it should be the *tonal* element of music which alone carries this impact.

I have chosen to discuss Cooke's ideas at some length because they seem particularly clear and simple. Once we accept the general idea of analogical relationships between music and extra-musical domains, however, the possibility for other ways of expressing meaning are immense. I have already outlined one possible 'meaning' of Schenkerian structures in section 3 of this chapter. Many other possibilties suggest themselves. For instance, one may wish to find in symphonic form some metaphor for human life. The transformation or metamorphosis of theme parallels the changes we experience in ourselves and our ideas. The unification of diverse themes within a coherent structure parallels our attempts to endow our chaotic lives with meaning. And so on. This is, surely, part of the power of music, and this power is possibly enhanced by the manifest lack of practical meaning of the type supported by language. Musical semantics is of a similar type to poetic semantics. This does not mean that either subject is necessarily opaque to scientific understanding, but that we may be mistaken to seek for musical meanings in the same way as psychologists have so far attempted to elucidate the semantics of normal speech.

I would like to end this section by commenting briefly on the work of the noted American musicologist, L. B. Meyer (1956, 1973). He has made a distinction between two forms of meaning in music, *embodied* meaning, and

designative meaning. Designative meaning is that which refers outside the music to objects or events in the non-musical domain. We have been primarily concerned with designative meaning in this section. Embodied meaning, in contrast, is the significance that a musical passage can have for a listener in terms of its own structure and the interaction of that unfolding structure with the listener's musical knowledge and expectations. The musical structure can create certain expectations (or implications) which it can then either fulfil or thwart. Among those which are fulfilled, some are fulfilled at once, others after a delay. This creates a dynamic flux of tensions and resolutions which can influence the emotional and aesthetic responsese of a listener.

Like Cooke's theory, Meyer's requires that a listener represents the music he hears in terms of the tonal and other formal categories of the musical culture. It is, however, a broader theory than Cooke's, in that it gives an explicit semantic role to large-scale musical structures, whereas Cooke concentrates on small melodic patterns. Meyer's approach also shows how the same melodic pattern could have quite different meanings in different contexts according to whether or not it fulfilled implications of earlier material. Because the theory is broader it is also more difficult to bring into the laboratory, and I know of no empirical research which bears directly on Meyer's central ideas. This is a shame because he is clearly one of the most influential and psychologically well-informed of contemporary musicologists. I shall give some examples of Meyer's notions of melodic implication in Chapter 5, but would recommend Meyer's (1973) book to anyone who is seriously interested in musical semantics.

2.7. Conclusions

I hope that the diverse topics reviewed in this chapter have shown that it is fruitful to consider music in relation to language. It allows us to notice fundamental similarities (e.g. the Chomsky–Schenker parallel) but also highlights differences in an illuminating way. For instance, the fact that categorical perception in music is not so complete and automatic as it is in language raises productive questions for future consideration. What is it about the two systems which makes for the difference? The fact that a generative grammar for music seems to be a less realizable goal than for language forces us to consider the fundamental differences in aim of linguistic and musical communication. In the process, our perception of both domains is sharpened.

The linguistic analogy is neither 'true' nor 'false'. Like all analogies, it achieves a partial fit with its subject. The 'true' element which I would like to emphasize most strongly is the notion that we represent sequences of individual elements by assigning theme roles in abstract underlying structures, some of which, particularly those with hierarchical organization, have strong family resemblance to one another. It is the relationship of elements

to one another within these structures, rather than their temporal or spatial proximity that determines whether or not they are psychologically close. In the following chapters we shall not explicitly pursue the analogy further, but we shall find that the aspects of musical cognition emphasized by the analogy have profound and detailed implications for every musical activity we examine.

3. The performance of music

3.1. Introduction

In its broadest sense, performance covers the whole range of overt musical behaviour. A little child's improvised play-song, the humming of a popular melody, participation in corporate ritual such as hymn or folk singing, and dancing to music, are just some of the diverse modes of performance which merit psychological study. In a narrower sense, though, a musical performance is one in which a performer, or a group of performers, self-consciously enacts music for an audience. In our Western culture, such music is often written by someone not directly involved in the performance. The performers *realize* a pre-existent composition.

In this chapter I shall concentrate on performance in this latter narrow sense. There are several reasons why I do this. Firstly, most of the contemporary research is about this type of performance. Secondly, I shall wish to treat instances of performance where the performer is also the originator of the music (improvisation) as a special case of composition, and so reserve discussion of it for Chapter 4. Music of non-literate cultures is discussed in Chapter 7, and some aspects of children's musical behaviour are examined in Chapter 6. Thirdly, in performance of a 'composition', there is an objective record of the composer's intentions, usually in the form of a score. Without such a record we have no easy way of characterizing a piece of music independently of a particular performance of it, and so questions such as how *well* a performer realizes the music become very hard to answer.

There are three main stages of involvement with a musical score at which we can study performance. First is the unpremeditated performance which a musician is capable of providing at first sight of a score. This is commonly known as sight reading. Second are the performances generated over a period of repeated exposure to a score. Usually the aim of such performances is to improve performance until it reaches some criterion of adequacy, because sight reading does not often produce a totally satisfactory performance. This type of performance is known as rehearsal or practice. Finally comes the more-or-less finished product of rehearsal, a polished performance which may well involve total memorization of a score. This we will call expert performance, although it must be pointed out that some musicians can perform much music well without extensive rehearsal. Good sight reading (and indeed, good rehearsal) are forms of expertise in their own right.

3.2. Sight reading

Almost all of our reading of language is sight reading. Unless we are trying to memorize a text or are scrutinizing it for some professional purpose, we tend to read a text just once, and we expect that to suffice for our purposes. In contrast, many musicians find fluent sight reading very difficult, and brave indeed is the performer who would step on to the concert platform with no preview of his material.

Part of the explanation for this difference may be that whilst the fluent sight reading of language is necessary for a full life in our culture, the same is not true for music. Enormous educational effort is expended on getting children to a state in which their language reading is reasonably fluent. On the other hand, it is not necessary for children to be able to sight read well for them to succeed at conventional musical tasks, most of which allow for, even assume, intensive rehearsal. Thus, music sight reading is taught neither so rigorously nor at such an early age as language reading.

There are other factors too. Children are already fluent language users before they learn to read. They are rarely such fluent music performers. Most children learn a new music performance skill, such as playing an instrument, *alongside* learning to read music. This double task can be an intolerable burden which many solve by memorizing each new piece at the soonest opportunity so that their performance does not depend upon their reading ability. The result of this is that some musicians give themselves very little practice at continuous reading. Some modern educational techniques attempt to circumvent this problem by giving opportunity to acquire some performing skill before introducing music notation (e.g. the Suzuki method of violin teaching).

Finally, and perhaps most importantly, there is a sense in which the *criteria* for successful language reading are more lax than those for music reading. For most purposes it is sufficient, in language reading, to determine the practical meaning of the text. Much reading is silent, and even when spoken, often little more is required than the ability to utter the correct words in the correct sequential order. In contrast, music reading requires the execution of a complex response where there is very little latitude for deviations in timing and quality. The only linguistic task whose performance demands would approach the musical task is the recitation, at sight, of some piece of fine literature, incorporating all the nuance of voice, expression, and timing which one would expect from a first class actor.

The question which many musicians ask is 'what makes a good sight reader?' This question includes two separate concerns—firstly, what can be said about the characteristics of the fluent sight reader—and secondly, what must a poor reader do to become fluent? It is an unfortunate but unavoidable fact that a reasonably comprehensive answer to the first question does not necessarily lead to prescriptions for the second. For instance, the finding

that fluent readers typically look further ahead than poor readers does not automatically yield the prescription that poor readers should practise looking further ahead. It may well be that increased ability for preview is the result of some other skill, such as the ability to detect pattern or structure in the score, and that simply trying to look ahead will not improve *this* skill. Therefore, whilst it is important that psychologists should try to to make prescriptions about the techniques for acquiring a skill, the enterprise involves many separate and complex issues. I shall discuss some of them in Chapter 6. Here my primary concern will be with the characteristics of performing skill, regardless of how the skill may be acquired.

3.2.1. *Eye movements in reading*

The first overt behaviour in any reading situation is the movement of the eyes over a page to expose succesive portions of the material to central vision. It is only centrally that we have the acuity to register precise details of visual material (although work on language reading, e.g. Rayner 1978, demonstrates the importance of peripheral information in the guidance of eye movements). At normal viewing distances the area of clear vision is a circle of approximately one inch diameter on the page. The mechanisms of the eye movement system operate to give the reader a series of brief 'snapshots' (known as fixations) of such circles. In fluent reading the duration of each fixation is about 250 ms (a quarter of a second) and the eye moves from one fixation to another in a rapid sweep known as a saccade, lasting about 50 ms. The available evidence suggests that we take in visual information only during the static fixations and not during saccadic movements.

The question of primary psychological interest is how the reader controls the sequence and location of fixations. The simplest hypothesis we could entertain is that eye movements are controlled by low-level features of the input. For instance, fixations might occur in regular left-to-right order, each fixation occurring a constant distance to the right of the previous fixation so that the complete text is fixated over a complete sequence. Such neat regularity is, however, hardly ever observed, either in language or in music. Instead we find vertical as well as horizontal displacements, leaps which omit significant areas, and varying amounts of backtracking.

It is possible that some of these deviations are simply random movements of a system over which we have imperfect control. However, a large body of recent research on eye movements in language reading leads us to reject this view. Instead, it appears that the irregularities in eye movements are under immediate cognitive control. Take, for instance, the eye movement pattern in the vicinity of a very common word such as 'the' (O'Regan 1979). Typically readers do not fixate a 'the' directly and their saccadic movements over this word are larger than average. It seems as though linguistic knowledge interacts with peripheral information to allow an identification in the absence of a direct fixation. The eye-movement control system immediately responds

by 'jumping' over the word it does not require to fixate. This is just one piece of evidence which contributes to the accepted view that moment-to-moment variations in the fixation sequence are motivated by the precise cognitive requirements of a reader at a particular time. The pattern of eye movements thus tells us something about these requirements.

Eye movements in music reading have not received the intensive study that has been given to eye movements in language reading. Nonetheless, the evidence that exists is consistent with the language data. For instance, studies by Weaver (Van Nuys and Weaver 1943; Weaver 1943) on piano readers show that the sequence of fixations is determined by the nature of the music. Piano music is written on two staves, so that it is impossible to view all the notes to be played together in a single fixation; one must fixate first upon one stave, then upon the other. One might imagine that the optimum strategy for reading would be a vertical sweep down (or up) the system, followed by a shift to the right and a further sweep [Fig. 3.1 (*a*)] Weaver found that this pattern was indeed used when the music was homophonic and chordal in nature. When the music was contrapuntal, however, he found fixation sequences which were grouped in horizontal sweeps along a single line, with a return to another line afterwards [Fig. 3.1 (*b*)]. Figures. 3.1 (*c*) and 3.1 (*d*) show examples of fixation patterns obtained by Weaver. Figure 3.1 (*c*) is from a chordal passage, whilst 3.1 (*d*) is contrapuntal.

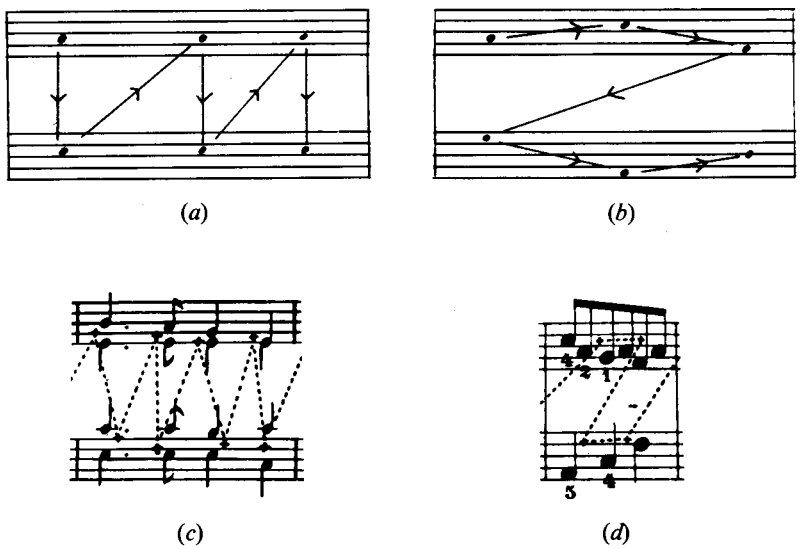


Fig. 3.1. (*a*) Vertical fixation sequence in piano reading. (*b*) Horizontal fixation sequence in piano reading. (*c*) Example of observed fixation sequence in chordal piano music (from Weaver, 1943). (*d*) Example of observed fixation sequence in contrapuntal piano music (from Weaver, 1943).

The general strategy appears to be to identify significant structural units in successive fixations. In homophonic music these units are chords, and so it is necessary to sample both staves in successive fixations. In contrapuntal music the significant units are melodic fragments which extend horizontally along a single stave.

How does such a fixation pattern help the reader? The available evidence suggests that readers require *preview* of structural units in a text if they are to organize fluent and rapid performance. Studies summarized by Shaffer (1976) illustrate this rather well. He examined the behaviour of experienced copy-typists under conditions of controlled preview. Texts were displayed on a computer console. Each time the typist input a character on a keyboard three things happened: all the characters displayed were shifted one space to the left; the leftmost letter disappeared; and a new character appeared at the right of the display. The crucial independent variables were the number of characters displayed at one time, and the number of characters on the screen that had not yet been typed. This latter variable could take any value between a single character and a whole line. It was discovered that if a typist was able to see at least eight characters ahead, performance was indistinguishable from the normal situation with unlimited preview. As preview was decreased, however, performance slowed and became less regular. With preview of eight characters the typing speed was about ten characters per second. With preview of a single letter this dropped to about two characters per second. Shaffer found that it was also possible to slow speed by leaving preview in normal range but manipulating the text. First he randomized word order; this had virtually no effect on performance. Then he randomized letter order within words; this had a highly significant effect, causing speed to drop almost as low as with single letter preview. We can draw quite a firm conclusion from this elegant study. Typists require to preview a whole word, but no more, in order to achieve fluency. It appears that seeing a word in advance allows them to plan a set of partially overlapping hand and finger movements into a single co-ordinated unit.

No-one has yet published experiments with controlled preview in music, although the rapid development of computer music systems (e.g. Tucker, Bates, Frykberg, Howarth, Kennedy, Lamb and Vaughan 1977) makes such studies increasingly more feasible. However, it has been possible to estimate the extent of preview in normal performance by the modification of a technique developed for measuring what is known as the *eye–voice span* in language reading. The technique (as used, for instance, by Levin and Addis 1980, and Levin and Kaplan 1970) involves asking subjects to continue reading out a prose passage *after* the text has been unexpectedly removed. The distance between the word being uttered at the time of removal and the final correct word uttered provides an estimate of the extent of preview. In normal reading situations the eye-voice span of an experienced reader is four to six words. I have modified the technique for instrumental music reading, by

asking various instrumentalists to read single-line melodies at sight (Sloboda 1974, 1977a). When the score was removed, proficient readers could produce up to seven further correct notes. If these performers were looking only so far ahead as required to organize fluent performance, then we may conclude, with some confidence, that the units in terms of which fluent performance is organized are not typically larger than seven consecutive notes of a melody. This seems to be true for all instruments tested, and is not a result of constraints imposed by particular instruments.

Of some theoretical importance is the finding that measures of this *eye-hand span* do not always yield precisely the same result. Depending upon the particular note in the melody where the score is removed, the span can be larger or smaller than average. It appears that there is a tendency for span to coincide with a musically defined phrase boundary, so that a boundary just beyond average span 'stretches' the span, and a boundary just before average 'contracts' it. This strongly suggests that phrase boundaries mark the boundaries between effective performance units which tend to be assembled in an 'all or none' fashion. It also suggests that the typical musical phrase is not, in itself, this unit, because most phrases contain more than seven notes. We must suppose that there exists some principled way of dividing a phrase up into smaller units, analogous to words.

Just as in the typing study, manipulating the 'text' gives further clues to the nature of the performance units. When melodies lacked normal harmonic progressions, span decreased significantly. Similarly, obscuring the rhythmic divisions between phrases by the addition of passing notes also decreased span. It seems that the reader subdivides a phrase into performance units in ways dependent on the harmonic and rhythmic structure of the phrase, and that when cues to these structures are obscured, preview is not so useful, and cannot, indeed, be sustained at normal levels.

Comparison of good and poor music readers showed that poor readers have lower spans than good readers (three or four notes) even when the melodies were structurally straightforward. Poor readers seem to behave with 'normal' music rather like good readers with 'obscure' music. If the ability to maintain preview is dependent on the ability to isolate structurally defined units, then poor readers are less capable of doing this, even when the structures are clearly present.

Before leaving eye movements, it is worth commenting that performance units in music, whilst analogous to words in some respects, cannot be very like them. The English language contains a finite number of words, each defined by a set of letters in a particular order. It is quite feasible for a typist to know every one of these words, storing the unique typing pattern for each word in memory. There is no similar agreed 'dictionary' of musical patterns. It is quite possible for a melody to contain a novel combination of notes. On the other hand, there *are* certainly familiar recurrent configurations of pitch and rhythm in many melodies (such as scale and *arpeggio* pitch movements,

dactyllic rhythms, etc.) which a reader could learn to recognise as units. Thus, music reading probably involves *some* recognition of frequently occurring patterns, but this is likely to be supported by some more general strategy for organizing groupings of notes which can function even when the patterns are novel. One such strategy would be a grouping according to metre. A metrical unit is like a frame, which can be used to hold and describe a very large number of note sequences. The same frame can be applied repetitively to any metrically regular piece of music, bar by bar. Such units are, of course, easy to find in a score. Bars are marked by bar lines; smaller units are often marked by beams. An efficient 'default' grouping strategy would therefore seem to be—take the bar as the performance unit, unless it contains more than seven notes, in which case take the half-bar. Since musical phrases are normally defined metrically (as well as harmonically and melodically) then the observed 'phrase-boundary' effect would be consistent with such a strategy. Furthermore, a metrical organizer has one extremely useful feature—it incorporates a regular pulse by reference to which finger movements can be targetted, and by reference to which the next performance unit can be 'set up'.

In other words, such an organizer is an aid to fluency and pacing. Suppose, for instance, that the organizer being used is a four beat bar with the internal structure signified by Fig. 3.2 (*a*). Level A represents the whole bar, and, if we set a constant tempo, then the onset of each bar can be timed from a clock operating at this level. Organization of the performance of the subsequent bar can be paced against a countdown of the previous bar. An eye movement sequence must be terminated in time to provide the information for the next unit before the countdown reaches zero. Levels B to D represent a possible way of internally structuring the bar, using a hierarchic binary branching tree down to the quaver level. The bar marker generates timing for half-bar units; the half-bar markers generate timings for beats; and so on. Of course, the reader need not use such a deeply structured organizer as this; he could use a simpler two-deep hierarchy such as in Fig. 3.2 (*b*). Data reviewed later in this chapter (sections 3.2.3 and 3.2.4) favours the notion that experienced performers use an organizer more like 3.2 (*a*) than 3.2 (*b*). However, the general principle shared by any such organizers is that they specify *when* each note in a group should occur, so that the performer can initiate ballistic finger movements by reference to the countdown for each note.

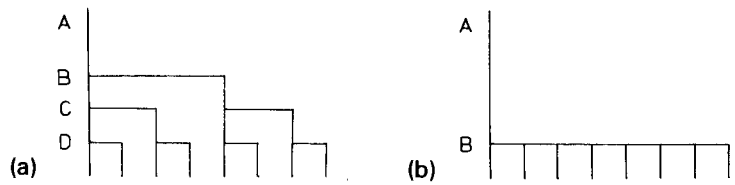

Fig. 3.2. Possible metrical organizers for performance.

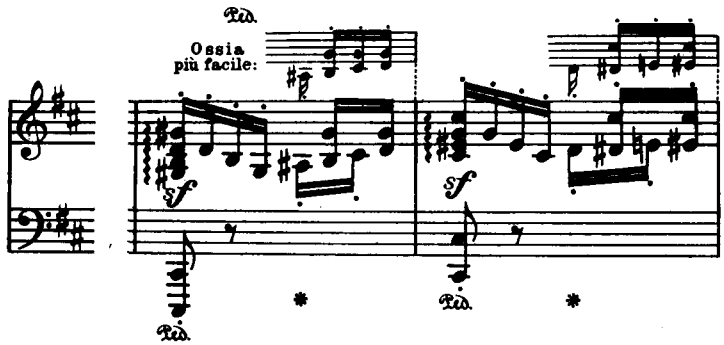
3.2.2. *Errors in reading*

Eye movements give useful information about the organization of music reading, but it is the performance itself which provides the most direct evidence of reading behaviour. A crude but nonetheless informative measure of reading performance is what one might call 'notational accuracy'—the extent to which a performer plays the correct notes at their approximate notated values.

In a classic study Pillsbury (1897) demonstrated that experienced language readers are prone to make misreadings which transform wrongly printed words into their correct form. For instance 'internalional' might be seen as 'international'. Under many circumstances these perceptual transformations are unconscious. Readers are not aware of the original stimulus; they believe they are seeing the correctly printed word. The received explanation for this phenomenon is that readers are able to identify words on less than complete information, given their knowledge of the spellings of words. For instance, if a reader of English identifies three letters of a four letter word as W–RK, he should be able to identify the word as WORK. There is no other word in the language that fits the available information.

When people read continuous prose they are even more susceptible to this kind of error than when viewing single words. This is because they now have an additional source of information—context. For instance, the sequence 'She raised her wine glass to her . . .' strongly suggests 'lips' as a continuation. It may not be necessary for someone to actually 'read' the word in order to 'see' it. In normally constructed text, such 'seeings' are usually correct. It is when text incorporates the unexpected that trouble can occur. The phenomenon of *proof-reader's error* is well known to psychologists (Vernon 1931). This is the failure to detect spelling or typing errors when scanning through a typescript. The proof-reader makes unconscious inferences which restore the incorrect words to their correct form, and so the errors are not detected.

By deliberately manipulating texts and introducing errors we can learn something about the nature of the inferences which expert readers make. For instance, readers are more likely to spot misprints if they occur at the beginnings of words than elsewhere (Haber and Schindler, 1981; Sloboda, 1976b). People are more likely to overlook spelling errors which are visually similar to the correct form (Healy 1980).



Proof-readers' error also occurs in music. Wolf (1976) quotes a striking example of such error from the experience of a professional pianist/teacher, Boris Goldovsky:

> A student whom Dr Goldovsky describes as 'technically competent but a poor reader' prepared a Brahms *Capriccio* (Op. 76 No. 2) which she brought to her lesson. She began to play the piece through but when she arrived at the C sharp major chord on the first beat of the bar 42 measures from the end, she played a G natural instead of the G sharp which would normally occur in the C sharp major triad. Goldovsky

told her to stop and correct her mistake. The student looked confused and said that she had played what was written. To Goldovsky's surprise, the girl had played the printed notes correctly—there was an apparent misprint in the music.

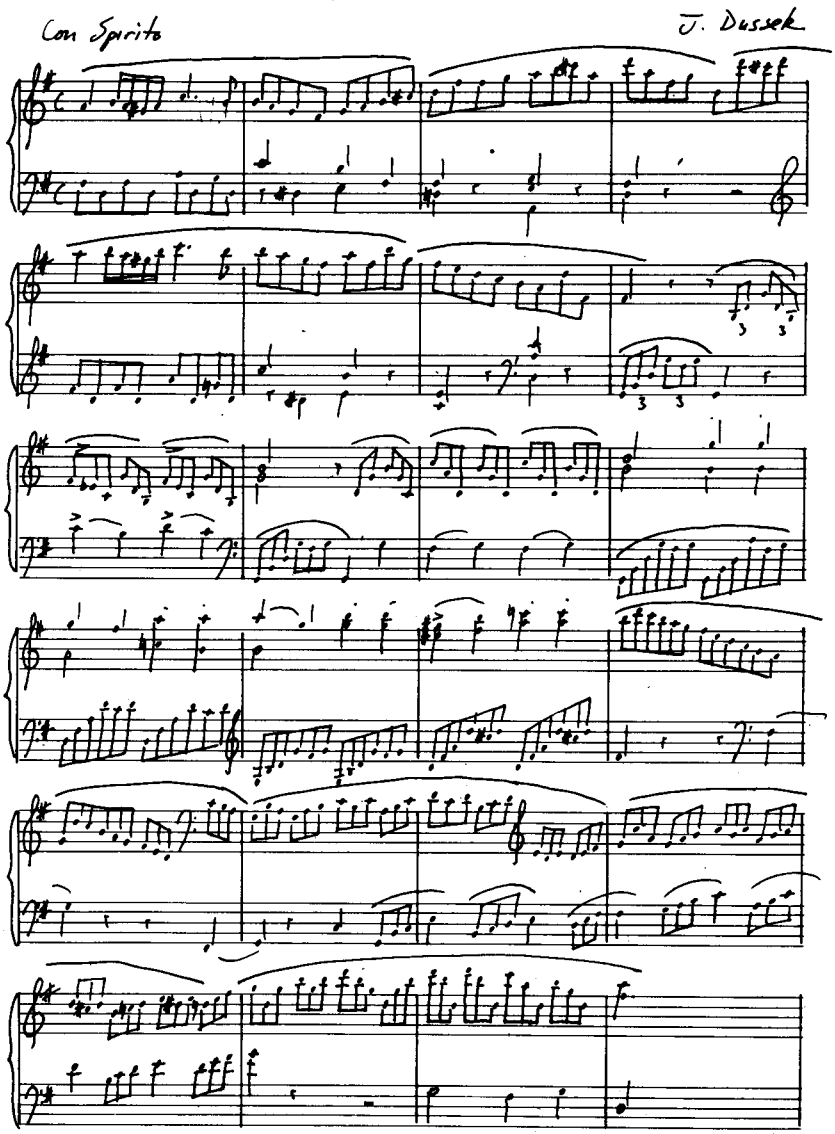
This misprint occurs in most standard editions of Brahms' piano music. It appears, therefore, that many hundreds of musicians had never noticed the misprint. Goldovsky proceeded to test skilled readers by telling them that the piece contained a misprint which they were to find. He allowed them to play the piece as many times as they liked and in any way that they liked. None of them ever found the mistake. Only when he specified the bar in which the misprint occured were most readers able to spot it.

It is easy to understand why this misprint was so hard to detect. But for the misprint, the bar in which it occurs is an almost exact transposition of the previous bar. The underlying harmonic movement is the very common V–I (from G sharp to C sharp) over a C sharp pedal. In addition, the notation in the previous bar has already 'set' the G as a sharp. There are thus multiple and powerful cues for a knowledgeable reader to interpret the crucial G as a sharp (see Example 3.1).

Example 3.1. Bars 76–78 from Brahms, Capricio, Op. 76, No. 2. Reprinted by kind permission of Peters Edition Limited, London

What is important to note about this story is that it was a relatively *poor* reader who was the first to uncover the error. Because she did not have the expectations of more accomplished players she required more information from the score to determine her performance, and so, paradoxically, read more accurately than more accomplished players.

This demonstration, although striking, is anecdotal, and one of my own experiments (Sloboda 1976b) was designed to verify the phenomenon under laboratory conditions. Example 3.2 shows one of the stimulus pieces used in the experiment. It is by the eighteenth-century composer J. Dussek. The musically literate reader is invited to attempt a sight performance of the piece (preferably tape-recording it for subsequent examination) according to the following instructions, which approximate to those given to my experimental



subjects: 'Please sight read this short piano piece at your own pace. Attempt to play exactly what is written, but do not stop if you make an error. Do not extensively preview the piece but start playing within five seconds of looking at the page. You may begin now.'

The stimulus materials were prepared by taking little known keyboard pieces by minor classical composers and rewriting them with deliberate notational errors. The errors had two characteristics. Firstly, they involved a shift in the notated pitch of one step on the stave, leaving all other features (accidentals, rhythm, etc.) unchanged. Thus a notated quaver on B flat might become either a quaver on C flat or on A flat. This had the consequence that the visual appearance of the error was very similar to that of the original. Secondly, they were chosen to be musically inappropriate in their contexts. This could be either by creating a dissonant harmony or by violating normal melodic progression. The errors were judged as 'blatant' by musicians. This is particularly important since there are no definite dividing lines between what is acceptable in music and what is not. There is always a grey middle area where the unexpected may in fact be a legitimate violation of norms which extends and transforms style rather than simply being a mistake. The errors chosen for this experiment were well outside such grey areas. They were downright wrong.

The results of the experiment were quite clear. All subjects tested showed 'proof-reader's error'; that is, they played some altered notes as they should have been rather than as notated. This was even though no subject was familiar with any of the test pieces, and in spite of the fact that every subject 'tumbled' the point of the experiment by noticing *some* of the deliberate errors.

Example 3.3 identifies the 'misprints'. The notes which I altered are ringed. It can be seen that the errors are distributed equally between upper and lower staves. They are also distributed within musical phrases. One third of the errors occur at the beginning of a phrase, one third in the middle, and one third at the end. Table 3.1 shows the proportion of altered notes which were restored to their originals by the subjects, for each stave, and for each position within the phrase. The data for the upper stave (containing the primary melodic material) are strikingly similar to those obtained with words. Alterations in the middle of phrases are more likely to be restored than those at beginnings or ends. We may, therefore, argue that phrases form psychologically effective units such that the reader's attention is concentrated on the material occurring at phrase boundaries, and that some form of inference allows the reader to economize on input from intermediate positions.

A further striking feature of the results is the pattern of errors in a second performance of the test pieces that subjects made. As one might expect, their performances improved, as shown by a significant drop in the total number of performance errors. This shows that they had learned something about the pieces from their first performance. However, the proportion of proof-

Example 3.2. Material from Sloboda's (1976b) sight reading study.

readers' errors did *not* decrease. On the contrary, it *increased* slightly. This suggests that, as they gained a firmer hold on the structure of the pieces, they became *more* likely to infer the expected notes. Clearly, at this early stage in learning, subjects were beginning to store the music, not only in terms of individual notes, but also in terms of higher-order structures. This ability is clearly a hallmark of skilled reading.

It is relevant to ask whether musical proof-reader's error occurs for other performers than pianists. Keyboard music presents particular difficulties precisely because it is on more than one stave, and because several notes are often to be performed simultaneously. Most other instruments are capable of playing only one note at a time, and the music is presented on a single

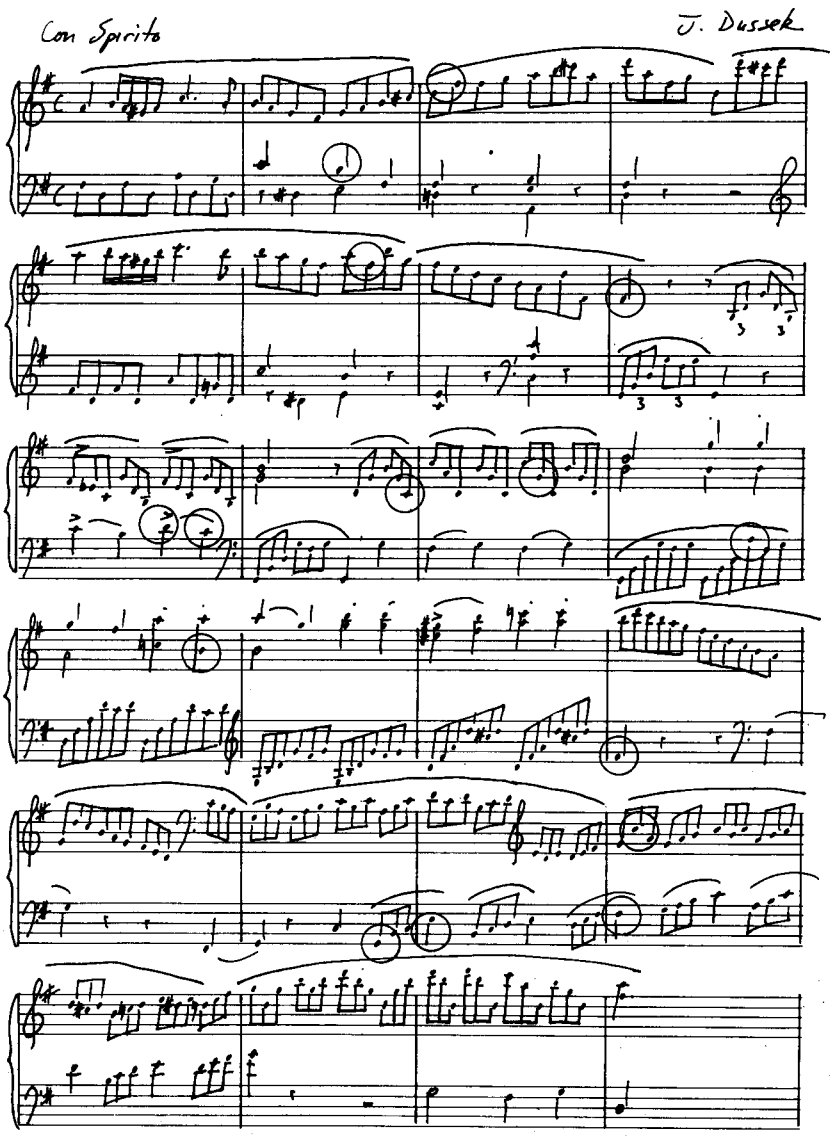


TABLE 3.1
Number of errors on altered notes at each position in phrase

Subject	Beginning	Middle	End
	Upper stave		
A	7	19	12
B	5	10	4

Mean	9.0	9.3	6.6
%	42	43	31

stave. The 'real time' demands are, therefore, reduced, and inference may be less necessary. This issue has not yet received experimental investigation.

Because it is relatively difficult to induce errors in normal skilled reading, many language investigators have degraded the visual stimulus in some way to make perception more difficult. The most fruitful way of doing this has been to expose portions of text for very brief durations, less than a single fixation. By varying the exposure duration we can learn something about the time-course of information pickup.

I have applied this approach to music in a series of experiments (Sloboda 1976a, 1978) where varying numbers of pitch symbols were displayed briefly on staves for subjects to write down. The advantage of this technique is that

Example 3.3. The material of Example 3.2 with altered notes ringed.

it allows comparison between musicians and non-musicians, since the pitch transcription task is one which non-musicians can easily carry out as straightforward visual copying. Figure 3.3 gives examples of the kind of stimulus material used. Subjects were supplied with blank staves on which to write their responses, which they were allowed to do immediately after the end of the brief exposure. Exposure durations varied from 20 ms up to 2 s.

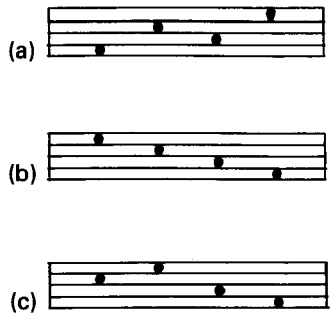

Fig. 3.3. Examples of stimulus materials used by Sloboda (1978).

At the briefer exposures (up to 100 ms) both musicians and non-musicians were very poor at recording the position of notes accurately. They were rarely able to record more than one note correctly. However, when forced to guess all the notes in a display, musicians were significantly better than non-musicians at retaining the approximate *contour* of the original. If one note was higher than its left-neighbour in the stimulus then it tended to be recorded as higher in the response, even though it may not have been placed on the correct stave-line. The ability to retain contour was particularly good when the contour of the original was a straight ascending or descending line [Fig. 3.3 (*b*)] or contained only one change of direction [Fig. 3.3 (*c*)].

We may suppose that durations below 100 ms are just too short for the visual processing mechanisms to gain accurate positional information about the notes, but that more global information about the shape of the note contour is available. This accords with data from other visual experiments (e.g. Massaro and Klitzke 1977; Navon 1977). What is of particular interest here is that the ability to use contour information seems to depend on musical experience. The music reader seems primed to store information about scale or *arpeggio*-like patterns in particular, and this suggests that such information is used in normal reading. This may be because such patterns are usually associated with a stereotyped finger and hand-movement pattern, so that rapid early identification allows advance motor planning. if one can accurately identify just the first note of such a pattern, and one has some contextually supplied knowledge of the harmonic structure at that point, then identification of the contour may be enough to uniquely specify the required action.

As the exposure duration was increased, both musicians and non-musicians increased in their ability to record the notes accurately. However, non-musicians' performance peaked at about three notes, whereas musicians were able to record six notes from a single exposure. This difference remained even at exposure durations of 2 s when there could be no *visual* problems for either group. The superior performance of the musicians is due to their superior *retention* of the stimulus material. They have means of coding and

storing the notes (as music) not available to the non-musicians, who have to remember the stimuli as purely visual patterns.

A partial clue as to the nature of the musicians' coding comes from an experiment by Halpern and Bower (1982). Using a similar technique to mine they varied the harmonic structure of the stimuli. Half of their stimuli were 'good' melodies, following normal rules of harmonic and melodic progression. The other half were 'bad', designed to violate as many musical conventions as possible. They found that musicians performed better with 'good' melodies than with 'bad', but that non-musicians showed no difference between the two types of melody. Clearly, music-specific knowledge was responsible for the advantage enjoyed by 'good' melodies with the musicians. These melodies could be coded into higher-order structures, thereby reducing memory load. However, even on the 'bad' melodies musicians retained a large superiority over the non-musicians. So structure is not the whole story. In my own experiments, many of the stimuli were randomly generated, and so 'bad'. This did not prevent musicians from showing massive superiority over non-musicians. This is rather different to the outcome in Chase and Simon's (1973) classic chess experiments. Here, masters reproduced 'bad' chess configurations as poorly as novices.

One possible reason for this difference is that the music stimuli are far simpler than the chess stimuli. They contain fewer elements distributed over fewer possible positions. Each pair of adjacent notes will have some musical meaning *whatever* their positions. A random sequence of six notes can always be represented as three pairs of notes, each encompassing a common musical interval, so that it is always possible to impose *some* musical structure on the sequence. Another reason concerns differences in experience at the specific task. Although chess masters have undoubtedly spent longer looking at chess positions than have novices, they probably have not had more practice at recording chess positions from memory. In contrast, skilled music reading involves the continuous performance of short sequences of music from memory, and musicians have developed specialized mechanisms precisely for this task that novices will not possess. One could predict that if a chess master devoted considerable effort to developing memory reproduction skills for chess positions, he would soon develop superiority over novices even for 'random' boards.

3.2.3. *Expressive aspects of sight performance*

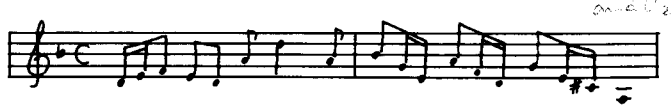
Although errors of reading can reveal something of underlying psychological processes it is often difficult to induce skilled performers to make *any* errors without experimental intervention. By error, in this context, we mean a performer playing the wrong note or making gross errors in timing and rhythm. If skilled performance is error-free, how can we get behind such performance to understand the psychological mechanisms which control it?

One possibility is to ask skilled sight readers what they do. Wolf (1976)

interviewed four expert sight-readers, and although they produced some insightful remarks it is hard to know whether these remarks are more than informed rationalizations about largely unconscious and automatic processes. For instance, they displayed uncertainty about how much music they took in at a single fixation, or how far ahead they looked. One performer, when asked what problems he experienced in sight reading, simply replied 'for me personally, there are none.'

A different approach, pioneered by Seashore (1938) but first applied to sight reading by Shaffer (1980) is to record accurately the microstructure of a performance; the minute variations in touch, timing, and intensity that characterize any human performance. In some cases, these variations may be relatively uninteresting; random fluctuations due to noise in the system (such as limits in the acuity of feedback mechanisms, muscular tremor, lapses of attention). In other cases, however, the variations can be shown to bear systematic relation to structural features of the music.

This is particularly important to our understanding of sight reading in situations where there are no explicit instructions in the score to make variations in touch and timing. Consider a Bach fugue, for instance. Bach generally supplied no dynamic markings, touch, or phrasing instructions. The only explicit information given, in addition to the notes themselves, concerns the tonality (signalled by the key signature) and the metre (signalled by the time signature and the barring). It would be quite inappropriate, however, for a performer to consider that each note should be played in the same way. Such a 'dead-pan' performance, whilst technically error-free on our prior definition, would not be considered musically effective.



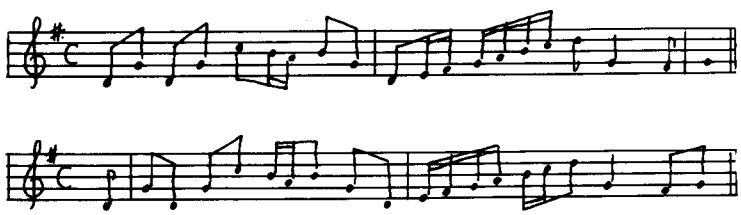
Even inexperienced performers soon become aware that their performance must be expressive. Too often, though, this can mean a haphazard application of timing and intensity changes plastered at will over the music. One simple test of how principled a performer's expressive playing is is to ask him to provide two consecutive performances of a relatively unfamiliar piece. If he is able to provide very similar expressive changes on the two occasions, in the absence of explicit score instructions, then we can infer the existence of some rule-based system for assigning variation to his performance. We can rule out the possibility that such performance details simply demonstrates good memory for the details of the first performance. As Shaffer (1981a) argues,

> the pianist could not memorize this amount of detail: musicians are no better than anyone else at remembering arbitrary analogue information, and Eric Clarke, at Exeter, has demonstrated this by asking pianists to reproduce short melodies they hear, containing timing deformation in a single pair of notes. Almost inevitably the pianist bends the deformation in the direction of a notatable rhythm. Hence the pianist playing Bach could only make consistent use of expressive variation across performance by having an expressive grammar with which to construct the variation according to features in the music.

Shaffer has provided evidence from two consecutive performances at sight of a Bach fugue (*Well-tempered clavier, Book 2*, Fugue 7) by an experienced pianist. A grand piano was linked to a computer in such a way that information about the precise duration and intensity of each note played could be stored (for details see Shaffer 1980). The subject had not played this particular fugue for many years; and following the first performance he was asked to play the fugue again with no instruction to play it the same or different. Shaffer found similarities in expressive performance at many levels. For instance, *within* bars the ranked intensity of individual notes tended to be the same for the two performances. Some notes were given accents on each performance even though the score did not specify this. On a larger scale, increases and decreases in the duration of bars showed a remarkably similar pattern.

What type of rules govern the assignment of expressive variation? Long-term variations, such as gradual changes in speed or intensity, are directed by relatively large-scale aspects of musical structure which often require the performer to appreciate and remember thematic landmarks in the music. For instance, a sequence repeated at increasingly higher pitch can signal the approach of a climax, and an appropriate response is often to increase the intensity for each repetition of the sequential pattern. This requires the reader to spot the pattern, and then visually recognize that what is about to be played is a further continuation of the pattern. At the other extreme, variations occuring within a bar (especially at the beginning of a piece) are unlikely to be determined by the large-scale structure of the piece, and so do not rely on an appreciation of this structure. The variations are linked to the microstructure of the music, the relative importance of the various notes within a bar. One fundamental aspect of this microstructure is the metrical organization, and it is on this aspect that I wish to concentrate.

As discussed in Chapter 2, section 5.4, there are two ways in which a listener can determine the rhythmic parsing for a section of music. On some occasions the patterning of pitches and durations suggest a particular grouping, so that if the performer plays the correct notes for the correct approximate durations, the metre can be determined. On other occasions, however, the patterning of the notes will not suggest a single interpretation, or may even be misleading. An example which caused me some perplexity on first hearing is the opening of Bach's *Clavier Concerto* in D minor (Example 3.4). I took the first two notes to be an upbeat, giving notes 3 and 7 as the major stresses. This intepretation is consistent with the rule that long notes generally denote major stresses. Of course, the correct parsing puts the



Example 3.4. From J. S. Bach, Clavier Concerto in D minor, First movement.

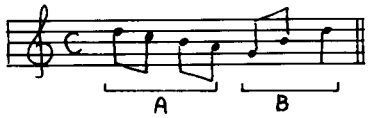
major stresses on notes 1 and 6. I believe that the only way to guarantee that a listener parses this correctly on first hearing is for the performer to make appropriate expressive variation of a magnitude sufficient to overcome the tendency of a listener to mis-parse.

Using Shaffer's laboratory, I have recently attempted to provide evidence about the use of metrically related variation in piano sight-performance. The basic technique was to present a metrically ambiguous melody under two notational conditions in which bar lines and beams were shifted along the melody, keeping note values and fingerings the same (see Examples 3.5. and 3.6). This is a crucial control, because observing the performance of a *single* notated melody would not be enough to demonstrate that variation was related to notated metre. It might also relate to the precise patterning of pitches and durations, and the fact that different notes use different fingers, etc. In this paradigm we have two melodies whose note and finger patterning are precisely the same. All that differentiates them is the positioning of metrical stress. Therefore, systematic differences in expressive variation *must* be a result of the shift in metre.

Pianists were asked to provide five faultless and similar performances of each of Examples 3.5 and 3.6 at sight. These examples were embedded in a larger number of short melodies, and no subject noticed the fact that the two melodies were, in fact, identical. Each set of five performances represented the spontaneous response to each melody in isolation.

Examples 3.5. and 3.6. The melodies used in Sloboda's (1983) study.

A note-by-note analysis of the differences in timing and intensity (see Sloboda 1983, for full details) showed there to be many significant differences between the performances of the two melodies. For instance, five out of the six pianists played the first bar of Example 3.5 in such a way that note 5 was more legato than its predecessors. In Example 3.6, however, note 5 received no special treatment. This is one example of what emerges from the data as a 'half-bar' effect. The subjects used a variety of devices to differentiate the note immediately following the half-bar (and so falling on the third beat) from its predecessors. These were essentially either an increase in intensity, or an increase in legato touch, or a slight delaying of the onset of the following note, or a combination of these. Individual differences were apparent in the nature of the choices made from these options.



The devices discovered will be of no surprise to performing musicians,

corresponding roughly as they do to notions of *accent*, *slurring*, and *tenuto*, respectively. However, the fact that pianists can deploy these devices at sight shows that they are cued rapidly and fairly automatically from a first inspection of the score. Since there are no explicit notational cues which mark the half-bar, the performance variations must arise through some analysis of the notes which assigns them to structures in which the third beat of a four-beat bar achieves special prominence. Of course, the first beat of each bar is also given special treatment in performance, but there is an explicit notational cue here, the bar line.

These preliminary data leave us a long way from understanding the total process by which metrically related variations are assigned to a performance. The main problem is that a performer does not mark every stress, and when he does mark it he makes a choice from the available options, as well as deciding on the *magnitude* of the variations he chooses. We may suppose that individual performers develop 'styles' so that one makes more use of touch variation, another of intensity variations, and so on. Highly proficient performers may even be able to alter performance style at will within certain limits.

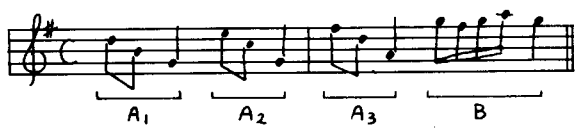
There is also the question of relating performance to perception. Expressive features of performance are useless unless they can be detected by listeners. Similarly, it is pointless to expend energy on achieving levels of performance accuracy (for instance, in timing or tuning) that cannot possibly be appreciated by listeners, because the performance resolution is much finer than the discriminatory powers of listeners. This area is one in which little research has been carried out. The principal problem is that one cannot simply use data from standard psychophysical measurements to make prescriptions for performers. Under 'ideal' conditions a listener may, indeed, be able to detect certain small differences in timing or tuning, but in the welter of a complex musical event discrimination may be much poorer. Experienced performers soon come to realize just how much they can 'get away with' in live performance. I have often been amazed, when listening to a recording of my own performance, just how unnoticeable were errors which, at the time of performance, struck me as catastrophic. Indeed, part of the art of sight reading is knowing which parts of the music will not be salient for a listener. One learns how to create an impression of accuracy in a performance that is actually far from faithful to the score.

We may view the process of assigning expressive variation at sight to comprise three major stages. First is the formation of a mental representation of the music, from examination of the score, which identifies features to be marked expressively in performance. For instance, a four-beat bar such as that depicted in Example 3.7 may be represented as two equal sub-units nested within the bar. To respond appropriately to a rising sequence such as that depicted in Example 3.8 more complex representations based on pitch and tonality need to be computed. The three-note pattern which repeats itself

Example 3.7.

three times at higher pitch suggests increasing intensity through A1, A2, to A3. A tonal representation of the scalar and cadential approach to the tonic will place B as the culmination of the sequence, and so suggest an intensity climax at B. The elements A1–3 and B also have internal metrical structure which, if represented, can provide the basis of expressive variation *within* each element. Since the first note of each element falls on a major stress within the bar it could be marked by a greater intensity than its neighbours. A possible intensity contour that could be derived from computing these multiple representations (scalar, tonal, and metrical) might be:

3 1 2 | 4 2 3 | 5 3 4 | 64445



where the numbers represent positions on an ordinal intensity scale. It is, of course, possible to represent a melody on only one of these dimensions and still produce *some* expressive variation. The dimensions can be computed independently. For instance, someone who computes only a tonal representation might assign the following intensity contour:

3 3 3 | 4 4 4 | 5 5 5 | 66666

whereas someone computing only a metrical representation might assign this intensity contour:

4 2 3 | 4 2 3 | 4 2 3 | 42223

There are, of course, further levels of representation which would take us beyond a single phrase such as Example 3.8 to place it in relation to other thematic material in a longer piece. Still confining ourselves to intensity variation, we may want to set the overall level for the phrase with respect to what has gone before or what is to follow. Let us suppose, for instance, that Example 3.8 was preceded by an identical two bar phrase in a longer piece.

Example 3.8.

We might, then, wish to represent Example 3.8 as an 'echo', in which case the entire four bar section might be assigned the following intensity contour:

6 4 5 | 7 5 6 | 8 6 7 | 97778 / 3 1 2 | 4 2 3 | 5 3 4 | 64445

in which the calibration for the second phrase is reset three intensity steps lower than the first.

We may hold it as a working hypothesis that the smaller the amount of music a reader has to preview to discover the cues for a particular representation, the more likely it is that the reader will form that representation. In much music, preview of one bar is the maximum required to form an appropriate metrical representation. The important metrical groupings fall within a bar's span. On the other hand, tonal progressions can span many bars, so that preview becomes less possible, and accurate prediction becomes the only way of making the right expressive decisions. As a performer becomes increasingly familiar with an idiom such prediction is increasingly possible, but all performers will experience times when they take a 'wrong view' of a piece of music peformed at sight. For instance, one may believe that a particular cadence is the resolution of a section, and so emphasize it through *crescendo* and *allargando*, only to discover that it is the penultimate cadence of the section—by which time one has 'spent one's last ammunition.'

The second stage in the expressive process involves gaining access to a 'dictionary' of expressive variations which are accepted as effective in communicating the structural markings which have been identified. In other words, we must assume a mutually agreed 'language' of expression between performers and listeners. It is possible that part of this language is based on relatively primitive mechanisms of auditory grouping in temporal sequences which all people share. For instance, a note which is louder than its neighbours will, all other things being equal, be heard as separate from them. Some of these mechanisms are discussed further in Chapter 5.2. Other aspects of the language are culturally determined, and depend on the shared musical experience of performer and listener (for instance, the use, in classical music, of an *allargando* to signal the final cadence of a movement). Paradoxically, it may be this second type of variation which is easiest for a performer to learn and apply, because it *is* a self-conscious product of a culture to be explicitly identified and talked about.

On the other hand, the small-scale moment-to-moment variations which make performances 'alive' are not so easy to describe. In listening to a master performer we experience his grasp of the *structure* of the music (i.e. we are enabled to form a representation of the music resembling that which dictates his performance) but we tend to lose the information about the precise means by which the form is conveyed. As we noticed earlier, people are very bad at remembering analogue information. In terms of metrical information, we may experience a very keen sense of metre through a good performance but be quite unable to say *why* the performance made the structure so transparent. This phenomenon is not confined to music. We find it anywhere that performing expertise is involved. A master can reveal to us the dramatic impact of a difficult monologue that is just dull and wordy in the hands of a lesser actor; but the general listener appreciates only the power of the

interpretation, not the precise means by which the power is achieved.

Performing expertise first requires analytic listening powers of a developed kind so as to be able to 'latch on to' the minute timing and intensity variations that make a master performance and then *imitate* them. In my own experience, and that of many musicians, there is no really satisfactory way of *describing* expressive variations in a way which allows one to incorporate them into one's own performance. Expressive techniques are passed from one musician to another by demonstration. That is why master musicians are nearly always passionately interested in hearing the performances of other masters. It is why good teachers *have* to be, in my view, good performers. I can recall occasions when my own teacher taught me more by *playing* the passage under discussion than by talking about it for many minutes.

If, however, performing expertise requires listening expertise, we are left with the problem of what allows a person to listen to, and store the kind of detailed information that most of us find so difficult to retain. As an instrumental teacher I have noticed very great differences between even quite young children in the ability to notice expressive variation in the performance of others. For many learners, teaching by demonstration is useless simply because they do not appear to pick up what is being demonstrated. Others are capable of immediate and accurate imitation and retention. I view this ability as one of the best predictors of high levels of musical achievement. It is unfortunate that the cognitive bases for it are not well understood.

The third stage in the process is what has often been referred to as 'motor programming'. This is the setting up of a sequence of commands to the performing muscles which will reveal in sound the expressive devices selected from the 'dictionary'. There are two important features of fluent behaviour which a theory of motor programming must account for. One is the fact that elements in a motor sequence overlap in time. When, for instance, a performer executes a scale passage, the second finger must already be moving towards its position before the first finger is released. Because the degree of temporal overlap is variable (depending, among other things, on the speed of performance), the second movement cannot be initiated on the basis of some cue from the first movement. This is one of the classic problems of serial behaviour outlined in Lashley's seminal (1951) paper, which has greatly influenced current thinking. The second, related, feature is that fluent motor behaviour results in specified *goals* being achieved rather than specified movements being carried out (Shaffer 1982). In terms of piano playing the goal of motor programming is to ensure that a particular note is begun at a particular time and played with a particular loudness. This will be achieved by different *movements* depending upon the preceding hand position and also by what must follow. Expert pianists may use different fingerings on two consecutive performances of a passage, yet achieve precisely the same sound each time.

These features emphasise the fact that skilled human performance is seldom a rigid movement sequence where each movement is triggered in an

inflexible way by the preceding movement, and forces us to realize that performance is the result of an interaction between a mental *plan* which specifies features of the intended output and a flexible programming system 'which has learned through experience to compute the patterns of muscle contraction that will achieve the goal (of producing the specified output) over a broad range of starting conditions' (Shaffer 1981b, p. 331).

This conceptualization accounts for many aspects of musical performance. For instance, it makes sense of the phenomenon of knowing exactly what a passage of music played at sight *should* sound like, but being unable to negotiate the correct notes. In this case the performer has formed an adequate plan of the music he is playing. In terms of my three-stage division of the process he has successfully carried out the first two stages; forming a structurally based representation of the music; and assigning expressive variation to elements of the representation by reference to an expressive 'dictionary'. The failure comes in getting the hands to do what he knows they should do. A common cause of this in my own experience of piano playing is miscalculation of an unfamiliar leap, or 'running out of fingers' in rapid passagework. At such points the expert sight reader can invent a new plan, consistent with the structural context, which he *is* able to program, so 'covering' his error with a plausible alternative.

The dissociation between plan and program also allows us to understand something which many teachers identify in their (otherwise musical) pupils as a 'failure to listen to themselves'. This typically occurs when a teacher criticizes a pupil for failing to make an expressive variation in a case where the pupil is convinced that he *did* make the variation. What could be happening here is that the pupil has formed a plan of the music where a particular note sequence is marked for expressive variation, but that the motor programming does not take account of the marking (or takes insufficient account for reliable auditory detection). The pupil bases his judgement that the expressive variation has occured on the basis of an internal monitoring of his *plan*, whereas the teacher is monitoring the *output*. The inability to monitor one's performance at the level of expressive detail is quite common, and not confined to music. Many people are unpleasantly surprised when they experience recorded versions of their own verbal or motor behaviour.

Finally, the dissociation helps to explain why two quite separate activities are necessary for the acquisition of high degrees of musical skill. On the one hand, a performer needs to listen to, analyse, and discuss, much music. These activities allow him to be able to represent music more fully; and provide him with richer plans. On the other hand, he also needs to indulge in many hundreds of hours of practice at his instrument. To a certain extent, the precise nature of what he plays is not important so long as it presents to the motor system the whole range of ballistic problems which will be encountered in the musical repertoire for his instrument. Only such practice will expose the motor system to the 'broad range of starting conditions' that will allow the

system to build up effective computation routines for solving programming problems rapidly and accurately in new situations. The pedagogic use of scales and studies has, therefore, a very sound psychological basis. They ensure that the learner is exposed to the whole range of programming problems in a systematic way.

The two types of activity described here can, of course, be carried out entirely separately, and this accounts for the existence of two common 'types' of musician. The first type is the musician who can play relatively simple music with the utmost sensitivity and has a profound critical appreciation of other people's performances, but falters when high levels of speed or fluency are required. Such a person tends to spend a lot of time involved with music but neglects systematic practice. He has a highly developed skill for representing musical structure, but his motor programming is inadequate to convert representations into sound. The second type is the musician who can tackle the most demanding pieces in the repertoire from the technical point of view, but often performs them insensitively. Such a person tends to spend hours each day at his instrument, diligently attending to scales and other technical exercises, but neglects to deepen his understanding of music through analysis and critical listening. He has a finely tuned motor programming system but possesses impoverished peformance plans on which the system can act.

The master musician, of course, combines excellence in both these separate skills. Fluent sight reading is, it can be argued, a prime example of a skill which demands both these sub-skills. One needs a high degree of representational skill to be able to rapidly construct an appropriate performance plan on the basis of visual information where relevant structural cues are often only implicit, and one needs a high degree of motor programming skill to be able to assemble a fluent motor sequence at an appropriate speed. If a selection panel for some instrumental award had only five minutes in which to examine each candidate, then I believe there are good arguments for devoting the whole of that time to an observation of a candidate's sight reading performance. There can be few tasks which demand as complete a musicianship.

3.3. Rehearsal

Most musicians probably expend the majority of their musical time and effort on rehearsal. The nature and quantity of rehearsal carried out is, therefore, likely to be the most important determiner of performing skill. However, we know almost nothing about the precise ways in which musicians of differing skill go about their rehearsal. The undoubtedly useful and insightful pedagogical literature (e.g. Buck 1944; Hughes 1915) is largely built upon informal observation and personal experience. From this wide body of experience we can glean certain generalizations. Firstly, many novices find it difficult to

rehearse in a productive manner (i.e. one that significantly improves performance). Their principal strategy seems to be to simply play through a passage again and again, hoping, as it were, that the mistakes will be 'ironed out'. Teachers and expert performers insist that more is required. Troublesome sections must be 'taken to pieces'. Secondly, experts insist that secure knowledge of a piece of music involves forming multiple representations of it. One of the principal problems facing moderate performers is the dissociation of the performance sequence from full conscious control. Each short section is cued by association from the preceding section so that when something goes wrong the performance cannot be rescued; memory simply 'dries up'. As a teacher, I have noticed that pupils often can gain entry to a memorized piece only at certain points. If they are stopped for discussion, they have to go back to one of the entry points to continue the performance. In contrast, experts insist that full knowledge of a piece of music entails the ability to start in at any point at will. The conscious mind should know what is coming next independently of what the fingers are doing. Achievements which experts advocate as a guarantee that a piece is properly learned include the ability to think a piece through away from the instrument, or to write it out from memory. Thirdly, most teachers acknowledge that rehearsal is transferable, so that each piece rehearsed lessens the rehearsal requirements for future pieces. Conversely, there are times when intensive rehearsal of a single piece fails to yield significant improvements. Some limit or bottleneck is reached which can only be overcome by moving on to other pieces and returning to the troublesome piece some months, or even years, later.

I wish to concentrate the substantive portion of this section around a study by Gruson (1981) which is, to my knowledge, the only recent attempt to look at musicians' rehearsal behaviour in a detailed way. Her subjects were forty piano students taking individual lessons and three professional concert pianists. Their experience was roughly assessed by noting the level of achievement on the local examination board's grading system. There are ten grades in this system which would bring a performer up to the level of proficient amateur, and each grade represents roughly one year's work on the instrument. The level of experience of the professionals was, of course, way off the top of this grading scale. Each subject was given three novel pieces, consistent with his or her grade level, to practise for 30 minutes. An audio-tape recording was made of each practice session; and then each recording was scored according to a detailed observational scale (devised by Joseph 1978). The choice of pianists as subjects was arbitrary. We have every reason to suppose that their general practising strategies are typical of musicians.

Taking all subjects together, Gruson found that uninterrupted playing accounted for about one quarter of the total practising time. The other most frequent occurrences were, repeating a single note (16.9 per cent), repeating a bar (16.7 per cent), slowing down (16.0 per cent), and errors (14.3 per cent). Of these behaviours, two (repeating a single note, and making errors) are

specifically warned against by many teachers as counterproductive. Repeating a single note is unhelpful, it is argued, because the aim of rehearsal is to build up fluent integrated performance units of several notes. Errors are unhelpful because they tend to reinforce inappropriate motor patterns; the ideal is to start by playing so slowly that errors are never made. At the other end of the scale, certain advocated rehearsal techniques almost never occurred among this group of subjects. Playing with hands separately occurred only 0.97 per cent of the time, and repetitions of sections larger than the bar occured only 2.6 per cent of the time.

To examine the differences in rehearsal behaviour between pianists of different levels Gruson performed two analyses. First she calculated correlation coefficients between the incidence of each behaviour category and skill level. There were four significant positive correlations. These were behaviours which increased in frequency with increasing skill. They were: repeating a section larger than a bar ($r = 0.72$), playing hands separately ($r = 0.49$), verbalizations ($r = 0.37$), and time spent practising each piece (as opposed to playing something other than the music, stopping, etc., $r = 0.40$). The verbalizations included particularly self-guiding statements like 'slow down', 'I made a mistake, I'd better try again'. Three behaviours showed significant negative correlations; that is, they decreased with skill. They were: making errors ($r = -0.31$), repeating single notes ($r = -0.31$), and pausing for more than two seconds ($r = -0.31$). These results show that conventionally advocated rehearsal techniques increase in frequency with increasing skill, whilst non-advocated techniques become less frequent.

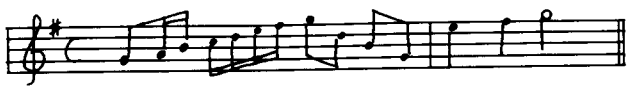
Gruson's second analysis used discriminant function analyses to determine which combination of practising behaviours could most parsimoniously discriminate students into three groups corresponding to apprentice (grades 1 to 8), senior student (grade 9 to diploma), and professional. This gave broadly similar results to the correlational study, and yielded repeating sections as the most reliable discriminator. Seventy-nine per cent of the subjects could be accurately classified on the basis of their use of this single behaviour. Gruson's hypothesis is that the increased use of repeating sections indicates an increased awareness of the structure of the music to be learned, where the sections repeated are isolated as significant units. The breaking down of the music into appropriate units becomes an aid to memorization and the construction of a fluent performance. For this hypothesis to be fully corroborated, we would need to see whether the sections repeated could, in fact, be isolated on *a priori* musical grounds.

Gruson's study had a second stage in which she asked a subset of her subjects (grades 2 and 6, and diploma students) to continue practising the pieces over ten sessions. This was in order to see whether continuing experience with a piece of music altered the way in which it was rehearsed. On the whole, she found few changes at any level of skill. The subjects seemed very consistent in their rehearsal behaviour, so that those behaviours which

discriminated between them on the first session (particularly repeating sections) still discriminated between them on the tenth session. It looks as though skilled pianists have a repertoire of rehearsal strategies which serve them well right through the acquisition of a new piece; the less skilled are equally consistent in adopting strategies which may not be so advantageous. Gruson concludes that the major influence on rehearsal behaviour must be the experience gained from 'many hours of practising a wide variety of music pieces'. On the most cautious calculation 'many' must mean 'thousands' at the very least.

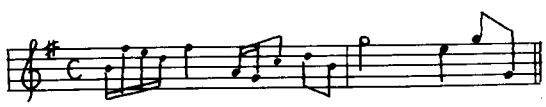
Gruson's study clearly leaves many questions unanswered. For instance, we do not know whether the differences in rehearsal strategy actually make the rehearsal more effective. It would be interesting to elicit trial performances after the first and last practice sessions. If the strategies of the experienced players are more effective, then we would expect them to show a greater improvement between the first and last sessions than the beginners. Another difficulty with the study is that age is confounded with experience. The beginners tended to be under the age of eleven, whilst the professionals were all over twenty-five. Some of the observed differences might be due to age changes in general cognitive strategies rather than specific musical experience. A study is needed where the different skill groups are matched for age. None the less, Gruson's study is a pioneering example of the kind of work which urgently needs to be done if we are to gain further insights into the acquisition of performing skills.

3.4. Expert performance



Expert performance demands a large number of sub-skills. Each of these sub-skills merits psychological investigation, and some of them have received considerable psychological study. There are specific technical skills such as vibrato in string playing and singing (Clarkson and Deutsch 1978; Seashore 1938), hand independence in piano playing (Shaffer 1981b), dynamic control of wind players (Patterson 1974), synchronization in ensemble performance (Rasch 1979), and so on. But clearly the expert is more than someone who possesses these several skills. He achieves his expertise through the simultaneous deployment of all these skills in a sustained fashion, and in a manner subservient to the overall structure of a musical composition.

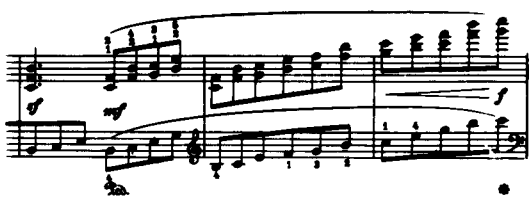
As a teacher I find that one of the greatest stumbling blocks for many pupils is the requirement to attend to several dimensions of musical experience simultaneously. A pupil may be quite capable of playing a passage with appropriate dynamics, but when asked to add some phrasing then loses dynamic control, and when asked to make some third adjustment loses the other two features. Each skill is present, but to utilize it precludes significant attention to other aspects. We may express this in traditional theoretical terms by saying that each skill requires allocation of attention from a limited



'pool' of attentional resources. Somehow, the expert has managed to escape these limits. It is usually held that the expert has no more attentional resources than anyone else; rather, each skill requires little or no attention for its execution. It has become 'automatic'. In the following section I shall try to unpack some of the implications of this for music performance.

If a performer is able to perform a particular piece of music expertly, then we would be most surprised to discover this to be the *only* piece he could play. This is because we rightly assume that some of the skills displayed in the particular performance are *general* skills, learned through the performance of previous pieces of music, and applicable to future works. These skills are *used* in the learning of a new piece, but they are not significantly altered through the learning of a single new piece. The expert performance of a given piece of music is the result of the interaction of specific knowledge of this piece alone with general knowledge acquired over a wide range of musical experience. This point is worth making since for most performers it will be the *specific* problems of a particular piece which will dominate their concerns. It is therefore easy to forget that specific activities arise from, and build upon, a vast storehouse of general musical knowledge. What distinguishes the expert from the novice is the extent and availability of this knowledge.

Example 3.9 is a simple excerpt around which we can base a discussion of some of the elements of expert performance. What would be involved in arriving at an expert performance of this? Perhaps the first thing to discuss is the role of memorization, since many expert performances are indeed from memory. It is clear that memorization of a piece is a performing advantage since it frees the performer's eyes from the score and guarantees the availability of information about what is to come next. Although the job of memorization is to hold the specific sequence of notes which makes *this* piece unique, there are clearly general skills involved too. These general skills can be demonstrated by considering the additional problems posed by trying to memorize Example 3.10. Although the two excerpts have the same key, metre, and number of notes, Example 3.10 presents more difficulty because its parts are less familiar, and because the principles of construction or patterning are less straightforward. It is easy to give a concise description of



Example 3.9.

Example 3.10.

Example 3.9 such as 'a rising major scale of one octave, tonic to tonic, followed by a descending arpeggio in the same octave', etc. In contrast, it is hard to think of a description of Example 3.10 which would be more concise than an enumeration of the notes.

An important skill of memorization is the ability to encode music in terms of familiar groupings and structures. Sometimes the structure is 'hidden' and adequate performance can be achieved only when the pattern is discovered. An example from recent personal experience comes in the piano part of Samuel Barber's song 'Sea-snatch' (Op. 29 No. 6). Example 3.11 shows bars 7–9 of the piano score. I made no headway with this at all until I realised that the right hand repeats the same four-chord sequence four times (at different octaves, and minus the very last chord). Having then applied the same fingering pattern to each of the four sequences, practice rapidly improved performance. The principal reason why I did not see this pattern at the outset was the irregular beaming which visually grouped the chords within each bar, breaking up the repeated groups whose discovery was essential to my performance.

Example 3.11. From Samuel Barber, 'Sea Snatch', Op. 29, No. 6. Copyright © 1954 by G. Schirmer, Inc. Used by permission.

On other occasions the need is to find a familiar structure to which the current music can be *related.* We may remember an unusual chord as a more familiar one with something added or taken away, or an unusual melody as a scale passage with an interruption. In music of any length it is possible to use earlier events within the music to assist memory of later ones. Sometimes the same music is repeated exactly, but even when transposed or transformed, the earlier music provides a framework for economical coding. Teachers will often have had the experience of a pupil who despairs of learning a long movement until it is pointed out to him or her how fingerings worked out for one passage can be adapted for other similar passages. Sometimes learners fail to notice that two distant passages contain identical notes and so need only be learned once.

Considerations like these suggest that effective musical memory depends upon the ability to represent music in terms of groupings of notes which can be related to familiar stylistic patterns and structures, and also to other sequences within the same piece. This does not necessarily mean that these groupings will be at the forefront of consciousness during a highly polished performance from memory. Aspects of small-scale structure can become

subsumed into larger performing units which are not 'analysed out' on every occasion. Taking the excerpt from the Barber song again, I found that as my fluency improved I no longer had to consciously *think* of the music in groups of four in order for my fingers to do what was required of them. Gradually the whole section became a single fluent statement, although I could impose the subdivisions on it if I wished. Most performers find that there comes a time when they can play through a well-learned piece completely on 'auto-pilot', devoting their conscious attention to something else. This experience, which some musicians describe as 'floating', and in which the hands seem to have a life of their own, is certainly an exhilarating one. It may, however, have its dangers in public performance. Unless one is supremely confident it is hard to refrain from asking oneself 'do I know what is coming next?' and panicking if the answer appears to be 'no'.

More modest examples of 'floating' underlie practically every example of skilled performance. Take Example 3.9 again. It should be within the capacity of any skilled musician to look at this for a few moments and then give a fluent performance on an instrument. A pianist, for instance, will choose an appropriate fingering. This is not a trivial matter since the options for fingering are many. The art of fingering consists in choosing a sequence which will allow legato where the music requires it and which will leave the hand in such a position that notes to follow are within its compass. There are several legitimate solutions to Example 3.9, but a very common one will involve starting on the right hand thumb (call it 1), following with 2 and 3, and then tucking the thumb under the hand for the C, continuing 2, 3 ,4 ,5, up to the G, and returning down the arpeggio with 3, 2, 1.

This is a good fingering for several reasons. Firstly, it allows the first bar to be played legato. In allegro vivace a semiquaver passage is unlikely to be executed with precision unlesss adjacent fingers are used wherever possible. Continuous legato playing up or down a scale is possible because of the opposition of the thumb to the other fingers. In this example, the thumb can be sliding rightwards under fingers 2 and 3 so that it is in position to play the fourth note on time. Secondly, the fingering allows top G to be played with the fifth finger, so allowing an easy reverse of movement down the octave without change of hand position. Finally, it allows the thumb to fall on the second beat of bar 1, so providing the opportunity for using its extra strength to accent the note if required.

Although there exists this explicit rationale for a particular fingering, most experienced pianists will find themselves playing these fingers without conscious choice. Their hands just seem to 'fall into place'. When pianists talk of music which 'lies well under the hands' they are, in part, reporting that many fingering problems are soluble at sight in this effortless way. They tend to agree about the music of which this is true, reflecting their common experience with a musical/pedagogic literature. Most performers in our culture receive intensive exposure to the classical and romantic repertoire where

scales, arpeggios, and diatonic triads form a very large part of the substance of most compositions. The fingering problems associated with these features will have been solved many times in a performer's career, and it is not difficult to see how a relatively simple set of heuristic rules could provide adequate solutions to a large number of these problems. The observation of musicians' fingering sequences and the modelling of the heuristic strategies which could underlie them seems a particularly tractable and worthwhile area of study in which there is, at present, to my knowledge, no significant work.

Because ease of fingering does relate to past experience, most musicians will have had the experience of coming to a new composer or idiom whoses writing seems at first difficult to perform, but after moderate exposure becomes easier. The piano music of Olivier Messiaen, for instance, often seems unperformable to classically trained pianists who encounter it for the first time. It contains none of the traditional scales and arpeggios, and most of the chords are unfamiliar. However, after learning several pieces it becomes possible to recognize typical chord structures and sequences whose fingering problems are closely related to one another. Gradually, solutions become available without conscious effort.

A substantial objection can be made to this line of reasoning. Surely, one may argue, an expert performer who plays something from memory will have solved his fingering problems during the rehearsal stage and will have settled upon a definite fingering which he memorizes along with the notes. Whilst agreeing that this is possible, and may sometimes happen, I would wish to argue that expert performance is often characterized by the fresh reconstruction of performance parameters such as fingering on every occasion. I have several reasons for believing this. One is that expert performers are often prolific, of their nature and of necessity. By this I mean that an expert performer can learn a new piece to concert standard very quickly, and can have many pieces in repertoire concurrently. The argument from economy suggests that he will only learn what new information is needed to perform the new piece, using his general musicianship to supply the rest. This will, perhaps, be particularly true of orchestral players, accompanists, and exponents of new music. There is just not the time to learn each piece to the level of complete 'floating'.

A second reason concerns the existence of variability between different performances of the same piece by the same performer. The reason that it is worth going to live music performances is that each performance will be different. Regular concert-goers will talk of a performer as being 'particularly inspired' on one day, 'detached' on another, and so on. Doubtless, some of this talk is not due to anything the musician does, but the phenomenon is too omnipresent for it to be all in the mind of the listener. Musicians themselves are aware of times when their performances 'reach new heights' or 'fail to come alive'. If all aspects of a performance were predetermined in a memorized plan, such variability would be inexplicable. If, however, many

performance decisions are made anew at each performance, then it becomes easier to understand performance variability. Of course, such a process does not necessitate variability. A performer could make the *same* decision each time. Variability, therefore, also implies some *optionality* in whatever system it is that controls the construction of a performance. Such optionality is indeed highly probable when we are dealing with complex patterned material like music. Such material often displays structural ambiguity; that is, it can be grouped in different ways if different principles are invoked (rhythmic, harmonic, melodic, etc.,) or a given element can be serving a double function with respect to surrounding elements (see Chapter 2, section 5.4). Performance, on the other hand, is unambiguous—one has to assign definite values of loudness, timbre, and duration to each note. On one occasion a performer may choose performance parameters which emphasize a note in virtue of its rhythmic importance. On another occasion he may choose a less emphatic performance in virtue of the subsidiary harmonic function of the note.

Expert performance is also characterized by what commentators often call grasp of the large-scale structure or 'architecture' of a composition. One factor which may contribute to this grasp is the internal consistency of a performance. In much music we would expect to find the same theme performed in the same way on each of its occurrences through a movement. For instance, if we choose a given articulation for the first entry of a fugue, subsequent entries should have similar articulation (unless there is some principled reason for change). Inexpert performance is often characterized by inconsistency. The way a theme is played on subsequent occasions is likely to be determined by local contingencies. In a fugue, for instance, it is relatively easy for a keyboard player to give attention to the articulation of the first entry, because it is unaccompanied. A subsequent entry may comprise one line among two or three to be performed at the same time, with all the fingering problems this poses; and articulation often suffers as a result.

Over a longer time scale expert performance is characterized by control over the progression of speed and dynamic. It is not a trivial achievement to keep a piece at the same speed throughout, or to return to a starting speed after variation. The marshalling of dynamic resources to arrive at a climax at precisely the right musical moment is similarly hard to achieve. Unintentional 'drift' in speed, mismanagement of *crescendi*, reaching a maximum too soon or too late: these are commonplace faults of inexpert performers, and well known to any teacher.

There is almost no scientific work on the features of large-scale performance which contribute towards a listener's judgement of expertise. A notable exception is the work of Shaffer (1981b) on timing, and we may use his study as an example of the direction that such work could take. He recorded piano performances of classical music in such a way that the time intervals between successive notes could be accurately measured. It was then

possible to examine the variability of timing in some detail. Of particular interest was the *covariance* between note durations. Two quantities covary positively if they tend to increase or decrease together. In a smooth *accelerando*, for instance, the durations of notes near to one another in time should covary positively. Notes at one point in the sequence tend *all* to be faster or slower than notes at other points. In contrast, two quantities covary negatively if one decreases as the other increases. Shaffer's data show that in expert metrical performances of Bach and Bartok the durations of adjacent notes tended to covary negatively. This suggests the operation of a compensatory mechanism such that if one duration is shorter than an envisaged ideal, the next note is given a longer duration, so that the *pair* of notes has a duration close to the intended ideal for that pair. This means that some monitoring and timing is taking place at a level above that of the individual note. An oversimplified, but generally correct, conclusion to be drawn from Shaffer's rather complex data is that timing in expert performers operates hierarchically. The performer generates a pulse which specifies the start of a *group* of notes (be it a bar, beat, or whatever) and then uses learned procedures for timing notes within the group. Clearly, the likelihood of timing 'drift' will be reduced if the performer can operate with such a pulse. One may hypothesize that inexpert performance is characterized by an inability to maintain performance with reference to a pulse. Rather, timing is determined locally by procedures for halving or doubling preceding durations, or for playing common rhythmic patterns. Unfortunately, Shaffer did not compare his expert performers with non-experts; but one informal observation supporting the notion of a deficiency in pulse control is the inability of many inexpert musicians to count out a steady beat whilst playing music where the beat is variously subdivided. This is similar to Ibbotson and Morton's (1981) finding that non-musicians are less adept at a particular tapping task than are musicians. The task entails tapping a steady beat with one limb whilst tapping a rhythm with the other. Curiously, the ability to do this seems to depend partly upon the combination of limbs used. Most people can tap a beat with the left hand against a right hand rhythm, but not vice-versa.

The reader will have noticed a concentration on piano performance in this chapter. This is partly because I am a pianist myself, and have the greatest awareness of performance issues on this instrument. It is also because most of the available research uses pianists. To what extent are the principles isolated for piano performance applicable across the whole range of musical instruments? At the highest level I would wish to claim a degree of generality for the observations made in this chapter. The influence of structure and patterning on the construction of performance plans and motor programs arises from the nature of tonal music and its psychological representation, and not from the nature of the instrument which realizes it. At a lower level, however, the technical and expressive problems presented by the various instruments are very different. Pianists escape a whole set of problems con-

cerning pitch, intonation, and timbral modulation, which face string players, singers, and wind players. The means whereby performers achieve control over pitch and timbre are not well understood, although there is some evidence for the existence of a homeostatic feedback loop which allows performers to make micro-adjustments to pitch so as to keep it in line with an intended pitch (Deutsch and Clarkson 1959).

Modulations of pitch and timbre are not simply 'problems' to be overcome. They are part of the expressive repertoire of music. Spectral analysis of natural sounds produced by, for instance, professional horn players show that, during a single long note, there is not just one typical 'horn spectrum' but as many as 30 or 40 different spectra at different times, which give rise to the aural impression of a 'living' sound. If a computer-synthesized horn uses only one spectrum for the whole duration of a note (leaving aside the initial attack portion as a separate problem), the resulting sound is completely flat and 'un-horn-like'. Furthermore, performers can *control* pitch and timbre modulation to achieve expressive variation related to the musical structure, just as pianists use timing and loudness variations. Researchers since Seashore (1938) have made inroads into the measurement of the dimensions of these variations, but little attempt has been made to account for the control structures which *assign* variations in the service of musical communication. Sundberg's (1978, 1982) preliminary work with singers is a notable exception.

The research of Rasch (1979) is one of the few recent examples of work with instrumental performers other than pianists. He was concerned with *synchronization* between three independent performers in string and wind trios. His professional subjects played classical pieces from their repertoire, and the relations between the onset times of notionally simultaneous sounds were examined. One finding was that the violin lead the other instruments in the string trio by some 4–8 ms on average. This may have implied an intentional strategy which 'highlighted' the main melodic instrument. However, the 'scatter' of asynchrony was quite high, and the mean asynchrony between any two instruments was between 30 and 50 ms. This suggests an error component which would be consistent with a homeostatic timing mechanism which kept on target by corrective overshooting and undershooting adjustments. Interestingly enough, these asynchronies mostly went unnoticed by listeners. The performances of the professional ensembles gave the impression of perfect synchronization. This is somewhat surprising, since in ideal experimental conditions (e.g. Hirsh 1959) subjects can easily judge which of two sounds separated by 20 ms came first. This is one piece of evidence which confirms my earlier remark that we need to examine perceptual acuity in real music contexts rather than generalize from the result of 'ideal' psychophysical studies. There are several possible reasons for Rasch's finding. One has to do with the fact that the different instruments occupied different 'pitch streams' (see Chapter 5.2).

Rasch has also shown that perfect synchronization actually impairs the

ability of listeners to identify the component notes of a chord, so that a small degree of asynchronization contributes to the perceptual clarity of the separate lines. This is a reason why some computer-synthesized polyphonic music lacks the contrapuntal clarity of live performances. Advanced programs incorporate a timing 'jigger' to better simulate live sound.

Finally, Rasch discovered a small number of relatively large onset difference times in his data (i.e. from 100 to 200 ms). These *were* clearly audible to listeners. It is possible that these were technical errors, but we must be open to the possibility that some of them were *intentional* timing deformations related to the musical structure. We cannot, however, know this for certain without controls of the sort imposed by Shaffer (1981b) or Sloboda (1983). For instance, intentional variation should be repeated in a second performance.

Although the literature on expert performance is sparse, it is possible to state with some certainty what the principles underlying such performance are, albeit at a level of some generality. Firstly, we see the existence of knowledge of large-scale groupings or patterns within the music which control performance. In many instances this control is hierarchical; parameters which apply to a larger grouping determine the settings for elements within the group. In contrast, inexpert performance is typically controlled by the superficial characteristics of the musical 'foreground'. Secondly, hierarchical control is supported by highly flexible procedures for solving local problems. These procedures operate rapidly, and often without the need for conscious monitoring. The inexpert performer cannot exercise higher-level control because his resources are fully committed to managing the solution of these immediate local problems. Thirdly and finally, the expert has the means to adequately monitor his own performance and take corrective action before he deviates too grossly from plan. Adequate monitoring is not so much a question of listening as of knowing what to listen for. There must be a clear representation of the intended sound if appropriate adjustments are to be made to the actual sound. It is probable, though, that what allows expert performers to make feedback adjustments so effectively is that they are not dependent on consciously monitored feedback at all times and levels. An important feature of skilled motor programming is the ability to operate relatively independently of conscious feedback. Thus, a performer can choose how and when to monitor his performance, knowing which aspects can be safely left to learned programming procedures. For a fuller discussion of experimental work on feedback in performance the reader is referred to Sloboda (1982), which also contains a brief account of social and motivational factors in music performance, which fall outside the scope of this book.

4. Composition and improvisation

4.1. Introduction

In the previous chapter we examined how performers go about the task of realizing in sound a pre-existing composition, either held in memory or specified by a score. We now turn to the creative process itself, whereby new pieces of music are generated.

There is a vast body of literature on the musical compositions which figure prominently in our art culture, but most of this deals with the product of composition, not the process. Even critical analysis, which, according to Meyer (1973), 'attempts to understand and explain the choices made by a composer in a particular work' (p. 18), is concerned more with the musical relationships evident in the finished product than with the moment-to-moment psychological history of the genesis of a theme or passage. The analyst may assert that a theme has the structure it does because it was the composer's intention to create a particular balance, or a particular contrast. He cannot, however, say whether this intention ever figured *directly* as a goal in the compositional process. The theme may have arisen as the result of some unrelated strategy, retained because of the subsequent *discovery* by the composer that it did, in fact, possess a quality of balance or contrast that recommended it. It is also possible that certain features of a composition highlighted by critical analysis were no part of the composer's intention, conscious or otherwise. In a system of inter-related sounds as large as, say, a symphony, there are bound to be some relationships discoverable by analysis which were neither noticed nor designed by the composer.

How, then, are we to gain psychological insight into this central and fundamental musical process? It seems to me that there are *four* possible methods of enquiry. First is the examination of the history of a particular composition as displayed in the composer's written manuscripts. Sketches and notebooks, if datable, can show how a composition grew and changed over the time during which it exercised the composer's mind. Some composers. such as Beethoven, made sketches which were returned to and remoulded over periods of years. Even where sketches do not exist we can sometimes discover something about the compositional sequence from the final manuscript. For instance, we shall see that differences of ink in Mozart's orchestral manuscripts show that he often wrote out the melody and bass

line of entire sections before returning at some later date to 'fill in' the harmony lines.

Second is the examination of what composers say about their own compositional processes. Many composers have been reluctant to do this. However, a few have tried to say in a general and retrospective fashion what happens when they compose.

Third is the 'live' observation of composers during a session of composition. This requires a rare degree of co-operation from a composer and, to my knowledge, there is only one published example in the psychological literature (Reitman 1965). During such a session one can observe the notes written down, their sequence and grouping in time. In addition, one may obtain concurrent comment from the subject about what he conceives himself to be doing. It has become usual when observing problem solving behaviour of many sorts to ask the subject to 'think aloud', supplying what is known as a 'protocol' for subsequent analysis.

Fourth and last is the observation and description of improvisatory performance. This is the special case where the composer is also the performer, producing a novel musical statement without premeditation in a public context. One may argue that improvisation reveals more of psychological interest than does a score. The improviser has fewer opportunities to cover his tracks. However, the constraints of improvisation—immediacy and fluency—make it likely that there are processes which improvisation and composition do not share. Indeed, it would be very unwise to assume that all composers or all improvisers go about their art in the same way. The most superficial reading of the musical literature provides abundant evidence that different practitioners habitually go through very different mental steps to arrive at a finished composition. As Neisser (1983) has succinctly expressed it, 'practise does not make all practitioners alike, it just makes them all effective'.

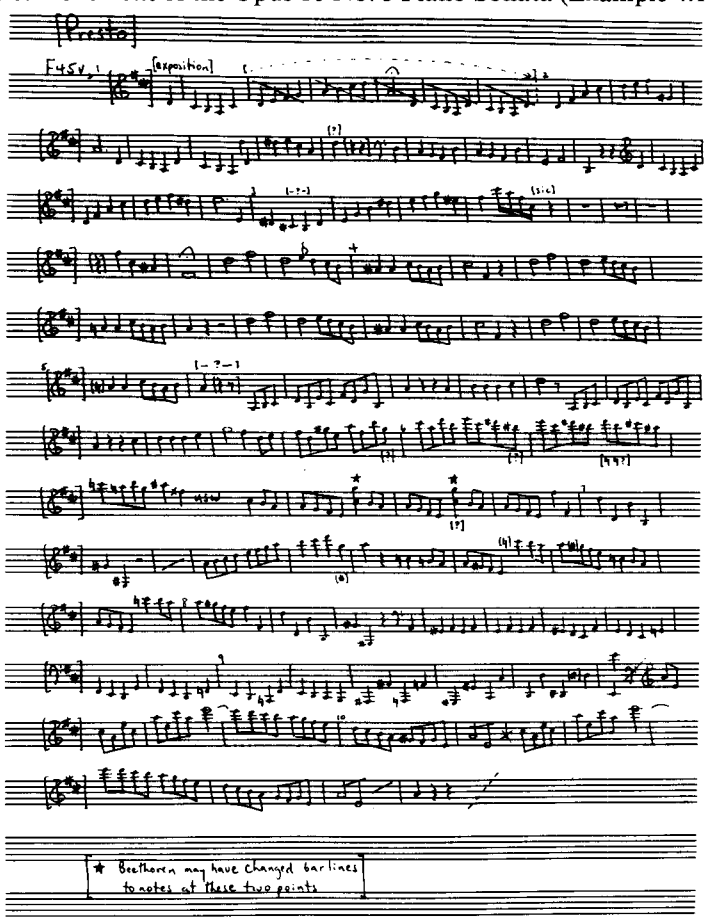
My intention in this chapter is to say something about what each of these four methods can contribute to psychological understanding, with illustrations, where possible, from the musical and psychological literature. I shall be highlighting two facets of the psychological activities involved. One is the persistent occurence of superordinate structures or plans which seem to guide and determine the detailed note-by-note working out. The other is the degree to which these plans can, particularly in composition, be rather provisional. They can, for instance, be changed in the light of the way a particular passage 'turns out'. The reader should be warned that composition is the least studied and least well understood of all musical processes, and that there is no substantial psychological literature to review. Whilst I hope to retain an empirical spirit in what I say, it is more probable here than elsewhere that my story will be inadequate, or simply wrong. I am emboldened to proceed only because of the absolute centrality of this aspect of musical cognition.

4.2. Manuscript evidence

4.2.1. *Sketches*

A sketch is an incomplete or preliminary draft of a work (or part of it) which was written prior to the final manuscript. Composers have differed in the extent to which they made use of sketches, particularly in the extent to which they were prepared to commit early ideas to paper. The sketches of many composers are nearly complete drafts of the final version, requiring little or no radical revision. Many of the extant sketches by Mozart, Haydn, and Schumann, for instance, display this 'finished' quality (Forte 1961). Beethoven, on the other hand, was a prolific sketch writer, filling many notebooks with fragments and sections which show considerable difference from the finished work. He often worked on a particular composition over a period of years. For instance, a first sketch of the opening theme for Op. 111 is found in a notebook which predates the final version by almost 20 years.

This feature of Beethoven's compositional life has led some commentators to an over-romanticized view of Beethoven as a tormented genius struggling with intractable raw material to mould it into the service of higher art. Early commentators on the sketches offered them primarily as *moral* comment on the character of the composer. Johnson (1980) sees the classic transcriptions and commentaries of Nottebohm (1887) as concerned with 'portraying the demonic opposition [. . . of the raw musical material] and leaving us to marvel at the spiritual power which eventually subdued it' (p. 4).



Our concerns are rather different. We must ask whether the sketches are capable of revealing anything about the cognitive processes which led to the genesis of particular works or passages. How did an initial idea come to the composer; what types of transformations and combinations were applied to the original ideas; what goals were being worked towards; in virtue of what were initial sketches rejected as unsatisfactory?

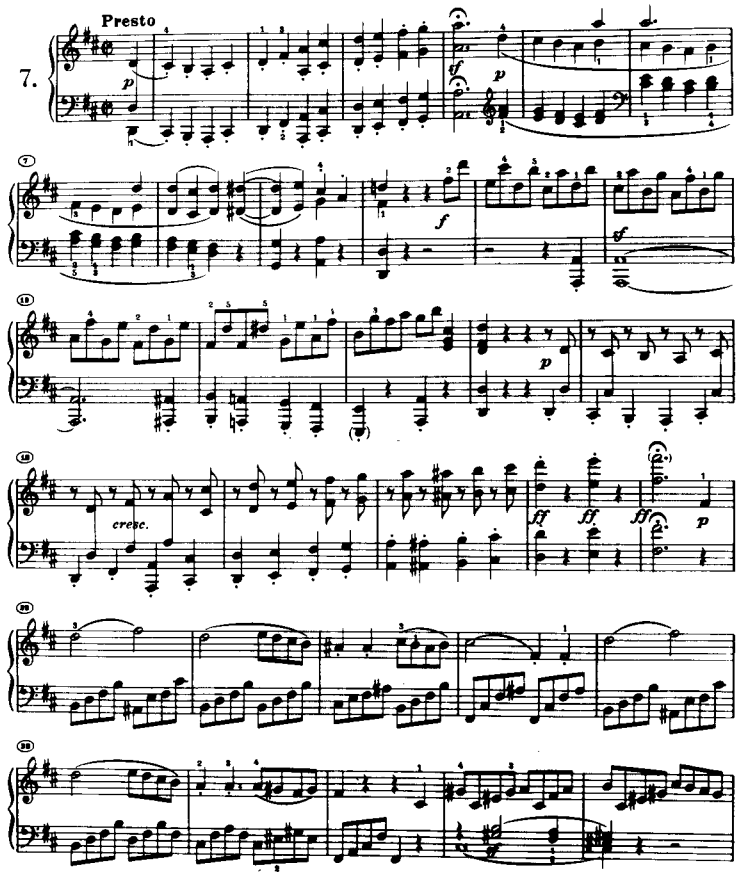
Johnson (1980) argues that musical analysis of the sketches has not yielded any fresh insights into the finished compositions. He identifies two principal reasons for this. One is the overdependence by modern musicologists on prior analysis of the finished work, and the assumption that it alone has the well-formed structure prescribed, for instance, on a harmonic level by Schenker (see Chapter 2). The sketches then tend to be branded as failed experiments—themes which go places that Beethoven didn't want. For us it would, perhaps, be more fruitful to consider the sketches as signs of competence, necessary and enabling resources for the compositional process. As psychologists we seek not so much fresh insights into the finished composition as fresh insights into the *means* by which a composition is finished.

The second reason for lack of progress is identified by Johnson as a deep pessimism among musicologists about the possibility of understanding the compositional act. He quotes Kramer (1973) as symptomatic of this attitude:

'The creative act is mysterious . . . It is an act so complex, motivated by so many impulses—as remote and impersonal as the entire web of knowable history, and as remote and intensely personal as the sum of one man's experience—that the material evidence (records of the act) are little more than occasional memos of a deeper, continual process' (pp. 516–17). Whilst Kramer is undoubtedly right, he describes conditions which appertain to many, if not most, processes of psychological interest. Psychologists, and indeed most other scientists, are used to operating in such situations. Progress is possible because there are ways of achieving a partial understanding of a system on quite restricted data.

Let us, then, take a small example from Beethoven's sketch books which illustrates the potentials and problems of sketch study. I choose the sketch of the first movement of the Opus 10 No. 3 Piano Sonata (Example 4.1) from

Example 4.1. From sketch of Beethoven, Piano Sonata, Op. 10, No. 3. First movement. Transcribed by Johnson (1980).



the Fischof Miscellany (transcribed by Johnson 1980; F45V, 1) more or less at random, but because it is reasonably extended, and shows many typical features of his sketches.

The first problem is to know the time scale of the composition of the sketch. Changes in paper, ink, or writing style, could signify a long break in the compositional process; but shorter breaks are of psychological interest too. For instance, what happened in this sketch on line 1 where five bars are crossed out? Were these bars the result of a compositional 'slip of the pen' noticed immediately and corrected, or do they represent a genuine first attempt which was then perceived as unsatisfactory, to be followed by more compositional thought? I believe we have some reason to prefer the latter explanation. The sketch as a whole reveals several clear musical features: first the repeated use of the descending four-note scale from the tonic D as a thematic motif; second the use of the four-bar phrase as the basic musical statement; third, the use of classical sonata form as a large-scale structure.

We can take these three features as constraining what was written, either before pen was set to paper, or very shortly after writing began. Both versions of the first phrase lead the music upwards from a tonic D harmony to the dominant A. In the first (deleted) attempt a simple ascending scale is used. In the second attempt the first half of the ascent is arpeggiated, taking the melody up to F sharp before descending by way of G sharp to the A. The two versions are not similar at a superficial level, but they do honour the constraints outlined above, as does the final version of the theme (Example 4.2) which is different from both sketches. We will never know precisely what motivated the rejection of the two sketched themes in favour of the final version, but the sketches provide compelling evidence that successive solutions were generated within the limits set by initial constraints or plans. Whatever alternative was generated, it had to leave the initial thematic motif intact, and had to move from a D harmony to an A harmony in four bars. We see in this sketch a persistent harmonic and rhythmic plan, albeit provisional, for the *structure* of the section, within which melodic alterations could be made.

Some aspects of such a plan are, however, provisional. This is clear when we examine the final version (Example 4.2). Here we discover that, after the first phrase, Beethoven abandons the strict four-bar phrase scheme. The next three phrases each have *six* bars, so as to produce an asymmetric first subject section of $4 + 6 + 6 + 6 = 22$ bars. This unconventional scheme makes the first section musically novel, although stretching rather than abandoning the original conception. The harmonic movement of the first subject section and the phrase structure of the B minor bridge passage are preserved.

In sum, then, structural similarities and contrasts between the sketches and the final version suggest a hierarchy of constraints within which Beethoven was operating. He was making successive attempts at 'filling in' a structure which, in certain respects, was already specified in his mind. We

see, however, that some initial constraints (such as the four bar phrase structure) were abandoned during the compositional process in the service of some newly discovered goal.

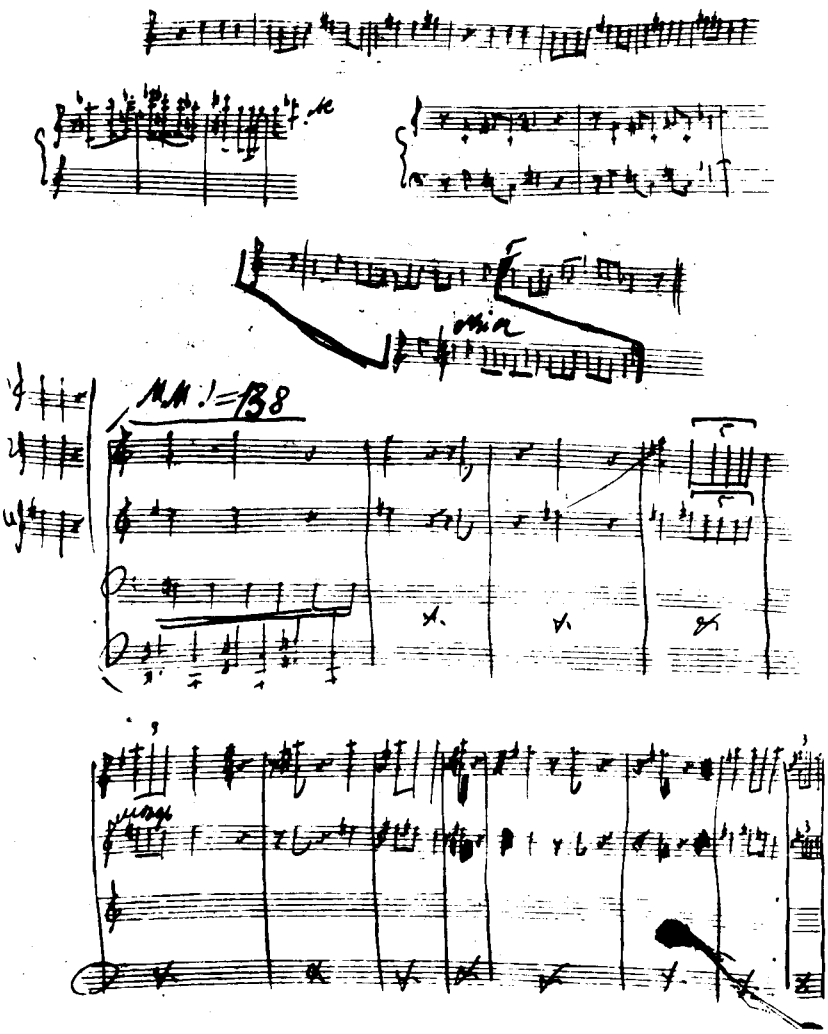
A second problem for us to consider is the extent to which significant compositional thought takes place at times when the composer writes nothing. When comparing two consecutive sketches it is unwise to assume that they are close neighbours in the compositional process. They may be separated by extensive unwritten compositional thought. In Beethoven's case this is particularly likely in view of one of his own remarks from a written conversations with Louis Schlosser in 1822 (Hamburger, 1952; reprinted in Morgenstern 1956):

I carry my thoughts about with me for a very long time, before writing them down . . . I change many things, discard others, and try again until I am satisfied; then, in my

head, I begin to elaborate the work in its breadth, it narrowness, its height, its depth and, since I am aware of what I want to do, the underlying idea never deserts me. It rises, it grows, I hear and see the image in front of me from every angle, as if it had been cast, like sculpture, and only the labour of writing it down remains, a labour which need not take long, but varies according to the time at my disposal, since I very often work on several things at the same time.

This passage confirms what we deduce from the sketches, that a distinction can be made between the basic idea and the detailed note-by-note working out. The former is present in the mind over a longer time span; the latter is subject to repeated experiment.

A third problem concerns the extent to which a sketch means for an outsider what it means for the composer. It can be argued that the purpose of writing a sketch is to be able to remind oneself of a musical idea that one must lay aside for some time. It is an *aide memoire*, not a full record. A composer may use cryptic or skeletal signs in the knowledge that these will be sufficient to retrieve the whole idea. In Beethoven's case, sketches are often confined to a single melody line without harmony or counterpoint. It would be extremely unwise to imagine that Beethoven thus *conceived* of a melody before assigning it a harmonic or contrapuntal context. Rather, we should conclude that Beethoven wrote this much only, knowing that he would be able to retrieve or generate afresh the remainder from examination of what he had written. A teacher's lecture notes are personalized in a similar way. They allow him or her to retrieve what was in mind at the time of preparation, but there is no guarantee that a colleague would reconstruct the same lecture from the notes.

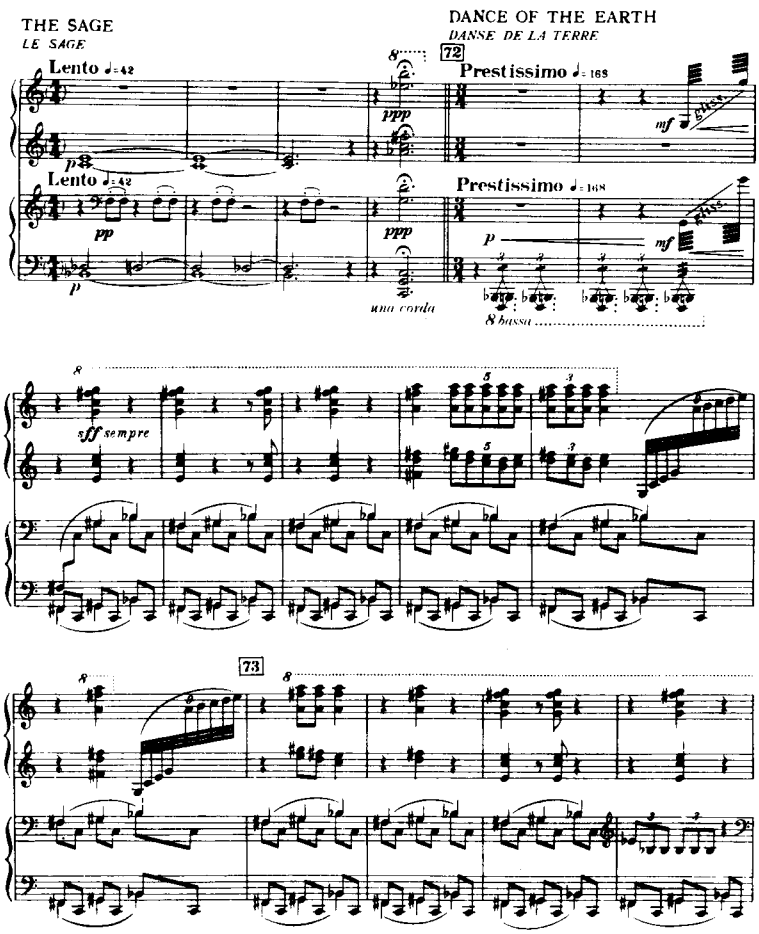


There is neither time nor space here to enter into an exhaustive study of sketching processes in different composers. It is a lengthy task in which significant musicological and psychological effort is still required. However, it is never wise to confine even preliminary remarks to one case. As a comparison I now turn to something from a completely different period and style—the sketches that Stravinsky made for his *Rite of Spring*. A collection which comprises about four-fifths of all the sketches for this work is now reproduced, with commentary by Robert Craft (Stravinsky 1969). In Stravinsky's case there is little need for transcription since the original is highly legible in most places.

There are some instructive comparisons we may make with Beethoven's sketches. Like Beethoven, Stravinsky very often records a mixture of ideas on the same page—sometimes successive workings out of the same material, sometimes different material. Secondly, also like Beethoven, he does not stick to the chronology of the final work, but jumps forwards or backwards in sequence. Thirdly, like Beethoven, many of the sketches are skeletal—a single melody line, a chord sequence, a rhythmic pattern: rarely does one find a full orchestral score. Once again the sketches seem to act as *aides-memoires*,

recording the themes and ideas from which the rest can be reconstructed at a later date.

Stravinsky differs from Beethoven as well. Whereas Beethoven's sketches use predominantly the single melodic line, a great number of Stravinsky's sketches depict several simultaneous strands. The chord structure is often fully specified, together with the main contrapuntal elements, and a preliminary indication of how the parts should be disposed among the orchestral instruments. These differences are not surprising in view of the profound differences in style and content between the music of the two composers. In his early and middle periods, at least, Beethoven worked within a conventional harmonic and formal framework. The 'rules' of diatonic harmony and sonata-form were well known. Within this framework, the melodic element became both the main individuating factor of a particular work, and also the main determining factor for the other features. Someone conversant with the classical style could, without too much difficulty, reconstruct a plausible sonata movement from the melody line alone (indeed, this kind of task is often used as a pedagogic exercise). Stravinsky, however, was working within a set of constraints whose bounds were much less well defined. His use of tonality was novel, both in terms of the immediate harmonic effects he created and also in terms of harmonic movement. For a full analysis of Stravinsky's musical style the reader is referred to Forte (1978). Suffice here to say that in this work Stravinsky was forging a new style with respect to the prevailing musical culture and also extending his *own* style. In such a situation it becomes likely that Stravinsky *needed* to capture more of the textural detail in his sketches. Such detail was sufficiently novel to constitute the *essence* of the composition, not something which could be reconstructed from a single line.



Another difference between Stravinsky and Beethoven concerns the number of preliminary sketches made before something approaching a final version was produced. Stravinsky made, on the whole, considerably fewer sketches than Beethoven. We may often observe single sketches of a few ideas which are then combined into a contrapuntal whole on the same page. The ideas themselves are often unchanged from the first sketches. Subsequent sketches show their combination and extension rather than their transformation. When transformations do occur, they are often radical and bold, leaping to the final version without any notated intermediaries. Craft draws attention to one striking example of this on p. 35 of the sketches (Example 4.3). The page is headed 'Dance of the Earth' and at the bottom we find a sketch which is essentially the final version of the first statement of the main theme of this section. Above it are four melodic fragments. Three of these arer quite clearly incorporated into the final version; but the very first sketch appears, at first, to be quite anomalous. It is a simple folk-like chorale in consecutive thirds which does not appear in the section, or anywhere else in

Example 4.3. Page 35 of Stravinsky's sketches for *The Rite of Spring* (1969). Reproduced by permission of M. F. Meyer.

the work. Despite its unfamiliarity, Craft convincingly argues that it is, in fact, the point of departure of the genesis of this section (given in the final version piano duet arrangement in Example 4.4). He writes:

> We discover, first, that the composer translates the melody from the top to a middle voice (second stave of the piano score in Example 4.4); second, that he forms harmonic aggregates from it, superimposing the notes as if they were *appogiature*; third, that he exploits its whole tone context—the harmonization in major thirds—in an ostinato bass-figure with the F sharp (rather than the C) as the root tone; and fourth, that he renovates the rhythm (p. xxiii).

Example 4.4. From Stravinsky, *The Rite of Spring*, Dance of the earth. Piano duet version. Copyright © Boosey and Hawkes Limited, London. Reproduced with permission.

This is not an isolated example, and Craft uses the sketches to postulate a basic compositional technique for Stravinsky.'Many of the composer's first notations were simple folk-like melodies which he transformed by a number of face-lifting devices including changes in note order, the extracting of essences, and the grafting of new rhythms and characters of tempo.' It is only the existence of these apparently anomalous folk melodies side by side with their transformed versions in the sketches that allows us this unique insight into Stravinsky's compositional processes.

We may ask what allowed Stravinsky to jump from first idea to radically transformed final version in one step? It is unwise to assume that Stravinsky had a surer technique, or that the transformations he used could be applied

with less extensive cogitation than Beethoven. The probable difference between the two composers is the time scale over which each was prepared to let an idea develop. Beethoven kept themes with him for several years. He needed to notate intermediate versions while he moved on to other things. Stravinsky, however, moved from initial conception to final theme over a much shorter time span, during which he worked on few other sections, and certainly on no other compositions. We know, in addition, that he composed at the piano (Stravinsky 1936, p. 14). It is plausible to suppose that ideas intermediate between initial and final versions were tried out on the piano, modified, and discarded, without any need for notation. The time scale was short enough for the whole process to be kept in mind until the final version. The structure of the work—short, contrasting episodes—would help such a strategy. At one level, each small section of 20 or 30 bars could be composed as a self-contained entity.

It is worth commenting, as Craft does, that many of the initial folk-like melodic fragments share common characteristics; such as single step movement up and down the scale, a slightly obsessive character brought about by repetitions of single notes or short motifs, harmonization in parallel thirds, etc. Such similarities lead one to suppose that there is a central core of thematic ideas to which Stravinsky returned again and again for his basic compositional material. It is this thematic unity at the heart of diversity which helps to make the work one of the most powerful compositional achievements of the twentieth century.

4.2.2. *The final manuscript*

It is clear that the study of sketches can, despite all the difficulties, provide some valuable insights into the compositional process. As mentioned earlier, however, not all composers have left sketches. Some composers write very little prior to the final draft. This, together with remarks attributed to such composers as Handel and Mozart has led, in some quarters, to a view of their composition as a form of dictation from inspiration, where the sounds of a work parade themselves fully formed in the imagination—the composer's task being simply to capture them with the pen. And so, composers of fluent inspiration, such as Mozart, are contrasted with composers such as Beethoven who had to do conscious work on their material, as their sketches show.

This division of composers into two classes is, I believe, a gross oversimplification based on an erroneous equation of sketching with conscious compositional effort, and on inadequate attention to the details of what composers say about their own compositional processes (see section 3 of this chapter, to follow). Beethoven's comment already quoted on p. 107 asserts that there was much compositional effort before anything was committed to paper, even though he was a prolific sketcher. Also, the evidence we have of

how composers such as Mozart wrote out their final manuscripts is inconsistent with a 'dictation' hypothesis.

It is a little unclear what the constraints of 'dictation' are, but we may start by assuming the constraints that exist in 'real' dictation, where a musician is required to notate an unknown passage played or sung to him by someone else. In this case, the length, speed, and complexity of the passage will be crucial to success. The subject will be engaged in a struggle to 'keep up' with the music, missing out fast passagework and complex harmony whilst making some attempt to get down the more straightforward and slow-moving sections. Clearly, Mozart scores show no evidence of this type of struggle. Perhaps, however, we should loosen the constraints a little. Maybe the composer has control over the speed of 'playback' so that he is able to stem the flow of inspiration for long enough to adequately record all the details. In this case we would expect to see a score written out 'vertically' with each section completely transcribed before going on to the next section. However, recently published facsimiles of Mozart's autographs (for instance, Mozart, 1979) tell a quite different story. It is fortunate for us that Mozart changed ink during the writing out of *Die Zauberflote* ('The Magic Flute'). The second ink used has faded more quickly than the first, so that the passage of time has revealed the writing history. In many of the movements, Mozart's first task was to write out the entire melody and bass lines on the outer staves, leaving gaps for the inner parts. At a later date, using a different ink, he then went back over the score to write out the inner parts.

In order to hold to a 'dictation' hypothesis, this data forces us to postulate some form of storage of the received composition such that Mozart could return to it at will and obtain repeated 'playbacks'. In other words, there would have to be *two* dictation processes: an initial one when the inspirational stream was 'fixed' in memory—a mental process requiring no overt activity; then a series of playback dictations whereby what was fixed in memory became fixed on paper.

Even this story, however, leaves unsolved puzzles. Why, for instance, should Mozart write out melody and bass first? Surely any order of writing out would be as efficient as any other. Suppose, for example, that a playback allowed a single line to be copied. Why not, then, work down the score from top to bottom? Then there is a further puzzling feature of the Mozart manuscripts. There are occasions when, in the first ink, Mozart has filled out the whole score for a few bars. At other points, isolated passages in a few interior parts are written in the first ink. Such points are not musically arbitrary. They consist of linking passages between sections, closing orchestral cadences, important counter-subjects, and other points where interior parts have particular prominence or importance. It seems as if Mozart was anxious to 'fix' these particular passages on paper, perhaps in the fear that they would be less easy to retrieve on another occasion.

We move, then, towards the notion that whatever was held in Mozart's memory was not a simple serial concatenation of notes—some mental tape-recorder which could be turned on or off at will. Rather, it was a structured and sectionalized representation which identified crucial parts within a super-ordinate plan. The first writing allowed Mozart to fix the crucial individuating elements of the composition on paper. These elements would allow the reconstruction of the rest even if the overall plan was lost from memory. For Mozart, writing out was not so much dictation as the negotiation, in a planned way, of a highly structured internal representation.

There is, of course, no manuscript evidence which could possibly be pertinent to the question of a prior 'mental dictation', at least for those composers who did not leave sketches. It is entirely consistent with the manuscript evidence that Mozart 'heard' his compositions as once-for-all hallucinations, played for him on an imaginary orchestra by his unconscious mind. The representation of such 'performances' in a structured memory form could well have been the result of a conscious strategy for retaining the details of the hallucination, just as we argued earlier that such strategies were responsible for success in remembering Allegri's *Miserere* (Chapter 1).

Such a picture is, however, profoundly unsatisfactory for a cognitive psychologist, because it leaves unexplained the unconscious processes by which a highly structured composition could come to appear, fully formed, in the composer's consciousness. If any composer was, or is, such a 'recipient' of unconsciously formed compositions, then the prospect for analysing and understanding the compositional process are not good.

In fact, when we move on to consider verbal evidence, we will find very few instances where compositional processes are totally inscrutable to the individual concerned. The most convincing case of 'unconscious composition' on a large scale is that of Rosemary Brown, who claims to receive compositions from dead composers by dictation. The works so produced, mainly for piano, are certainly coherent, and characteristic of the various composers she names. Although she is a reasonably competent pianist who is acquainted with the classical and romantic piano repertoire, she has no formal compositional training. Her verbal reports and her writing technique are consistent with a literal note-by-note dictation process, and, unless she is the perpertrator of an elaborate hoax spanning many years, her compositions provide incontrovertible evidence for the possibility of unconscious composition on an extended scale. Parrott (1978) reports a first hand observation of Rosemary Brown at work:

> I have watched the process many times and have often filmed it. You will know better than I how normal composition actually occurs: I have certainly never seen anything like the process Mrs Brown uses. The music literally flows onto the paper in a continuous stream—sometimes both clefs together, sometimes one first and then the other. And all the time Mrs Brown chats away: 'Not so fast; did you say natural

or flat? This G or the octave higher?', etc. And as fast as she can write, so it's taken down.

4.3. Composers' writings on their own compositional processes

To give a flavour of the kind of insight we can gain from examination of composers' writings, I wish to begin this section with four short extracts from the writings of various composers, without comment or identification.

(*a*) It has been my own experience in creative activity that a motive or a two to four measure melodic phrase occurs to me suddenly. I put it down on paper and immediately extend it to an eight, sixteen, or thirty-two bar phrase, which naturally does not remain unaltered, but after a shorter or longer 'maturing' is gradually worked out in definitive form. . . . This work now proceeds at a rate which depends primarily on my awaiting the moment at which my imagination is capable and ready to serve me further.

(*b*) You may ask me where I obtain my ideas (for a theme). I cannot answer this with certainty: they come unbidden.'

(*c*) Whence and how (my ideas) come, I know not; nor can I force them. Those ideas that please me I retain in memory, and am accustomed, as I have been told, to hum them to myself. If I continue in this way, it soon occurs to me how I may turn this or that morsel to account . . . agreeably to the rules of counterpoint, to the peculiarities of the various instruments.

(*d*) The first stage in the composer's work is . . . 'inspiration.' The composer . . . 'has an idea' . . . consisting of definite musical notes and rhythms which will engender for him the momentum with which his musical thoughts proceed. The inspiration may come in a flash, or as sometimes happens it may grow and develop gradually. [In this latter case] the inspiration takes the form . . . not of a sudden flash of music, but a clearly envisaged impulse towards a certain goal for which the composer was obliged to strive . . .

After inspiration and conception comes execution. The process of execution is first of all that of listening inwardly to the music as it shapes itself; of allowing the music to grow; of following both inspiration and conception wherever they may lead. A phrase, a motif, a rhythm, even a chord, may contain within itself, in the composer's imagination, the energy which produces movement. It will lead the composer on, through the forces of its own momentum or tension, to other phrases, other motifs, other chords. . . .

[The composer] is not so much conscious of his ideas as possessed by them. Very often he is unaware of his exact processes of thought till he is through with them; extremely often the completed work is incomprehensible to him immediately after it is finished. Why? Because his experience in creating the work is incalculably more intense than any later experience he can have from it; because the finished product is, so to speak, the goal of that experience, and not in any sense a repetition of it.

These quotes show, I believe, that composers have been capable of providing

coherent and articulate accounts of their inner experiences. They span about 150 years, yet contain so much that coheres across the accounts that one has some confidence in taking them to isolate some of the fundamental features of the compositional process and the creative experience. Before we examine the psychological implications of these quotations in detail it may be as well to identify them:

(*a*) Richard Strauss (1949); translated Morgenstern (1956).

(*b*) Beethoven (1822); from Hamburger (1952). This should be read in conjunction with the quote on p. 107, which comes from the same letter.

(*c*) Attributed to Mozart (1789?); from Anderson (1938).

(*d*) Roger Sessions (1941).

I would like to focus on the agreement across accounts about the existence of two stages in composition: the first called 'inspiration' by Sessions, where a skeletal idea or theme appears in consciousness; the second called 'execution', where the idea is subject to a series of more conscious and deliberate processes of extension and transformation. This dichotomy is by no means confined to musical composition, and is to be found in every branch of creative activity, as collections such as those of Ghiselin (1952) and Vernon (1970) show. It is as if the creative artist has a consciously known repertoire of things he can do with basic material, but has no such repertoire for generating the first germs on which he exercise his craft. The inspiration seems almost externally 'given', much as a sculptor may be given a lump of stone of particular shape and texture to work upon. Compositional skill entails the existence of a repertoire of ways of extending and building from the given, by discovering and using its inherent properties in principled ways. It is much easier to discover what composers do with themes, through examination of sketches and writings, than to discover where first themes come from. Analytic writing on musical compositions shows how extended works are built from kernel themes by means of such devices as transposition, augmentation, subdivision and recombination of elements, changes of rhythm, etc. Much of what we identify as compositional style inheres in the habitual ways in which composers modify initial thematic material.

Yet even if a composer is selective in the types of transformation he uses, there is still too much freedom. Anyone can learn 'tricks of the trade' and concatenate them together, but the result can be weak and lacking in integrity. It is clear that skilled composers are very hard on themselves, rejecting many permissible developments as unsatisfactory; but just as they are unable to articulate where inspiration comes from, so they are very unclear about the criteria by which they choose among the available ways of developing a theme.

It seems to me that the choice of the 'right' development may be governed by considerations of large-scale structure and balance, as discussed in Chapter 2. The art of composition lies, in part, in choosing extensions of initial thematic ideas that honour superordinate constraints, often to be formalized

in terms of hierarchical structures governing sections or movements. Schenkerian notions of melodic and harmonic movement constitute one way in which such superordinate constraints may be expressed, but doubtless there are others too. We may parsimoniously account for much of the sequence of compositional behaviour if we suppose that skilled composers are often unable to use superordinate constraints as starting points for *generative* processes, but are able to use them to *recognize* satisfactory musical material generated in some other way.

Newell, Shaw, and Simon (1962) have postulated a general theory of problem solving in which they distinguish two classes of process, the first of which they call *solution-generating* processes, and the second *verifying* processes. Typically, solution-generating processes involve the use of heuristics (strategies) for producing candidate solutions. Development of skilled problem solving involves finding better heuristics, i.e. ones which produce fewer bad solutions, and take less time. Heuristics are always less than perfect. They do not guarantee success; and it is arguable that in ill-defined problem solving situations such as musical composition, where the composer is at liberty to change the nature of the problem as he proceeds, algorithms (foolproof solution generators) are of limited value, even if discoverable. Because heuristics are not perfect, there has to be a process of verification whereby trial solutions are tested against criteria for success.

What we are wont to call compositional processes, those events over which composers have greatest conscious control, can possibly be identified as solution-generators in the theory of Newell *et al.* These are the repertoires of ways of 'turning themes to account' by exploiting and transforming their properties in principled ways. The process of judgement, whereby a particular development is accepted or rejected as achieving compositional goals, can be identified as the verification processes postulated by Newell *et al.* It is here where, arguably, testing of a trial solution against higher-order constraints takes place. This process also changes with increasing skill, as a composer develops more comprehensive and large-scale goals. Initally, a young composer may rely on a superficial understanding of the forms of his culture to determine his goals. For instance, he may notice surface features of a sonata form movement, such as the introduction of a second subject in the dominant key. As he grows in knowledge of his medium he may begin to extract the more fundamental principles of harmonic and melodic movement that underlie particular forms. He will understand why the standard features of sonata form usually 'work' musically; but he will also see how and when such features may be dispensed with to produce new forms which also 'work'. The verification is then based on 'intuition' that what has been composed is, in some sense, effective.

Composers throughout the whole of the last two centuries have insisted that the best route to the development of compositional skill is detailed study of Bach and the contrapuntal masters. Composers as varied as Schumann,

Kodaly, and Stravinsky, emphasize, in their different ways, the common principles underlying tonal music of the last 500 years in virtue of which it is fruitful to immerse oneself in the 'old masters'. From this immersion one gains the essential familiarity with the potentials and possibilities of the tonal medium from which one can forge one's own style. Verdi puts the point as succinctly as any (Werfel and Stefan 1942):

> *No study of the moderns!* Many people will think this strange. But today, when I hear and see so many works put together in the way a bad tailor puts clothes together on a standard model, I cannot budge in my opinions. . . . When a young man has gone through a severe course of training, when he has achieved his own style, then, if he sees fit, he can study these works, and he will no longer be in danger of turning into a mere imitator. (From a letter to Giuseppe Piroli, 1871.)

From a psychological point of view we may explain the benefit of such study as forcing the student to concentrate on basic underlying properties of the tonal system rather than on the particular compositional forms which are fashionable in the culture, and which constitute only a small subset of the ways of writing acceptable tonal music.

We may summarize our discussion so far by reference to a diagram of a 'typical' composer's compositional resources and processes (Fig. 4.1). There appears to be a distinction between those processes on which a composer is able to report fairly easily and those on which he is not. For convenience these have been labelled 'conscious' and 'unconscious'. Square-edged boxes depict knowledge or structures that are stored in long term memory. The

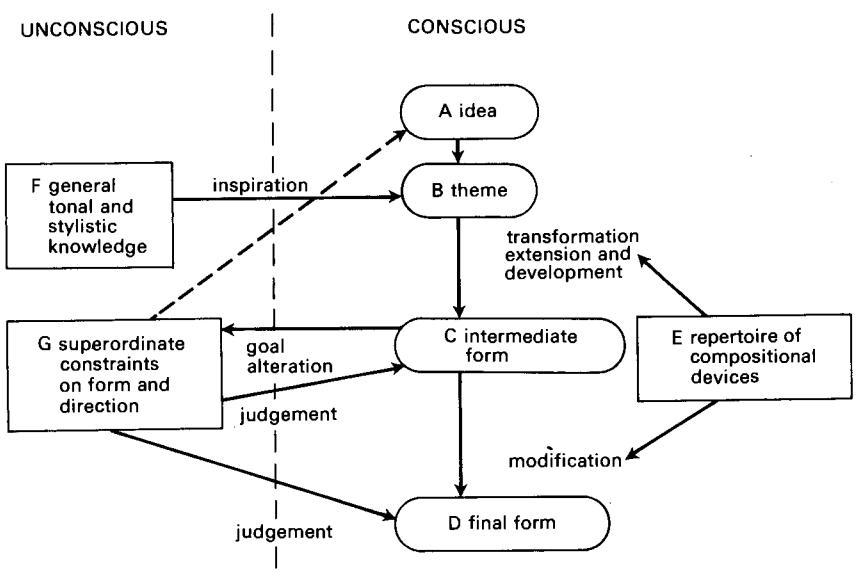


Fig. 4.1. Diagram of typical compositional resources and processes.

curved boxes contain the transitory materials that constitute successive versions of a composition as it grows in the composer's mind. The square boxes represent items of long-term knowledge which a composer has built up over the years, and which can be applied to new compositional problems. The lines joining boxes represent processes which transform or use the contents of the various boxes.

Box B represents the thematic kernel that springs 'unbidden' to mind out of the storehouse of thematic knowledge (F). Box A is optionally present in view of the comments (e.g. Sessions 1941) that sometimes a more or less specific idea of the *kind* of music required precedes an actual theme in awareness.

Box C represents the results of applying compositional techniques of transformation and modification (E) to the original theme. Its contents are then judged against criteria of 'rightness' (G) and, if found wanting, are modified until a satisfactory final form (D) is reached. The pathway 'goal alteration' acknowledges the fact that discovered properties of intermediate themes can actually overwrite originally held goals, so that the composition can appear to the composer to generate its own momentum or 'life', almost independently of his will.

It should be emphasized that Fig. 4.1 is not a 'theory' or an 'explanation' of the compositional process, but simply an economical way of describing some of the elements present in composers' accounts of their activities which makes clear the possible relationships between them. A rigorous psychological theory of composition would need to specify the contents of the various boxes and the nature of the transformations operating upon them in some detail.

The most rigorous test of the efficacy of theories in modern cognitive science is the production of a working computer program whose external behaviour mimics that to be explained. No such program has, to date, been written. The few documented programs (e.g. Sundberg and Lindblom 1976) do not attempt to model actual compositional sequences of the type portrayed in Fig. 4.1. In particular, there is no interplay between the generative process and processes of verification. The computer 'gets it right' at the first attempt.

It is also worth noting that in an effective theory of composition, the conscious/unconscious distinction is irrelevant. Both types of process must be fully specified, and it is the internal logic of a process which is of importance. We may suppose that, for different composers, the line dividing conscious from unconscious processes may be drawn in different places. Indeed, the whole issue of individual differences is an important topic of study. It would be oversimplistic to assume that there is only one route to an acceptable composition. A full analysis of such differences is beyond the scope of this book, but a single example illustrates the kind of issue which arises here.

Tchaikovsky, in his letters (Newmarch 1906; reprinted in Vernon 1970), frankly identifies a particular point of failure for him—form:

> I cannot complain of poverty of imagination, or lack of inventive power; but, on the other hand, I have always suffered from my want of skills in the management of form. Only after strenuous labour have I at last succeeded in making the form of my compositions correspond, more or less, with their contents. Formerly I was careless and did not give sufficient attention to the critical overhauling of my sketches. Consequently my *seams* showed, and there was no organic union between my individual episodes. This was a very serious defect, and I only improved gradually as time went on; but the form of my works will never be *exemplary*, because although I can modify, I cannot radically alter the essential qualities of my musical temperament.

Translating this into the formalisms embodied in Fig. 4.1, we may say that the route F–B–C–G is strong, but that the G–C and G–A–B routes are not. It is more likely that properties of a theme control the eventual structure rather than a strong conception of the structure exerting control over the thematic process.

Tchaikovsky clearly sees his own compositional process as inadequate, and others such as Hindemith (1952) stress the point that there may be as much separating the master composer from the 'ordinary' composer as there is separating the composer from the novice. Of the themes and motives which form the substance of inspiration, Hindemith says: 'they are common to all people, professionals and laymen alike; but while in the layman's mind they die away unused in their earliest infancy . . . the creative musician knows how to catch them and subject them to further treatment.' This treatment is precisely the moulding, transforming process that we have identified with the B–C–D route in Fig. 4.1. However, Hindemith goes on to claim that 'if only the work involved in reaching this goal really counted, there would be many a genius. The petty composer could do the same, technically, as the real genius did, and he would almost be justified in feeling godlike . . . because he was able to turn his bubbling inner singing and ringing into music, which [the layman] could never do.'

Hindemith then asks what separates the genius from the workaday composer and identifies the mark of the master as 'vision', which concept he explains in the following way:

> A genuine creator . . . will . . . have the gift of seeing—illuminated in the mind's eye as if by a flash of lightning—a complete musical form (though its subsequent realization in a performance may take three hours or more); [and] he will have the energy, persistence, and skill to bring this envisioned form into existence, so that even after months of work not one of its details will be lost or fail to fit into his photographic picture. This does not mean that any F-sharp in the 612th measure of the final piece would have been determined in the very first flash of cognition . . . but in working out his material he will always have before his mental eye the entire picture. In writing melodies or harmonic progressions he does not have to select them arbitrarily, he merely has to fulfil what the conceived totality demands . . . The

man of average talent may have visions too; but instead of seeing them in the clarity of lightening, he perceives dark contours which he has not the divination to fill out appropriately . . . [He] may manage the few basic rules of construction with all their combinative possibilities pretty well, and yet the highest degree of subtlety, in which each technical item is in congruence with the respective part of the vision, again may be attained only by the genius. There are relatively few masterworks in which this ultimate congruence can be felt.

Hindemith sees the acquisition of compositional mastery as one in which the demands of box G in Fig. 4.1 gain greater control over the compositional process so that the conception (A) exercises greater constraints over the compositional process from the outset. The subservience of detailed working out to a controlling plan or 'scheme' has been proposed as a partial explanation of introspective remarks attributed to Mozart and other composers (Gardner 1980), although it is clear that by 'vision' Hindemith means considerably more than the ability to plan a composition according to some stock structural formula (such as minuet and trio, rondo, or sonata form). He is referring to some underlying thematic and harmonic unity which transcends particular forms.

In the light of Hindemith's comments it becomes easier to understand the achievements of someone such as Rosemary Brown. We may see that she has grasped some of the rules of construction used in the music of classical and romantic masters. The compositions she produces are, however, mainly of simple episodic form, and lack the organic mastery sometimes achieved by the composers she claims to transmit. She is a good, albeit, unconscious imitator of surface styles. But for the total insulation of her compositional processes from her awareness she would be as little worthy of note as the countless unmemorable imitators in every sphere of creative endeavour. There is no evidence of the 'vision' that her composers had in such abundance in their lives.

The general issue of the psychological status of verbal reports has been a central one in cognitive debate. It is obviously naive to suppose that verbal introspections can be taken as true descriptions of mental processes in every respect. Nisbet and Wilson (1977) draw on a wide body of evidence in support of the view that, in many cases, people attempting to report on their cognitive processes do so not on the basis of true instrospection, but on the basis of *a priori* theories about plausible causes and effects. They reconstruct, in a more-or-less rational fashion, what they infer *should have* gone on to produce the results of cognition. Nisbet and Wilson's evaluation of the literature on creative processes leads them to the conclusion that

creative workers describe themselves almost universally as bystanders, differing from other observers only in that they are the first to witness the fruits of a process that is almost completely hidden from view. The reports of these workers are characterized by an insistence that (*a*) the influential stimuli are usually completely obscure—the individual has no idea what factors prompted the solution; and (*b*) even the fact that

a process is taking place is sometimes unknown to the individual prior to the point that a solution appears in consciousness.

Whilst it it true that *some* compositional processes seem obscure to consciousness, the material reviewed here suggests that Nisbet and Wilson's conclusions may be too sweeping. There are many aspects of the process which are open to conscious inspection and control. Furthermore, the insistence by many composers that there are processes that they cannot report upon encourages us that they are *not* 'telling more than they know'; that they are really attempting to describe the phenomenal experience *without* inference.

Ericsson and Simon (1980) argue that Nisbet and Wilson are overly pessimistic about the degree to which we can treat verbal reports as reliable indicators of cognitive processing. They point out that reporting verbally on introspective data characteristically means *remembering* a past sequence of events. The distinction between what can be reported and what cannot is not necessarily one between conscious and unconscious processes, but may be one between what can be readily recalled and what cannot.

They cite evidence which suggests two conditions under which material that has been the object of focal attention may not be recalled: cases where a solution is reached in a single step without intermediate or partial solutions; and cases where a process or a product is transient, being held in focal attention for only a brief moment before being superseded by new material. They argue that these factors are 'adequate to account for the phenomena of sudden insight that are the subject of so many anecdotes in the literature of creativity.' The studies cited in support of sudden insight are based on 'retrospective accounts of purportedly real creative acts, often reported many years after the event'. Ericsson and Simon's view is supported by evidence from studies where subjects were asked to introspect *whilst* solving the problem (e.g. Bulbrook 1932; Durkin 1937; Henry 1934). They argue that studies such as these show that the progress to solution was either gradual or determined by trial and error. No additional unconscious processes were required to be postulated.

A related cause of memory failure is concerned with the fact that the thought processes preceding 'inspiration' are often diffuse, unplanned, and undirected, and may be interspersed with other cognitive tasks which form the prime focus of attention. Although such unstructured thought is difficult to recall, there is evidence (e.g. Klinger 1971) that it is not unconscious. If people are asked to verbalize their processes *at the time* they are able to do so; but memory for the events fades very quickly.

No-one would wish to deny the immense complexity of the processes involved in musical composition. The arguments of Ericsson and Simon are simply a reminder that we may be making life too difficult for ourselves if we succumb fully to the prejudice of the contemporary psychologist against

using verbal reports as data. With a clear understanding of the conditions under which they tend to be unreliable, we can proceed to a relatively free use of this vast storehouse of psychologically relevant data. The thrust of Ericsson and Simon's argument is that we will gain the most detailed and accurate picture by examining verbalizations made *concurrent with* the act. It is to such data that we now turn.

4.4. Observations of composers at work

This section is based on two observations. One is reported by Reitman (1965) and involved obtaining a verbal protocol from an unnamed composer who was set the problem of writing a piano fugue (Sanchez and Reitman 1960). This yields a number of insights, but has inadequacies too. The complete protocol is unpublished, and there is no record of the concurrent musical protocol, the notes tried out at the piano and written down. Accordingly, the second observation is one made on myself as I composed a section of a work for choir and organ. As I worked on this section I wrote down as many of the steps of my thought as I could capture, alongside the relevant musical notation.

4.4.1. *Reitman's protocol of fugue composition*

To specify a fugue is to specify certain features which the final composition must possess. A strict fugue contains two or more independent contrapuntal voices which enter, one after another, with the statement of a single theme. The entry of the second voice is accompanied by new, contrasting material in the first voice which constitutes a 'counter-subject'. When each voice has entered, the music develops through the segmentation and recombination of the thematic elements in various ways; towards the end of the fugue one normally finds some dramatic intensification of the texture, through harmonic and dynamic climax, through the overlapping of thematic entries in the various voices (stretto), and other conventional devices. The prime constraints on a fugue are that each voice should possess some continuity and individual coherence, and that there should be a minimum of free writing where the voice material is not derived from the theme and counter-subject material (see Bullivant 1971).

A composer's problem, when working in any medium, is to set additional constraints over and above those loosely specified by the compositional type. There are an infinite number of possible fugue themes and possible fugues. The composer clearly cannot search through all possible themes in an unprincipled way. He must, in technical terms, 'reduce his problem space'. We find, in Reitman's protocol, evidence of external constraints operating, such as the need to find something which fits under a pianist's hands. When attempting to compose the countersubject the composer says: (erasing) 'I

think we'll abandon the idea of the enlarged syncopation to get away from repetition of the theme . . . and try to do something more pianistic.'

Probably more important than such constraints, however, are those *internal* constraints generated by what has already been composed, following some general principle of consistency or balance. Throughout the protocol, observations such as 'I'm playing through measure six to try and get my ear attuned to that kind of material' are common. It seems that the composer is attempting to discover initially unnoticed properties of what he has already composed to help him generate ideas for continuing. He is indulging in what Reitman calls 'after-the-fact adoption of a convention which is consistent with what has already been done'.

There comes a point in some compositions where the constraints, external or self-imposed are so many that the element of search or choice seems to be reduced or removed altogether. Towards the end of his protocol the composer calls out '*Voilà!* From here the ending is quite obvious, and there's no problem. This is the solution . . . The structure of the piece is solved now . . . I don't think it can miss.' It is a universal phenomenon of expert mental life that points occur in a problem-solving process where one 'turns onto a familiar road' traversed so many times before that the novelty and challenge of the particular problem disappears. Such points depend, of course, on the expert knowledge of the problem solver, and may be undetectable when reached by a novice working on the same problem.

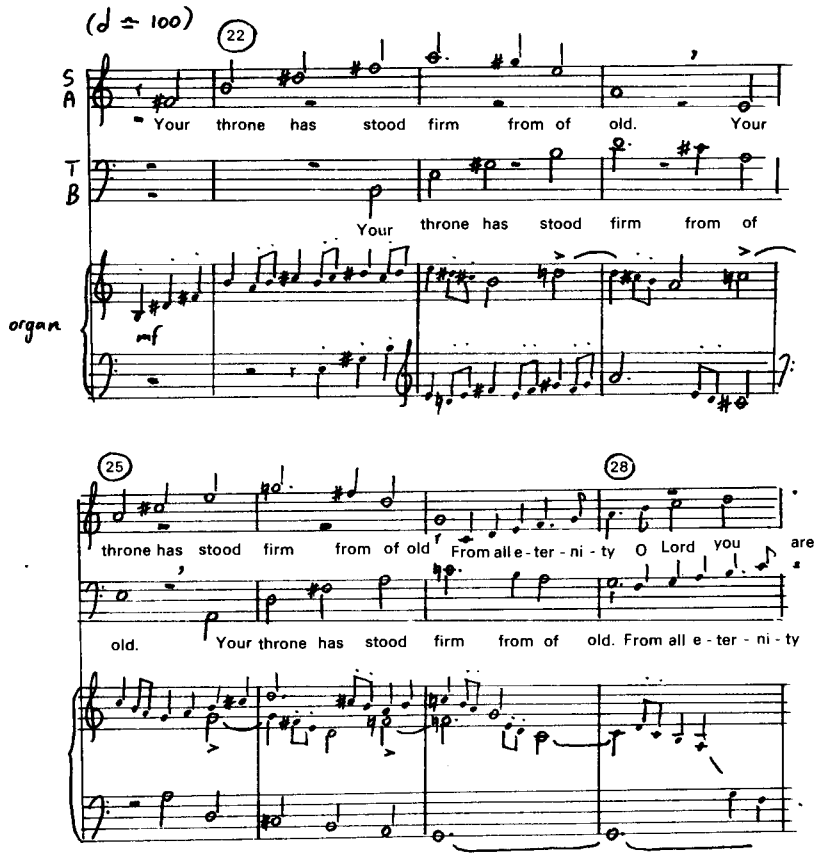
I am a moderately poor Bridge player, and, sitting at the tables of the mighty, have often been astonished when, three or four tricks into a hand, the declarer lays down his hand with the claim that 'the rest is obvious'. This is followed by some explanation of his intentions of play, to which the others at the table immediately acquiesce; and I am left trying confusedly to follow what seems so obvious to the others. My self-esteem is only somewhat restored by the observation that sometimes such a declarer is wrong. A keen opponent says, 'I'm sorry, but do you mind actually playing that out?' and the unlucky declarer discovers some unforeseen twist of card distribution or tactic which undoes his strategy. The same is true of music composition, and Reitman's composer had the insight to add 'of course, you never can tell until you get to the end; it's always dangerous . . .' Some unforeseen conflict between the various constraints adopted may prevent any satisfactory ending from being found.

When multiple constraints build up over the course of a composition, it can become impossible to find ways of progressing which honour all the constraints. In such situations the protocol reveals the composer temporarily dropping some constraints, producing continuations which honour only some of the features defined earlier. He then readjusts in one of two ways: he either modifies the new material so as to bring it back into line with earlier constraints; or he may change the constraints. Thus, at one point the composer ignores all attributes of a pair of melodies except the arrangements

of harmonic intervals they form, ignoring the rhythmic aspect to generate a continuation.

What we are unable to do from the brief set of selected fragments presented by Reitman is to get any idea of the detailed *musical* working out of the general principles of problem solving which emerge with clarity. There is no opportunity to experience the music that the words are about. Accordingly, the next protocol gives some of the crucial musical material in addition to the words.

4.4.2. *A self-generated protocol of choral composition*



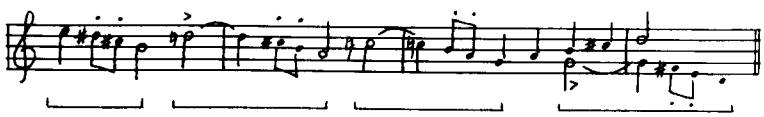
A few autobiographical details are necessary to set the context. I conduct a small amateur choir, and some years ago I decided to try and write something for the choir, taking up again a compositional interest that had absorbed me in early adulthood. My compositional style might best be described as 'twentieth-century English church' as exemplified by such composers as Herbert Howells. The style is traditional, placing great emphasis on melody, counterpoint, and a strongly tonal harmonic framework. I came to this work with a cluster of general constraints: the work must be learnable by an amateur choir; it should be for four voice parts plus organ accompaniment; it should conform to my general style—I was not deliberately intending to transform or extend my repertoire of compositional devices.

I chose to write a setting of Psalm 92, in English translation. The psalm has five verses, and the general mood is vigorous, joyful, and triumphant ('The Lord is king, with majesty enrobed'). The demands of contrast suggested to me that the third verse could take a more serene setting, and so a vague three-section notion was born; an initial vigorous setting of verses 1 and 2; a restful slow section for verse 3; returning to a triumphant close for the last two verses.

My initial compositional effort got me to the beginning of the last line of verse 2, and then I became blocked. My initial idea for the words 'From all eternity, O Lord, you are' seemed to lead nowhere, and I abandoned the project for at least a year.

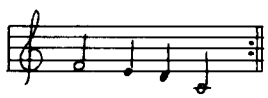
It was some months after this abandonment that I first developed an explicit interest in the process of composition. When I returned to the task of completion in the summer of 1981 it occurred to me that it would be of interest to capture some of my compositional steps in a protocol. At this stage I was relatively naïve with respect to the literature reviewed in this chapter, and I had few preconceptions about the kind of thing such a protocol would show.

The protocol begins at bar 27 of the composition, where the abandoned theme was sketched in. Example 4.5 shows the score from bar 21 through 29 as it stood when I began. Since the protocol is fairly short, it can be given in full, with commentary and musical examples. The protocol is in italic type; comments and explications follow each segment of protocol in normal type.



Example 4.5.

I should add that the original written protocol is highly cryptic, using personalized abbreviations and deviations from grammatical usage. The version presented here is as literal a translation into grammatical English as possible.

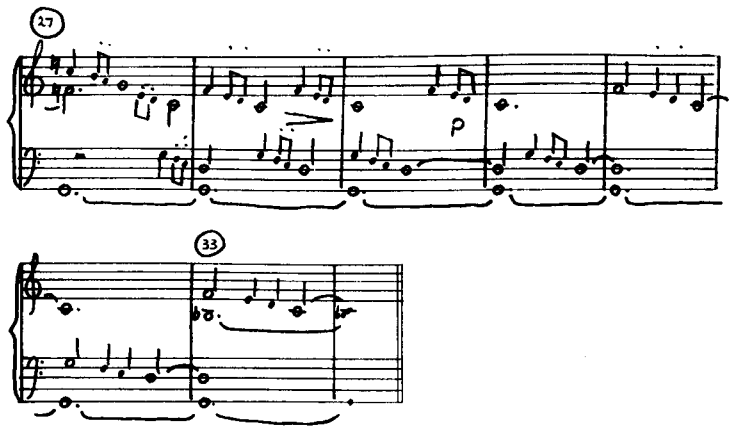


A. *How am I to continue at bar 29? The next verse is going to be quieter and slower. A theme is needed for 'From all eternity'. The tentative one where composition broke down before didn't seem right, partly because it was over too quickly.* This initial passage can be seen as a statement of the problem to be solved, and the setting of two immediate constraints. There was a general need to 'wind down' from a rather extrovert and 'busy' texture into something more easeful for the next verse; and a particular need to find a theme for the last line of verse 2. Lengthening the vocal phrases, which up till now had been short and separated, could be one way of introducing the required 'easement'. These constraints, however, were not yet specific enough to suggest actual notes.

B. *I decide to progress the accompaniment so that it slows down. It occurs to me that the word 'eternity' can be represented by a repetitive circular motif. We already have a circular four-note fragment in bars 23–27 (Example 4.6). So I try to use it to slow down (Example 4.7). The writing of bars 27–33 then becomes routine. A B flat is added at bar 33 on the intuition that harmonic movement is needed by now.* The vocal theme for 'Your throne has stood firm' is a rather self-contained 'closed' phrase. It did not have implications for any particular continuation to me. The accompaniment is, however, much more flowing and open ended at this point. To overcome the 'block' in the vocal material I decided to develop the accompaniment in the hope that this would, in its turn, suggest what the voices might do. The word 'eternity' suggested the possibility of a repetitive cyclical motif, and the accompaniment happened to contain such a motif, introduced at bar 23 for reasons I have now forgotten. It consists of a falling four-note scale, which returns to a higher note to fall again and again (see Example 4.6).) I seem to have decided

Example 4.6.

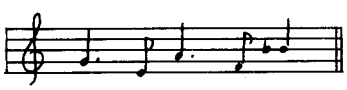
that the passage from bar 27 to 33 should be harmonically static (over a dominant G pedal). The task, then, was simply to repeat the falling motif over and over, at the same pitch, but with a spacing out and slowing so that from bar 31 there is just one cycle per bar (Example 4.7). Once the problem



Example 4.7.

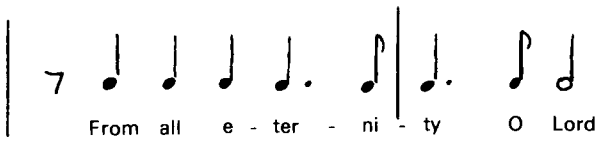
had been narrowed this far, I was able to compose fairly mechanically, thus the comment that this section is 'routine'. The full organ part for bars 27 to 33 is given in Example 4.8.

At bar 33 the problem was perceived as one of maintaining interest whilst continuing with the repetitive melodic material. The solution that occurred to me was to alter the tonal implication of the G pedal by adding a B flat in the harmony, suggesting a reinterpretation of the key as tending towards F major.

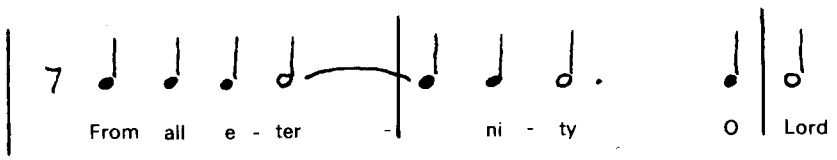


C. *Now I leave the accompaniment and return to the voices. The basic rhythmic pattern of the earlier, unsatisfactory theme (Example 4.9, bars 27–28) seems right, but it needs slowing down. The rise in pitch is right too, but it needs to be less extreme. If we incorporate alternate rising fourths and falling thirds (Example 4.10) that produces a coincidence. Starting where I feel it to*

Example 4.8.

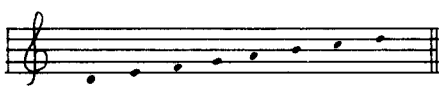


Example 4.9.

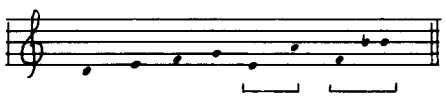


Example 4.10.

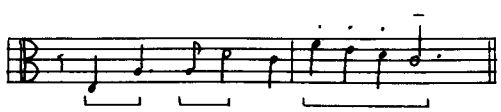
be right (bar 31) it comes out on B flat at the same time as the accompaniment (Example 4.16, bar 33). In this rather condensed section of protocol the accompaniment is now left. It provides a suitable bed over which new voice material can be added. The first, unrecorded step was to delete the abandoned voice entries in bars 27 and 28 (Example 4.5) so that by bar 29 only the organ was sounding. Clearly, I liked the basic rhythm of the abandoned theme, and its ascending pitch direction: but the speed of the rhythm and the rate of pitch rise were both too fast for the intended 'easing up' role that this theme had to fulfil. The first modification that occurred was to double the duration of the dactyl pairs (from Example 4.11 to Example 4.12). The second modification was to allow *alternate* notes to carry the pitch rise, with intermediate notes dropping back below (changing from Example 4.13 to Example 4.14). I cannot be sure why I chose the interval of a rising fourth at this point. It is possible that I was looking back to earlier thematic material to find some grounds for consistency. The very opening theme of the work, in fact, contains two germinal elements; ascent by rising fourths, and a falling scale of four notes (Example 4.15).



The 'coincidence' refers to the happy discovery that when I started the

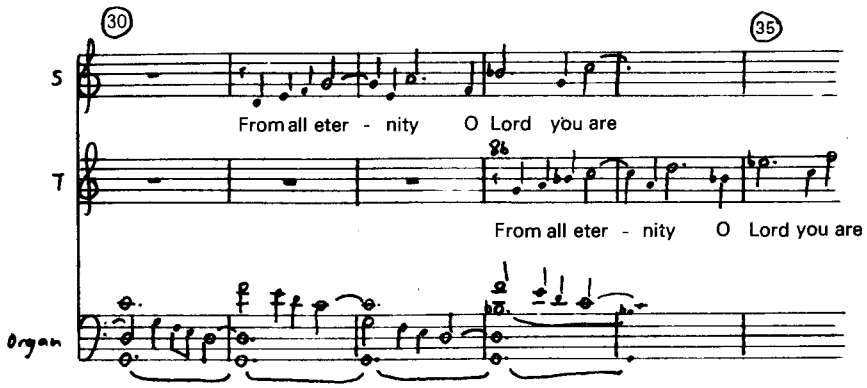


Example 4.11.



Example 4.12.

Example 4.13.



Example 4.14.

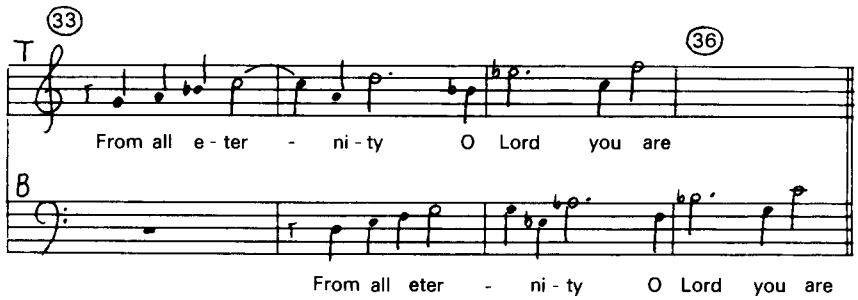
Example 4.15.

first vocal entry on D in the soprano line at bar 31, which, for reasons now lost to me, seemed the right time and note to start, the theme's already determined structure led it to B flat at precisely the point at which I had already decided to introduce a B flat in the accompaniment (see Example 4.16). This seemed to act as a confirmation that I was 'on the right track' at this point.

D. *The soprano theme finishes on C (bar 33), but I want that repetitive upward movement to continue. I will have to give the theme to another voice an octave lower. My first thought is to follow on, starting in bar 34. My second thought is to start in earlier (bar 33) and grow on out of the soprano ending. That works for the tenor voice.* The organ harmony at bar 33 is unresolved (see Example 4.8) and so this creates the feeling that the music is still moving towards a point of resolution. I experienced a strong sense that the upward movement started by the soprano voice should continue, but in a way that brought in another voice. The first thought was to start a lower voice in an imitation of the soprano in bar 34. This was discarded almost immediately in favour of an overlapping join in which the lower voice starts before the

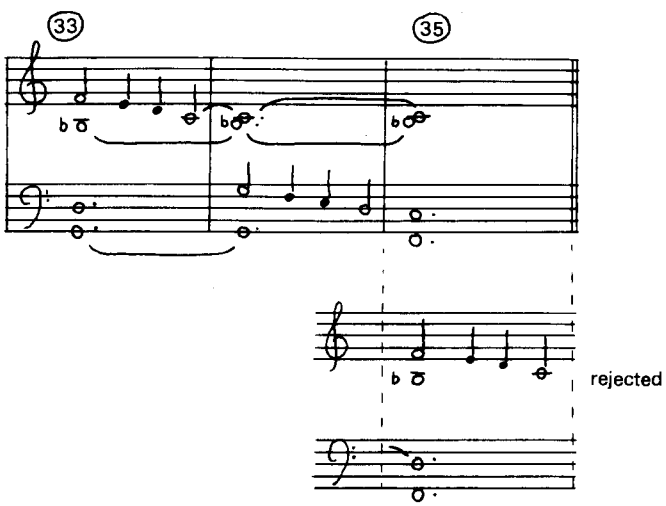
Example 4.16.

soprano finishes, so that the upward cycle of ascending fourths and descending thirds is unbroken. Giving the tenor voice a C at bar 34 determines a start note of G in bar 33, if it is to be a strict imitation (a constraint which I did not explicitly formulate, but one that seems to be a stylistic feature of the whole work). Such imitation allowed the tenor theme to be copied out to the F at the end of bar 35. Example 4.16 shows bars 30 to 35 as they stood after this stage.



E. *It would be boring to do that again for a third vocal entry. Would an entry fit in the rhythmic spaces, to make a sort of 'stretto'? I experiment with different interval separations. A bass part entering a fourth lower than the tenor seems to work quite well, so fit that in up to bar 36* (*Example 4.18*). It seems clear that I was constraining myself by the relatively strict contrapuntal requirement that each of the four voices should enter with the theme in sequence. My problem was, thus, how and when to bring in the next voice? I decided that it would be uninteresting to generate entry three in relation to entry two by direct analogy with the relation of entry two to entry one. Instead, I conceived of an earlier entry which allows for rhythmic interplay (Example 4.17). Once this was decided, it remained only to choose a pitch

Example 4.17.



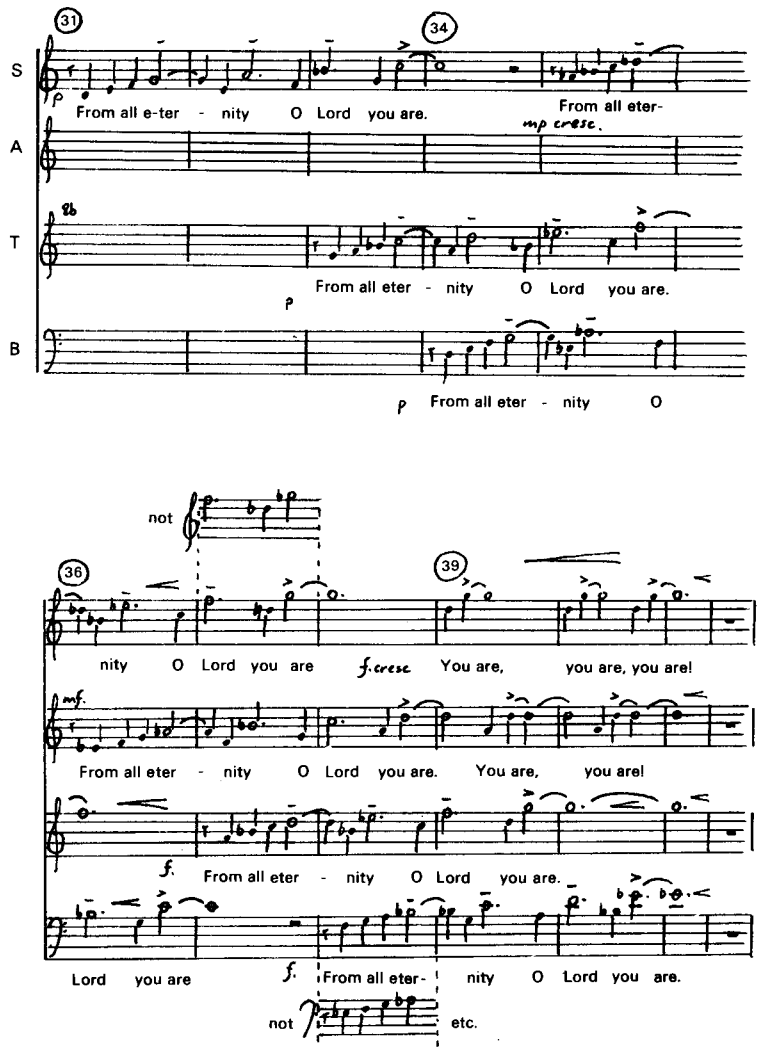
for entry three. The protocol suggests extended trial-and-error experimentation at the piano here (I always compose at the piano). Eventually I chose a bass entry on D as harmonically appealing, and wrote that out routinely to bar 36 (see Example 4.18).

F. *What happens to the accompaniment now? In experimentation I discover*

Example 4.18.

that a drop to F in the bass fits with the voice parts quite well at bar 35. I carry through a tied B flat from bar 33 to 34, repeat bar 32's left hand descending scale in bar 34, and tie the middle C in bar 33 through to 34. By rule, the tenor D in 34 should carry through to 35 as well as the tied treble notes. Does this sound a bit messy? In bar 35 we certainly cannot repeat the FEDC figure, because the voice parts have shifted to an E flat key space. Perhaps this is the time to stop the pattern, and let the tenor D go down to C. I try it. Now we have a totally static accompaniment (Example 4.19, bar 35), so we must look to the voices to see how this might develop.

Example 4.19.



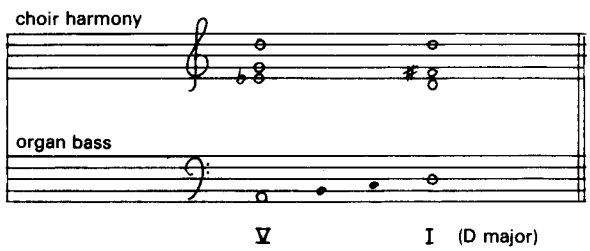
This section of protocol offers the most detailed comment so far, relating, as it does, to the composition of just over one bar of material for the organ. It was clearly a difficult and crucial moment for the direction of the music. The main problem was that there seemed no way of stopping the accompaniment just going on and on with the pattern established in bars 31

and 32. However, the voice parts were moving into remote harmonic regions, and so the accompaniment had to change somehow. The first decision was, then, to abandon the G pedal and drop to F at bar 35. The second decision was to abandon the repeated scale passage. The pattern established during bars 30 to 34 was that the last note of the scale passage should be tied over to the first beat of the next bar (see Example 4.8). If the left-hand passage at bar 34 is written according to this rule (repeating bars 32 to 33) this results in a tied D in bar 35. The chord produced by this (organ F, D, B flat, C; bass G, tenor E flat) was heard as unsatisfactory. It contained too many dissonances. By breaking the pattern and dropping the D to a C the chord was simplified and suggested as partial resting point. This suggestion was confirmed by the 'test' of putting a continuation of the right-hand scale pattern in bar 35 (F, E, D, C, as in bar 33). This created an unpleasant dissonance between the E flat in the vocal line and the organ E which was instantly rejected as a possibility. So, I was left with a simple unmoving chord at bar 35 (see Example 4.19) with no obvious implications for continuation. I returned to the voice parts to find the key to further development.

G. *I must bring the soprano voice in with the theme. I imitate the bass entry in relation to the tenor, so start on A flat in bar 35 (Example 4.20). If I follow strictly, this gets to D flat and G flat at bar 37. This is too harmonically remote, so I cheat and give D and G. Now that's four entries, but I have a feeling that this 'stretto' must be maintained for a while without working higher in pitch. How about taking the organ off at bar 35 or 36, then bringing it crashing in with some sort of perfect cadence later? Key? Who knows?* Here we find the completion (in principle) of the choral entries. I suspect that the fourth entry was given to the soprano rather than the alto because of its high tessitura. The soprano voice enters at bar 35 with the same pitch and time relations to the bass voice (at a suitable octave) as the bass has to the tenor. Once again, this pattern of successive entry can be repeated indefinitely. However, unlike the accompaniment at bars 30 to 35, there is a continual upward motion of pitch, and a movement round the circle of fifths in key, one step for each new entry. I seem to have wanted the continuing contrapuntal texture, but without further harmonic movement, so I was led to break my self-imposed constraint that the entries should be exact imitations. In bar 37, the soprano theme was shifted down a semitone from what it 'should be' so as to break the continuing movement round the circle of fifths (see Example 4.20).

At this point, an idea of the form of the next few bars presented itself in vague form. The organ stops, leaving the voices alone, intensifying the 'stretto' up to some climactic cadence, which is marked by the re-entry of the organ, fortissimo. Now there was a goal to control the next few bars, but, as yet, no idea of the final tonality.

H. *I notice that the vocal theme is four bars long, so it should be possible to bring it in each bar in a new voice* ad infinitum. *I bring the alto in at bar 36 on an E flat (same relationship to preceding voice as before). Then the tenor comes*

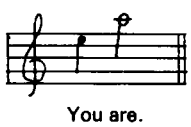


Example 4.20.

in on A in bar 37, the bass on E flat (no—we get an unwanted A flat). I try entering on F—this seems to work. I write out the bass part to bar 40. How do we fill in the soprano and alto whilst the bass is finishing? Repeat 'you are' more insistently, off beat with other parts (bars 39 to 40). It is not until this fairly late stage in working with the vocal material that I noticed the theme to be four bars long, deducing that it could, therefore, fit into an indefinitely long pattern where a new entry comes in once per bar in a different one of the four voices. This allowed the routine writing out of three more entries; alto at 36, tenor at 37, and bass at 38 (see Example 4.20). The first attempt

at the bass entry (following the strict pitch relationship to the previous entry already established) yielded an unsatisfactory harmonic result. The scale E flat, F, G, A flat moved too far away from the prevailing tonality, so, once again, I relaxed my constraints and allowed the theme to start on F, remaining in consonance with the other parts.

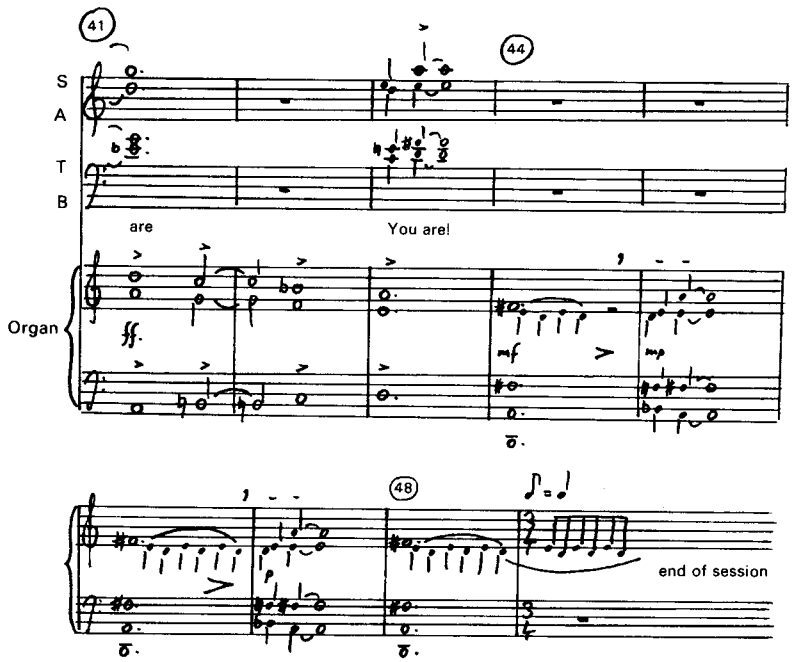
For some reason, I decided that there should be no further full entry after the bass, so the problem became what to do with the upper voices during bars 39 and 40. Anticipating an imminent climax, I hit upon the idea of taking the last two notes of the theme (ascending fourth) and repeating them with increasing insistence. This led to a chord at bar 41 which, in context, is harmonically unstable, and needs resolution (E flat, G, D). Even at this point, however, I was not clear where it should resolve.



I. *Now the accompaniment comes in at bar 41. I try various bass notes. A sounds well, suggesting a perfect cadence to D major. It is too direct just to go from A to D. I try A, B, C, D ascending. That sounds good.* At this point I was 'fishing' for the right organ harmony by piano experimentation. A bass A was recognized as the right note for bar 41, and I soon found the cadence required (Example 4.21). An elaboration (small intermediate notes B and C)

Example 4.21.

soon suggested itself. I now interpret my need for these notes as a prolongation of the unresolved dissonance, screwing up the tension until the very last moment. At this point, only the bass line of the organ part was plotted out.



J. *The choir has to have something on the D major chord (silence sounds wrong). I tighten the screw once more in the soprano with E, A (Example 4.22).*

Example 4.22.

I now find a choir harmony which fits, especially bearing in mind the E flat in the bass at bar 41 (Example 4.23). I think what sounded wrong here was the unresolved choir chord at bar 41. It needed to be resolved by the choir as

well as by the organ. I thus returned to the immediate choral context to find something which could be used, and arrived at the idea of moving the ascending soprano figure of bar 40 up a whole tone, to bring the sopranos to top A (Example 4.23, bar 43), the highest note in the whole piece, and an

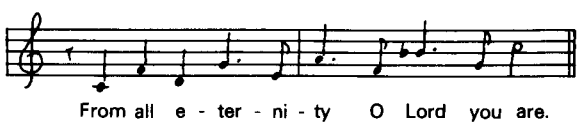
Example 4.23.

integral part of the D major chord planned for the organ. In this way, the chord of bar 43 becomes a climax, culmination, and summing up of the whole first section. I notice now, in retrospect, that the total composition has moved at this point from an opening G major to D major, the traditional tonic-dominant move of sonata form exposition; and that bar 43 contains the most emphatic statement of the ascending fourth motif which opens the piece. All this escaped conscious attention at the time, but, arguably, contributed towards my sense that this was a 'right' development. The filling in of the three outer choral parts at bar 43 was a piece of routine harmonization. Example 4.23 gives the final version of the choir parts in bars 41 to 43.

K. *The organ writing is a bit bare in bars 41 to 43. I add a right-hand part in descending fourths. Bar 44 is a straight D major chord, then the choir motif of bar 43 is repeated in a more luxuriant way (bar 45). I repeat bars 44 and 45 and this begins to form a flowing accompaniment out of which the next choral theme begins (Example 4.23).* Here the protocol ends.

The organ cadence, of such climactic importance, required more substance than a bare bass line. The notion of introducing a descending contrary motion line in the right hand must have come easily. As I now write, I notice that the melodic progression D, C, B, A is a slow version of the descending four-note scale which dominated the earlier accompaniment part (bars 22 to 33). The juxtaposition of this motif with the rising bass scale (derived from the opening of the vocal theme of the section at bar 31) makes a kind of grand, final statement of the thematic core of the whole section. In retrospect, the whole compositional process described here can be seen as a search for this crucial cadence. Through the fog of my compositional mediocrity loomed the dim shape of the 'inevitable' Schenkerian I–V movement, begging to be realized, but, at the outset, totally inarticulated. Climactic pivotal moment over, it then became easy to set the scene for my slower middle section. Bars 44 to 50 came quickly, allowing the organ to settle into a gentle rocking accompaniment for what was to come.

Something happened next which is of considerable importance in coming to understand the strengths and weaknesses of a protocol like this. Shortly after I arrived at bar 50, I began on the next section of the composition; but became immediately aware of a difference in the quality of the compositional experience. It was as if I had more urgent sense of direction. There came a wish to capture an unfolding shape before I lost it. As a result, I found myself incapable of continuing with the protocol, and embarked on an intense period of composition which produced the next 35 bars in an uninterrupted period of work.



This is not to say that I experienced a pure 'flow of inspiration'. Rather, it was as if I feared to lose some momentum if I stopped to record my thoughts in words. In retrospective examination of my manuscript, I sense a lyrical, overarching quality about the next section, giving it a unity and repose quite unlike the kaleidoscopic first section. It is in D major, and moves, with few intermediate steps, along the well-trodden harmonic path I–V–I, with a single melodic idea unfolding in the voice parts. I would hesitate to say that this section is *better* than the section for which a protocol exists, but I am quite certain that the compositional strategy was different. There was not the same sense of indecision and search. I was lucky enough to start with a set of constraints which, within the bounds of my compositional style, almost allowed the section to 'compose itself'. It seems probable to me that verbal protocols reveal most of the genuine compositional process precisely when the composer is rather unsure where he is going, and casts around among his consciously held stock of transforming and extending devices to come up with a possible solution. When things go smoothly, the requirement to provide a protocol may well alter, even disrupt entirely, the process one is trying to describe.

Tchaikovsky has expressed well the concentration that is often required when creative activity seems to flow particularly well:

I forget everything and behave like a madman. Everything within me starts pulsing and quivering; hardly have I begun the sketch ere one thought follows another. In the midst of this magic process it frequently happens that some external interruption wakes me from my somnambulistic state: a ring at the bell, the entrance of my servant . . . Dreadful are such interruptions. Sometimes they break the thread of inspiration for a considerable time, so that I have to seek it again, often in vain

(From Newmarch 1906; reprinted in Vernon 1970.)

What general psychological conclusions can be drawn from this protocol? The first is that the protocol and its subsequent explication leave much unsaid, detailed as they are. They do not come near to documenting the rationale for the choice of each and every note. For instance, there are many possible melodic patterns consistent with the constraints I identify for the vocal theme starting at bar 31. Why did I choose the one I did? In retrospect, I can formulate reasons why the theme I chose is better than an alternative such as Example 4.24. The chosen theme (Example 4.15) has more melodic

Example 4.24.

interest (this latter alternative is too repetitive), and it has more harmonic movement (the alternative spans an octave, and, as such, is harmonically rather static). I doubt if I would have consciously entertained this alternative at all. It is as if I was able to choose the *kind* of theme which had musical potential almost automatically. This is reminiscent of observations on other forms of skilled choice (e.g. chess playing; Simon 1979). In choosing moves, skilled players seem to consider fewer unpromising moves than do beginners. My own protocol is littered with unexplained choices. Something is *felt* to be right, or chosen without any justification at all. I take this to be a general characteristic of skilled problem-solving.

A second conclusion is that, at least in my case, the interplay between the discovered properties of previously composed material and some broader conception is paramount. All the way through the protocol I find myself deliberately using some feature of melody or harmony in previously written material as the starting point for a continuation. On the other hand, there are many cases in which superordinate considerations of harmony and structure prescribe changes which modify or overwrite the essentially imitative strategies which generate the first continuations. Just like Reitman's composer, I find myself engaged in trying to characterize what I have already got, so that continuations will be, in some sense, fitting or 'in style'; but I also have shifting, and often dimly perceived notions about the direction of a section which allow me to discern when strict imitation must stop.

Third, because characteristics of previously written material are often dis-

covered some time *after* the writing, but can still be important in shaping future events, I suspect that an important component of compositional skill is a degree of 'trust' in one's medium—a certainty that the habitual processes of generation will yield material which is richer than one first sees, and which, even if initially unsatisfactory, usually contains within it discoverable properties which can be used to profit. This trust is partly engendered by the sheer fact of previously solved problems; but it also has something to do with increasing awareness of the richness of a medium such as the tonal system. There are so many different kinds of relationship which hold between a set of notes that even the simplest theme can become an almost inexhaustible source of discovery. The consequent delight that any creative worker experiences in the sheer fecundity of his medium is, arguably, not simply a pleasant by-product of creative activity, but the essential source of motivation which keeps him involved with his own material through 'blocks' and blind alleys in the creative process. Such delight is amply documented by the practitioners of all sorts of skill; from mathematicians to poets (for example, Poincaré 1924, and Spender 1946; both reprinted in Ghiselin 1952, and Vernon 1970).

In discussing my protocol with fellow psychologists and musicians, the question has often arisen of how one might use such protocols to generate fruitful scientific research into composition. Protocol gathering is a species of natural history, and although it is an essential first step in understanding any complex mental process, it does not, on its own, allow detailed theory building and testing. For this, two lines of attack seem possible. One would be to focus on a simple compositional task, such as the harmonization of a short melody, attempting to specify *all* the cognitive steps which underlie the choice of particular chords by a particular composer. This would naturally lead to some form of computer simulation to test the adequacy of one's theory. Another related possibility would be to take some circumscribed compositional task, maybe the same one as before, and ask a range of musicians of varying ability and experience to carry out the task. By a comparative analysis of the behaviour of the different subjects it might be possible to specify some of the ways in which compositional skills change with experience.

4.5. Improvisation

The keynote of the compositional process seems to be the moulding and perfecting of musical ideas. Although an idea may come spontaneously, unbidden, and instantaneously, its subsequent development may take years. In improvisation, the composer has no opportunity to mould and perfect his material. His first idea *must* work. Is, then, the improviser a different sort of animal to the composer? Is he the musician who, like Rosemary Brown, seems to exert no conscious creative effort in the production of coherent

music? The record tells us that this cannot be so; we know that composers such as Beethoven were also master improvisers. The same man that could chisel away at a theme for 20 years could also produce live compositions of extreme accomplishment.

I wish to argue in this section that what distinguishes improvisation from composition is primarily the pre-existence of a large set of formal constraints which comprise a 'blueprint' or 'skeleton' for the improvisation. The improviser can, therefore, dispense with much of the composer's habitual decision making concerning structure and direction. He uses a model which is, in most cases, externally supplied by the culture, and which he embellishes and 'fills in' in various ways. Such models frequently have a recursive sectional form, so that the performer becomes very familiar with the structure of the basic section, which can, to a large extent, be considered independently from other sections. This means that the improviser does not have to be constantly referring back to the detailed working out of earlier sections as, it may be argued, a composer must. He can rely on the given constraints of the form together with his own 'style' to give the music unity.

If we look at one of the forms in which improvisation flourishes, we can see how it helps the improviser to construct his performance. 'Theme and Variations', for instance, is a common form in classical, folk, and jazz idioms. A typical structure is

phrase:	A A B A	A_1 A_1 B_1 A_1	A_2 A_2 B_2 A_2	etc.
section:	theme	first variation	second variation	etc.

In this structure, the theme is composed of four phrases (typically each eight bars in length). The second and fourth phrases are repeats of the first phrase; the third phrase is different, but stylistically and thematically related to the first. The theme will be characterized by a certain underlying harmonic progression, and this progression will be repeated in each new variation. The improviser maintains interest and momentum by embellishing and transforming the melody and the texture within this repeating harmonic framework. Once the character of the A phrase variant has been determined, the remainder of the variation becomes highly constrained. An improviser can, for instance, 'run off' the last phrase of a variation as a rough copy of the first phrase, whilst giving some advance thought to the construction of the next section.

It will help us to see musical improvisation in perspective if we compare it to a verbal skill which has roughly the same sort of demands, such as the recounting of a story by a skilled story-teller. First, the story-teller has knowledge of a particular set of episodes which constitute the 'plot' of his story. This is similar to the knowledge of a particular melody or chord sequence in music.

Second, each element of the plot contains reference to well-known objects, situations, people, etc., whose detailed characteristics are not necessarily

specified in the plot, but which may be used to elaborate and keep the tale fresh on any particular occasion of telling. For example, the plot may specify a character such as a farmer, who, without damage to the plot, can be further specified as old, lonely, jolly, tall, etc. on particular occasions. Minsky (1977) has used the term 'frame' to describe the cognitive structure that is accessed when a word like 'farmer' is introduced. This frame specifies attributes appropriate to the object or situation that can be specified, together with details of limits and constraints on those specifications. For instance, in a folk tale, a farmer will be an adult human being, so it is possible, although not necessary, to specify an age between, say, 15 and 70. Tellers and listeners frequently operate with 'default' values for attributes which are not actually specified. Such values may be chosen to be consistent with earlier information, or may arise from 'stereotypes'. For instance, when a farmer is mentioned, many listeners will assume a middle-aged, rather rough-cut male; and so a storyteller may choose to leave some details unspecified, knowing that the listener will still be able to make sense of the story through shared frames and stereotypes.

In music, we may equate 'frames' with characteristic harmonic or melodic progressions that underlie many different types of music. For instance, cadences are harmonic frames; particular types of melodic movement such as scales, arpeggios, gap-fill or changing note patterns (Rosner and Meyer 1982) are melodic frames. As in stories, many of these frames can be filled quite simply, with a couple of notes or chords, but can be fleshed out with various types of embellishment; passing notes and passing chords, for instance. There are many options for the way in which a musical frame may be filled. Performers and listeners within a culture will know about stereotypic ways of filling in such details. The composer and improviser achieve aesthetic impact by finding novel or surprising ways of embellishing a frame without changing its basic character.

A third feature of stories is their tendency to conform to certain structural specifications. One common type of story is the 'problem–effort–resolution' structure. An initial situation is specified. This situation presents some problem for a principal character or group of characters. They attempt to solve the problem; and this often involves the resolution of intermediate sub-problems. Finally, the goal is reached. Such structures allow both listeners and teller to keep track of the complex internal details of a story by labelling them according to their roles in the familiar structure. When stories do not conform to familiar structural models they are very hard to understand and remember (Bower 1976). The teller can use such a shared structure to pace his storytelling. If he senses his audience losing grip of the plot, he can add explanatory sentences to refresh memory of the position he is at within the structure (e.g. 'now the prince needed to find just one more thing before he would be able to slay the wicked dragon'). Similarly, if the plot seems too simple or bare for his audience, he can go down an irrelevant digressory path, provided that

he is able to leave a 'marker' which tells where he is within the main structure.

We can roughly equate story structure with 'form' in music, as exemplified by 'theme and variation' or 'fugue', etc. When such structures are known by listeners, they are able to appreciate the function of present events, and through their anticipation of future constraints they can appreciate the art that produces novel sequences to fulfil the relevant function in the correct time. In jazz ensemble music, for instance, there is often a distinction between a fairly invariant 'chorus' played by the whole group, and a 'solo' where an individual performer is given the opportunity to come to the fore in an improvisatory fashion for a fixed number of bars before leading back into the next chorus. A listener who knows this structure can realize that the solo is about to end, and wonder how on earth the soloist is going to return satisfactorily from his harmonic and melodic excursions in a way that appropriately leads into the chorus. When such a performer does 'get home' in an appropriate but novel way, the listener can derive satisfaction which would be denied to someone who did not appreciate the demands of the structure. Similarly, the performer's own knowledge of the structure allows him to plan excursions whilst retaining markers which tell him exactly when he must arrive at a particular musical event.

In a sense, every act of story-telling that is not a verbatim recall is an act of improvisation. However, such improvisation reaches a peak in feats such as the singing of epic poetry in the Homeric tradition, preserved into the twentieth century among the folk singers of Yugoslavia (Lord 1960; Parry 1971). The singers are often illiterate, yet each singer has a large repertoire of poems (as many as 100), some of which are several thousand lines long and take more than an hour to sing. Parry's observations and recordings show that epic singers composed their songs anew on each occasion. No two performances were the same.

Neisser (1982) summarizes the main features of this epic poetry:

> (the songs) show repetition of units at two levels of analysis, known as *themes* and *formulas*. Themes are types of events that occur in many different songs; a council of war, the arming of a warrior, the return of the hero in disguise. The formula, a much smaller unit, is 'a group of words which is regularly employed under the same metrical conditions to express a given essential idea' (Lord 1960, p. 30). The singer may have a dozen formulaic ways to describe daybreak: 'when dawn put forth its wings', 'when it was dawn and white day', or 'when the sun had warmed the earth', for example. When he comes to a part of the action that takes place at dawn he uses the one that best fits the metre and his mood. He knows dozens of themes and thousands of formulas, not from having memorized them but from having heard and used them, as we know the words and phrases of our own language.

This poetry is of special interest to us because it is *sung* and so involves musical improvisation too. The composer and musicologist Béla Bartók had a particular interest in Eastern European folk music, and collaborated with Lord in transcribing and analysing some of the musical recordings made by

Parry (Bartók and Lord 1951). The epic poems were always sung by a man, accompanying himself on the gusle, a one-stringed variety of lute which could provide a few different single notes for a drone-like accompaniment. The sung music was a version of chant. As far as one can undertand the comments of Bartók and Parry, who did not transcribe many of the epic poems, these chants were short simple melodies which were repeated with minor variations in the successive lines of the poems. Bartók was more interested in the shorter 'women's songs' where the degree of verbal improvisation was much less, but where the music was of considerably more complexity. His analysis identified various 'principal tones' which constituted the basic melodic frame for successive verses. The painstaking transcriptions show that a singer would embellish each verse in a different way, and would not use the same embellishments on two performances of the same song. There was much use of interpolations; glides, grace notes, ornaments, and passing notes.

In general, although vocal music is no stranger to improvisatory treatment, purely instrumental music seems to have encouraged more ambitious musical improvisation through the ages. One reason for this is that words constrain vocal music in many respects. A sung melody can be embellished only at the expense of directness of word communication. The 'basic' folk melody usually has only one note for each syllable. If more notes are added, then words must be repeated, or new syllables be created, or existing syllables lengthened and sung to several notes. The second of these devices is apparent in the Bartók transcriptions, where nonsense syllables (e.g. 'Aj' or 'Ahaj') are interpolated between words. Similarly, English folk songs are often embellished with 'fa la' or 'fol de rol', etc. The third device is known as melisma, and is common in many types of vocal music. Excessive use of melisma does, however, destroy the natural metre of the words, and can lead to severe difficulties in understanding them. In Gregorian chant, for instance, it can sometimes take five minutes to sing one sentence; a distortion which can only be tolerated if the words are well known to the listeners.

Although improvisation has flourished in various cultural and historical settings, I shall base the remainder of this section around jazz improvisation. Jazz is a contemporary Western form in which improvisation is paramount. It is a convenient form to study because (*a*) the idiom of most of its styles is derived from popular Western music (in its widest sense), and so is straightforwardly tonal; and (*b*) being contemporary, it can be experienced by any listener with access to a radio or a record player. We can only guess, from imprecise reports of observers, exactly how an improvisation by Mozart or Beethoven sounded. (For some observations on contemporary non-Western improvisatory forms, see Chapter 7).

There are two primary jazz forms; the 12-bar blues and the 32-bar song. The melody is often a 'standard' which is played in a fairly straightforward way to begin with. Repeated improvisations retain the basic harmonic sequence (although with the possibility of varying the harmonic detail); but

the *essence* of improvisation, both here and in the 12-bar blues, is in the melodic line. This is partly due to the fact that the prototypical and original jazz medium is the brass ensemble where, because each player can produce only one note at a time, solo performance is necessarily melodic. Jazz piano came later, but it copies features of brass ensemble playing. The left hand typically provides chords and rhythm; the right hand 'plays the solo', carrying a single melodic line which is the focus of improvisatory effort.

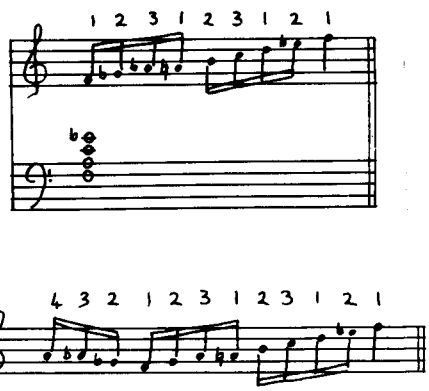
All this, though, does not uniquely specify *jazz*. It would be quite possible to produce something perfectly 'Mozartean' using the 12-bar blues frame. What gives a performance its jazzy character are the particular types of melodic, rhythmic, and harmonic devices which form the basic building blocks for larger sequences. Such devices are almost exactly analogous to the *formulas* of epic poetry. They constitute the vocabulary of jazz. However, just as Yugoslav singers do not memorize a dictionary of formulas, so jazz improvisation is not normally learned by arming oneself with a list of characteristic chords and progressions. Jazz is learned through listening intently to other musicians and performing with them. Books and notation are not necessary; many great jazz performers could not read a note of music.

The pianist David Sudnow has performed a valuable service by writing a book which records his progress at learning jazz improvisation (Sudnow 1978). He provides a detailed exposition of his experiences at various stages of his development. In pulling out the principal features of his account, we can reinforce and expand the characterization of improvisation already given in outline.

When Sudnow approached the task of learning jazz he was already a competent classical pianist. The first new thing he learned was the 'anatomy' of typical left-hand jazz chords—practising placing single chords in the various keys of the chromatic scale. This was so that his hand would come to take up the appointed finger configurations rapidly and accurately without hitting adjacent wrong notes.

Second came the task of combining chords into the sequences typically found in songs. This entailed the co-ordinated ballistic movement of arm, hand, and fingers, to negotiate the sequence in a smooth but strict rhythm. At first, much visual monitoring was required, but eventually, common song sequences could be negotiated independently of visual control.

Next, standard (non-improvised) song melodies were combined with their appropriate chord sequences, so that the first statement of the 32-bar song could be given. All this was preliminary to the main task, that of melodic improvisation over a standard left-hand chord sequence.



At the outset, Sudnow did not know how to start nor once started, where to go next. The hand

> might as well have gone anywhere, but once it did, there was nothing for it to do, and I discovered from the outset that if you don't know where you are going, you can't go anywhere except incorrectly. The hand has to be motivated to particular

next keys to depress, and when there was nowhere for it to go it became totally immobilised, stumbled around . . . (p. 18).

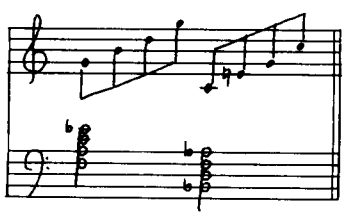
He had no *formulas* to put into play. This was despite much experience of listening to jazz improvisations. He found the improvised passagework of his favourite performers so fast and complex that he simply could not get a detailed, note-by-note grasp of the structure. He reports that 'a three second stretch of play, within the course of an ongoing jazz improvisation (on record) I had listened to for many years, demanded several hours to catch the details sufficiently . . .' (p. 16).

Sudnow's teacher dealt with this problem by giving him some specific formulas. He would say 'with this particular chord you can get a characteristic sound by playing this particular scale.' An example of a chord-scale combination that Sudnow learned in this way is given in Example 4.25. He learned enough of these scales to have one available for each of the twelve chromatic dominant-seventh chords, and became fluent at playing them rapidly, both ascending and descending. At first, he could begin these scales in only one or two places. He reports that 'over the first years of play, nearly every time I played this particular scale, I either started on the F with the thumb (Example 4.25) or on the fourth finger (A) then moving down to the F (Example 4.26). This rigidity in a scale that could, in principle, be started on

Example 4.25. and 4.26. Jazz formulas learned by Sudnow (1978).

any note, was attributed to lack of useable knowledge about what finger to use if starting on other than the familiar note. To start, for instance, on the B natural and move upwards would require a second finger. But Sudnow knew the sale only as a single 'handful'. He knew a start note and the rest 'just happened'. So, in his early improvisation, he would simply find the appropriate scale for a particular chord, varying only the octave in which it was started or the number of notes used.

Gradually a repertoire of characteristic jazz formulas was built up in this



way: 'arpeggios to be taken and scales to be linearly played, various "licks" constituted by certain intervallic relationships.' It was at this point that Sudnow tried his chances with a jazz trio at a club. His graphic description makes it clear just how far from true improvisation he yet was:

> . . . and now a run for chord A is played, starting near the middle of the keyboard, and rises up, while the pathway I know best for chord B is played starting at the middle also. So that I started going up with a fast, spluttering, and nervous scale course, and the next chord came up and I had to shoot back down to the middle of the keyboard, to get the thing I knew how to do well done for it, and then there was the next chord. . . . An upward-moving line would more or less end when the next chord's sustaining had to be terminated, no matter where it was. Or, in order to get to the next starting place, I would end it a bit sooner, to give myself time to relocate, feeling the upcoming chord as an encroaching presence whose necessity was fixed by adherence to the chord chart of the song . . . so that what the left hand was doing in its pre-set ways was guiding what the right hand was then obliged to do. (p. 37.)

Sudnow continued for a few more years on essentially the same course, adding more and more formulas to the repertoire. Then, one day in the third year of his play, he began to have a different experience with his playing, which he calls 'going for the sounds'. This experience was essentially one of selecting and anticipating *particular* notes in the melodic improvisation. He explains that, up to that point

> there was, with respect to the finely textured note-to-note nature of my play, an order that was guaranteed by the path's formal theoretical construction . . . (e.g. a scale) . . . I was not doing note-to-note selectional work. I decided where to start out each run, which run to choose, how fast to play it. But, we may say, no intentionality of aim was given to particular pitch achievments—only these broad 'parameters' received a motivated determination. (p. 39.)

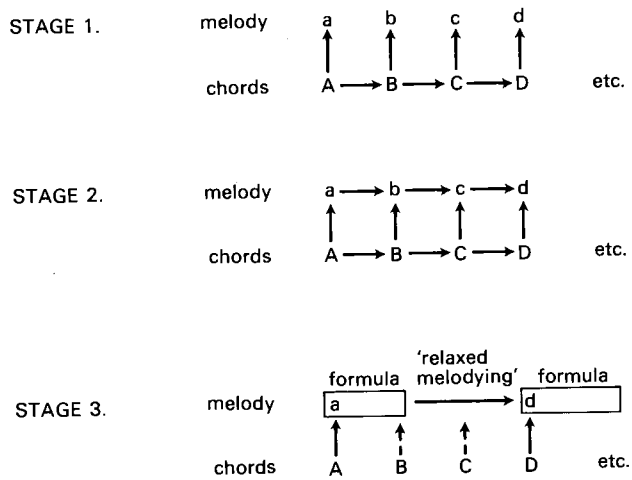
Now, in contrast, Sudnow started to plan particular note effects. He did this primarily by attempting to relate a particular melodic line 'backwardly' to what had been done before, on the previous chord. So for instance, two adjacent chords might be given the realization shown in Example 4.27. Here,

Example 4.27. Imitatory improvisation. From Sudnow (1978).

the second group of four notes is a melodic imitation of the first group.

Previously, Sudnow had only the capacity to respond melodically to each chord as it came up by 'pulling something out of the bag' in respect of that

chord alone (Fig. 4.2, stage 1). Now he was able to choose a continuation which both fitted the chord and was similar to the previous melodic fragment (Fig. 4.2, stage 2). This new way of playing led at first to a loss of fluency.



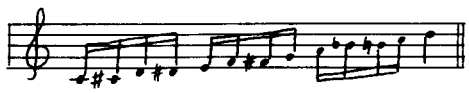


Fig. 4.2. Three stages in the development of David Sudnow's jazz improvisation.

Because the hand was attempting more ambitious things, it more often went wrong. For instance, to transpose a melodic pattern up or down a fixed number of semitones requires different fingering and hand configuration according to the particular black and white note pattern that the new key has. The melodic fragment in Example 4.27, if transposed to start on E flat, has a black-white-black-black key sequence, in contrast to the original all white sequence. This requires a shift in hand shape and, if uncertainly known, entails the possibility of hitting a wrong note. The well learned scale formulas were, however, played impeccably by this stage.

At this stage a typical experience is described as follows:

> I would play a figure, go for its repetition, get some way into it, and stumble. To fill what I felt to be the remaining empty space, keeping this jazz going, I would do something quite unrelated to the explicit continuities I had partially achieved. I would accomplish the beginning of a reiteration (transposition, inversion . . . exact duplication, etc.), and then, for example, use up a remaining allotted chord time by taking on any notes that were thereabouts to take. (p. 56.)

Gradually, Sudnow worked towards something more assured and principled to do when the imitation attempt failed. He calls this the 'chromatic way'—and it essentially involves a bunched hand which plays a close set of notes which, although not necessarily composed totally of semitones, would have a chromatic character (e.g. Example 4.28). Such devices 'were afforded potentials for keeping action going in a sector, for making streams of notes,

Example 4.28. Chromatic improvisation. From Sudnow (1978).

for doing a fair amount of unthoughtful, weakly geared aiming for sounds. They allowed sustaining, at the same time, a connective tissue of action within attempts to tie up courses taken with one chord to those taken with the next' (p. 60).

Still Sudnow knew he was not really playing jazz the way he wanted it. It was too 'lungeful', composed of sporadic 'bits' of motivated improvisation joined together by *ad hoc* connections. It was after listening to the jazz pianist Jimmy Rowles (and watching him) that a breakthrough came. Rowles 'sat rather low down and stretched back, almost lazy with the piano like a competent driver is nonchalant behind the wheel on an open road. Still, there was a taking care with the melody, a caressing of it, a giving each place its due. He was never in a hurry . . .' (p. 81).

Rowles' relaxed swaying way at the piano contrasted with Sudnow's own 'frantic' attempts to negotiate fast passagework. Rowles played more slowly, with more attention to the basic melody. In trying to imitate Rowles, Sudnow began to find that

> within my practice sessions little spates of that jazz on the records unpredictably showed themselves to me, and then disappeared. No sooner did I try to latch on to a piece of good-sounding jazz that would come out in the midst of my improvisations, than it would be undermined. . . . But there is no question that the hang of it had been glimpsed . . . All prior ways of being seem thoroughly lacking, and the new way is encountered with a 'this is it' feeling, almost like a revelation. . . . For a brief course of time while playing rapidly along, a line of melody would be generated, interweavingly flowing over the duration of several chords, fluently winding about in ways I had never seen my hands wind about before. (pp. 83–4.)

At first, Sudnow was unable to characterize exactly what he was doing in these moments, but gradually he came to realize that it was a sort of 're-leasing' from the rigid formulas which sent him scampering up and down the keyboard, on the basis of a new understanding that 'note choices could be made anywhere, that there was no need to lunge, that usable notes for any chord lay just at hand, that there was no need to find a path, image one up ahead to get ready for a blurting out . . . Good notes were everywhere at hand, right beneath the fingers.' He found

> for example, that where it before seemed required to reach for a big path for a chord, forseeing its location and organizational requirements . . . a single note would do to make melody over the course of several chords' durations. I could take my time in going for a long run, could linger, finding right beneath a non-venturing hand all sorts of melodying possibilities. (pp. 94–5.)

This allowed him to escape the tyranny of a rigid time schedule which had so hampered his earlier attempts. In the old way of playing, each chord was like a starting gun for some new pattern. So, the previous pattern had to get finished in time, maybe breaking off in an unplanned place. Sometimes he would fail to get to the new start in time, so the hands moved unintentionally out of phase, and the next figure would be hurried to get back on schedule. The new style allowed

> mobile ways with the terrain such that commitments to arrival times could be continuously altered and shifted about in the course of the negotiations, a steady beat to the song as a whole sustained all the while. . . . It was to permit nonstuttering and nontripping disengagements from the terrain when a saying was not at hand, disengagements that would not make the music stop but would be silences of the music. (pp. 103–4.)

So now, the relation between the chords and the melody was looser; chords would still suggest typical formulas, but maybe a formula could run over into the next chord, then leaving the hand in a position to do some of the new relaxed melodying, taking time to introduce the next formula (Fig. 4.2, stage 3).

Very often a 'wrong note' in an attempt to play a formula could be used to good purpose. Instead of stumbling to correct the mistake, the note could be exploited in a jazz-like way. We see, therefore, an increasing understanding of the potentialities of almost *any* note to be used to effect in jazz. This presumably comes about through the years of experience of exploring the sounds that a keyboard makes. The improviser is relaxed and unhurried because he knows that, wherever he lands up, there are a dozen different ways of getting from there to the next place.

This confidence in the availability of plenty of 'escape routes' is, surely, a hallmark of skill in any impromptu accomplishment. To take a non-musical analogy from personal experience; my profession entails the fairly frequent giving of lectures and seminars to other members of the profession. When I began doing this, I was particularly terrified of the questions session which followed my 'set piece'. I was afraid of many things: not knowing the answer to a question, having some devastating criticism pointed at my work, not being able to put together a fluent reply without preparation. These fears began to subside as (*a*) I realized that I had a natural advantage over my audience; that of knowing the details of my own material, through many months of involvement with it, far better than anyone in the audience, and (*b*) I developed a repertoire of ways of handling awkward or unpleasant questions without faltering or becoming confused. The most important thing in situations like this is not to provide the *best* answer, but to provide *an* answer of some respectability with the fluency and immediacy that signals competence. Now, I usually face a question session in a relaxed and confident frame of mind because I know that I will always be able to find *something* appropriate to say. The jazz improviser can enjoy his improvisation because

he knows that there will always be *something* he can play. Within this competence he, like all improvisers, knows that for much of the time he will produce quite ordinary improvisations; but from time to time, according to circumstance of mood and choice, something superlative will come up.

Here, then, is a fundamental difference between improvisation and composition. The composer rejects possible solutions until he finds one which seems to be the best for his purposes. The improviser must accept the first solution that comes to hand. In both cases the originator must have a repertoire of patterns and things to do with them that he can call up at will; but in the case of improvisation the crucial factor is the speed at which the stream of invention can be sustained, and the availability of things to do which do not overtax the available resources. In composition, fluency becomes less important; but it is much more important to keep long-term stuctural goals in sight, and to unify present material with what has gone before.

As we said at the beginning of this section, what absolves the improviser from the task of evaluation and long term planning is the relatively rigid formal 'frame' within which his improvisation takes place, and which dictates the large scale structure of his performances. Because this frame persists over many improvisations, the performer builds up a repertoire of 'things that have worked well in the past'. Commentators on jazz have emphasized that there is often less improvisation on the concert platform than one might imagine. The musician is often 'playing safe' by using improvisatory devices which have worked well in other circumstances, so as to create the best effects he knows how. A so-called improvisation may, in fact, be a carefully planned and rehearsed performance; although there is nothing about the performance as such that would allow us to know this. To evaluate the degree of true improvisation, one would need to ask for two or more performances of the same piece for comparison. This observation is not to denigrate the musicians concerned. Improvisation is still at the heart of their art, but the social and commercial pressures of the concert platform do not encourage the risk-taking that improvisation inevitably involves. For real improvisatory jazz at its best one may have to seek out the late-night backroom informal sessions where, amidst a dedicated and sympathetic audience, experiments that fail, as well as those that reach new heights, may be observed.

As when discussing composition, we may ask how these informal observations on improvisation may lead to more rigorous scientific study of the processes involved. Sudnow's commentaries, for all their merits, were formulated some time after the improvisational acts in question, and at a level of some generality. There is a need for detailed and controlled study of *in vivo* improvisations. Although concurrent protocols could not easily be obtained from an improviser, the next best thing would be an immediate retrospection. By recording an improvisation and then playing it back to the performer, with as many pauses and backtracks as required, we could hope to obtain a detailed record of the conscious decisions involved in constructing

the improvisation. Experimental studies also suggest themselves. For instance, one could pre-record simple repeated chord sequences and ask performers of varying ability to provide as many different melodic variations as they can. Effects of the 'stereotypicality' of the chord sequence, or its speed, could then be examined. There is a rich untapped vein of data here which urgently awaits psychological attention.

5. Listening to music

5.1. Introduction

The two musical activities we have considered in detail so far, performing and composition, each entail the production of an externally observable end-product. Performance involves making a sequence of sound-producing movements, and composition involves making a score or some other communicable record. In contrast, listening to music is, in many situations, a passive affair. When I go to a symphony concert or listen to a gramophone record there may well be a lot of *mental* activity, but there is not necessarily any observable physical activity. The principal end-product of my listening activity is a series of fleeting, largely uncommunicable mental images, feelings, memories, and anticipations. When trying to understand what happens during music listening, the psychologist, therefore, is at a considerable disadvantage. In the previous two chapters we used concrete evidence from performances, scores, sketches, etc. to infer something about the cognitive processes that produced them. Such types of evidence provide what we may call 'records' of the music concerned, because they have a detailed event-by-event correspondence with the music. Many, if not most, instances of music listening do not provide 'records' in this sense.

Sometimes there is a specific behavioural activity attached to listening. For instance, one may dance, clap one's hands, or tap one's feet in response to the music. From such behaviour the psychologists may be able to infer something about the listener's ability to derive rhythm and metre from music (see the discussion of rhythm in Chapter 2, section 5.4); but such a response is hardly a *record* of the music. Rather, it is a generalized response to rhythmic characteristics which can be shared by very many pieces of music. By simply examining the response, one would not know *which* piece of music had been heard.

We approach closest to obtaining a musical record when we ask a listener to *recall* what he has heard, as we may do when teaching someone a new song. However, unless the material to be recalled is very short we are in danger of seriously underestimating the amount of musically related mental activity that has taken place. I have frequently been unable to recall details of a long piece of music after a first hearing, even though I was totally engaged with the music while it took place. As when listening to a lecture, or reading a novel, the details of argument and plot may fully engage one's intellect *whilst* one experiences the unfolding of ideas, but they may leave few recoverable traces at the end of the session.

The principal problem facing the student of listening processes is to find a valid way of tapping the moment-to-moment history of mental involvement with the music. As we examine research in the field of perception, attention, and memory in music we shall find that this problem has not really been solved satisfactorily. Most research evades this crucial issue by examining responses to very brief segments of music, made up of between two and twenty notes. Such segments hardly present listeners with the range of patterns and relationships which they must deal with in even the simplest short song.

In defence of such research one may, of course, argue that music is made up of a large number of small fragments chained together, and that music perception is simply a concatenation of a series of perceptual acts on such fragments. If so, however, then all the art of classical composition must go for nothing, because, as has been argued earlier, events quite far apart in time can be intimately connected structurally. Intelligent listening, we may argue, picks up such relationships; it spans large numbers of notes so as to be 'structural hearing' (to use the phrase coined by Salzer 1952). Composers write for listeners, not analysts, and the testimony of many listeners is that they *can* discern the large-scale relationships which analysts characterize.

What we may, more modestly, claim for studies on short musical fragments is that they shed light on elementary listening processes whose results are then used by higher processes about which little is known. In a similar way, students of language perception have discovered a great deal about the way in which listeners deal with isolated sentences (e.g. Fodor, Bever, and Garrett 1974), but these findings do not allow a very clear picture to be formed of how listeners or readers deal with whole paragraphs or books. For that, one has to find ways of observing behaviour in response to the larger units (Bransford 1979; Clark and Clark 1977; Sandford and Garrod 1981).

A further problem hinders our attempts to appreciate the significance of music listening studies. We must distinguish effects which are due to real and abiding features of normal listening from those which are special effects of the experimental task, which may involve activity quite unlike that of normal listening. Let me give a common example. Many studies require a listener to hear two short extracts of music and then to judge whether they are the same or different in some respect. The normal inference drawn from such studies is that if a listener can reliably tell when a particular type of difference is present, then he extracts this information in normal listening, and conversely, if he cannot reliably detect a difference, then he does not extract such information in normal listening. In fact, neither inference is necessarily valid. *Success* at discrimination in the experimental task may be a result of the subject's being able to focus on the dimension concerned for a brief period. This does not imply that he will choose to, or be able to, focus on this dimension in continuous listening where other dimensions of sound also demand his attention. For instance, fine differences in timing or tuning may

be noticeable in very short sequences, but be completely unrecoverable in longer ones. *Failures* of discrimination in the experimental task may be due to lack of cues that would be supplied by a more extended context. For instance, we shall see that listeners are often unable to tell short sequences apart when they have slightly different pitch intervals but identical up–down contour. It would be wrong to conclude from this that listeners cannot use pitch interval information in extended listening. It seems that in more realistic listening situations pitch information becomes crucial in discrimination (Dowling and Bartlett 1981).

Another example concerns the degree of familiarity that a listener has with the materials. In most music perception experiments this familiarity is low—the listener is exposed to sequences that he has never heard before. In contrast, real-life listening often involves the repeated hearing of the same material so that its internal structure becomes better and better known. Most serious listeners to music will have experienced times when they suddenly 'see' some new relationship between elements of a well-known piece of music—music that they may have lived with for many years. The experimental literature has told us very little about such processes, although recent work by Pollard-Gott (1983) has shown that subjects change their coding of segments from Lizst's Sonata in B minor after only a few opportunities to listen to the complete work. Briefly, she found that repeated exposure increased the likelihood that subjects would notice 'deep' harmonic or thematic similarities between segments, as opposed to 'surface' features, such as speed or tessitura.

I do not wish to dwell at any further length on the hazards and shortcomings of 'music perception' research. I have put these cautionary comments at the beginning of this chapter because it is a source of great disappointment to me that the one area of music psychology in which research is flourishing should be characterized by a relative insensitivity to the problems of relating research findings to normal music listening. This disappointment is shared by others (e.g. Davies 1979) but rarely voiced in print.

Another factor which prompts cautionary remarks at this point is the 'halo effect' which can surround a body of research which has the credentials of a *paradigm* as typified by Kuhn (1962). A paradigm is signalled by the existence of a set of agreed research problems, a methodology capable of solving them and generating new, but similar, problems, and a group of scientists who interact around these problems. When, as often happens, such a group 'captures' prestigious communication channels, in journals and elsewhere, generating a continuous series of co-ordinated and logically connected research articles, it is tempting to accord the research a significance which is not necessarily justified by its long-term achievments. The history of psychology is littered with forgotten paradigms. Many of them were initially motivated by important and substantial psychological problems, but in the end sub-

sidiary problems raised by the research became the main focus of potentially indefinite elaboration which contributed nothing to the original substantive question. I speak as one who has been seduced by the attractions of paradigm-driven research; and I have dabbled at the edges of a paradigm (Sloboda 1976c, 1977b) which is, I believe and hope, already being consigned to obscurity. I would not wish to go so far as to say that music perception research is unproductive, or to argue that science should proceed in any other way. I would argue, however, that we need to be constantly checking that questions of real musical importance are being asked and answered. It is all too easy to take currently researched issues to be *the* issues of music perception, just because a substantial body of research is *there* in all its solidity, interconnectedness, ingenuity, and undoubted methodological soundness.

If this causes me to stand a little lightly to the current research, mentioning some, but by no means all, of the experimental approaches to music perception, then I must say that I feel happy to do this, not least because there are several very good and fairly exhaustive reviews of experimental work in this area which absolve me from duplicating the effort here. I would advise the reader who is seriously interested in music perception to read one or all of the following: articles by Deutsch, Dowling, Shepard and Ward; all in Deutsch (1982a); and the authoritative survey and bibliography provided by Spender (1980).

5.2. 'Natural hearing': primitive grouping mechanisms in music

The first area of study that I wish to examine relates to a fundamental question about music. This question is: what natural mechanisms and propensities of the human auditory system can determine the way in which we hear musical sounds to be grouped? The principal characteristic of music is that sounds stand in significant relation to one another, not in isolation. For music perception to 'get off the ground' listeners must start to notice relationships and identify significant groupings. At the highest level such groupings will be large and complex, corresponding to formal structures within a work. At the lowest level they will be relatively simple, features of the sound pattern which characterize small groups of notes.

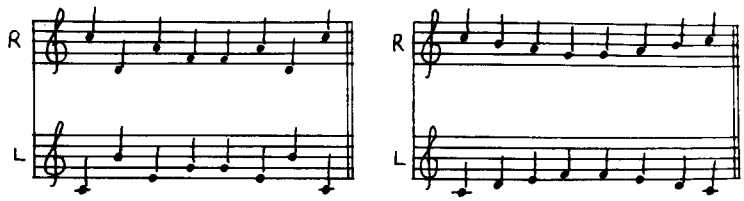
Studies of visual perception have revealed a number of basic and universal grouping tendencies which go under the name of 'Gestalt principles of perception' because they were first given systematic demonstration and formulation by the Gestalt school of psychologists (e.g. Wertheimer 1923). Although visual examples are most commonly cited, these principles can be seen as having application to any perceptual domain, representing as they are held to do, primitive and innate grouping tendencies. It seems that very young children and animals are subject to the operation of these principles as well as human adults (Gibson 1969).

If these principles are innate and universal, then it is possible that they

have been incorporated into the brain's way of operating in order to solve perennial perceptual problems faced by living organisms that interact with a natural environment. Some of these problems have been identified (see Sutherland 1973, Hochberg 1974, and Marr 1982, for vision; Bregman 1981, and Kubovy 1981, for hearing). For instance, the principle of 'common fate', which states that elements that move in the same direction are perceived together, allows a solution to the problem of how to identify the elements of a visual scene which belong to a single moving object that may be partially obscured or occluded by other visual elements. This principle explains why an animal which may be perfectly camouflaged against a background whilst stationary becomes instantly visible once it moves. Striking demonstrations by Johanssen (1976) show that conjoint motion of lights fitted to the joints of otherwise invisible humans is sufficient for an observer to reconstruct a percept of them which can not only identify them as humans, but allow a normal observer to make accurate estimates of their age, sex, and actions as well.

Most of the natural mechanisms of visual grouping are motivated by 'action' requirements. They help the organism to orient and move about the environment effectively, to locate and track objects in that environment, and so on. We should expect auditory grouping mechanisms to have their roots in similar requirements. Deutsch (1982b) suggests that a primary function of auditory grouping mechanisms is to assist in the enumeration of sound-producing objects in the environment. Such objects are likely to be of importance because they are other animals (friendly or unfriendly) or because they signal significant change in the environment (e.g. fruit falling from trees).

We may imagine the sounds of a forest at night, a potentially bewildering confusion of overlapping sounds. Yet it is possible to separate and group the sounds. We hear the complex sound-pattern created by the wind rustling in the trees as unified, yet separate from the chirps of insects. And we hear the calls of three birds of the same species *as* three sounds. To each source is assigned the correct 'package' of sounds. Gestalt grouping mechanisms underlie our ability to 'parse' the acoustic environment effortlessly. Thus, Deutsch argues that 'similar sounds are likely to be emanating from the same source, and different sounds from different sources. A sound sequence that changes smoothly in frequency is likely to be emanating from a single source. Components of a complex sound spectrum that rise and fall in synchrony are also likely to be emanating from the same source' (Deutsch 1982b, p. 101). These likelihoods govern the way we group complex sound 'scenes'. The existence of such grouping tendencies is, arguably, one of the happy chances that allows us to hear *musical* groupings spontaneously. Let us look at the operation of some of these tendencies in more detail.

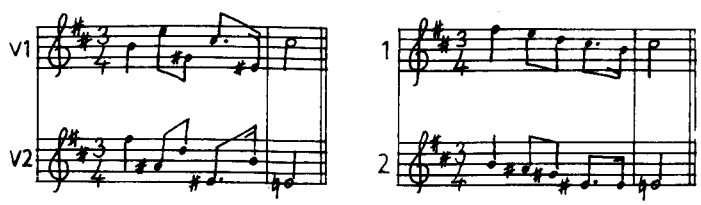


Sound sources usually have definite physical locations, and a possible way of sorting out a complex set of sounds is to group them according to perceived

location. One way of locating the direction of an unseen sound source is through the comparison of the sound signals that arrive at each ear. When a sound to the left of a listener is turned on, the first impulses arrive at the left ear slightly before they arrive at the right. The technical term for this time differences is 'onset asynchrony'. Humans, and many animals, have precocious ability to locate an unseen sound source through onset asynchrony. Quite young babies will turn their heads to look in the direction from which a sound has come.

A listener can also locate a steady tone through phase differences between the two ears. Because sound is transmitted through air by a series of air molecules, and because points of maximum compression move outwards from the source at a finite speed (taking about 680 μs to traverse the 23 cm between the two ears), there is a time difference between the energy peak at the two ears which can be detected. In this case, though, the energy differences are small compared to sounds which have sharp onset or offset bursts (known as transients). Therefore, sounds with transients, such as clicks and chirps, are more accurately localized than steady tones. The wise hi-fi salesman uses this fact when demonstrating the power of his stereo systems. Music with percussive elements will give rise to a more compelling 'stereophonic' effect than will the 'smooth' characteristics of voice or string sounds.

There are other problems with grouping by localization. Echoes and reverberations can cause sounds to arrive at the ear from other directions than the source. Also, the auditory system has no way of distinguishing between a single sound coming from directly in front of the face and two identical sounds coming from equidistant sources on either side. For these and other reasons it has been argued that location is a less important grouping cue than *pitch* (see Bregman 1981; Bregman and Campbell 1971; Deutsch 1982b; Kubovy 1981). In nature, sounds coming from the same source over a brief duration will also tend to have the same, or similar pitch. If pitch *does* change it is more likely to be smoothly, or in small steps, than discontinuously or in large steps. Additionally, in nature, perceived pitch and perceived location are often mutually reinforcing; confirming the *same* grouping of sounds.

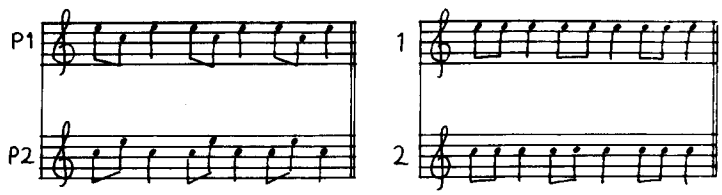


Man-made sounds, in music and in the laboratory, can deliberately set grouping cues in opposition, creating illusory or ambiguous percepts which demonstrate the relative strengths of the grouping tendencies. A good example of this work has been provided by Deutsch (1975) who played listeners two simultaneous tone sequences through headphones, one to each ear. The two sequences are shown in Example 5.1. The commonest perceptual experience which arose from these stimuli is shown in Example 5.2. Listeners heard all the high tones emanating from the right headphone and all the low tones emanating from the left headphone. Deutsch calls this phenomenon the *scale illusion* because listeners hear the stimulus as two smooth scale passages rather than as the two angular melodic contours which were actually present.

Example 5.1. and 5.2. The scale illusion. From Deutsch (1975).

Butler (1979) has demonstrated that this pitch grouping phenomenon is highly robust. Deutsch used pure tones with headphones, but Butler used real instrumental sounds (e.g. piano) with spatially separated loudspeakers. Even when the notes from one speaker had a distinctive timbre, listeners still predominantly grouped by pitch.

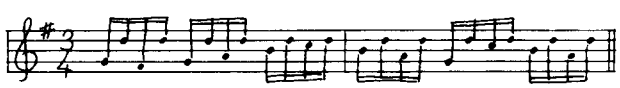
Composers seem to have discovered this phenomenon long before it was brought into the laboratory. The best known example occurs at the beginning of the last movement of Tchaikovsky's Sixth Symphony. Example 5.3 gives the first and second violin parts as played. Example 5.4 shows what most



Examples 5.3. and 5.4. An analogue of the scale illusion. From Tchaikovsky, sixth symphony, last movement.

listeners hear. Those who know the work by ear before they see the score sometimes cannot believe that there has not been a typographical error! The 'illusion' does not require the sounds of the two violin sections to come from the same direction. The perception is still the same when the two sections are on opposite sides of the conductor's rostrum.

It is not totally clear *why* Tchaikovsky chose to write the parts in this way if they are really indistinguishable from the case in which the violins had actually played Example 5.4. It is possible that typical violinists produce subtly different sounds when negotiating an angular rather than a smooth melodic sequence, which would be heard as a difference in texture or timbre.



A less well-known example is to be found in the second movement of Rachmaninov's Second Suite for Two Pianos, Op. 17. Example 5.5 shows a transposed version of the notes played by first and second piano towards the end of the movement. I was recently involved in a performance of this work, playing first piano, and was subject to the compelling illusion that Example 5.6 was being played. This was even though I could see my hand playing two

Examples 5.5. and 5.6. A perceptual illusion experienced in Rachmaninov's suite for two pianos, Op. 17, second movement.

notes, and not just repeating one. It was as if someone had suddenly retuned the lower note I was playing to the same pitch as the upper one. We may suppose that Rachmaninov wrote the parts in this way because it would be difficult for a pianist to repeat the same note in the figuration of Example 5.6 with the kind of speed and dynamic control which the music requires (about six quavers per second with a controlled decrescendo to pianissimo).

In the examples we have considered so far there are two *really* distinct sound sources producing simultaneous sounds. Pitch grouping causes some of the sounds to be mislocated. There are other cases when grouping by pitch (or *pitch streaming* as it is often called) allows a single sound source to be heard *as if* it were two independent sources. Thus, a solo instrument can create an illusion of polyphony by interleaving the notes of two contrapuntal lines separated in pitch. This device has frequently been used by composers, especially in the baroque period. Example 5.7 shows this device at work in the right hand of J. S. Bach's Prelude in G from book 2 of the Well-Tempered Clavier.

Example 5.7. From J. S. Bach, *Well-Tempered Clavier*, Prelude 8, Book 2.

Whether or not the single melodic line is heard as one or two pitch streams depends crucially on the pitch separation and the speed of the component notes. Miller and Heise (1950) presented listeners with a sequence containing two notes that alternated at a rate of ten per second. They varied the pitch separation of the two notes and found that intervals of less than about one seventh of an octave were heard as a *single* stream, whereas intervals greater than this caused the notes to separate out into two independent streams. In terms of the chromatic scale, this means that intervals of a minor or major second produce *fused* percepts which correspond to musical trills. Notes a minor third apart or greater tend to be heard as separate, producing stream *fission*. Van Noorden (1975) has shown that if the rate of alternation is slowed beyond about six notes per second, it becomes possible to hear wider intervals up to an octave as fused to form a single stream. The effect is, within limits,

open to conscious control. It is possible to switch one's perception of an intermediate case so that at one time it is heard as a trill or single line, at another time as two independent lines. There seem to be limits, however, beyond which the percept is not open to such switches. Intervals of a tone or less, when repeatedly alternated, tend not to give rise to fission. No matter how slow the speed of performance, they are heard as a single line.

None the less, Example 5.7 suggests a case in which intervals of a tone or less *may* be heard in separate streams. Here, the C at the end of the first bar is heard as belonging to the lower stream, and does *not* fuse with the upper stream of repeated Ds. We may suppose that larger patterning context overrides the immediate factors, so that the repeated Ds are heard as one line, and the rising and falling scale as another. This tendency is accounted for under another principle of Gestalt grouping, the principle of *good continuation*. We may illustrate this by an almost exact visual analogy. In Fig. 5.1 (*a*) the lower dot is seen as forming a group with the two adjacent upper dots. In Fig 5.1 (*b*) it is 'captured' by the lower dots and becomes part of a curved line distinct from the upper straight line.

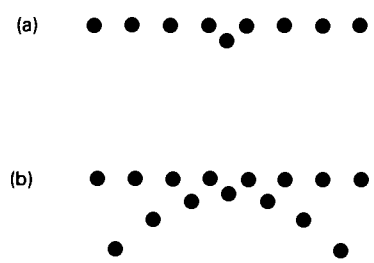


Fig. 5.1. Example of gestalt principles of perceptual organization.
(*a*) The lower circle appears joined to its neighbours (principle of proximity).
(*b*) The circle is 'captured' by the curved sequence (principle of good continuation overrides proximity).

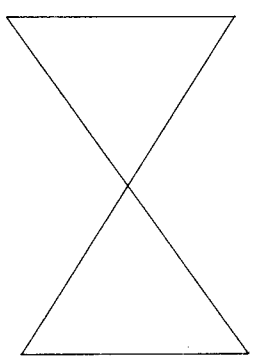
The basic pitch streaming phenomenon demonstrated by Miller and Heise also has a fairly direct visual analogy (as noticed by Kubovy 1981). If two nearby point light sources are switched on and off in alternation in a darkened room, the impression is often of a *single* light moving backwards and forwards between the two locations. This well-known visual illusion is called the *Phi phenomenon*. The likelihood of the two lights being seen as a single moving light is decreased if the speed of alternation is increased, or if the sources are moved further apart. Under these latter conditions one is more likely to see two independent 'flashing' light sources. When tones are substituted for lights, and pitch distance for spatial distance, the Phi phenomenon becomes the pitch streaming phenomenon.

We can suppose that the striking parallel between these phenomena has

its origin in the general properties of natural objects which the perceptual system has developed to deal with. Two sounds very close to one another in time but widely separated in pitch are unlikely to come from the same object. Likewise, two visual events very close to one another in time but widely separated in space are unlikely to come from the same object. As the time separation between events increases, however, the possibility of them belonging to the same object increases. A high sound may come from the same animal as a low sound once it has had time to adjust voice register. A light on the left may come from the same object as a light on the right if it has had time to move between the two locations, unseen.

The work of researchers such as Miller and Heise (1950) and Van Noorden (1975) has demonstrated pitch streaming in very simplified perceptual situations. Dowling (1973) extended these studies to more musically realistic stimuli. He took familiar melodies (such as 'Frère Jacques', 'Happy Birthday', etc.) and interleaved pairs of them so that listeners heard note 1 of tune A, then note 1 of tune B, then note 2 of tune A, then note 2 of tune B, and so on. These composite sequences were played at a rate of eight notes per second (four of each tune). Listeners were required to identify the component melodies. Dowling found that recognition of the melodies was almost impossible when they overlapped in pitch. They merged into a single, unrecognizable sequence. However, when the melodies were moved apart in pitch, so that their notes did not overlap, the melodies could easily be recognized.

Dowling found one condition in which overlapping melodies could be recognized. This was when listeners were asked to search for particular named melodies. Melodies perceived in this way were done so with effort, however. They had none of the ease and spontaneity of recognition enjoyed by the pitch-separated melodies. The process was one of active search rather than passive awareness. A visual analogy may again be helpful. Figure 5.2 will be seen spontaneously as two triangles. You do not naturally see the



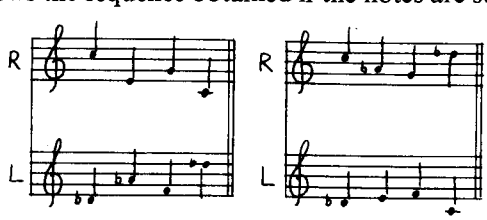


Fig. 5.2.

numeral 7; but if I ask you to *find* a 7 in the figure, you can do so. In the former case, your perception was governed by the spontaneous and largely automatic Gestalt principles of grouping (the 'laws' of proximity, closure, and symmetry being operative here). In the latter case you use prior knowledge about the shape of a figure 7 to overcome your natural grouping tendencies and achieve a more difficult, less spontaneous, way of seeing the figure.

Dowling also found that unfamiliar melodic patterns (learned by the listeners during the experiment) could not be recognized so easily when interleaved with other melodies, even when there was pitch separation of as much as an octave. This shows that the use that can be made of pitch streaming is not invariant, but can be helped or hindered by acquired knowledge about music.

This conclusion raises a general question about *all* the demonstrations we have examined in this section. Do they *really* show the natural auditory system at work, unaffected by the musical experience that most of us share? Many of the experiments use materials which make most *musical* sense when grouped by pitch. The grouping could be a result of application of knowledge about likely melodic patterns in music. This argument applies, for instance, to Deutsch's scale illusion. The melodies produced by each sound location are angular, with atypical pitch contours, whereas those arising through the supposed operation of pitch streaming conform to one of the commonest of all melodic patterns, the diatonic scale. Musical knowledge would, therefore, contribute to the tendency to group by pitch. There is, of course, a curious circularity here. It may be precisely *because* pitch grouping is a a fundamental auditory phenomenon that many common musical sequences move within restricted pitch ranges.

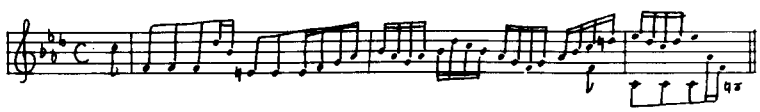
None the less, it should be possible to tease apart the contributions of fundamental auditory groupings and musical knowledge. One way of doing this would be to modify Deutsch's (1975) stimuli so that pairs of simultaneous melodies made more musical sense when grouped by location than when grouped by pitch. Example 5.8 shows such a pair. Here, the sequence played to the right ear forms a C major arpeggio/chord whilst that played to the left ear forms a D flat major arpeggio/chord. Each pattern is commonly found in tonal music, and has a strong and simple harmonic structure. Example 5.9 shows the sequence obtained if the notes are streamed by pitch,

Examples 5.8. and 5.9.

taking the upper note in each pair for the first stream, and the lower note for the second stream. Both streams contain unusual pitch leaps (diminished fifth, augmented second) rather than the smooth scales of Deutsch's illusion, and do not have straightforward harmonic implications. If the tendency to group by pitch is lessened in such sequences, then musical knowledge is implicated in streaming mechanisms.

A second way of determining the part played by musical knowledge in such effects is to look for differences between experienced musicians and novices. If differences exist, then musical knowledge is implicated. This approach has been taken by Smith, Hausfield, Power, and Gorta (1982) who compared musicians and non-musicians on several varieties of the scale illusion. They found that musicians were more likely than non-musicians to stream by pitch, even when there were conflicting cues (such as timbre) suggesting a streaming by ear. They argue for the conclusion that musicians are more likely to expect 'tunelike' stimuli than non-musicians.

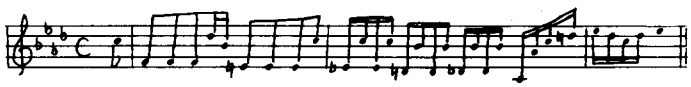
The most convincing demonstrations that pitch streaming is a primary auditory grouping mechanism, regardless of musical knowledge or structure are, perhaps, those that require perceptual judgements that have nothing to do with music as such, and point to the existence of pitch streams by implication, rather than because listeners are asked to directly *identify* streams. I will give just one example of such a demonstration. Fitzgibbons, Pollatsek, and Thomas (1974) asked subjects to detect a small temporal gap in a sequence of four tones, the first two of which were high in pitch (2093 and 2394 Hz) and the last two of which were low in pitch (440 and 494 Hz). This sequence (HHLL) was presented with the gap (G) in three possible positions: HGHLL, HHGLL, and HHLGL. In two cases the gap was between notes close in pitch, in the other case (HHGLL) it fell between two notes widely different in pitch. In the former two cases gap detection was nearly perfect, but in the latter case, detection of the same gap was significantly poorer. The interpretation given to these results is that listeners are able to notice time relationships *within* pitch streams more easily than time relationships between different pitch streams. Such relationships are not preserved in the automatic 'parsing' mechanisms which split such stimuli into two independent parts on the basis of pitch.



Such demonstrations provide strong evidence that pitch streaming is a real 'pre-musical' phenomenon, although musical knowledge may interact with and modify its effects. Pitch is not the only 'primitive' cue to grouping. Other cues, such as timbre and amplitude are described by Deutsch (1982b). I do not intend to deal with them in a detailed way here. Rather I would like to conclude this section by looking at some more complex and musically sophisticated ways in which composers can use pitch relationships as the basis for creating dynamic impetus in extended melodies.

This discussion owes much to the theoretical approach to melody outlined by Meyer (1973). According to Meyer, one of the functions of a melodic line

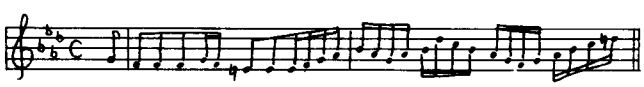
is to create *implications* for future events. In earlier writings (Meyer 1956) he used concepts of 'creating expectancies' in listeners, but this is a slightly misleading way of talking. The implications are inherent in the melody itself, by virtue of its structure; such implications may or may not be picked up by a listener and used to form expectancies on a given hearing.



For Meyer, implications are objective features of a melody which create some patterning or direction which admits of continuation. One implication, for instance, of an ascending five-note scale passage on its own is for a sixth note to be added to continue the sequence. An implication of the sequence CDCDCD is that CD should be repeated again; and so on. These are very simple implications. Any interesting melody has multiple (and sometimes conflicting) implications. A composer may not necessarily realize all of the implications of a melodic opening. Some he may not notice, others he may deliberately go against for musical effect. Even those that he does realize in a continuation may not be noticed as such, even by an acute listener. Rather, they contribute to an undifferentiated awareness that this is a good or interesting melody.

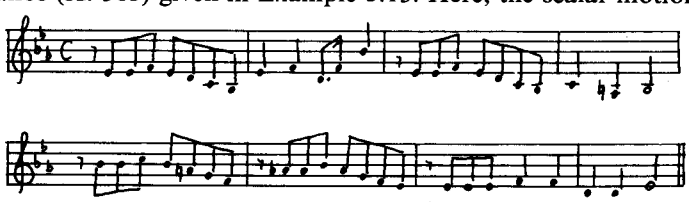
There are many devices for creating implications which rely on tonal or rhythmic factors. Here, I want to consider the use of pitch separation alone as an implicative device. Consider the melody which J. S. Bach uses for the F minor Fugue from book 2 of the Well-Tempered Clavier (Example 5.10).

Example 5.10. From J. S. Bach, *Well-Tempered Clavier*, Fugue 12, Book 2.



The opening nine notes contain some quite large pitch separations between adjacent notes. Thereafter, the melody moves in scalar fashion. The ideal performing speed for this fugue is about four quavers per second. This places the melody in the range established by Van Noorden (1975) where intervals of up to an octave between successive notes can be heard either as separating the two notes into distinct streams, or merging them into one, depending upon one's 'set'. So the opening of Bach's melody can be heard as a single unified line; but it has ambiguity—it can also separate out into two lines, an upper one created by notes 1, 5, and 6 (C, D flat, and B flat), and a lower one created by notes 2, 3, 4, and 7, 8, 9 (F and E). On the other hand, the material after note 9 proceeds by scalar steps of major and minor seconds, each note therefore being necessarily perceived as part of a single line with its neighbours. So these semiquaver runs serve as a sort of retrospective 'glue', bringing together the potentially separable lines of the opening notes. A different continuation could, in contrast, have sustained and accentuated the line separation (Example 5.11). Bach's intention seems to have been to create a tension between two potentially separable melodic lines which is

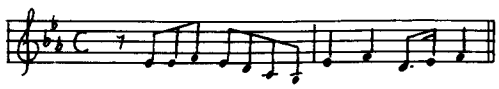
Example 5.11.



then resolved by 'knitting' them together. In Rosner and Meyer's (1982) terminology, the melody has features of a type labelled 'gap-fill' where an unfilled interval is created, then filled through scalar movement.

This is not the whole story, however. Each melodic line of the opening has its own implications which are not realized in the immediately following notes. Each creates a *direction* of pitch movement. The lower line on its own creates an implication for further downward movement (F→ E→). Conversely, the upper line has an implication for further upward movement. The topmost note is C, then D flat; an even higher note is implied. Both these implications are left unfulfilled in bar 2, but they are both realized on the first beat of bar 3: the lower movement through the second fugal entry which drops to middle C; and the upper movement through the simultaneous achievment of top E flat in the first voice, the highest note in the piece so far. This resolution of unfulfilled implications contributes to the sense of closure experienced as the second theme enters, and gives the melody a dynamic forward movement that makes it vital and satisfying. Consider how lifeless Example 5.12 is in comparison, where there is no upper pitch line, and therefore no sense that the final E flat resolves an earlier implication.

Example 5.12.



A second example of the implicative use of pitch streaming is provided by the principal theme of the last movement of Mozart's Concerto in E flat for Two Pianos (K. 365) given in Example 5.13. Here, the scalar motion of the

Example 5.13. From Mozart, Concerto for two pianos (K.365), last movement.

opening creates a unified melodic line spanning the F above middle C to the B flat below it. The last note of bar 2, an upper B flat, stands isolated from this line by a perfect fourth. In bars 3 and 4, the melody continues in the initial lower register. Arguably, the single upper note creates an implication for further notes in that pitch range. Such implication is only realized in bar

5, where the melody leaps up to this B flat before descending in scalar fashion to bring the melody back to the opening E flat. Bar 5 is, therefore, motivated by what has gone before in a way that it would not be without the bar 2 that Mozart supplied. If we rewrite the first two bars as in Example 5.14, then the pitch leap at bar 5 comes as arbitrary and surprising.

Example 5.14.

My treatment of these examples has been discursive and analytic in the musical sense. However, I have imputed psychological consequences of listening to them which have not been strictly demonstrated. What kind of evidence could we supply that a supposed implication of a melody has actually been detected by a listener? One, rather naïve, approach would be to play listeners the opening parts of melodies, and ask them to provide fitting continuations. For instance, we could compare listener's responses to the first four bars of Example 5.13 with the same four bars as modified in Example 5.14. If they pick up the implication of the high B flat, then Example 5.13 should result in significantly more continuations in a pitch range around that B flat.

I call this approach naïve because it assumes that implication is likely to be detected on a first hearing in a way that could guide conscious choice. It is equally possible that, for many listeners, the implications of a good melody are revealed gradually over many hearings, and that, even when revealed, can be used only to *recognize* fitting continuations rather than to *generate* one's own continuations. Such considerations make it quite likely that no positive results would be obtained with this technique. None the less, something of the sort is clearly worth trying. The only experiments I know to have used a similar technique (Carlsen 1981) involved presenting subjects with simple two-note sequences and asking them to provide plausible continuations. The types of implications that can be contained in two-note sequences are very limited, and hardly begin to tap the range of devices used by real composers. As far as they go, however, Carlsen's results show some evidence for pitch range sensitivity. His subjects showed a marked tendency to choose a third note close in pitch to the second note given. Sixty per cent of all continuations began within a major second of the second note given. It would be interesting to know whether subsequent continuations employed the 'gap-fill' technique, moving back to the first note through scale-like movement, but Carlsen analysed only the first note of each subject's response.

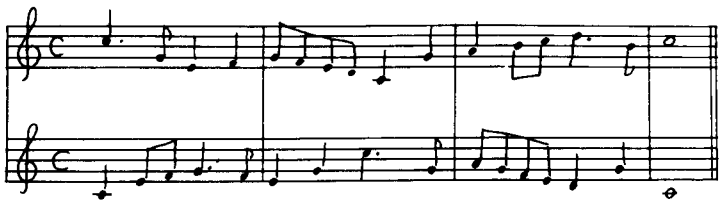
The mechanisms of melodic perception required to notice implications of the type discussed above involve more than can be supplied by the involuntary and immediate processes of auditory grouping. They require *attention* to the salient aspects of a complex stimulus, and *memory* of past

events which stand in important relationships to present material. The next two sections deal with these aspects of music listening.

5.3. Attention in music listening

We begin our consideration of attention by returning to Dowling's (1973) experiments with interleaved melodies. We saw earlier that subjects could recognize both melodies provided that they did not overlap in pitch, but formed separate perceptual streams. However, Dowling reports that subjects did not identify both melodies at the same time. More commonly they would identify one of the melodies on a given hearing, and the other on the next hearing. They seemed to be *selecting* either one or the other stream to monitor; but were not able to monitor both streams at once. This result points to the existence of a serious problem in music listening. A great amount of music is polyphonic; that is, it has more than one line of music proceeding at the same time. If we can attend to only one line at a time, how do we ever achieve a full experience of the polyphonic structure?

Pioneering studies on attention to speech (Cherry 1953) have shown that when two speech messages are presented simultaneously it is possible to shadow (verbally report) one of them, but that almost nothing is known about the characteristics of the other message. Thus, for instance, the non-shadowed message may change language, or repeat the same phrase over and over again without the subject being aware of it. These studies, and others like them, have been used to support the notion that our perceptual system incorporates a single, limited capacity attentional 'channel', through which only a small part of our sensory experience can pass at any one time. This mechanism operates like a 'filter' which lets through only material which is defined by some distinguishing sensory feature (like pitch, or ear of entry) at any one time. All other material is lost before it can reach those higher mechanisms which recognize and classify input. Broadbent (1958) provides the classic formulation of such a position.



More recent studies have challenged the 'filter' theory in various ways (Allport, Antonis, and Reynolds 1972; Deutsch and Deutsch 1963; Shiffrin and Schneider 1977; Triesman 1964). For instance, Allport, Antonis, and Reynolds asked pianists to sight-read piano music at the same time as shadowing a prose message played over headphones. They found that performance on both tasks was just as good when carried out together as when carried out alone. Such a finding is incompatible with the filter theory, which would predict that subjects could attend either to the sight-reading input (visual) or to the speech input (auditory) but not to both. An alternative way of explaining attentional phenomena is to propose that processes *may* take place simultaneously provided that they do not use the same kinds of cognitive mechanisms. In Cherry's and other speech experiments, both messages were verbal. In the study of Allport *et al.*, one message was verbal, the other

was musical. Each message required a different *type* of processing.

If we examine everyday situations where we are able to do two things at once, we see that most of them have similar properties to the demonstration of Allport *et al.* We can hold a conversation whilst driving a car; listen to the radio whilst doing housework, and so on; but we *cannot* listen to a radio talk whilst reading a book.

What is the relevance of this to music? It suggests that our difficulties in attending to two concurrent melodies are not so much due to an incapacity to take them in as to an incapacity to subject them to the same kind of *analysis* simultaneously. In situations where nothing is required of an observer other than the detection of some simple event, he is capable of monitoring very many simultaneous 'channels', even when only a single sense modality is involved. For instance, Shiffrin and Schneider (1977) report demonstrations that people find it as easy to monitor 49 separate spatial locations for the occurrence of a brief visual event as they do to monitor only one location. It is when some integrative response is required to the material in each channel, such as detecting sequential structure (as in understanding a sentence or recognizing a tune) that problems begin to occur. As Neisser (1983) puts it, 'there is no way to avoid assigning the verb in speaker B's sentence to the noun in speaker A's, with resulting organizational chaos.' When we hear two people speaking at once, what each of them says is an independent message, bearing no necessary relation to the other. Trying to construct the two independent but simultaneous structures yields misleading and unintended results as elements are assigned to the wrong structure. It is hardly surprising that the conventions of normal human linguistic communication are designed to ensure that only one person speaks at a time.

In Dowling's (1973) experiment, the two interleaved melodies could be just as unrelated to one another as two randomly chosen verbal messages. In most contrapuntal music, however, the various lines are *not* independent. They are constructed with skill and care to be related to one another. Each line possesses not only its own 'horizontal' melodic identity (enabling it to stand on its own as a valid musical sequence) but also a 'vertical' harmonic function with relation to the other concurrent lines. At any instant, the simultaneously sounding notes make up a chord which has its own musical identity. The progression of chords found in the piece constitutes the harmonic structure of the music, and this structure acts as a single underlying framework in which the individual lines can be placed. We may hypothesize that this underlying harmonic unity makes it easier to attend to several simultaneous melodic lines. This hypothesis was tested in an experiment (Sloboda and Edworthy 1981) where subjects learned two melodies which cohered harmonically when played in the same key (Example 5.15). After each melody was learned on its own, subjects heard trials where the two melodies were played together. The melodies were always separated in pitch by at least an octave, so that they were easily heard as separate streams. On

Example 5.15. Melodies used by Sloboda and Edworthy (1981).

each trial, one of the melodies contained a pitch error on one of the notes. Subjects were required to say which melody contained the error, and, if they were musically literate, to mark the error on a score.

The crucial experimental variable was the key relation of the two melodies. In condition A the melodies were in the same key. In condition B they were in keys a perfect fifth apart (e.g. C and G.) In condition C they were in keys an augmented fourth apart (e.g. C and F sharp). We predicted that, if harmonic coherence aids simultaneous attention, subjects should correctly locate most errors in condition A and least in condition C. The results exactly upheld these predictions. Subjects were 80 per cent correct in condition A, but only 67 per cent correct in condition C. Condition B gave intermediate results (74 per cent).

How does harmonic coherence aid attention? Our current hypothesis is that polyphonic music is perceived as an ambiguous pattern capable of 'figure-ground reversal.' There are many well-known examples of this. Rubin's 'faces-vase' figure is one of the best known. It oscillates between being seen as a white vase on a black background, and as two black faces looking at each other across a white background (Fig. 5.3). Shape and contour is

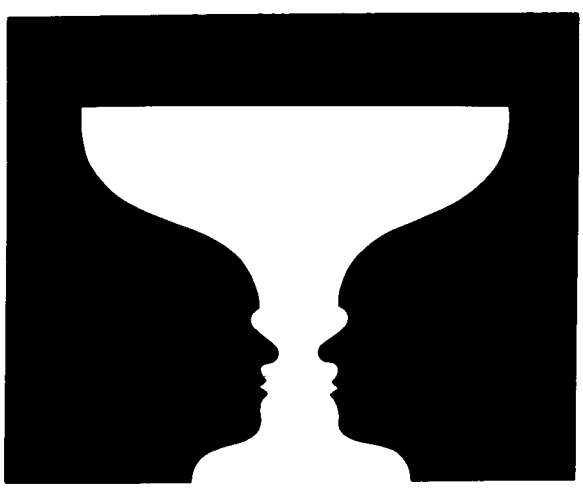


Fig. 5.3.

seen as being possessed by the elements which form the figure at a particular time. The background is seen as a contourless occluded surface.

In music we propose that only one melodic line can be treated as 'figure' at any one time. When so treated we may say that this line is being given 'focal attention'. Focal attention allows the noticing of relationships within the melodic line, so that the melody may be recognized, related to previous material, and so on. The other line, or lines, form the background. They are registered, but are not processed focally. Instead, they are fragmented into a series of individual notes which are heard 'vertically' as chords which support or accompany the focal melody. Thus, there are two types of process taking place, melodic processing of the focal line, and harmonic processing of the other parts. Furthermore, each note of the melody being focally processed has a harmonic function which is confirmed by the notes in the other parts, so both the melodic and the harmonic processes contribute to the building up of a unified structural representation for the whole piece.

A diagram may help to make clear the relationships being proposed. Consider a piece of music containing three contrapuntal lines. Fig. 5.4(*a*) represents the primary relationships noticed when line A is the subject of focal attention. The listener extracts the 'horizontal' melodic relationships between notes in A (represented by double lines) but he does not hear B and C as melodies. Rather, their individual notes are heard as harmonizations for the concurrent note of A, assisting the understanding of the structure of A. Fig. 5.4(*b*) represents the case where a listener is hearing precisely the same music, but this time giving line B focal attention. Now A and C become background harmony.

How does this formulation explain our experimental results? We suppose that listeners will succeed in incorporating most contrapuntal material into

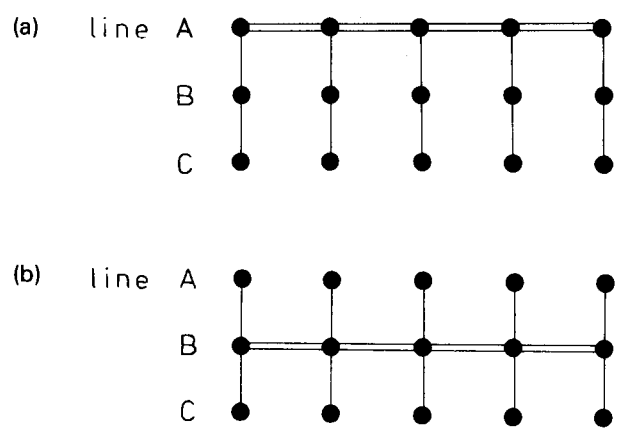

Fig. 5.4. Two different possibilties for focal processing in a contrapuntal sequence.

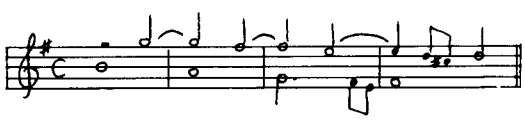
their representation of the music when the chords supplied by the background parts are familiar ones which support a plausible tonal harmonization for the focal melody. When the two melodies of Example 5.15 are played in the same key, they mutually reinforce a simple and common harmonic structure. Bars 1 and 2 are subsumed under the tonic chord (I), bar 3 subdominant to dominant (IV–V), and bar 4 tonic again (I). With such a conventional progression, the experience of most listeners is that a wrong note 'sticks out like a sore thumb' because it creates an odd and unexpected harmony. It does not matter what line is being given focal attention; the 'queer' harmony is heard. If the wrong note is in the focal melody it will be detected as a deviation from the known melodic pattern. If, however, the focal melody 'matches' the listener's memory of it, then the inference is that the wrong note must be in the other, non-focal melody.

If our explanation is the correct one, then there is a simple prediction which may be tested. This is that when there are *more* than two simultaneous lines, location of wrong notes will become less efficient, even when all lines cohere harmonically. This is because in the case where the mistake is in a non-focally processed line, the listener has to guess at random between these lines. All he will know is that there was a wrong note, creating an odd harmony, which was *not* in the focal melody. By simple application of probability theory we would expect the 80 per cent performance with two lines to drop to 53 per cent with three lines, and 40 per cent with four lines. This prediction is yet to be tested.



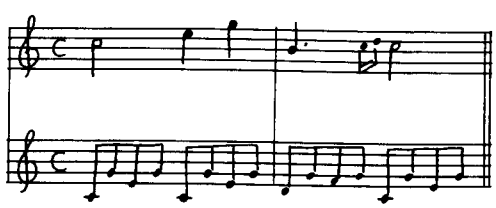
Informal support for this prediction comes from a common experience of ensemble conducting. When a conductor is rehearsing a group he will often hear 'something go wrong' but be unable to say with certainty which part went wrong without going back and hearing the section again. It appears that he was focally processing a part which did not go wrong, and needs to redirect his focal attention to locate the mistake.

If focal processing is limited to one part, it becomes pertinent to ask how, if at all, it is possible to justify the claim made by some listeners that they *can* follow all the simultaneous parts of a contrapuntal piece. One factor which may allow things to seem that way is a high degree of familiarity with the individual parts, through repeated hearing. Each part is then so well known that it does not need to be continuously monitored to refresh the experience of its being 'there'. This kind of listening is rather like the experience we achieve when casting our eyes round a familiar visual scene, such as our own room. Although the eye can only focus on one thing at a time, the fact that each glance fulfils an expectancy of what *should* be there allows a real experience that the whole scene is present in one's perception. In familiar music, the 'mind's ear' can dart around between the parts, always knowing what it is going to find at any given moment, and finding it, thus confirming to the knowing mind that all the parts *are* present.

Even if each contrapuntal line is not well known as such, it is also possible

to know a piece very well *as* a melody plus accompaniment (in the case where the same contrapuntal line has always been the object of focal attention). In such a case, each chord may be so well known that the listener has the possibility of *constructing* a non-focal line by picking out a given note from each chord and integrating a new line. In such cases all the contrapuntal lines may be *implicit* in what a listener knows, simply awaiting a reorganization of his knowledge to be made explicit. In such a way may a listener suddenly realize that the 'accompaniment' of a well-known passage actually has its own melodic integrity. It is not that there are notes present which he has not noticed before. It is simply that he has not heard them *as* melody before.

Another way of achieving the impression of total awareness in polyphony has more to do with the composer's art than with the listener's knowledge. In the cases discussed so far we have assumed that a note in any one part is associated with a simultaneously played note in every other part. Whilst this is true of some chordal counterpoint, such as hymn harmonizations, it is by no means true of all counterpoint. It is possible to lighten the listening load considerably by limiting significant events to one or two lines at any one time. Consider, for example, the counterpoint of the top two lines in no. 18 of J. S. Bach's Goldberg Variations (Example 5.16). These lines (which form



Example 5.16. From J. S. Bach, Goldberg Variations.

a canon) are distinguished by the fact that there is not a single occasion when notes begin simultaneously in the two parts, although the notes are sustained in such a way that the two-part texture is continuous. We may argue that listeners can focally process each melody, by switching from line to line as each new note is played. Secondly, once one has realized the canonic relationship it is possible to predict the next event in the upper line by reference to what has just happened in the lower one. This is a quite different situation to that of Dowling's 'interleaved melodies' experiment. First, the rate of switching between parts is much less (about one per second rather than four per second). Second, because of the musical relationship between the two parts, understanding one part can directly help a listener understand the other part.

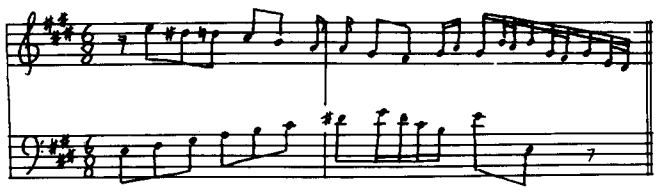
In this Bach example both contrapuntal lines are equally important. In some cases, however, the composer may quite clearly mark one line as containing the most significant material, with another part relegated to a secondary role where texture may be more important than the precise melodic sequence. For instance, in the orchestral music of Rachmaninov one often finds subsidiary countermelodies of a 'busy' scalar nature whose function is to provide a restless undercurrent to some more salient theme. Although a

connoisseur may come to know every note of such countermelodies, there may be a sense in which this is knowing more than Rachmaninov intended. It is enough for adequate listening that one can detect 'that kind of thing going on' which can be done, perhaps, without too much focal attention, in the 'spaces' between significant events in the primary melody.

If, indeed, focal attention can only be in one place at a time we may move to consider a compositional problem. Is it possible for composers to write music which will tend to direct the focal attention of first-time listeners to the intended part? We ask this question on the grounds that it is not correct to say, for most music, that all parts are equally important for a first-time listener; that he would 'hear the music rightly' whatever part he happened to focus on. This may possibly be true for a fugue; it is not true for a symphony or a sonata. In such works there are nearly always primary themes which must be apprehended, because later transformations and extensions of these themes form the substance of the compositional structure. It would hardly do if a listener focally processed the lower line of Example 5.17 (Mozart's Piano Sonata in C, K. 545) at the expense of the upper line.

Example 5.17. From Mozart, Piano Sonata in C (K. 545), first movement.

Almost no experimental work relates directly to this question, but it is possible to point out some of the most easily observable 'attention grabbing' devices. First, it appears that, all other things being equal, it is the line with the highest pitch range that tends to be focally processed. When listening to, say, a hymn tune harmonization, many listeners are simply unaware that the lower parts comprise melodic lines. In the vast majority of classical music, principal themes are stated by high-pitched instruments, with lower ones playing subsidiary material. For instance, in string music it is nearly always violins, rather than violas or cellos, which present the principal themes; and in piano music it is nearly always the right hand. Why should this be? One possible contributory factor is that outside lines are heard better because they are *on* the outside and so are not 'surrounded' by other lines. Thus, the highest and lowest lines of a polyphonic texture should be most salient, with inner lines being less salient. We still need a further reason for the topmost line 'winning out' over the bottom line. One possible reason is that high notes in normal musical textures mask one another less than do low notes. 'Masking' is a technical term of psychoacoustics which refers to the detrimental effect the presence of one tone has on the ability of a listener to hear



a second tone close in pitch or time to the masking tone (see Moore 1982, for a good introduction to this topic).) The masking power of a particular note may be assessed by varying the intensity of nearby notes to the point when they can only just be heard. This intensity is called the auditory threshold. The auditory thresholds of notes close in pitch to the masking tone are considerably raised by the simultaneous presence of the masking tone. However, as one moves the test tone further away from the masking tone in pitch there comes a point where the masking tone no longer has any effect on the threshold. One hears the test tone just as easily with the masking tone as without it. For any particular tone it becomes possible to estimate its 'critical bandwidth'. This is the frequency range within which it has a masking effect on other tones. Estimates of the critical bandwidth at various frequencies have been provided by Scharf (1970) and others. Table 5.1 shows the kind of results obtained, translating frequency values into approximate musical intervals.

TABLE 5.1
Sample masking ranges of musical tones (adapted from Scharf 1970)

Approximate frequency of masking tone (Hz)	Musical note name of masking tone	Average musical interval from masking tone within which threshold of another tone is raised
110	A2	octave
220	A3	perfect fifth
440	A4 (concert A)	major third
880	A5	major second
1660	A6	minor second

These rough estimates show that within the range of normal music, low tones mask over wider musical intervals than do high tones. In the range of a double bass, two octaves below middle C, tones as much as an octave apart will mask one another. In the range of a piccolo, two octaves above middle C, tones as close as a major second apart will not mask one another. In a thick contrapuntal texture there is real reason, then, to suppose that upper notes are more audible than lower ones. In a reverberant environment, the perception of low notes is also hindered by their greater tendency to persist in the environment after being played, creating a 'muddy' low-pitch noise, which makes lower parts less discriminable. Finally, we have to consider the fact that crucial acoustic information may be carried, not by the fundamental frequency of a musical note, but by its weak upper partials or harmonics. For low-pitched instruments these partials are likely to be masked by the higher pitched instruments, so making them less distinctive. All of this cannot, however, be the whole story, since I at least experience a strong 'set' for the upper line in simple two-part 'staggered' counterpoint where the effects

of masking and acoustic environment are not significant (e.g. Example 5.18, Two-part invention in E by J. S. Bach). It seems likely that experience with normal music, where the upper parts are known to be more important, on the whole, has resulted in a learned disposition to attend to the upper voice when there are no strong counter-signals.

Example 5.18. From J. S. Bach, Two part Invention in E.

A second type of characteristic of melodic lines which capture focal attention is a feature which discriminates them from the other lines in some way. Thus, a line may be louder than other lines, or have a distinctive 'solo' timbre. It may introduce change against an unchanging background. For instance, in Example 5.7 we tend to focally attend to the lower pitch stream which moves, rather than to the upper one, which is stationary. For the same sort of reason, the upper line of Example 5.17 invites attention because the lower line simply repeats the same figuration over and over again.

A third and related device is *change* of quality or texture in the focal line. This exploits a natural tendency, sometimes called the 'orienting response', to attend to a new event in a complex environment rather than to familiar ones. One principal way of introducing change is to add a new voice in a distinct pitch stream to a polyphonic texture. Successive entries of a fugue fulfil this condition.

Fourth, we may postulate a principle of 'attentional conservatism' such that a listener will tend to remain with a particular line once drawn to it unless there are strong enticements for him to shift attention. Thus, the composer can increase the likelihood of keeping a listener on the right line by avoiding sudden change in other parts.

Of course, composers rarely use such devices in isolation. An important part may be topmost in pitch, and loudest, and the most novel of the parts. The scientific evaluation of the relative effectiveness of these devices and the precise conditions under which they apply awaits detailed study of controlled musical examples where each attentional device can be manipulated separately.

5.4 Memory in music listening

The way one hears music is crucially dependent upon what one can remember of past events in the music. A modulation to a new key is heard only if one

remembers the previous key. A theme is heard as transformed only if one can remember the original version of which it is a transformation. And so on. A note or chord has no *musical* significance other than in relation to preceding or following events. To perceive an event musically (that is, to recognize at least part of its musical function) is to relate it to past events. It is, therefore, important for us to know how good we are at remembering past musical events, and to know what factors assist our memory.

We may begin by considering a very thorough series of experimental studies by Deutsch on memory for individual notes (Deutsch 1970, 1972, 1973; Deutsch and Feroe 1975; and others summarized in Deutsch 1982c). The basic experimental task is simple. Listeners hear two notes, separated by a five-second interval. They are required to judge whether or not the notes have the same pitch. In fact, the notes have the same pitch on half the trials On the other half they differ by a semitone. The interest of these studies lies in the ways in which Deutsch filled the five-second interval. In the basic control condition the interval was silent. Most listeners were then able to perform the pitch judgement with 100 per cent accuracy. In another condition, the interval was filled with spoken numbers, either to be recalled or ignored. In both cases listeners were still able to make the pitch judgement with 100 per cent accuracy. Another, crucial, condition interpolated randomly chosen notes between the two test notes. These interpolated notes were drawn from the same octave as the test notes. In this condition performance dropped to 68 per cent *even though* listeners were instructed to ignore the interpolated notes.

This result shows that intervening notes have a highly disruptive effect on memory for pitch of an earlier note. This is not some *general* deficiency in perceiving or remembering sequences, since the performance was not affected by intervening numbers, even when the numbers had to be recalled. It seems that the effect is specific to pitch.

In further conditions Deutsch discovered that the disruptive effect was greatest when one of the intervening notes was close in pitch to the test notes. Maximum disruption occurred when an intervening note was two-thirds of a tone above or below the first test note. The disruptive effect also generalized across the octave. The same pattern of results was obtained if the intervening tone sequence was shifted up or down an octave.

At first sight, Deutsch's results suggest a very gloomy conclusion about musical memory. Memory for individual pitches seems incredibly poor, if it cannot survive a few succeeding notes. How is it possible to remember notes across structures of symphonic proportions, containing tens of thousands of notes? The general answer to this problem would seem to lie in the opportunities which most music affords for listeners to classify and organize what they hear. Deutsch's sequences were atypical in two respects. They did not confine themselves to the intervals of a common scale (using fractions of a semitone in some instances), and their notes were randomly chosen so that

they were not designed to form common musical patterns within the scale framework. To see how musical memory is possible we will have to consider the two aspects of organization that Deutsch's materials violated—scale and sequential pattern—and show how they may be used by listeners to construct representations of music which do not rely on the preservation of precise pitch information.

5.4.1 *Scale*

Within a musical culture such as our own, there is general agreement about the scales from which music is constructed. In our culture the predominant scales are the diatonic major and minor scales. Furthermore, there is general agreement about the absolute pitches which scales should be based upon. This is so that a correctly tuned instrument can be played in ensemble with any other instrument. Thus A4, the traditional 'concert A' used for orchestral tuning is set at 440 Hz. With equal temperament instruments, such as piano, it is possible to set each of the twelve chromatic notes to definite pitches which allow all twelve major and minor diatonic scales to sound 'in tune'.

Given this 'fixity' of musical pitches, the possibility arises that music listeners could learn to associate particular pitches with musical note names. If they can do this, then it is possible that memory could be improved through the recoding of sensory pitch information into verbal information—remembering note names rather than raw sounds.

People with the ability to name individual heard pitches, or accurately sing named pitches are said to possess 'absolute' or 'perfect' pitch (see Ward 1963a, 1963b; Ward and Burns 1982, for reviews). This ability seems to be learnable by anyone prepared to undergo lengthy and systematic training (Brady 1970; Cuddy 1970). However, by no means all musicians have absolute pitch (AP), and a study by Sergeant (1969) shows that, among a sample of 1156 professional musicians, there was a high inverse correlation between age of commencement of musical training and the possession of AP. Almost all musicians who began training before the age of six had AP, but almost none of those who began after eleven did.

An elegant study by Siegel (1974) demonstrates the kind of memory advantage that absolute pitch confers. Her subjects were presented with two notes, separated by a silent five-second interval. These notes differed in pitch by either one-tenth of a tone or by three-quarters of a tone. Subjects were asked to judge whether the second note was higher or lower than the first. Siegel used two types of subject: music students with AP; and music students of an equivalent standard without AP. Siegel found that whilst the two types of subject did not differ in performance on the one-tenth tone intervals, the AP subjects did much better than the non-AP subjects when it came to the three-quarter tone intervals. The AP subjects were able to assign different verbal labels (note names) to the two notes. When the notes were only

one-tenth tone apart such verbal coding no longer worked, because it provided the *same* name for both notes. Thus they had to fall back on a 'sensory' coding which the other subjects reported using all the time.

Verbal coding aids retention over longer time spans, as shown in a second experiment where the time interval between the two test notes was varied. The interval was now filled with other random notes at the rate of four per second, making the task very similar to the one in which Deutsch found such poor performance. For the one-tenth tone test interval, performance of both types of subjects dropped very rapidly as the time interval was increased. However, for test intervals separated by a semitone, only the performance of the non-AP subjects dropped. The AP group were just as good after 15 seconds as they were after 5 seconds.

These results not only demonstrate the superior memory performance exhibited by subjects with AP. They also demonstrate the categorical nature of absolute pitch (see also Chapter 2.4). It is not the case that people with AP have finer pitch discrimination than anyone else. They cannot remember pitch within one-tenth of a tone over a five-second silent interval with any degree of accuracy. What they *can* do is assign the pitch to a *class* or *range* of pitches which are given the same name. Within a name category (spanning perhaps 30 Hz in the range of A4) they cannot remember pitch differences reliably. Furthermore, the results show how subjects with this categorizing ability can overcome the disruptive effect of intervening notes demonstrated in Deutsch's subjects, and by the non-AP subjects in this study.

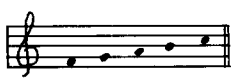
Do these results suggest that people with absolute pitch have the best equipment for listening to and remembering music? If they do, then all of us without AP should, maybe, strive to obtain it. In fact, there are other types of ability which can be even more important in most tonal music. These include the ability to identify musical intervals and key. Of these, more shortly. AP would seem to be most advantageous in situations where music, whilst using the notes of the chromatic scale, violates the normal rules of harmonic and melodic construction, producing unfamiliar intervals and sequences where no key or tonal centre is implied. Much music in contemporary 'atonal' idioms would seem to fulfil these criteria; and those musicians particularly singers, who need to work with such music, have their task made much easier if they possess AP. There are situations, however, in which AP can be a nuisance. Listening to, or performing key-transposed music can be very difficult. The sounds produced are constantly violating expectancies created by one's own prior knowledge of the music or by the printed score. When scales or tunings are non-standard then it is possible to devise experimental tasks in which possessors of AP are actually at a disadvantage, because their categorizations are inappropriate to the task (e.g. Cuddy 1977, reported in Ward and Burns 1982).

Many musicians possess an ability which they prize much more than absolute pitch, and this is often called 'relative pitch'. This is the ability to

say what musical interval separates two simultaneously or successively played notes, or to be able to sing a named interval above or below a given starting note. This ability is important because melodic or harmonic identity is conferred on a set of notes through the interval relationships they hold to one another, and not their absolute pitches. A melody can start on any pitch within audible range and still be recognized *as* the same melody provided its pitch intervals (frequency ratios) are the same. This feature of music offers a possible explanation for why it is that relatively few people with the appropriate opportunities learn absolute pitch. When a child is taught a song, he is reinforced for producing the correct intervals, not a particular set of absolute pitches. He hears songs sung at various pitches (e.g. father sings the same song in a lower register than mother) and in general has every incentive to record interval information at the expense of absolute pitch (Pick 1979).

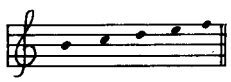
Siegel and Siegel (1977a) have demonstrated that relative pitch improves with training, and that highly experienced musicians can identify intervals reliably, accurately, and independently of stimulus context. Furthermore, musicians report hearing intervals as sounding qualitatively different from one another. Thus, a major third comes to sound not so much 'larger' than a minor third as a different *type* of sound. Each interval acquires its own unique character or colour that makes it unmistakable and not confusable with any other interval. Just as absolute pitch is 'categorical' so is relative pitch. Two notes do not have to be separated by the *exact* correct pitch interval to be heard as a major third, or whatever. Rather, their separations must fall within a *class* of separations about a central point. Categorical perception of intervals was demonstrated by Locke and Kellar (1973; see Chapter 2.4). It has also been demonstrated by Siegel and Siegel (1977b) who asked subjects to judge the magnitude of various standard and non-standard intervals. Although only 23 per cent of the intervals were actually 'in tune' (on just temperament tuning), subjects judged 63 per cent of them to be in tune, judging 'sharp' and 'flat' intervals to be equal in magnitude to correctly tuned intervals. There were even cases where subjects judged a sharp interval to be flat, and vice-versa. In this case it appears that they noticed a mistuning, but were unable to retain the precise pitch information which would allow them to tell whether the interval was sharp or flat. This loss of precise pitch information has many musical uses. For one, it allows the existence of the equal-temperament chromatic scale, which slightly distorts many of the 'perfect' small integer ratios of the harmonic series. These distortions are not noticeable under normal conditions, and provide musicians with the advantage of being able to play music which modulates round the circle of fifths without sounding more and more out of tune; unlike just intonation, where intervals in keys remote from the originally tuned key sound grossly mistuned. A technical discussion of tuning and temperament is beyond the scope of this book, and the interested reader is referred to Barbour (1951).

Just as absolute pitch aids memory under certain conditions, so does



relative pitch. Idson and Massaro (1976) have provided one demonstration of this. Subjects were trained to recognize three-note sequences derived by permuting the notes A, C, and D sharp in different orders. The notes were given arbitrary labels (A, B, and C respectively) and subjects were required to identify a sequence as one of six possibilities, ABC, ACB, BAC, CAB, CBA. When they had learned to do this task accurately a 'masking' condition was introduced, where each note of the sequence was followed by an irrelevant note (e.g. AMBMCM, where M is the masking note). This masking note could be either in the same octave as the test sequence or in another octave. Idson and Massaro found that a same-octave mask disrupted identification of the test sequence, but that identification performance remained high if the mask was in another octave. In a second condition, subjects learned to identify not sequences but single notes. There were three notes, each given an arbitrary name (A, B, and C). Subjects learned to say which of the three notes had been presented on a given trial. Then they had to continue the task with various masking notes introduced, as in the first condition. It was found that *any* masking note, and not just one close in pitch to the test note, was highly disruptive of identification.

It is important to note that the first 'sequential' test could be done on the basis of relative pitch information, whilst the second task requires absolute pitch memory. We may interpret the results by saying that interference is more likely to disrupt comparison of present with past notes on the basis of absolute pitch than on the basis of relative pitch. When subjects are looking out for learned pitch intervals or contours they can perform the necessary perceptual and memory operations provided that interfering material does not fuse with the test material into a single pitch stream (see this chapter, section 2). When, however, subjects are trying to hold a particular absolute pitch in memory for comparison with later material, they are disrupted by *any* interference.



Idson and Massaro's experiment involved recognizing a stimulus which, although containing interval information, also retained the absolute pitch of the original. A common occurrence in music is the *transposition* of a melodic theme to a new key within the same piece of music. If we do, indeed, remember sequences of notes in terms of pitch interval, we should be able to recognize transpositions *as* repetitions of the same melodic stimulus. Experiments by Cuddy and Cohen (1976) and Cuddy, Cohen, and Miller (1979) have shown that both musically trained and untrained listeners can discriminate true transpositions of three-note sequences from those where one of the notes has been raised or lowered by a semitone relative to the other notes. This ability is, however, greatly affected by the precise nature of the sequence to be transposed. For instance, Dowling (1978) has shown that it is difficult for listeners to discriminate between 'real' and 'tonal' transpositions (see Chapter 2.4). Bartlett and Dowling (1980) have shown that discrimination of real from false transpositions is best when the transposition is

to a key closely related to the original. Cuddy, Cohen, and Miller (1979) have shown that if the sequence to be transposed is embedded in a tonal context, it is easier to recognize than when in a non-tonal context. All these findings suggest that memory for pitch intervals alone does not account for the way in which listeners deal with tonal sequence.

Much of the evidence points to the importance of establishing a key, or tonal centre, for memorization of melodic sequences. This provides an economical way of representing a melodic sequence in terms of scale steps within a key. An example will help make this clear. Consider the sequence in Example 5.19. Viewed as a set of successive intervals this could be seen as

Example 5.19.

Example 5.20.

Example 5.21.

the ascending sequence tone–tone–tone–semitone. If we consider intervallic relations between non-adjacent notes, we would add minor third (A–C), major third (F–A and G–B), perfect fourth (G–C), augmented fourth (F–B) ,and perfect fifth (F–C). Viewed as components of a scale, however (in this case C major), we could see it as four ascending adjacent intervals of one scale step starting on the fourth degree of the scale. The intervals between non-adjacent notes are then simple multiples of a single scale step. If we hear melodies in this second way, then we can argue that shifts of a melodic contour up or down *in the same key* are likely to be heard as 'the same melody' because a most important aspect of the melody—scale-step interval—is retained. If Example 5.19 is to be described compactly by the notation:

Key: C major
Start: 4
Sequence: +1, +1, +1, +1

then Example 5.20 is described in exactly the same way, except that the start of the sequence is now note 7 of the scale (B):

Key: C major
Start: 7
Sequence: +1, +1, +1, +1

Describing Example 5.20 in terms of its pitch interval relations, however, gives a very different pattern to that of Example 5.19. The intervals between successive adjacent notes are now semitone–tone–tone–semitone. Among the non-adjacent intervals there is no longer a perfect fifth or an augmented fourth, but a diminished fifth is added. The fact that people find such sequences (called 'tonal answers') as similar to the original as 'real' transpositions (which preserve the actual pitch intervals) is strong evidence for

viewing listeners' representations of tonal sequences as embodying the kind of notation given above. Such notations allow the economical coding of real transpositions too. Here, instead of changing the starting note, we change the key. Example 5.21 is a real transposition of Example 5.19, and in our notation would be represented:

Key: F major
Start: 4
Sequence: +1, +1, +1, +1

The foregoing offers a possible explanation for why real and tonal transpositions are often confused. Can it also explain why transpositions to related keys are easier to recognize than transpositions to remote keys? I think it can, if we look more closely at the nature of the experimental tasks which gave rise to this finding. A listener hears one short melodic sequence, and then, without any intervening preparation, hears another transposed sequence. Unless the key of the transposed sequence is close to the initial key in the circle of fifths it is possible that a listener is simply unable to decide a key (or tonic) for the new sequence. If he cannot do this, then he will not be able to assign the correct scale-step intervals to the new sequence. Once a listener has established a key, there is an inherent conservatism which makes him reluctant to shift key (see Chapter 2, section 5.3). Key modulation in much music is effected through movement around the 'circle of fifths', from C to G, G to D, D to A, and so on (or in reverse). A feature of such modulation is that the scales of the two keys share all their notes except one, the leading note, or seventh of the new scale. Thus G major contains all the notes of the C major scale except F which it replaces with F sharp. This has two consequences for transposition. One is that many transposed sequences can be successfully represented in two ways, either as resulting from a change of key, or as resulting from a contour shift within the same key For instance, the sequence CEGAG may be represented as:

Key: C major
Start: 1
Sequence: +2, +2, +1, −1

When the transposed sequence GBDED is heard, it can then either be represented:

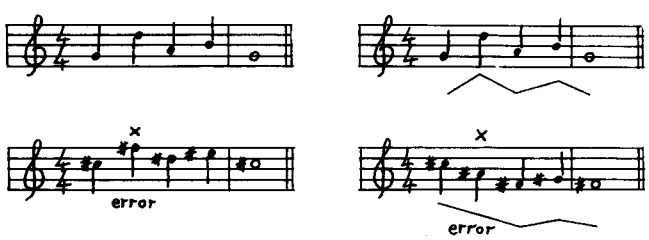
Key: G major
Start: 1
Sequence: +2, +2, +1, −1

or

Key: C major
Start: 5
Sequence: +2, +2, +1, −1

This double coding means that a listener has *two* chances of hearing the transposition: crucially, it does not rely on him shifting his key frame.

The second consequence of the close relationship between keys like C and G is that the introduction of the one note *not* shared by the two keys is a strong and unambiguous cue for a key shift to the key which requires the least change of component notes to accommodate the new note. Thus CE DBC, becoming G B A Fsharp G, is strongly suggestive of a modulation from C major to G major. The first three notes of the second sequence (GBA) perform a vital pivotal function. They link the two sequences in a 'tonal space'. Probably most listeners hear these three notes as continuing in the original key of C. Then the F sharp forces a motivated key-shift one step up the circle of fifths. Consider in contrast the impression of CEDBC followed by F sharp A sharp G sharp E sharp F sharp. Here, the first notes of the transposed sequence cannot fulfil a linking function, since none of them are in the scale of the previous sequence. This has the effect of casting the listener adrift from his tonal bearings. He has to forget all about the first scale, and try to construct a plausible scale for the second sequence from scratch. His immediate memory of the first scale may interfere with this attempt, and his efforts to interpret the second sequence may cause him to lose details of the first. It is not surprising that recognition of such transpositions is hard. In much real music, two statements of a theme in distant keys will be separated by the kind of preparatory modulations that allow a listener to keep his tonal bearings and so know in advance what scales are likely to be encountered. In such cases, the transposed theme is recognized with ease.



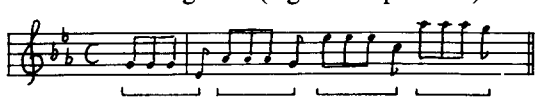
There is now a small body of research on the mechanisms by which key can most readily be detected by a listener. Some suggestions have already been discussed in Chapter 2, section 5.3. Butler (1983) reports experiments showing that one cue signalling key is the presence of intervallic patterns which are unique to that key, or which can be found in the smallest number of other keys. The interval C–D, for instance, can be found in *five* major scales—C, G, F, B flat, and E flat. On the other hand the tritone F(E sharp)–B is only found in two scales, C major and F sharp major. In Butler's experiments sequences which made this tritone relation most salient were those which gave listeners the strongest sense of a key centre. A third note added to the tritone specifies a unique key. For instance, the sequence FBC can occur only in C major (Brown and Butler 1981).

Once a key is established, each note of the implied scale has a unique configuration of intervallic relationships with the other notes of the scale (because of the uneven distribution of tone-semitone intervals up the scale—see Balzano 1980). Thus, the interval F–C *heard as* in C major has a different tonal quality to F–C *heard as* in F major. In the former case the notes have an implied scalar relationship to a B *natural*, whereas in the latter case they relate to a B *flat*. To hear F–C as in C major is to appreciate the relationship of these notes to an unheard but 'implied' B natural.

These considerations help us to understand why context is of such crucial importance in the recognition of transpositions. In Cuddy, Cohen, and Miller's experiments (1979), the diatonic context helped listeners identify the key of each passage. When the context was non-diatonic it was impossible to assign a key to each passage, and thus impossible to code the sequences in terms of scale steps. Probably the best that could be done would be a rough estimate of interval contour (e.g. 'a large interval up followed by a smaller one down'). Such information would be too crude to be useful in distinguishing exact transpositions from 'false alarms' with similar up-down contours.

Perhaps, however, this 'crude' up-down contour should not be dismissed as playing no role in musical memory. Davies (1978) and Dowling (1978) among others have proposed that such contour information *does* form the basis of our musical memory in some real listening situations, and can be useful even when more exact scalar or intervallic representations are not achieved. Such information could certainly not allow us to *recall* a melody other than very approximately, but it might indeed be sufficient, in some contexts, for a melody to be *recognized* as a repetition or transposition of an original (especially if combined with other information, such as, for example, rhythm).

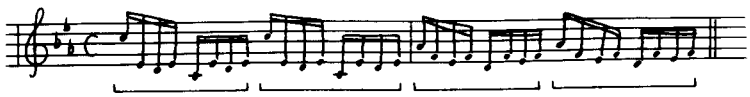
Edworthy (1983) has attempted to assess the importance of contour memory by means of an experiment where listeners heard two melodies, the second of which was a transposition of the first at the tritone (e.g. C major–F sharp major). The transposition preserved the exact intervals of the original except at one point where a deliberate alteration was introduced. Listeners were required to locate the alteration. There were two types of melody, short (5 notes) and long (15 notes). Example 5.22 gives an example of a typical five-note melody. There were also two listening conditions. In the 'pitch' condition, the altered note was another note chosen from the key of the melody which did not change the original up-down contour (see Example 5.23). Subjects were asked to monitor the pitches of the notes to detect the alteration. In the 'contour' condition, the melody was altered within its key so that the up-down contour was different at one place (see Example 5.25). Subjects were asked to monitor the up-down contour, *not* the precise pitches, so as to locate the contour alteration.



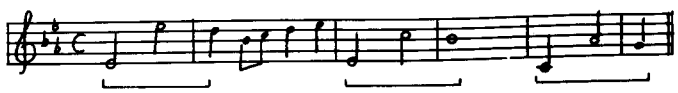
Examples 5.22.–5.25. Examples of stimuli in Edworthy's (1983) study.

Unsurprisingly, the short melodies gave more accurate results than the long ones. The important result, however, is that although the contour condition gave the best results for short melodies, the *pitch* condition gave the best results for long melodies. It seems that as soon as melodies of any length are heard, up-down contour coding becomes inefficient. Subjects must switch to a more difficult form of coding which retains pitch interval information in some form. In the light of the preceding discussion it seems that this processing involves the coding of the melody as a sequence of tonal elements in a particular scale or key.

Dowling and Bartlett (1981) provide similar conclusions to Edworthy in a study where short extracts from Beethoven string quartets were played. Subjects had to classify other extracts from the same work, heard after a delay, as similar or dissimilar on a rating scale. Some of the extracts were 'lures' chosen to resemble the originals in melodic contour but to differ in exact pitch interval, others were dissimilar in both contour and pitch interval. Subjects judged both these types of extract as 'dissimilar' to the original; with the same-contour lures being heard as only marginally more similar than the different contour lures. In further experimentation, Dowling and Bartlett found that shared contour was a better predictor of perceived similarity only when the delay between original and comparison was short. When the delay was longer, an exact pitch-interval match was required for high similarity judgements.



Taken together, these results suggest that contour is a characteristic of music which is most important for listening over short, rather than long spans; and that if a composer wishes to direct a listener's attention to the *contour* similarity of two sequences they must both be rather short (nearer 5 notes than 15) and be close together in the composition. The cases that spring to my mind certainly fulfil this condition. In the first movement of Beethoven's Fifth Symphony, the crucial melodic element is four notes long, and when pitch interval is altered so as to leave only contour identity then the repetitions are often contiguous (e.g. Example 5.26). In Bach's Prelude

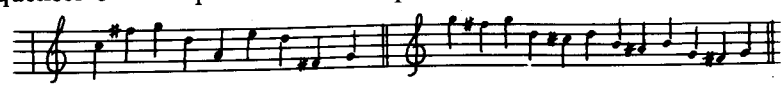


Example 5.26. Adapted from Beethoven, Fifth Symphony, first movement.

in C minor (Well-Tempered Clavier, book 2), the repeating motif is eight notes long, and because virtually the whole piece is based on contiguous repetitions of the motif which preserve contour but not precise interval relations, the contour is highly salient (Example 5.27).

Consider, though, how even a small amount of intervening material can camouflage a contour identity. The popular song 'Over the Rainbow' has a three-note motif which is subject to contour repetition (Example 5.28). It was not, however, until I was encouraged to view this very familiar melody

Example 5.27. From J. S. Bach, *Well-Tempered Clavier*, Prelude 2, Book 1.



Example 5.28. Opening melody bars of 'Over the rainbow', Music by Harold Arlen, lyric by E. Y. Harburg. Copyright © 1938, 1939 (renewed 1966, 1967) Metro-Goldwyn-Mayer, Inc. analytically (by Rosner and Meyer 1982) that I noticed the contour repetition of bar 1 by bar 3. My 'parsing' of the melody had grouped the third note (D) with the other notes in bar 2, undermining its relationship to the previous two notes.

5.4.2. *Sequential pattern*

It seems incontrovertible that musical sequences which can be represented as occurring within a key or scale are easier to remember than those which cannot. However, this generalization needs qualification. Consider the two sequences of Example 5.29. If one spends a few seconds studying each of

Example 5.29.

these with a view to reproduction it will soon become apparent that (*b*) is much easier to remember than (*a*). This is despite the following facts:

1. (*a*) begins with a three-note sequence which uniquely specifies the key as G major, whereas (*b*) does not.
2. (*a*) contains only notes from within the G major scale, whereas (*b*) contains two chromatic notes (C sharp and A sharp).
3. (*b*) is longer than (*a*).

What makes (*b*) easier to remember is that it seems somehow simpler. One hears it as a three-note pattern which repeats four times down a G major arpeggio. Deutsch and Feroe (1981) have provided a detailed formalism which captures some features of music which appear to accompany ease of memorization. They see simple tonal melodies as operating within *alphabets* of notes. An alphabet is a culturally specified pitch-ordered set of intervals which embodies some tonal principle. The primary alphabets of our culture are the diatonic and chromatic scales and arpeggios. Taking any one of these alphabets one can construct an ordered ascending or descending sequence from any note. Applying the alphabet of the G major scale to the note G would give the ascending sequence G A B C D E, etc. Applying the alphabet

of the chromatic scale to the same note would give G G sharp A A sharp etc. Applying the alphabet of the G major arpeggio would give G B D G etc. It is proposed that within each of these alphabets, moves of a single step are the simplest and most easily manageable type of change, and that sequences which can be shown to be constructed out of a combination of such moves in the various alphabets are perceived as simple and easily memorable. For instance, Example 5.29 (*b*) can be expressed as a simple hierarchical structure based upon single step movements in the alphabets of the G major arpeggio and the chromatic scale (see Fig. 5.5). At the top of the hierarchy we start

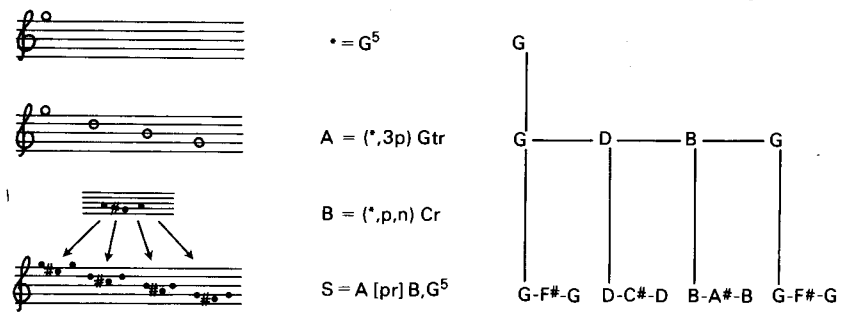

Fig. 5.5. Formal representation of an hierarchically organized tone sequence. Adapted from Deutsch (1981) and Deutsch and Feroe (1980). Key: * = reference note (i.e. the note on which the sequence is constructed); p = downward movement of one step within an alphabet; n — upward movement of one step within an alphabet; Gtr = alphabet of the G major triad; Cr = alphabet of the chromatic scale; A[pr]B = the application of pattern B to each element of pattern A.

with a single note, G4. We than apply the G major arpeggio alphabet to this note, descending in consecutive steps for four notes. We then construct a subsidiary pattern in the chromatic scale which is obtained by taking a note, moving one scale step down, and then returning to the original note.

We now apply this pattern to each note of the arpeggio in turn to produce the final melody. Figure 5.5 shows the consecutive steps in the construction, and also shows the symbolic notation that Deutsch and Feroe have developed to describe such sequences economically.

These theoretical formulations build directly on work by Simon and Sumner (1968) and Restle (1970) concerned with temporal patterning. However, Deutsch and Feroe point out that similar hierarchic structures seem to be implicated in the way we represent other complex inputs such as visual scenes (Palmer 1977) and large-scale environments (Chase and Chi 1981) as well as language (see Chapter 2); and thus represent a general feature of human cognitive functioning.

Deutsch (1980) has provided first-hand evidence for the theory by asking musicians to recall melodies by dictation. Some melodies could be economically described as hierarchic structures [such as Example 5.29 (*b*)]. Others [like Example 5.29 (*a*)] could not. Recall for the former type was 94 per cent

correct; that for the latter was only 52 per cent. Furthermore, if the structured melodies were temporally segmented into groups of three (by the introduction of a brief pause after each third note) corresponding to the major hierarchical subdivisions, performance rose to 99 per cent. If, however, the segmenting was in groups of *four*, thus 'breaking up' the melodic groupings by threes, performance dropped to 69 per cent. On the other hand, temporal grouping of *any* sort improved performance on the unstructured sequences by about 10 per cent.

These results introduce an important factor which we have not so far considered in our treatment of music listening; that is the role of timing and rhythm. It is well known that introducing temporal gaps into sequences of any sort increases the tendency for sequences to be perceived as groups or chunks between each gap (Bower and Winzenz 1969; Restle 1972). This is, in part, to be explained by Gestalt grouping principles. The 'law of proximity' states that elements grouped closely together on a particular dimension tend to be perceived as single unit, separate from other, more distant elements. A visual analogy to the auditory phenomenon is provided by the following pattern:

.. ..

This is seen as five unequally sized groups.

However, as we have already seen (Chapter 2, section 5.4) such simple groupings can be supplemented by a more sophisticated type of grouping based on metre, and displaying much of the same hierarchical structuring as Deutsch and Feroe have proposed for pitch grouping. The operation of both types of grouping is well demonstrated in a study by Smith (1983) who examined memory for rhythmic patterns by asking musicians and non-musicians to listen to rhythmic sequences performed on a synthesized drum, and then attempt to reproduce them. Figure 5.6 gives an example of the type of rhythmic pattern used, together with two alternative ways of grouping the pattern. Above the pattern is a representation of the sound amplitude over

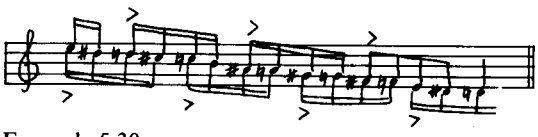

Fig. 5.6. Adapted from Smith (1983).

time. Gestalt grouping by temporal proximity yields the four bracketed groups given. Below the pattern is a representation of its hierarchical metrical structure. This assigns the sequence a 3-beat metre which groups notes *across* the boundaries of temporal groups. Each metrical group begins with a stressed note at the beginning of a bar. When Smith analysed her subjects' errors she found that musicians tended to group by metre, and that their responses tended to maintain the regular metre of the original. The errors of non-musicians tended not to retain the metre, but their responses preserved the more primitive temporal-proximity grouping. Smith found that

> Many subjects reported using a 'counting' strategy, tallying the number of sounds that formed a group, and the number of such groups in the sequence. This meant that although they might tap out the correct number of sounds, the intervals within and between groups of sounds were distorted.

We see, therefore, in Smith's study, not only the importance of relatively abstract underlying patterning in determining memory for rhythm, but also the fact that the use made of such patterning depends upon musical experience. This reminds us of the generally applicable, but sometimes overlooked, fact that many aspects of the ability to deal with music are crucially dependent on musical experience. Such experience allows the learning of the characteristics of common structuring principles in music, and mechanisms for detecting them. We shall return to a more thorough examination of the changes that take place in musical behaviour as a result of experience in the next chapter.

Several other studies confirm the importance of hierarchical organization in the perception of rhythmic patterns (e.g. Handel and Todd 1981; Povel 1981); and Jones, Kidd, and Wetzel (1981) have provided a preliminary demonstration that rhythm can act as a cue to attentional streaming in an analogous way to pitch. In general, rhythm has been 'tonality's poor relation' (Davies 1978) in studies of psychological response to musical structure. We are now beginning to see, however, that not only is rhythm just as important an organizing principle as tonality, but that the two systems are mutually interactive. Thus, in much tonal music, knowledge of the tonal structure can help determine the rhythmic structure, and *vice versa*. We have mentioned before (Chapter 2) how repetition of tonal patterns can act as a cue to metre (Steedman 1977). Thus Example 5.29(*b*) acquires a 3/4 metre as a result of the repeating three-note pattern. Conversely, rhythmic stress (as communicated through accent or timing variations—see Chapter 3, section 2.3) provides a cue for determining tonal structure. In much music, principal harmonic notes fall on the main beats, with subsidiary or passing notes at other points. Thus, the chromatic sequence of Example 5.30 is most likely to be heard in D minor if the upper accenting scheme is used, but in E minor if the lower scheme is used. In each case the accents specify the primary harmonic notes.

Example 5.30.

5.4.3. *Memory in extended music*

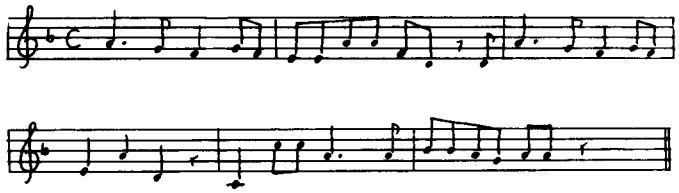
The literature I have reviewed in this chapter shows that we are beginning to build up a detailed, objectively verified, picture of the way listeners represent and memorize short melodic sequences. The question we return to, raised at the beginning of the chapter is, how does this help us to understand what goes on in listening to extended passages of music? One, rather naïve, view would be that listeners form representations in memory of each short sequence in the sort of way outlined here, and then simply retain these sequences in the correct serial order; in much the same way as one might try to remember a list of unrelated sentences. This view raises two problems: firstly, how does a listener segment or 'break up' a continuous musical texture into short sequences of the appropriate sort; secondly, how does he keep what may be many hundreds of such sequences distinct and correctly ordered in memory? We will examine these questions in turn.

To solve the segmentation problem, listeners must be capable of detecting 'closure' at various levels. Sometimes physical characteristics of the music, like a pause, or a change of instrumentation will suggest a suitable segmentation. But there is much music where such cues would not be sufficient. There is some evidence that listeners perceive more abstract types of closure, specified by harmonic or rhythmic considerations. In Chapter 2 we discussed the 'click migration' experiment of Sloboda and Gregory (1980) as providing evidence for perceptual segmentation of melodies into phrases separated by cadences. A study by Tan, Aiello, and Bever (1981) is more particularly relevant to the present discussion because it tested *memory* for parts of a sequence. In this study sequences of equal-duration notes were constructed which contained two melodic phrases, each phrase ending with a melodic cadence. Example 5.31 shows one of the sequences used. When played or sung it will give Western listeners the impression of breaking into two halves, a partial 'close' coming after the tenth note. The sequence leading up to this note (D G E C) is most readily interpreted in this context as a perfect cadence, moving from the harmony of G to that of C. Notes 11–14 form part of a new chord (D minor) leading to a final perfect cadence in C. Tan *et al.* played such melodies to subjects and then asked them to judge whether a particular two-note 'probe' had or had not been present in the melody. Of particular importance were three types of 'true' probe; the pair of notes ending the first phrase (E C in Example 5.31), the pair of notes beginning the second phrase (F A in Example 5.31), and a pair of notes which 'straddled' the phrase boundary (C F in Example 5.31). They found that subjects were less likely

Example 5.31. Example of stimulus used by Tan, Aiello, and Bever (1981).

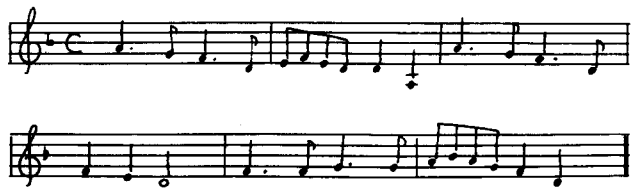
to recognize the latter type of probe as having occurred than the other two. It appears that they were more likely to form accessible memory representations of intervals *within* phrases defined by cadences than they were for notes equally close in time but coming from two different phrases.

Closure can also be signalled by rhythmic or metrical features of music. For instance, there is a tendency for much melodic music to be constructed in multiples of two-bar units. Thus, a common phrase length is four bars: the 16-bar song contains four four-bar phrases. Meyer (1973) has proposed that a musical form achieves the double ends of articulation or segmentation together with unification and forward-movingness by putting the various cues to closure 'out of phase' with one another. Thus a melody may achieve rhythmic closure at a particular point, but its lack of harmonic closure implies the need for a continuation. On this argument, the end of a well-constructed piece of music is not simply the point where the sounds stop; it is the point where closure is simultaneously achieved at all the various levels. Let us then assume that there are cues which listeners can use to segment music into manageable and 'meaningful' short units.



Our second question relates to the problem of holding a large number of such segments in memory. Estimates of memory capacity for a set of items which are not related in any principled way suggest a limit within single figures (e.g. Miller 1956). As more items are added, memory for other items is lost. The only way to overcome such limitations appears to be to find some way of linking or relating, the items together. In some spheres of memory this is done by 'importing' a structure which can act as a mnemonic to link otherwise unrelated elements together. In music, such relations are, to a large extent, already present in the patterning and structure of a composition. The composer deliberately writes so that the individual segments have a similarity and connectedness that links them together into larger units. It is precisely by discovering such similarities and connections that the limits on memory can be overcome.

First, for instance, economy of coding is achieved if repetitions can be identified and noted. Then, rather than making two representations of the sequence in question, it can be represented once in memory, and 'called up' on its various occurrences through the piece by some sort of 'marker' which locates the repetitions in the longer sequence. Second, inexact similarities could be noticed, and sections coded as *variants* of earlier sections. Maybe on a first hearing, the listener would not have the resources to code all the differences, but would be able to remember it as 'almost like' something that had gone before. Third, the listener could extract some underlying



progression or pattern in a sequence of musical statements; such as traversing a familiar tonal path, or moving towards a climax, or conforming to some known form such as theme or variations. This would help him to reconstruct the correct ordering for the sequences, which would no longer be arbitrary, but guided by some rule or pattern. Fourth, the listener may be able to construct an emotional or representational 'plot' or 'drama' from the music, which he can use to help recall and order the various components. For instance, the requirements of the 'plot' at a particular point tells one that the next theme is 'cheeky' or 'resigned'. Delis, Fleer, and Kerr (1978) have provided evidence for this kind of process in an experiment where they found that people remembered musical extracts best when they were labelled with concrete representational titles as opposed to abstract conceptual ones. They argue that the concrete titles allow some kind of story to be constructed, to which the various segments of the music can be associated. In much music, there is, of course, no representational title, and so the listener must construct his own 'story' from the character of the music; but the principle is the same.

The general picture I would like to propose on the basis of such suggestions is that the listener is engaged in building up a multidimensional representation of the music he hears, and that depending upon his knowledge and cognitive style, his early memory for the music will select different dimensions from the many available ones. What is crucially important is that these memories will not necessarily be composed of isolated episodes in the music. It is equally possible that he will have extracted quite global information which specifies some parameters of the overall structure (such as metrical construction or harmonic framework, recurrent melodic types, or emotional 'argument').

How can we demonstrate such processes at work? I can, at present, think of no satisfactory way of tapping what goes on when music of really extended proportions is heard; but one intermediate approach, which David Parker and I have recently begun to explore, is to ask listeners to attempt to reproduce, by singing, moderately extended short musical forms which have a definite melodic phrase structure, but which have too many notes for a perfect first recall to be likely. We can then examine the errors made in reproduction, and also how a representation is built up over repeated hearings, and repeated opportunities to recall the melodies. Our preliminary findings are encouraging. Even people with quite little musical training are capable of providing competent responses; and we find that often the very first recall preserves much high-level information contained in the original whilst losing specific details. For instance, Example 5.33 shows a transcription of a subject's first attempt at recalling Example 5.32. Whilst many of the individual notes do not match the original, it has the correct metrical structure (three two-bar phrases in common time, the correct harmonic sequence (two I–V–I phrases in D minor followed by an implied move to the relative major key of F), and several of the characteristic melodic and rhythmic patterns of the

Example 5.32.

Example 5.33.

original. It seems very much as if this subject was reconstructing some of the details according to constraints laid down by his knowledge of the higher order structure and style of the melody, using general musical knowledge to 'fill in the gaps' in a plausible manner. Further discussion of this study maybe found in Sloboda and Parker (1985).

I hope that the preceding discussion will make it more apparent why I wish to claim that a 'feat of memory' such as Mozart's memorization of Allegri's *Misèrere* (see Chapter 1) does not involve inexplicable processes which set him apart from ordinary musicians. Rather, it distinguishes him as someone whose superior knowledge and skill allows him to accomplish something rapidly and supremely confidently which most of us can do, albeit less efficiently, and on a smaller scale. If we examine the structure of the Allegri *Miserere* we find several features which could assist memory processes of the kind we have been discussing. The work has a simple episodic structure in which a polyphonic 'chorus' is repeated several times, separated by a repeated simple and homophonic chant-like verse passage. Mozart would have had prior access to the words of this choral piece, and possibly to the reports of other listeners, which would have given him a pretty clear idea of the type of structure to expect. The primary problem for him would be to 'fix' the part writing of the 'chorus'. In this, he would be assisted by the several exact repetitions during the course of the performance. Within this section there is a reasonably straightforward harmonic sequence which supports a particularly salient and ornate soprano melody. It was the alleged beauty of this melody, heard in its harmonic and acoustic context, that was responsible for the refusal of the Vatican to publish the music. The fact that this music could only be heard in the Sistine Chapel no doubt added to its fame.

There are several strategies that Mozart could have used to memorize the crucial section. One would be to focus his attention on a different vocal part on each of the hearings (see this chapter, section 2). I suspect, however, that a priority would have been the exact replication of the celebrated soprano line together with the correct harmony. It would not have been so important that the disposition of the harmony notes among the inner voices should be absolutely correct. After all, there was no possibility of the 'illicit' copy being checked against the original score. With the primary melodic line and some of the more salient inner parts fixed, it is quite likely that Mozart could have used his stylistic knowledge to 'fill in' what he did not hear for certain. Furthermore, he would probably have had that 'instant' recognition of chords and intervals which we discussed in the context of 'relative pitch'. Thus he would know that he had heard, say, a dominant seventh chord, without necessarily hearing out the individual notes. Yet his knowledge of the contents of a dominant seventh would allow him to infer the notes 'in the mind's ear'. After a first hearing, he would have identified troublesome sections which needed more attention on a subsequent hearing, because they did not contain instantly recognizable chords or patterns. Finally, for someone with as much musical knowledge as Mozart, there exists the possibility that he recognized sequences as identical to, or similar to, sequences in other pieces already well-known to him. Once recognized, such a sequence can be disposed of as something already available in the memory representation of another work.

These comments, whilst speculative with respect to Mozart, are clearly testable with respect to contemporary musicians who can produce both written evidence of their memorization attempts and verbal protocols of their strategies. Let us hope that such research is undertaken soon. Research on other cognitive tasks (such as copy drawing from memory, e.g. Pratt 1983) offers promising models, as well as confirming the general kinds of explanatory proposal put forward here for music.

6. Musical learning and development

6.1. Introduction

Musical skill is acquired through interaction with a musical environment. It consists in the execution of some culturally specific action with respect to musical sounds. However, musical skill is constructed from a base of innate abilities and tendencies. Every human advance involves building on what is already present. Because all human brains are similar, and because certain aspects of experience are common to all humans (e.g. the experience of the physical world and its properties) it has been possible to isolate certain early aspects of skill acquisition which seem to be shared by all humans. For instance, we all acquire the basic skill of manipulating objects in the first year of life; we acquire competence in our natural language by the age of three or so. Further than this, it has been proposed by some psychologists, notably Piaget (e.g. 1950, 1952) that the *type* of learning we are capable of at any age is determined by the general features of our intellectual equipment at that age. Thus, the reason why children seem not to be able to reliably master mathematical concepts until the age of seven or so is that until that age they do not have the type of cognitive resources that would allow them to grasp necessary notions such as transitivity or conservation.

On this view cognitive development is to be partly explained in terms of the ordered acquisition of new 'general' cognitive abilities and structures ('general' because they are involved in a whole range of specific skills and not just one). Piaget's well-supported view is that there is a universally shared order of passage through various cognitive 'stages' and that each stage is characterized by a fairly rapid advance in skill acquisition as the new capacity is applied to the whole range of specific skills the child is engaged with. These stages should not be seen as mysteriously emerging in the child simply as a result of some biologically determined 'release' of new capacities at various ages. Rather, they are brought about by adjustments or 'accommodations' that occur as the child learns particular skills. When the time is right, these adjustments 'colonize' other areas of endeavour.

If we look at musical development through Piagetian eyes, we should be alert to the possibility of discovering invariant sequences of musical development, possibly linked to general changes in other cognitive domains. These sequences would account not for the precise aspects of musical behaviour found—this would depend upon culture, motivation and op-

portunity, but for the *types* of musical activities to be found at particular ages in virtue of the general cognitive capacities they require.

There is, however, another powerfully argued view of human cognitive capacity, associated particularly with the work of the linguist Chomsky (see also Chapter 2). This states that the human organism is biologically predisposed to excellence in a few *specific* cognitive skills, language being one such, and that there exist special mechanisms for acquiring these skills which do not necessarily form part of a 'general' cognitive capacity, but are confined (at least initially) to the skill in question. Taking this approach we should be alert to the possibility of discovering early aspects of musical development which point to capacities specific to music, and not mirrored in other domains.

These two views are not mutually incompatible, and Gardner and Wolf (1983) have pointed out that elements of both may be required to fully explain the course of cognitive development. They argue that human development is characterized by both separate *streams* of specific skill acquisition, possibly supported by special biologically determined mechanisms, and common *waves of symbolization*, where a new achievement in one stream 'spills over' into apparently unrelated streams. The streams are largely linked to, and supported by specific cultural roles—orator, singer, artist, craftsman, etc. Within each stream, explicit instruction or tuition is common. The waves, on the other hand, seem not to be culturally salient. No-one, until very recently, has explored the notion that general cognitive style could be changed through instruction independently of particular skills. Rather, the 'spillage' across skills seems to be a spontaneous human propensity. It might even be a defining characteristic of human thought that there exists some mental medium abstract enough to provided the means of passing general skill between two different specific skills.

It is not my intention to give an exhaustive account of developmental theories as they relate to cognitive psychology. General introductions to the work of Piaget are given by Flavell (1963) and Boden (1979); and a readable critical approach is provided by Donaldson (1978). Reviews of developmental theories in relation to music are provided by Funk and Whiteside (1981) and Shuter-Dyson and Gabriel (1981); the latter also being a comprehensive source reference for research into musical development. What I would like to do here is to use the broad theoretical framework I have outlined above to motivate the division of this chapter into two separate, but complementary, halves.

The first half follows the spontaneous acquisition of musical skill by Western children from birth up to the middle years of childhood. The second looks at the later development of specialized musical skills, which typically take place in a self-consciously educational milieu. These two processes may be roughly labelled by the terms enculturation and training respectively.

The main elements of *enculturation* seem to be these. First, we find a shared

set of primitive capacities which are present at birth or soon after. Second, there is a shared set of experiences which the culture provides as children grow up. Third, there is the impact of a rapidly changing general cognitive system as the many other skills supported by the culture are learned. These elements combine to yield a roughly similar sequence of achievements for the majority of children in a culture, and a set of roughly similar ages at which the various achievements occur. Enculturation is also typified by a lack of self-conscious effort and a lack of explicit instruction. Young children do not *aspire* to improve their ability to pick up songs, although they do improve. Adults do not *instruct* young children in the art of song memorization, yet children come to be able to memorize songs.

When we turn to *training* we take up a rather different set of concerns. We now concentrate on specific experiences which are not shared by all members of a culture. Rather, they are specific to the sub-culture where aspiration to excellence in a particular skill is encouraged. Such experiences allow a person to build on the general foundation of enculturation to achieve what we may call expertise. Very broadly, we may say that, in our Western culture, musical enculturation is the dominant process up to the age of about 10; thereafter musical training plays an increasingly important part. In general, it appears that training is more likely to contribute to depth of knowledge and accomplishment *within* a particular skill than it is to have broad implications for the whole cognitive system. Gardner's 'waves of symbolization' seem to be particularly potent during the first years of childhood when learning on all fronts is most rapid. At this time the cognitive system seems particularly susceptible to broad upheavals. In contrast the typical adult displays a highly 'skewed' profile of cognitive attainments. Someone may be a master jazz improviser whilst retaining the reasoning powers of a 10-year-old. Someone else may have a profound grasp of mathematics whilst retaining the musical accomplishments of a child. And so on. We see, therefore, a cutting of deeper channels within individual streams rather than general 'waves' of development.

Training also involves self-conscious effort on the part of the person concerned with the specific aim of becoming more accomplished. Typically he seeks, or is given, methods for increasing accomplishment. These methods are conveyed through instruction. As well as seeking to describe and understand the changes that take place during a particular type of training, the psychologist is also interested in evaluating the efficiency of different training methods, and, on the basis of such evaluation, offering prescriptions about the best way to train a particular skill. This evaluative/prescriptive approach is the basis of a branch of psychology known as educational psychology.

Over the past thirty years, relations between educational psychologists and cognitive psychologists have not always been cordial. Cognitive psychologists have viewed educationalists as unconcerned with understanding the psychological mechanisms which account for the success or failure of particular

training methods. They have caricatured the typical educational study as randomly allocating children to a number of different types of instructional regime and simply prescribing the instruction which gave the best results. On the other hand educational psychologists have seen cognitive psychologists as unconcerned with solving practical problems, and caricatured the typical cognitive study as dealing with some microscopic portion of a real task and hedging any possible prescription with so many qualifications as to be useless in a real training situation. Both these views have more than an element of truth in them, and it remains as difficult as ever to make instructional prescriptions which are soundly based on real understanding of the psychological processes involved. None the less, I believe that both sides are coming to acknowledge the importance of trying to make links between theory and practice; and writers of cognitive texts now find it almost obligatory to derive some training prescriptions from the results of pure research (e.g. Anderson 1980; Bransford 1979).) Particularly, it has been argued in various places (e.g. Levin and Williams 1970) that an intelligent teacher is more likely to benefit from a greater understanding of the psychological processes underlying a skill than he or she is from being given a particular training prescription. The increased understanding will allow the teacher to devise his or her own methods to suit particular pupils and situations and to modify them in principled ways.

This view has been supported from my own experience with teachers. For instance, I once asked an internationally known performer and teacher to take part in a sight-reading experiment. This was the one described in Chapter 3, section 2.1, where eye-hand span was estimated for 'tonal' and 'atonal' melodies. After the experiment had taken place, I discussed with the teacher my prediction that span would decrease on the atonal melodies. He was sceptical, on the grounds that he specialized in the performance of atonal music. He felt that his immersion in atonal music would counteract the possible effect of my mildly atonal stimuli. Moreover, he had not *experienced* the atonal melodies as any more difficult to read than the others. Later, I analysed the experimental data and found this player to provide results indistinguishable from other musicians whose staple diet was Bach and Beethoven. Like them, his span decreased for the atonal melodies. When I wrote to him with his results he wrote back saying that the results had forced him to change his attitudes to the teaching of sight-reading. How he put his changed attitudes into practice I do not know; but clearly there are any number of educational implications in this result, showing as it does that tonal relationships have an inescapably privileged status in the mental apparatus of a musician (presumably through their early and continued presence in the casual experience of all Westerners). However, I would not be happy to derive a single prescription for teachers from this information. I would expect the competent teacher to be able to make the best use of such information to suit his or her particular circumstances.

Educational psychology has a second major concern besides evaluating training methods, and this is the devising of *assessment* procedures which allow teachers to discover where a particular individual stands with respect to the average achievement for his age on some standardized test. In music such tests have often been labelled 'tests of musical aptitude'. One use of these tests is diagnostic, to isolate particular weaknesses which need extra training. Another use is predictive. High scores on particular tests seem to correlate with later achievement, and so, for instance, music schools use such tests to select candidates for entry to specialist training courses. Such tests are often designed with the explicit or implicit aim of detecting potential excellence in the absence of specific training. We shall examine to what extent they are capable of doing this.

6.2. Musical enculturation

6.2.1. *The first year of life*

The first evidence of musical awareness is some form of differentiation of musical sequences from one another or from non-musical sound sequences. It is not adequate to say, as many writers do, that heightened attention to particular sounds, as such, is evidence of musical awareness. It is well known that infants are particularly responsive to change in the environment (e.g. Kagan and Lewis 1965). It follows that any new or unusual sound will capture a young baby's attention. Parents who are delighted when their babies become quiet and attentive to the sound of a nursery rhyme should be wary of concluding too much about their abilities. It is possible that a child is simply responding to a change in auditory experience from the rapid pitch and amplitude modulations found in speech to the steadier parameters of song, or that he is particularly responsive to definite types of waveform (e.g. Hutt, Hutt, Lenard, Bernuth, and Muntjewerft 1968).

It is, indeed, a necessary precursor of musical awareness that a child should be able to notice differences in crucial dimensions of sound. For instance, he will be unable to notice the defining features of a particular melody if he cannot detect differences in pitch or time. None the less, real musical awareness begins only when the child is able to notice sequential relations between different sounds. How good, then, are young babies at detecting sequence? Studies by Chang and Trehub (1977a, 1977b) suggest that babies as young as five months are already sensitive to sequential structure. In one study (1977a) they repeatedly presented a six-note atonal melody to babies. They measured the perceived novelty of the melody by monitoring heart-rate. It is now well established that changes in heart rate are reliable indicators of perceived novelty, and that as the same stimulus is repeatedly presented, infants 'habituate to' (get used to) the stimulus, with a corresponding stabilization of heart rate (e.g. Bower 1971). When the babies had habituated

to the first melody, a second one was played. This could either be a melody with the same starting note as the first but a different up–down contour of pitches, or it could be the same melody transposed up or down to a different pitch level. Chang and Trehub found that heart-rate destabilized to the new melody with a different contour but *not* to the transposition of the old melody. By five months, therefore, it appears that changes in sequential pattern are already salient, whereas simple changes in pitch level are not. In another study (1977b) the same authors showed that five-month-old babies were also sensitive to changes in rhythmic patterns.

It is instructive to compare Chang and Trehub's precise but limited study to a much broader but less controlled study by Moog (1976). Moog carried out a large cross-sectional study of children's responses to a set of prepared tapes. The tape contained six 'tests'. Test 1 consisted of three children's nursery songs, sung by children. Test 2 consisted of words spoken to definite rhythms but without precise pitch. Test 3 consisted of pure rhythms played on various combinations of percussion instruments. Test 4 consisted of instrumental music. Test 5 took one of the tonally consonant items from test 4 and subjected it to various rewritings which introduced a high degree of harmonic dissonance. Test 6 consisted of non-musical sounds such as the sound of a vacuum cleaner and traffic noise. These tests were played to about 500 children at varying ages between three months and five years. Moog observed the nature of response to the various tests, and recorded details of any musical behaviour in response to them.

He reports that six-month-old children typically stop what they are doing and turn towards the source of the sound with facial expressions of astonishment, remaining motionless and attentive at first, then looking at their mothers and smiling. They will even stop feeding to look at the sound source. The response is not equally marked to all the tests. Tests 1, 4, and 5 (songs and instrumental music) attract much more attention than the others. Moog reports that 'if a subject responded to one series only, that one was always either the nursery songs or the instrumental music; if he responded to two series, then they were these same two. If more than two series of tests attracted the baby's attention, then songs and instrumental music were, in every case, among the tests to which he responded.'

It seems that babies are here selecting *quality* of sound as the criterion for attention—smooth treble-register pitched sounds. Test 3 (rhythms) attracted hardly any attention, even though it was much louder than any other test. Valuable as Moog's data are, they do not tell us whether the babies were noticing sequential aspects of the sounds. All the results could be explained on a simple preference for what Moog characterizes as 'sensuously beautiful sound'.

Up to the age of six months, babies show hardly any overt behaviour which could be called musical. It is, of course, necessary to make a distinction between behaviours which can be heard *as* music by adults and those which

reveal musical awareness in the child. When Ostwald (1973) talks of the newborn baby's cry as having musical qualities, he is clearly referring to the former interpretation. It is nonsensical to suppose that the baby *intends* anything musical by crying.

The earliest sign of intentional music-like behaviour seems to be the ability of some babies to imitate sung pitches. Kessen, Levine, and Wendrich (1979) investigated this in a study where mothers were taught a technique for training their three- to six-month-old babies to match a pitch sung by them on a pitch pipe. They found that after 40 days of practice, all infants were matching sung pitches more often than failing to match; and this was regardless of the musical ability of the parents. There is, however, no evidence that babies below the age of one can imitate melodic sequences, even as short as two notes. Furthermore, 40 days of intensive training hardly forms a part of the normal enculturation process of most babies.

A much more common behaviour which could possibly be musically relevant is the ability of infants to mimic the intonational contour of speech. This is part of the pre-speech vocal exploration often called 'babbling'. Such intonational babbling is primarily composed of microtonal pitch glides, smooth movements across a range of pitches. Gardner (1981) reports that children do not produce *discrete* pitch intervals until the age of 18 months or so. This conclusion is drawn on the basis of an extensive longitudinal study on symbolic development carried out by Gardner and colleagues (Gardner, Davies, and McKernon 1981). In this study they observed the development of a whole range of abilities, including musical ones, in a group of nine children during the first five years of life. This involved regular visits to the homes of all the children, recording their spontaneous musical behaviour, and also attempting to teach them simple songs. This study provides valuable fine-grained data on musical development, and we shall return to it on several occasions in this chapter.

Overt rhythmic behaviour is not noticeably present in the first year of life; although one must again take care to distinguish that which can be interpreted as rhythmical by an adult from that which is intended to be rhythmical by the child. My eight-month-old daughter repeatedly bangs her spoon on the desk of her chair, or repeats a nonsense syllable over and over in her babbling, but I would not wish to ascribe to either of these approximately regular occurrences a rhythmic intention. Rather, she repeats the action as soon as she can after finishing the previous one, and, because it takes roughly the same time to perform each repetition, a roughly regular pulse is set up. To ascribe rhythmic *intention* I would look for some of the following behaviours:

(*a*) subdivision of a beat, so that sometimes there are two or more events within a regular superordinate pulse;

(*b*) omission of a beat, with the picking up of the pulse at the correct time after a pause;

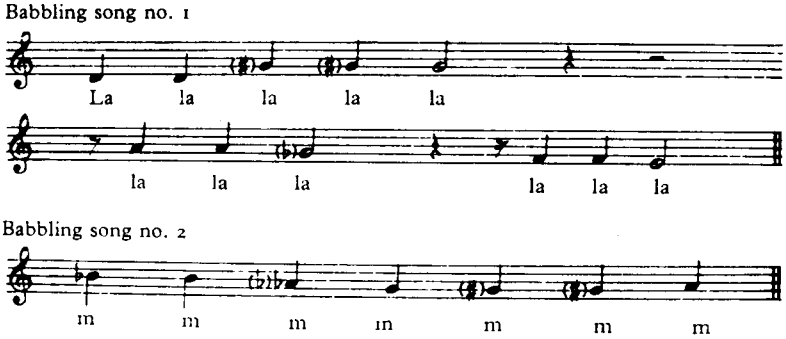
(*c*) imitation of a given rhythmic pattern;
(*d*) moving or beating in time to music.

None of these behaviours normally occur within the first year of life.

In Moog's (1976) study it was found that nearly all babies made some sort of movement response to his tests. The most common responses were swaying from side to side in a sitting position or bouncing up and down. These responses were most commonly observed to song and instrumental music rather than pure rhythms, and they were not rhythmically co-ordinated with the music. Between the ages of nine months and one year these movements increased in frequency, duration, and intensity. Moog also found that around nine months babies began to make distinctive vocalizations to the music. He calls these vocalizations 'song babbling' in that they tend to be varied in pitch but lacking in phonemic variety, often being 'sung' to an open vowel. Song babbling bears no relation to the pitch or rhythm of the music being played; it seems to be a characteristic response of pleasurable expression to the sounds. This is confirmed by the fact that movements and vocalizations occurred primarily to the song and instrumental tapes, and did not occur so frequently to the rhythm or 'noises' tapes. Indeed, babies over nine months began to make quite clear signs of displeasure at these latter tasks, turning away, pulling 'dissatisfied' faces, even showing signs of fear. The increase in vocalization to music over the first year is quite dramatic. At three months only 5 per cent of children made vocalizations. At six months this proportion had risen to 30 per cent and by nine months 100 per cent of the children tested vocalized during the music. It is not clear, however, from Moog's report whether he checked that vocalizing occurred more during music than at other times, or whether the results simply demonstrate an increasing propensity for babies to vocalize at any time.

Do babies of under one year *recognize* familiar pieces of music? The initial possibility of this occurring rests on the fact that parents very often sing the same nursery tune to their children over and over again. My daughter has 'Baa baa black sheep' from someone in the house at least a dozen times a day. At a later age, signature tunes to familiar TV programmes, often played records, and others, can be added to the list of repeating musical experiences. Moog (1976) reports that children towards the end of the first year are often able to make the appropriate movement when they hear 'action songs' which are associated with particular gestures. However, it is not necessary to have the melody. Children still make the appropriate movement if the words are *spoken* rhythmically. Dowling (1982) reports that 'my daughter at 18 months would run to the TV set when she heard the "Sesame Street" theme come on, but not for other melodies'. Clearly then, young children are capable of recognizing some aspect of familiar music. However, we must not conclude from this that they 'know the tune'. Their recognition may be based on the words, or on some distinctive texture or timbre. It is disappointing for me to discover that I can sing 'Baa baa black sheep' to almost any set of pitches

provided I retain the words and rhythm. My daughter will still stop struggling and look pleased.

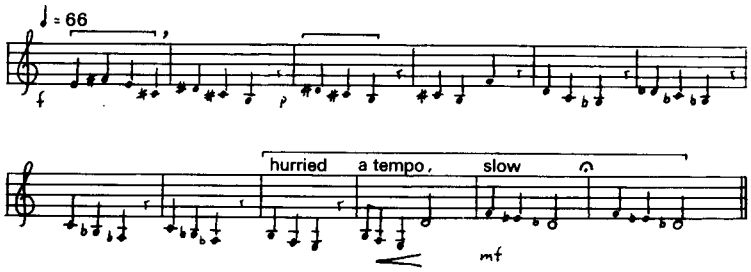


What, then, can we conclude about musical enculturation in the first year of life? It seems that children come to distinguish musical sounds from non-musical ones, as shown by greater attention, movement and vocalization. The primary qualities that mark the sounds they prefer seem to be those of the singing voice or instrument. It is possible that these responses arise from a biological propensity to respond in a special way to certain classes of sound. We also find that children can imitate individual sung pitches, and can discriminate short sequences with differing pitch or rhythmic contours if heard several times in a row. However, there is little or no evidence that children retain much precise musical information about songs they hear often; and their pitch and rhythm-like productions do not share the organizational features of the melodies that evoke them. It should be said, however, that these broad conclusions urgently require refining through the type of controlled experimental study that other aspects of infancy have now been enjoying for 20 years or more.

6.2.2. *The pre-school child (ages one to five)*

The first striking change in overt behaviour after the first birthday comes at about the age of 18 months when spontaneous singing begins to occur. The main characteristic of spontaneous singing is the use of discrete stable pitches (rather than the microtonal glides of the earlier 'song babbling'). These pitches are joined in sequence to form simple intervallic patterns. Although the child at this age has usually begun to speak, words are not usually used in spontaneous singing. This suggests that musical development at this age is proceeding along a genuinely separate 'stream' to speech. Moog (1976) has observed that 'single words or parts of words may occur, scattered around in a string of nonsense syllables or at the beginning of a babbling song which after beginning with the word continues with the repetition of a single syllable'. At this stage there is no evidence that children are attempting to imitate heard songs; rather it seems as though they are experimenting with melodic interval construction. Gardner *et al.* (1981) noticed that the most frequent intervals initially used approximated to seconds, and major and minor thirds. As the second birthday approaches, children begin to experiment with larger intervals such as fourths or fifths. In all cases the intervals are only approximate, and there is little evidence that children are producing the exact intervals of the diatonic scale. Several authors have attempted to transcribe these spontaneous songs using conventional notation. Whilst this provides a useful impression of the general characteristics of child song, one must be careful not to ascribe more tonal and rhythmic coherence than is actually present. The temptation for an adult listener is always to assimilate what a child sings to the adult categories.

With this cautionary statement in mind, we may examine some examples



of spontaneous song. Moog (1976) provides two typical examples of songs produced in the second year of life (Examples 6.1 and 6.2). A sharp or flat

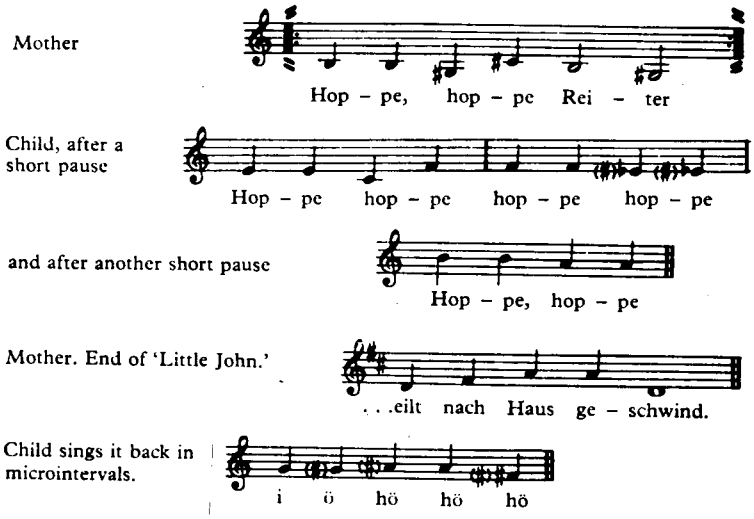
Examples 6.1 and 6.2. Spontaneous songs of one-year-old children. From Moog (1976).

sign enclosed by brackets indicates an approximate quarter-tone interval above or below the given note. We may see that the songs are dominated by simple repetitions of the same pitch, or small movements up and down in pitch. They are also rhythmically primitive, being dominated by simple repetition of a single note length. When pauses occur, they seem to be related principally to the need of the child to breathe, rather than any developed notion of rhythmic differentiation. It is, however, of interest that the end of Example 6.1 seems to involve a melodic and rhythmic imitation of a three-note figure. Clearly, though, these songs have little sense of adult tonality or harmony.

Between the ages of two and three, spontaneous songs become longer and begin to display greater signs of internal organization. Example 6.3 gives an

Example 6.3. Spontaneous song of a 32-month-old child. From Dowling (1982).

example of a song provided by a 32-month-old child (from Dowling 1982). Each note was sung to the syllable 'yeah' and brackets indicate regions of relatively accurate intonation. Elsewhere the notated pitch is only approximate. We can now see a quite clear and deliberate use of repetition. A descending major 3-2-1 is repeated nine times at different pitches with the



same rhythm. Furthermore, the intervals used often correspond exactly to the diatonic intervals of the scale. Although the pitch of the whole song wanders, and there is no overall sense of a stable tonal centre, each phrase tends to be tonally coherent. By two-and-a-half, the child seems to have assimilated the notions that music is constructed around a small fixed set of pitch intervals, and that repetition of intervallic and rhythmic patterns is a cornerstone of music. What he does not grasp is that there is any hierarchical structure governing groups of patterns which prescribe direction and closure. In general, child song at this age has an 'aimless' quality—it can go on and on without any sense of finishing. The decision when to stop is largely arbitrary.

By the age of two to two-and-a-half a new milestone is reached. Children begin to attempt to *imitate* parts of the songs they hear around them. The first aspects of songs that children imitate are the words—not the complete words, but particularly salient or often repeated sections. Moog reports children often imitating the 'ding ding dong dong' from one of the songs in his test series. Gardner (1981) reports observing 'an oink oink here, an oink oink there' from 'Old MacDonald'. Often these same few words will be repeated over and over. At the beginning there is little attempt to reproduce either the rhythm or the melody of the song concerned. Rather, children seem to couple such word patterns with the type of melodic fragment they have been producing in spontaneous song.

The next stage is the extraction of characteristic rhythmic and pitch patterns from the songs of the culture. In the study by Garner *et al.* (1981) study, this tended to occur towards the age of three. In Moog's (1976) study 50 per cent of the children had reached this stage by two years. This discrepancy is not something that should concern us unduly. Not only were the samples of different nationalities (Gardner—USA; Moog—W. Germany) but the sample sizes were very different. Gardner's generalizations are based primarily on in-depth studies of nine particular children. Moog's generalizations are based on a representative cross-section of 500 children. Both studies agree on the *order* in which the various milestones are reached; and we can see that within Moogs' study there were wide divergences between children at particular ages.

Moog provides an example of the kind of imitation provided by one two-year-old child in interaction with his mother (Example 6.4). We see here an exact imitation of the first four notes of 'Hoppe, Hoppe, Reiter' transposed to a new pitch. Then the child abandons strict imitation and begins spontaneous repetitive song-play on the word 'Hoppe'. In the second example, the mother sings the song 'Little John', and when she has finished, the child repeats the melodic contour of the last five notes (with much diminished intervals).

In general, melodic contour was imitated more often than exact pitch, and in no case did Moog observe *exact* imitation for more than a bar at a time,

Example 6.4. Song interaction between a two-year-old child and his mother. From Moog (1976).

and this only when the child was actually singing simultaneously with the model.

During the third and fourth years of life the child develops imitative capacity to the point where whole songs can be repeated. Generally the rhythm and the pitch contour is mastered before the ability to reproduce precise intervals and maintain the same tonality throughout a song. Most children can accurately reproduce the familiar songs and nursery rhymes of their culture by the age of five.

What happens to spontaneous songs during the child's increasing mastery of imitation? Firstly they get longer. Moog reports that three-year-olds will often produce continuous songs of several minutes' length. They do, however, occur less frequently as the preoccupation with imitation grows. By four years of age, about 30 per cent of Moog's sample were producing what he calls 'pot-pourri' songs. In these songs 'children make up new ones by putting together pieces of several songs which they already know. Words, melodic lines, and rhythms are mixed up, altered, taken apart and put together again in a different way and then fitted in between stretches of 'original ideas". Usually these 'pot-pourris' were free episodic structures with little sense of overall organization. However, in a few isolated cases figures or phrases from a learned song were altered according to a definite formal principle. One girl of three-and-a-half sang the whole of the Christmas carol 'Ihr Kinderlein kommet' in triple time instead of quadruple time. She did this by altering the dactyl pattern to a triplet wherever it occurred. Such grasp of formal structure at this age is, however, most unusual.

By the age of five, spontaneous song has declined dramatically in frequency

of occurrence. The child is now more self-conscious and is concerned with avoiding 'error' and achieving precision of imitation. This concurs with a general trend in children of this age for mastery of detail. Gardner and Wolf (1983) characterize this as a 'wave of symbolization' which moves children from a stage of 'topological mapping' to one of 'digital mapping'. In the earlier stage, children operate mainly with approximate relations of shape and size. In drawing, for instance, they will not be too concerned with getting the right number of fingers on a drawing of a human hand. In the later, digital, stage children become almost obsessed with exact quantification and classification. It is the age at which they will painstakingly put exactly the right number of fingers on each hand even at the expense of stylistic demands of the drawing. For instance, running figures often appear 'frozen' and lifeless because the child is more concerned to try for correct anatomical details rather than convey a sense of motion in which, at a younger age, maybe an extra arm or leg is added.

The same tendency may also account for the love of exact repetition. Moog reports that 'a dozen musically minded parents agreed that small children go on asking to sing the same song for weeks and months on end, just as they go on asking for the same stories over and over again . . . When they look at picture books they look for the same picture, and when they themselves draw they go on drawing the same things for a long time.'

There are a number of possible consequences of this concern with precision and repetition at age four to five. One is that the child is focusing on and using, maybe for the first time, the characteristics of song which are determined by superordinate structures of tonality and rhythm. Although the behaviour of the child may seem externally static, it is very likely that he is using his increasing knowledge of, and memory for, exact pitch and timing relationships to build up knowledge about higher-order structures in music, extracting a new level of knowledge about scales and keys, and about rhythm and metre. We see this knowledge at work in a study by Davidson and McKernon (reported in Gardner 1981) where they taught a new folk song to children aged four and five. They found significant changes between four and five in the imitative products of learning. The five-year-olds were able to maintain a single key throughout, starting on and returning to the tonic, even if some of the individual notes were wrongly remembered. In contrast, the key of the songs produced by four-year-olds tended to 'drift' as the song progressed. Secondly, five-year-olds were able to organize their reproductions in terms of an underlying pulse or beat. Their songs conformed to the beat even if individual rhythms were misremembered. In contrast, four-year-olds tended to organize rhythm 'locally', largely from placements of accents in the words, and they did not maintain a steady pulse.

Another consequence of the concentration on precision is that spontaneous musical experimentation may well cease to play any further real part in a person's life after the age of five unless it is specifically encouraged. Our

Western culture does not provide many opportunities for people to improvise. Much more importance is placed on the shared reproduction of well-known music (e.g. hymn singing, ritual singing among football supporters, the classical concert sub-culture, etc.) In our culture, composers and improvisers do not arise from normal enculturation; their skills are nurtured by specific, and culturally atypical support and training.

We have examined the development of singing between the ages of one and five in some detail. There are, of course, other aspects of musical behaviour and awareness which develop over these years as well; so we should now return and examine some of these.

We first consider the development of movement responses to music. In the second year of life, most children learn to walk. This allows a much increased range of movements, an increase which is represented in movements to music. Moog (1976) found that more than half of his 18-month-old subjects 'danced' in response to music, making circular or turning movements in conjunction with stepping. He also found a large increase in the frequency of 'conducting', that is, a waving of the arms in response to music. These movements are not rhythmically co-ordinated with the music. They seem to reflect a general motor enthusiasm and exuberance which music somehow elicits.

Around two years of age 'about 10 per cent of children begin, for short stretches of time, to match their movements to the rhythm of the music. . . . The few children who are able to do this at all are only able to keep up the co-ordination for a few bars at a time.' Up until the age of five there does not seem to be any marked change in the ability to move in synchrony with music (confirmed by Rainbow and Owen 1979; and Frega 1979). However, two trends are noticeable. First, the variety of movements increases. Second, and perhaps more significant, the number of spontaneous movements decreases very markedly. As children grow older they are more prone to a concentrated, still, attentive listening. By the age of five many children showed no spontaneous movements at all to Moog's tests. This may be part of the same developmental trend to imitation and precision that we noted earlier. Because there is no definite model for specific movements to be made, children prefer to make none.

To elicit movement responses in children of five years it seems necessary to *ask* them to make particular movements, such as clapping or tapping, to see whether they relate to the music. Moog did this, and found that very often the children would make 'any sort of clapping movement, sometimes not even rhythmically regular ones.' Only about two-thirds of the children kept in time with the music for even a short time. On the other hand, when asked to clap whilst singing a song they knew, they could clap in synchrony with the successive notes of the song. It is not clear, however, that children of this age are capable of maintaining a steady clapping *beat* whilst singing a song which variously subdivides the beat and contains silent beats. Rather they are able to use the same mechanisms that time the successive notes of the song to time successive hand-claps.

Here we see a type of dissociation that we shall have cause to consider again. This is the dissociation between implicit knowledge (in this case of metre) that children display in their enactive repertoire (such as in singing the songs they know) and the explicit ability to isolate and use such knowledge in tasks of perception and judgement. In this case, children of five have implicit knowledge of metre but seem not to be able to use this knowledge explicitly.

So much for movement to music. We now consider the development of discrimination. It appears, from Moog's extensive sample, that very few children differentiated between the 'normal' instrumental music and the 'dissonant' manipulations of it. Children attended, made rhythmic and vocal movements just as readily to both tests. 'Not a single child showed the least sign of displeasure' at the dissonances. In contrast *many* children made no response (or a negative one) to the pure rhythms (test 3). At age three, 37 per cent of the children simply ignored the test. Another 24 per cent showed signs of being uneasy; and one little boy asked his mother 'when are we going to have music again?' Another said 'that isn't music, is it, mummy?' We conclude from these observations that harmony is not particularly salient to the pre-school child, but that he has already identified music with some form of melodic content.

In respect of familiar music Moog discovered a gradual increase in true tune recognition up to the age of five. When a familiar nursery tune was played, without words, on an instrument only 40 per cent of four-year-olds recognized it. This proportion rose to 75 per cent of five-year-olds. By this age children are just beginning to reliably catch hold of the notion that melodic identity is carried by a pitch and rhythm pattern, regardless of timbre or words.

Finally, Moog examined the effect of environment on development. He summarizes his findings thus:

> Up till the age of about three we could not observe in response to music any significant differences determined by the environment; children from poorer homes reacted no differently to our tests from children in the upper income groups. Children who, according to their parents' reports, were inundated with music from morning till night showed little difference, in either the quantity or quality of their response, from children who were only allowed to hear carefully weighed amounts of carefully chosen musical stimuli. . . . But, between the ages of three and four, differences in home environment begin to show their effect in the field of music. Girls and boys who are taught songs and games by their parents, brothers and sisters, or in nursery schools, have a clear advantage over other children.

Moog also found quite marked differences between children from the *same* kind of background. It is impossible to rule out the possibility of innate differences in musical receptivity, although one should, perhaps, not move to that conclusion as readily as Moog does. What the results do suggest is that after the age of three a child does become receptive to certain types of environmental 'enrichment'. Before that age, immersing one's baby in music may not help him or her become a second Mozart.

How do we sum up the path of musical development between one and five? We see, I think, four main strands. First, the child's increasing propensity to *imitate* words, then melodic fragments, then whole songs. Second, a subordinating of a free improvisatory and unstructured note-play to the forms of the musical culture, by the incorporation of diatonic intervals, then phrases from well-known songs, and finally its disappearance in the service of exact imitation. Third, the increasing ability to organize song behaviour in accordance with tonal and metrical rules. Fourth, a concurrent lack of ability to extract metrical or harmonic information in a situation where some abstracting or evaluative response is sought. Children in this age do not reliably beat time to music, nor do they seem to notice gross dissonance. It seems as if knowledge becomes incorporated in action before it can form the basis of judgement.

This last point can be demonstrated through other aspects of cognitive development. For instance, children find it easier to recall a list of objects when they can be grouped under the headings of two or more common categories (e.g. 'fruits', 'items of clothing'); but at the same age they may be incapable of *judging* a categorized list to be more memorable than an uncategorized one. It is only at a later age that they can accurately judge which lists are likely to be easy and which difficult without actually doing the task of memorization. This reflective grasp of the situation is most generally observed to first occur between the ages of eight and ten (Hunter 1976; Moynahan 1973).

6.2.3. *From age five to 10*

Piaget's investigations of intellectual development led him to propose a profound change in general cognitive ability at around the age of seven or eight. He labels this a change from 'pre-operational' to 'operational' thought. The most celebrated 'symptom' of this change is the child's ability to perform well on tasks involving the notion of conservation of quantity.

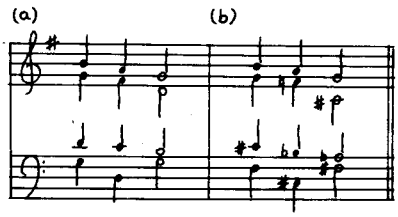
Let us take a common example. A child is shown a rolled-up ball of plasticine. Before his eyes, the experimenter then rolls it out into a long thin sausage. The pre-operational child tends to believe that there is now *more* plasticine (because in one crucial respect it *looks* more). The operational child knows that the amount is the same. More than this, he knows it *must* be the same. Other examples of conservation tasks involve pouring liquids from short squat beakers to tall thin ones, or spreading out a line of initially closely bunched counters. In each case the operational child is not fooled. He knows that the amount remains the same.

Several music researchers have attempted to construct musical analogues of these tasks. Pflederer (1964), for instance, played children the same melody at two different speeds and asked them if they were the same. Only 50 per cent of five-year-olds thought the two were the same. By eight years of age this proportion had risen to 94 per cent.

Although this task has a superficial resemblance to Piaget's conservation tasks, it differs in crucial respects. First, children do not observe the melody under continuous transformation between one speed and the other, and so have no independent way of knowing that the two melodies are of the same 'stuff' (Wohlwill 1981). Second, it follows that there is no logical *necessity* that such transformations should conserve musical quantities or qualities. That is to say, one could present two melodies at two different speeds which did *not* have melodic identity. In contrast, there is no way of deforming a piece of plasticine in such a way as to change the quantity. Children become competent at Piagetian conservation tasks precisely when they realize that transformations of configuration are *always* irrelevant to judgements of quantity.

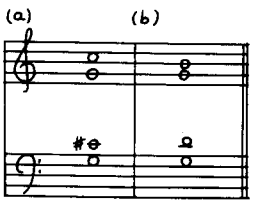
In music the notion of a melody undergoing a continuous observable transformation is problematic, if not incoherent. Each occurrence of music is a separate event in time, totally discrete from the next event. Therefore, there is no necessary relation between one musical event and the next. When Pflederer and others claim to show that children around the age of eight come to conserve musical quantities, it would perhaps be better to say that children of this age are capable of perceiving and remembering invariant aspects of otherwise different patterns. Whilst this ability is of profound psychological interest and importance, it is *not* conservation. Nonetheless, we may suppose that it shares with conservation the increasing awareness by children of the possibility of going behind surface perceptual features in their search for underlying patterns and structures.

If one were to sum up the main developmental trend in music between five and 10 it would seem to be the increasing reflective awareness of the structures and patterns that characterize music and which are already implicit in the child's enactive repertoire. For instance, at age five a child is already capable of singing the same song at different speeds or pitches. In one sense, therefore, this behaviour demonstrates the existence of knowledge that a melody is still the same after transformations. What the child of five lacks is the ability to translate that knowledge into a procedure for making a considered judgement in a perceptual situation where a change, such as in speed or pitch, is highlighted through temporal juxtaposition. The progress from enactive to reflective knowledge does not take place all at once, and we find various aspects of musical awareness undergoing this change in order over the middle years of childhood.



An early aspect of this change is illustrated by the work of Zenatti (1969). She presented children with three-note melodies, each followed by a second melody in which one of the notes had been altered in pitch. Some of the melodies were atonal. The others were tonal. Children were asked to locate the changed note. Zenatti found that five-year-olds performed equally badly on both types of melody, but by six or seven the tonal melodies were producing superior performance. The tonal melodies allowed the extraction of

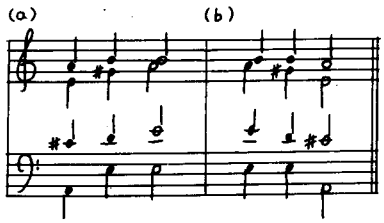
some structural information which could be carried over in memory to aid the comparison with another melody. Although this shows the beginnings of a dissociation of structural knowledge from a purely enactive context, it is still linked to a performance task which does not demand *direct* awareness of structure. We may ask when children are able to form *judgements* about musical sequences when asked to make such judgements in a direct way.



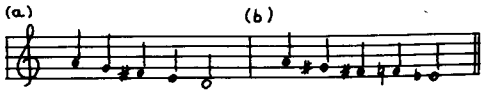
One way of examining this is to ask children to classify musical examples as'good', 'bad', 'complete', incomplete', etc. For instance, Imberty (1969) played excerpts from Bach chorales to children of various ages and asked them to judge whether excerpts were complete or incomplete. Eight-year-old children tended to hear melodies as complete when they ended on the tonic in the context of a perfect cadence; but even at age 10 they tended not to accept as complete perfect cadences with melodic resolution to the mediant.

I have examined the development of judgement in a slightly different context. In my study, children were presented with a pair of musical stimuli and were told that one was played 'correctly' the other one had 'mistakes'. Each member of the pair came from a different sound source, well separated in space and time. Children were asked to indicate (by writing or pointing depending on age) which sound source had produced the 'correct' version. There were four tests. In the first test the 'correct' item resembled a cadential sequence from a typical four-part hymn harmonization; the 'incorrect' item was derived from the correct item by modifying each chord so that it was dissonant. To the adult Western ear such dissonances are extreme (Example 6.5 gives one example of such a pair: all items in this study were played on the piano).

In the second test, the items were single chords, one being highly consonant, the other breaking one or more rule of conventional chord construction (see Example 6.6). In the third test, the items were sequences of



Example 6.5. A stimulus pair from test 1.



Example 6.6. A stimulus pair from test 2.

consonant chords. In one sequence of each pair the chords were in a 'musical' order that led to a conventional cadence. In the other sequence, the same chords were present but in 'scrambled' order (see Example 6.7). In the fourth and final test, the items were unaccompanied melodic sequences. One item was a diatonic melody which remained in a single key. The other item was a sequence with similar contour but containing notes from several distant keys so that the tonality became obscure (see Example 6.8).

Example 6.7. A stimulus pair from test 3.

Example 6.8. A stimulus pair from test 4.

In each test there were twelve pairs, so that with a score of 1 for the 'correct' item, the maximum score for each test was 12. A subject guessing at random would, on average, score 6 out of 12. I ran the experiment on five different age groups, five-, seven-, nine-, and 11-year-olds, and an adult control group. The average scores of each group on each test are given in Table 6.1. Circled scores are not significantly different from random guessing.

TABLE 6.1

Mean scores (out of twelve) on each test for each age group

Age	5	7	9	11	Adult
Test 1	7.3	9.1	11.4	11.8	12.0
Test 2	(5.5)	7.7	9.5	9.3	10.6
Test 3	(5.6)	7.3	9.3	10.5	11.6
Test 4	(6.4)	7.3	9.7	9.6	11.6

Scores joined by an underline are not significantly different from one another.

We may first observe that the five-year-olds performed very poorly. Only on Test 1 did they perform slightly above chance. In many cases I observed the children to be making choices on non-musical bases. For instance, one child always chose the same sound source, no matter what music came from it. Another child alternated between sound sources.

By age seven, performance significantly improved on all tests except Test 4 (unaccompanied melodies), although performance was still well below adult levels. At age nine, score on Tests 1 and 2 became indistinguishable from adults. It is pertinent to notice that around this age children began to show strong aesthetic reactions to the 'incorrect' items (dissonant chords)—screwing up their faces in disgust, or laughing and giggling. These tests require least 'work' because the incorrectness arises from simultaneous sounds. Each event is 'wrong' by itself and requires no memory of previous events in the same sequence.

It was not until the age of 11 that scores on Test 3 (chord sequences) approached those of adults. In this test, each chord on its own is acceptable; to detect incorrectness one has to notice the ordering of chords. Performance on Test 4 (unaccompanied melodies) did not improve between ages nine and eleven, and was still significantly below adult performance. Here, the 'work' required is arguably the greatest. Not only do incongruous events not happen simultaneously, but the cues to an underlying key or harmonic framework are much more sparse than in the case of fully harmonized chords.

This study shows, therefore, a progression from age five to adulthood, in which the listener becomes capable of reflective judgement on the musical quality of successively more 'difficult' aspects of music; starting with the ability to reject gross dissonance, and moving on the the ability to detect violations of normal sequential structure.

Two subsidiary findings are of note. Girls performed better than boys on most tests and at most ages. This result has been obtained in quite a lot of musical developmental research (Shuter-Dyson and Gabriel 1981). Secondly, musical training made no difference to the scores. Those children who were receiving regular instrumental tuition fared no better than those who were not. This is a strong indication that the skills we are dealing with here are true products of enculturation, and do not rely on specific training. They arise from the normal child's intellectual encounters with the music of his culture.

The final topic I wish to discuss in this section is the development of the ability to make finer classifications within music which is broadly 'acceptable'. This ability is often given the name 'style sensitivity' and relates to a person's ability to tell whether two extracts of music come from the same composition, composer, or period. Gardner (1973) investigated style sensitivity in an experiment where he played pairs of musical extracts to children, some of which came from the same composition and some of which did not. The children were required to say whether or not they thought the two extracts were from the same piece of music.

There was a significant age improvement in the ability to do this. The youngest children (aged six) had a high tendency to judge extracts 'different' and Gardner suggests that 'pieces had to sound identical or directly continuous in order to be judged as from the same composition'. Six-year-olds

had a very limited ability to explain their choices, and those that could offer comments based their discriminations largely on dimensions such as high/low, loud/soft, or fast/slow. Of the 16 pairs presented, six-year-olds judged only 9.7 of them correctly on average (chance score would be 8).

By eight years of age, average scores had risen to 10.5 on 16, and children were able to give 'same' judgements even when the two segments did not sound continuous. Subjects commonly described their perceptions using adjectives or metaphors drawn from outside music: 'peppy', 'dull', 'churchy', 'grown up', 'like a horse race'.

At 11 years of age the average score was 12.4, and subjects began to explicitly refer to aspects of instrumentation, rhythmic character, and texture in making their judgements. Although average scores did not increase above age eleven, subjects aged 14 began to justify their responses in terms of general style, using terms such as 'jazzy' or 'baroque'. Coincident with this was a greater ability to correctly differentiate 'different' pairs when they came from widely different stylistic eras. For instance, they were better at discriminating Boulez from Bach (300 years between them) than Schumann from Brahms (contemporaries). Thus, in this study, we see a progression from judgements based on simple physical features at age six to judgements made on complex multidimensional aspects of style and underlying 'language' by the age of fourteen.

We may summarize the main strands that emerge from our review of musical enculturation as follows. There is some evidence of special propensities which support the early establishment of a 'stream' of specifically musical development. Very young children seem particularly responsive to musically pitched sounds, and are also responsive to changes in pitch and rhythmic sequence. During the second and third years of life we see the emergence of improvisatory song which does not directly mimic the song of the culture (just as children's early speech is not purely imitative). By the age of five children are able to use underlying tonal and metrical structures to guide their song performance, even though they seem to have no reflective awareness of such structures, being almost totally unable, for instance, to identify gross dissonance in simultaneously sounding notes.

We also see the possible influence of wider 'waves' of intellectual development having their effect in the musical sphere. For instance, the increasing concern with precision and imitation around age five mirrors developments in other symbolic domains such as drawing (Gardner and Wolf 1983). This change also corresponds to a change from 'the stage of romance' to 'the stage of precision' suggested many years ago by A. N. Whitehead (1917).

Changes in musical awareness between the ages of five and 10 seem to reflect a general intellectual change from enactive competence, which is displayed only within the bounds of specific and directed activities, to a reflective awareness of the structures and principles which underlie such

competence. This change is characterized by Piaget as a change from pre-operational to operational thought. In music it is marked by an increased ability to explicitly classify music as conforming to rule or style, and an increasing advantage in memory and perceptual tasks for those sequences which conform to rule.

6.3. Training and skill acquisition

Musical training is the means to acquisition of specific skills which build on the base of enculturation. We have seen in the previous section that the normally enculturated child already has a set of musical abilities—such as the ability to recall songs and learn new ones; the ability to tell different types of music apart; the ability to make use of underlying features such as metre and tonality in organizing performance. In the 'training' phase, which may overlap with enculturation, and which may extend indefinitely into adulthood, we see the growth of a variety of skills—performance on instruments and voice, composition, aural analysis, conducting, etc. No single individual necessarily achieves expertise in all these skills, although a culture generally agrees on the skills required by an 'all round musician', and this set of skills becomes institutionalized in the training and examination procedures of music schools and colleges.

Each musical skill poses its own training problems and has related with it a long pedagogic tradition. In a book of this sort it would be impossible to examine all aspects of skill in the detail they deserve. We have already examined some aspects of the acquisition of performance skill (Chapter 3) and improvisatory skill (Chapter 4). What I want to do in this section is draw out some general principles of skill acquisition and training with illustrative examples drawn from some specific skills. My concern with principles is such that I do not pretend to be overly concerned with providing 'advice for teachers and learners'. There are several books of this latter sort, among which Buck's *Psychology for musicians* (1944) is outstanding. Despite its age I would still recommend it as essential reading for any performing musician. Its author has the main prerequisite for writing a book of this sort—a lifetime of high-quality teaching experience at all levels.

Psychology provides many, sometimes apparently conflicting, interpretative frameworks for understanding learning. I would like to organize this section by introducing just one detailed theoretical proposal, and showing, in discursive fashion, how it can be used to support broad generalizations about the business of learning and teaching. The theory is *Production System theory* as applied to skill acquisition by Anderson (1981, 1982). The basic attraction of Production System theory is that it is possible to construct machines (embodied in computer programmes) that operate according to the postulates of the theory. Some typical aspects of human thought and behaviour can be mimicked by such a machine. The basic elements of a Pro-

duction System are very simple and precise, yet behaviour of some complexity can be obtained when many of these elements are put together with a few simple rules for the way they interact. It is most important to bear in mind that production systems are not in themselves part of the human mind. Rather, they are formal analogies for mental processes. However, to simplify my task, I will talk *as if* production systems are part of the mind. This will save obscuring the argument by repeated qualifications.

Before embarking on detailed exposition, I would like to introduce a few general concepts associated with skill acquisition which I shall be filling out with the aid of theory and example. These are quite fundamental concepts, and turn up, in one form or another, in most writing on learning. First is the concept that skill learning involves acquiring *habits*. The principal feature of a habit is that it is *automatic*, and that it uses up little or no mental capacity to execute. The precursors of habits are conscious, deliberate, and effortful behaviours which commonly involve verbal control. Second is the notion that skill learning involves passing from *factual* knowledge (knowing that) to *procedural* knowledge (knowing how). Knowing what a skill entails is very different to actually executing it, and a theory of learning should be able to refine our understanding of exactly what changes when factual knowledge becomes procedural knowledge. One part of the change seems to be that knowledge comes under direct and more intimate control by *goals*. For most of us, to formulate the goal of performing some familiar task, such as saying a common word, is enough for the task to be accomplished. There seems to be no psychological gap between wanting (or intending) and doing.

Many of our goals are as small and short-lived as saying a particular word. Other goals are larger and more long-term, as, for instance, the goal of being able to play a musical instrument. The ability to form and sustain goals seems to be an essential condition of learning. Such ability is often called *motivation*. Other general conditions essential for most skill learning are *repetition* and *feedback*. People generally become skilled at some task by being presented with repeated opportunities to engage in elements of the task. The sheer amount of time that a person has spent actually doing an activity is one of the best predictors of level of skill. For any complex skill, such as writing a computer program, playing chess, or playing a musical instrument, moderate levels of ability are achieved by those who have devoted hundreds of hours to it. For real expertise, thousands of hours are required. Feedback (or reinforcement as it is called in some contexts) is essential so that only succesful procedures are learned; any procedure which leads to repeated failure is discarded.

We begin our detailed treatment with reference to a proposal by Fitts (1964) that the process of skill acqusition can be broken down into three phases or stages: the *cognitive stage*, the *associative stage*, and the *autonomous stage*. Anderson (1982) succinctly summarizes these stages as follows:

> . . . the *cognitive* stage involves an initial encoding of the skill into a form sufficient

to permit the learner to generate the desired behaviour to at least some crude approximation. In this stage it is common to observe verbal mediation in which the learner rehearses information required for the execution of the skill. The . . . *associative* stage involves the smoothing out of the skill performance. Errors in the initial understanding of the skill are gradually detected and eliminated. Concomitantly there is a drop out of verbal mediation. The . . . *autonomous* stage is one of the gradual continued improvement in the performance of the skill. The improvements in this stage often continue indefinitely.

Let us now consider what an aspect of the *cognitive* stage might look like for someone who is already competent to read and perform on one instrument beginning to learn a new instrument. I found myself in this situation when, after several years of piano playing, I took up the clarinet. When attempting to play my first simple melodies on the clarinet I had constantly to make recourse to verbal information, sometimes recalled with difficulty from memory, more often retrievable only from my instruction manual. The information was primarily in the form 'the fingering for note X is combination Y.' When the right set of fingers were engaged with the right set of keys, there was still the problem of producing a sound by blowing. This was not straightforward, and to produce any recognizable sound at all required constant adjustment of mouth, tongue, and lips, in accordance with another set of verbal prescriptions. There seemed to be so many different things to attend to at once that fluent performance seemed an impossible dream.

This sense of the crowding in of demands which cannot all be fulfilled is a characteristic of early learning in any endeavour, be it driving a car or learning a new language. There is just too much to think of, too much to remember. Such a sense can be profoundly discouraging, and may cause a learner to give up before any progress is made. The fortunate learner will have available a strategy, possibly imparted by a good teacher or a manual, which may help to circumvent such a block.This is the breaking down of the skill to be learned into a set of components which can be acquired stepwise. In each step the amount of new verbal information is small, and the learner is able to progress beyond the cognitive stage with this small package before proceeding further. In this way the learner is able to shield himself from the ultimate (and daunting oal), setting his sights instead on the very next stage.

On the whole, it seems fair to say that the younger the child, the less able he will be to devise and impose his own schedule. Even adults may find such a task difficult, and will benefit from the advance organization of material to be learned by an experienced teacher. A teacher has oversight which the novice lacks. He knows which aspects of a skill typically cause most difficulty, and which aspects, learned early on, help the course of later learning. On the clarinet, for instance, there is much to be said for acquiring some fluency in the lowest register before attempting music which 'crosses the break'. Each register re-uses the same fingering sequence, uncovering successive holes as the register is ascended. When one arrives at the top of the lowest register,

one must depress a register-shift key, re-engage all the fingers, and modify the blow in order to get the next highest note. On a B flat clarinet the top note of the bottom register is the B flat above middle C. A self-directed adult learner might, without guidance, decide to learn the C major scale, one octave up from middle C as his first task. This would involve crossing the break, with all its complications. The experienced teacher (or a good manual) will advise that a better scale to start on would be the F or G major scale that can be totally encompassed within the lower register.

The application of this principle can be extended indefinitely. For instance, in piano learning it makes sense to acquire patterns which do not require shifts in hand position before those that do. In violin learning it makes sense to master open-string positions before learning fingered positions; and so on. Only the experienced practitioner of the particular skill is fully qualified to devise generally useful training schemes by virtue of his oversight of the whole skill. It is, however, worth emphasizing the point that there are very many possible ways of segmenting a learning task which adequately fulfil the requirements of a learner; and it is perhaps more important that the *principle* of segmentation is adopted, than that the learner should have the belief that *one* of the many reputable schemes available is somehow best.

What is happening in a learner as he passes from the cognitive stage to the associative stage with respect to a particular section of skill knowledge? Our overview of concepts in skill acquisition suggested that he is acquiring some *procedural* knowledge in addition to the factual (or declarative) knowledge that was acquired from the printed or spoken word. To continue with the clarinet example, a piece of declarative knowledge might be the following:

D1. The clarinet fingering for Middle C is the left-hand fingers covering the top three holes.

A simple part of the equivalent procedural knowledge might, in Production System theory, look like Table 6.2.

Each of the statements P1 to P5 is a procedural step called a production rule. Each rule has the form IF condition(s) THEN action(s). It tells one, in simple and unambiguous terms, what to do when a particular state of affairs occurs. Although the language of a production rule is plain, it can often cause perplexity to a first-time reader. One basis for perplexity is that each rule, in itself, seems so trivial and lacking in substance. The reason for this is that by writing out a rule in English for conscious scrutiny one is subjecting it to far more attention than it would ever receive by the individual who possessed such a rule in his procedural repertoire. The whole point about a production rule is that it is so simple that the subconscious mind is capable of executing many dozens of them, without attention and effort, in a few seconds. What appear as single steps in thought to our *conscious* awareness, are actually composed of many subconscious but logically primitive steps which we have run through so many times that they have become completely

TABLE 6.2

Example of Production System

P1.	IF	the goal is to play middle C	
	and	the fingers are not in the configuration of having the left-hand fingers covering the top three holes (configuration L3)	
	THEN	the sub-goal is to achieve configuration L3	
P2.	IF	the goal is to achieve configuration L3	
	and	no configuration is presently in force	
	THEN	place the fingers in configuration L3	
	and	the goal is achieved	
P3.	IF	the goal is to achieve configuration L3	
	and	a configuration other than L3 is presently in force	
	THEN	the sub-goal is to achieve the state of having no configuration in force	
P4.	IF	the goal is to achieve the state of having no configuration presently in force	
	and	some configuration is presently in force	
	THEN	remove all fingers from the keys	
	and	the goal is achieved	
P5.	IF	the goal is to play middle C	
	and	the fingers are in configuration L3	
	THEN	blow	
	and	the goal is achieved	

automated. Thus, a clarinet player using the procedures P1-P5 would actually run through the cognitive steps contained therein in a fraction of a second. This is in contrast to the laborious minutes it took me to write out the productions, or you to comprehend them. I chose a very simple task, that of playing middle C, precisely so that the number of production rules would be few. If I had chosen a more complex and interesting task, it would have taken me many weeks to write out the production rules required, and it would take a reader many hours to comprehend them.

Let us tease out some of the characteristics of production systems, using this example. A crucial feature is the way that the rules embody a hierarchy of goals and sub-goals. In this example, the main goal is to play middle C. The two rules explicitly mentioning this goal as a condition (P1 and P5) are left-aligned to help make the goal structure clear. If the player is lucky enough to find his fingers already in the required position, then all he has to do is blow, and his goal is achieved (P5).) If, however, his fingers are not correctly positioned, then he must get them correctly positioned. So he for the moment sets aside his main goal of playing C and embarks on achieving a subsidiary goal, that of getting his fingers into the right configuration (P1). Rules P2

and P3 (indented one step) relate to this new goal. In this set of rules I have attempted to model the procedures of a fairly raw beginner. One commonly observes beginners completely removing the hand from the keys prior to each note, and then choosing the new configuration 'from cold'. This is, of course, wasteful of effort, and more experienced players learn procedures whereby the existing hand position is used to find the next position. So, for instance, if a sub-set of the required fingers were already in position, they would not be removed.

With our hypothetical performer we assume that if he finds his hands taking up the configuration for playing some other note than middle C, he must set aside the sub-goal of putting the hands in the middle C configuration and pursue a *third* subsidiary goal, that of 'clearing' the keyboard (P3). P4 is the production rule pertaining to this third goal (indented two steps) and its execution allows the goal to be achieved. The system then passes 'control' back to the second goal and now P2 pertains. This allows goal achievment, and finally control is handed back to the original goal, whereupon P5 can come into force and the task is completed. In a 'realistic' system, the goal of playing middle C would itself be a sub-goal of a larger process, and so when it had been achieved, control would pass up to the next higher, and so on. We can represent the goal structure inherent in our little example by reference to a diagram (Fig. 6.1). The goals are enclosed by boxes, and the numbered arrows show how the procedural steps pass control between one goal and another.

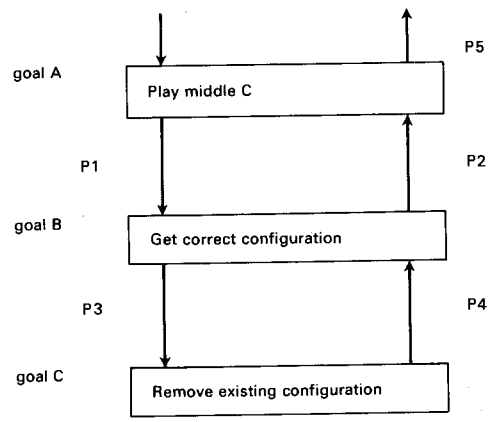


Fig. 6.1. Diagram of goal structure of production system for playing middle C.

It can be seen that a crucial aspect of a Production System is some means of remembering higher goals while sub-goals are being pursued. For instance, it would not be of much use to our clarinet player if he got to the point of executing rule P4 (clearing the keys) only to discover that he had forgotten what he had cleared the keys in order to do. What efficient performance

requires is some form of *goal stack*. The idea of a goal stack is very simple, and based on the mechanical analogy of the spring-loaded plate holders that one finds in canteens and restaurants. The design is such that as more plates are put into the holder the base drops so that the top plate is always just flush with the lip of the holder. When a plate is removed, the next highest plate 'pops' back into view. In this analogy the primary goal corresponds to the first plate put into the holder. The next plate is the first sub-goal, which 'pushes' down the original goal. The second sub-goal pushes down the previous ones and so on. When a particular goal is achieved it is jettisoned from the stack and forgotten, and the preceding goal 'pops' back into control.

When executing a complex skill it should be apparent that the goal stack can easily become very large. Capacity for holding goals in memory is not unlimited, and it often occurs, especially in early learning that the goal stack becomes overloaded, and some higher goals are lost. Some varieties of 'absent-minded error' can be attributed to goal forgetting (Reason 1977), such as going into a shop and then not knowing why one went in. In music performance, goal-forgetting can help explain why learners sometimes find it difficult to 'manage' large-scale form by appropriate long-term changes in dynamic and other performance qualities. They have so many subsidiary goals to fulfil in the execution of individual notes that the goal stack overloads, and the overall 'direction' of the performance is lost. We shall return later to the issue of how increased experience allows such difficulties to be overcome.

Another crucial aspect of a production system is that each rule operates entirely automatically (with certain restrictions which need not concern us here) if it finds evidence that its *conditions* pertain. When it does find such evidence, then the actions that it prescribes automatically take place. It does not seem to matter how many *other* production rules the system contains; as soon as the conditions for a particular rule pertain, then its actions are immediately and automatically carried out. The capacity of the human organism for skill learning is apparently unlimited.

The place where production rules 'look' to see if their conditions pertain is called *working memory* by Production System theorists. A close lay approximation to this term would be 'consciousness'. Working memory contains details of aspects of the external environment that one is currently observing. It contains items of declarative (factual) information that have recently been received or retrieved from memory; the current goal stack; details of one's own internal or bodily state; and like things. It specifically does *not* contain all the facts and memories that are stored in the mind and retrievable *somehow*. For instance, most readers will know the name of the city that is the capital of France. It is, of course, Paris. However, until the moment that the topic was raised, the fact that 'Paris is the capital of France' was not part of working memory—it was not in conscious awareness. Rather it had to be retrieved from 'long-term' memory, and the retrieval process

took time. In the case of this example, the time taken was probably not very long; but for less well-known facts, the time could be considerable, and indeed the search could fail on a particular instance.

The conditions of production rules are, therefore, contents of working memory. They can be facts about the observable world. They can be items of factual knowledge retrieved from long-term memory. They can be current goals (i.e. goals that are at the top of the goal stack). The actions of production rules can involve overt behaviours; but they need not do so. What they must do is alter the contents of working memory in some way. An overt behaviour will normally do this because it will result in an observable change in the environment or bodily state. However, other kinds of action are just as common. Sometimes some mental operation is demanded. For instance, in a production system for mental arithmetic, a rule might specify that two digits, both in working memory be added together, and their sum recorded in working memory. A third type of action involves either adding a new goal to the goal stack, or noting that a goal is achieved and jettisoning it from the stack. In our simple example, the rule P1 involves no overt behaviour. Its only action is to set a new goal.

Thus, although production rules have several similarities to the 'stimulus-response' link beloved of learning theorists in the behaviourist tradition, they are more sophisticated and versatile in many ways. They directly incorporate inner mental states and goals rather than trying to explain them away.

The production rules possessed by our hypothetical clarinet player incorporated specific knowledge about several things, including the finger configuration needed to play middle C. At one time he did not have such specific knowledge. It follows that these rules must somehow have been *constructed* as a result of his ongoing experience with clarinet playing. How were these rules added to his knowledge?

A primary postulate of Production System theory is that knowledge can only affect behaviour if there is a production rule that can act on it. Another way of putting this is to say that all behaviour is procedural, and that a fact cannot influence the course of behaviour unless there is a procedure that can use it. By analogy, although a book contains many ideas, those ideas can have no influence on the course of history unless someone reads those ideas and acts on them. Earlier on, we said that the passage from the cognitive to the associative stage involved acquiring procedural knowledge from declarative knowledge. At the outset of learning, there were no production rules which *directly* incorporated knowledge about the fingering for middle C. It would be wrong, therefore, to imagine that the fact 'the fingering for middle C is . . . etc.' could directly evoke the required behaviour. Rather, there must have been some more general procedures *already available* which could pick up and use the new knowledge. In Production System terms, there must have existed a set of production rules with 'empty slots' into which specific pieces of information could be fitted.

Perhaps the easiest way to get a grasp on this notion is to write out part of the set of production rules which, hypothetically, could have been present at the initial cognitive stage of performance. The terms (VA) and (VB) represent the empty slots which can be filled by a variety of specific values. In formal language, VA and VB are *variables*.

P6.	IF	the goal is to play a note (VA)
	and	information of the form 'the fingering for note (VA) is configuration (VB)' is not in working memory
	THEN	the goal is to place information of the form 'the fingering for note (VA) is configuration (VB)' in working memory
P7.	IF	the goal is to play a note (VA)
	and	information of the form 'the fingering for note (VA) is configuration (VB)' is in working memory
	and	the fingers are not in configuration (VB)
	THEN	the sub-goal is to achieve configuration (VB).
P8.	IF	the goal is to play a note (VA)
	and	information of the form 'the fingering for note (VA) is configuration (VB)' is in working memory
	and	the fingers are in configuration (VB)
	THEN	blow
	and	the goal is achieved.

P6 is an expression of the knowledge that if one wants to play any particular note and one does not know the fingering for that note, one must discover the fingering before one can proceed. The complete sete of production rules would thus incorporate a set of procedures for getting the required knowledge into working memory (by scanning long-term memory, consulting the manual, attempting to work it out from first principles, etc.). Only when this is done can P7 come into force. It is worth pointing out that P6 is a general rule which would help *any* instrumental learning to get off the ground. It is not specific to clarinet. It is, however, specific to music in its application, but is related to an even more general class of rules which can be obtained by turning *all* the specific values in the rule ('play', 'note', 'fingering', etc.) into variables. Roughly, such a rule would state that if you want to achieve a goal and you do not know what state of affairs would bring about that goal, then you must undertake to discover what that state of affairs is. Such a sentiment may seem trivial, but it remains true that without a procedure that embodied it, people would never be motivated to search for solutions that were not immediately obvious. In such a situation the problem would simply be abandoned.

We see, therefore, in most specific examples of learning behaviour the application (through specification of variables) of a set of very general procedures or strategies for setting about learning. With these strategies, it is

possible to make some kind of coherent attempt to master any task. Newell and Simon (1972) have constructed a computer system embodying these principles which they call 'General Problem Solver'. We cannot pursue the characteristics and capabilities of the General Problem Solver in any depth here. Suffice to say that it incorporates the general feature of goal structuring; breaking down a larger goal into a set of sub-goals to be achieved on the way.

It is pertinent to ask where these general strategies come from. Are we born with them, or do we have to acquire them? Although no-one has constructed a detailed answer to this question, it appears that we are born with a set of very specific production rules which allow us to respond instinctively to certain states of affairs. A young baby does not, for instance, realize what is trivially obvious to you or me, that if you lose sight of something and want to find it again, you increase your changes of doing so by searching for it. Rules of this generality are acquired gradually through childhood by some kind of process of abstraction from specific successes. The mechanisms for this abstraction process are little understood, although it is clear that humans have a particular gift for doing this, and that language is an important mediator of the process. What we can say with certainty is that when a child of 10 or so tackles a new learning problem, he or she has already acquired a large set of general abstract procedures which can be brought into play.

If we return to our specific production rules, it will be easily seen that P7 is a general version of P1, and that P8 is a general version of P5. By a similar process of replacing specific notes and fingerings with variables the corresponding general versions of P2, P3 and P4 may be constructed. This *general* set would, in some ways, seem much more economical that a set *specific* to middle C. This is because, for clarinet playing to be possible, one would need a different specific set for *every* note on the clarinet. In contrast the one *general* set will do for the whole instrument. This economy is, however, a false one precisely because the general rules will not work until specific fingering information has been found. If such information is not available, then the set of procedures which a rule like P6 would initiate might be very complicated, and uneconomical of time or effort. Under the right conditions, therefore, which we shall specify in more detail shortly, there is every reason for a learner to construct the large number of specific production rules which will absolve him from the need to search for particular information in the service of more general productions.

What, then, are the conditions under which a learner adds production rules like P1–P5 to his repertoire, where before only general rules like P6–P8 existed? Production System theorists are only just beginning to formulate a detailed answer to this question (Anderson 1982) but we can already see the general outlines of an answer. Such additions to knowledge occur when a general production rule is repeatedly and successfully used in conjunction

with specific factual information. The cornerstones of any procedural learning are thus *repetition* and *feedback*.

A naïve view of the role of repetition is that it somehow 'stamps in' new learning, as repeated swings of the axe gradually bite further into a piece of wood. The cognitive view espoused here is a little more sophisticated. We suppose that an adaptive system is necessarily conservative, and will not add a new *specific* production rule to its repertoire unless there is some evidence that it is going to be generally useful. This is because, once inserted into the system, a production rule is immensely powerful. When its conditions are fulfilled it automatically 'takes control'. The system has to be quite sure that it wants to give so much control to a single rule before incorporating it. The best evidence a system can have that a rule is going to be useful is that the situation which demands its application has occurred very often. In many 'natural' learning situations the repetitions which suggest the usefulness of a new procedure to the organism are supplied by the natural environment as the organism interacts with it in the pursuance of its fundamental goals. On the other hand, it is possible to self-consciously construct an environment in which one's cognitive system is presented with many more repetitions of the same circumstances than would otherwise occur. In this way one can 'force feed' the learning system. This is not to entirely distort the normal patterns of human learning. Children are often spontaneously repetitive in many aspects of behaviour, and the urge for repetition may well be part of a natural tendency which has survived in part because it is so beneficial to learning.

Pedagogic techniques of rehearsal, exercise, etc. are extensions of the natural repetitive urge rather than totally alien impositions. None the less, many experts will testify that rapid progress is often achieved only by degrees of repetitive practise far in excess of what is pleasant or intrinsically rewarding. To achieve culturally valued goals a learner must often find ways of making intrinsically disagreeable effort enjoyable, or at least bearable. Much of teaching and learning technique is concerned with this problem.

Feedback is also essential to an adaptive sytem in order to prevent unsuccessful or potentially damaging productions being formed. The learner must have a way of discovering the success of the application of a specific piece of declarative knowledge in a general production system. If it is repeatedly successful, only then will it become proceduralized. As Anderson (1982) puts it:

> if a new piece of declarative knowledge proves to be faulty it can be tagged as such and so disregarded. It is much more difficult to correct a faulty procedure. As a gross example, suppose I told a gullible child If you want something, then you can assume it has happened. Translated into a production it would take on the following form:
>
> IF the goal is to achieve X
> THEN the goal X is achieved

This would lead to a perhaps blissful but deluded child who never bothered to try and achieve anything because he or she believed it was already achieved. As a useful cognitive system he or she would come to an immediate halt. However, even if the child were gullible enough to encode this in declarative form at face value and perhaps even act upon it, he or she would quickly identify it as a lie (by contradiction procedures he or she has), tag it as such, and so prevent it from having further impact on behaviour and continue on a normal life of goal achievement.

Feedback comes in several ways. In some instances failure is indicated rather directly by a complete breakdown of behaviour or a manifest failure to achieve a goal. In our clarinet example, if a particular configuration is physically impossible to take up then this is dramatic evidence of something very wrong with the 'knowledge' with which one is operating. At the other extreme, a learner has no way of knowing whether he has succeeded other than by being told so. A good example of this would be the early stages of 'ear training' when a particular chord or interval is to be identified. The learner hears the chord, makes an attempt to identify it, and then receives the 'correct' answer from a teacher or manual. Most situations are intermediate between these two extremes, in that there *is* 'internal' feedback available to the learner, if he can notice it. A teacher can help by directing a learner's attention to such feedback.

When a production rule of a general sort repeatedly calls up a piece of specific knowledge and is repeatedly successful such specific declarative knowledge becomes incorporated into a specific version of the production rule. There is some evidence, however, that the cognitive system has a tendency to incorporate into a production rule *any* part of the contents of working memory that has appeared there on every occasion of the rule's operation, even if it is, in fact, irrelevant to the rule's success. This can be offered as an explanation of why it is often claimed that *distributed* practice is better than *massed* practice. To distribute practice is to spread it over several separate periods rather than massing it all together in a single session. Thus, if one has seven hours to devote to practice in a particular week, it may be better to do one hour on each of seven days rather than seven hours on one day.

In Production System terms, massed practice encourages the formation of production rules containing spurious conditions associated with the particular practice period in question. These conditions have to be fulfilled before the production operates. To take a ludicrously exaggerated example, we might imagine someone who only ever practised at night forming the production rule:

IF the goal is to play C
and it is night-time
and the fingers are not in the configuration Z
THEN the sub-goal is to achieve Z

This rule would work only at night! We call learning of this sort 'context'

or 'state' dependent. Music teachers and others often observe the effects of such learning. A pupil who is shown a fingering pattern or phrasing suggestion for one passage may fail to transfer it to an exactly similar sequence elsewhere.

What distributed practice seems to do is to allow more opportunity for context to be varied so that only essential and not spurious conditions get incorporated into a new production. In fact, one of the important consequences of persistently practising a skill for a very long time is that it becomes more and more 'decoupled' from particular contexts.

After relevant production rules have been added in the associative stage of learning, there follows a period of gradual improvement of the skill which Fitts calls the 'autonomous stage' in which performance gradually becomes faster and more fluent. There are several reasons why this might be. One is that several simple productions become merged into a single production sharing a common goal. Therefore, instead of a sequence of productions applying in turn, each taking some finite time to be found and used, only one production is needed.

For instance, if the goal is to play an arpeggio pattern (say C E G C in C major) then one could imagine an early stage of learning where there were four separate rules, one for each note of the arpeggio. Thus the first rule would apply if and only if the first note had not yet been played, and so on. If such rules were constantly and successfully applied in sequence, the cognitive system would eventually 'couple' them together so that the condition of having the goal of playing the arpeggio would, within one rule, entail the action 'play note 1 *then* note 2 *then* note 3 *then* note 4'. In traditional terms, the arpeggio would have become an integrated and automated performance pattern.

Such a 'compilation' could not take place, of course, until the performer were capable of *having* a goal such as 'perform a C major arpeggio'. This would in its turn depend upon having already understood what a C major arpeggio is, either by demonstration or by inference from its repeated occurrence in music. In performance from a score, a performance production rule such as the above would need a corresponding *perceptual* production rule which could *recognize* a C major arpeggio as being present on the page. Early instrumental learning is often hard because one is learning the perceptual and motor 'halves' of the skill at the same time.

It should be emphasized that the forming of a production rule for a performance pattern such as a C major arpeggio is not to specify every performance parameter. The performance will *not* be a rigid 'fixed action pattern' which comes out with the same timing and dynamic parameters each time. Rather, the rule specifies a series of sub-goals (of playing the various notes in turn) each of which may call up new procedures which determine the precise parameters for the notes according to transient information in working memory.

Another aspect of the 'autonomous' stage is the acquisition of further specific production rules which relieve the load on the goal stack. Consider once again the little production system for playing middle C (P1–P5). We observed that it had three levels of goal stacking. The third goal (removing all the fingers) was set by P3. We could eliminate the need for P3 (and thus P4) if we were able to incorporate a rule for going from each specific other finger position to the desired one. One such rule might be:

P9. IF the goal is to achieve the configuration of having the left-hand fingers covering the top three holes and the left-hand fingers are presently covering the top two holes
THEN cover the third hole and the goal is achieved.

To get to middle C from any other note would require about 30 such rules. To get from any note to any other note would require about 900. It is not unreasonable to suppose that the expert clarinet player has all 900 of these rules in his production system. The time and effort required to get them all there is great, but it is worth it for the elimination of one goal from the stack, and the consequent lightening of the load on working memory. Typically, such new productions will be acquired piecemeal, so that common transitions, such as moving from one note to the next member of a scale or arpeggio, are acquired early on, at a stage where the learner still reverts to P3 and P4 for more unusual transitions.

The task of writing a production system for a non-trivial aspect of musical skill has not yet been undertaken; nor yet has the even more crucial task of modelling some aspect of musical learning in detail. It is not clear, at this stage, whether the theoretical notions available are fully up to the job of music learning, and I do not wish to pretend otherwise. It does, however, seem to me that there is no other theoretical framework currently available which allows such detailed formalization of cognitive processes but at the same time supports many general but more vague conceptualizations and observations about learning. We thus move away from detailed analysis of production systems to some more general remarks which such an approach pulls into focus.

It has long been clear to insightful teachers that one does not create learning simply by offering people facts or prescriptions. Such offerings are of no use to people unless they can incorporate them in procedures they already have. Otherwise the facts remain insulated from any real influence on skill. Teachers in all spheres of activity, including music, often experience the sense that they are not 'getting through' to a learner. Facts are acquired and reproduced, yet there is some sense that the learner has not really grasped the essence of what is being said. For instance, I have had piano pupils whose playing has somehow been wooden and lifeless. I have talked to them about tonal variety, planning *crescendos* to points of accent or climax, rubato, etc.,

and at a 'declarative' level it has all been understood, in that they can provide definitions of what terms like *rubato* and *accent* mean. Furthermore, they have been able, under instruction, to obey the letter of these prescriptions in particular contexts. A pupil took my advice that a particular cadential chord should be accompanied by a holding back of the tempo; but the application of the advice achieved a grotesque result, an arbitrary 'hiccup' in the music, rather than a measured pause which emphasized the importance of the chord, but allowed the music to continue. It was clear that my pupil had no sense of the 'rightness' of my advice in virtue of which it would be possible to tailor it to the demands of the specific context. I do not know whether or how, such sensitivity can be taught. All a teacher can do is watch diligently for signs of it, and when it appears, encourage it and build on it. With all learners and at all levels there comes a point when a tactful teacher must just pass over a failing, knowing that, at this juncture, further comment will not improve it.

The greatest determiner of the progress of any piece of learning is the learner himself, the procedures he has available, and the motivations he has. To use an agricultural analogy, a teacher is like a gardener; tending, watering, pruning, and 'training' his plant. Without his attentions the plant would still grow, possibly not so straight and tall; but it remains true that the gardener cannot alter the essential form and nature of the growth. This is also, to a certain extent, true of the learner himself. Even in a self-consciously 'engineered' learning environment the learner cannot totally control his progress. He finds some things easier to grasp than others, he finds he has just not got the motivation or concentration to cross a particular hurdle, his recalcitrant fingers will just not take up the patterning he wants. And so, in many respects, the learner *observes* his own progress, sometimes with delight and sometimes with despair, rather as an outsider would.

In Production System terms we may say that a learner's conscious efforts tend to alter the contents of the 'declarative' part of his knowledge, but cannot actually get 'down among the production rules' where it really counts. He must patiently wait for the production system, operating according to its own laws and pace, to pull down from declarative knowledge that which it can make its own.

The engineering of learning is, thus, a hit-and-miss affair. No-one not even the learner himself, can be fully aware of the automatic thought procedures which form the basis of his competence. It is impossible, therefore, for anyone to plan the 'ideal' training diet in a way which is exactly tailored to the competences of the individual concerned. Rather, teachers and learners evolve broad strategies which, on the whole, seem to produce results. This helps to explain the huge gap between cognitive theory and learning/teaching practice. It is impossible to derive foolproof prescriptions for a situation in which, almost by definition, the crucial determining factors (the existing set of production rules within an individual) cannot be easily known. What good

teachers (and good learners) seem to do is build up a stock of commonly observed facts about learning environments and schedules which, on the whole, work for them. As a learner becomes more expert, the more likely are such conditions to be specific to that individual, because the shape of his knowledge is different from anyone else's. Our best hope of deriving generalizations would seem to be at the beginning of training, when one may hope that learners share a reasonably common heritage of procedures and motivations supplied by the interaction of biological propensities with the experiences of enculturation.

Thus, for instance, it seems true for our culture that most well-motivated children learn to read if they are supplied with some means of acquiring information about the sounds of letters and words together with a stock of suitably attractive books. The motivation to be able to read their *own* stories, when they want, seems strong enough for children to effectively teach themselves. Teachers assist the process by providing information and feedback when it is needed, and by some elementary structuring of sequence, so that, for instance, the words that a child first meets relate to well-known objects and ideas in his experience. The main conclusion to be drawn from a massive amount of research into teaching methods seems to be that, for the majority of children, it does not much matter what official 'method' is adopted, they learn to read just as well. The main factor determining success seems to be the individual teacher (Williams 1970). It has been observed that two teachers from the same school, with the same type of children, can produce consistently different results, although using the same 'method'. It is not unreasonable to conclude that good teachers are those who provide, reliably and efficiently, the information, feedback and encouragement that children seek as they go about the business of becoming skilled at reading. This can often boil down to such basic things as providing the kind of environment in which a child who wishes to pursue some learning is not likely to be interrupted by other children.

In music an early motivation is often the wish to be able to reproduce the musical sounds of the culture. In more cases than one might expect, the mere presence of a musical instrument in a home can allow a child the opportunity to learn some idiosyncratic music making—picking out combinations and sequences which sound familiar or interesting. In some cultures, where improvisation dominates, such idiosyncratic beginnings can, under their own momentum, produce an expert performer of some distinction, whose technique and style may be unusual, but effective for the music he chooses to play. In our own culture, where the emphasis is on reproductive performance of significant 'art' compositions, teachers feel a duty to steer their pupils towards the kind of technical and formal grasp which will eventually, enable a culturally acceptable performance of, say, a Mozart sonata, or a Chopin Etude. In this case, it is necessary to introduce learners to ways of holding their hands and moving their fingers which will at first, seem very unnatural,

but which are necessary if they are to execute fast passagework with the kind of fluency and control that the reproductive goal requires.

This contrast is exemplified by the difference between a largely self-taught jazz pianist and a graduate from a music conservatoire where a 'rigorous' technical approach is taken, and where learners are coached on the same relatively small concert repertoire that will enable them to participate in international competitions. The former will often have a technique which would be perceived as 'hopelessly awkward' by a trained concert pianist, yet it serves its purposes well. The latter will usually have a technique which is very similar to other pianists trained at the same school, often to the point where individuality becomes submerged. A 'balanced' relationship between teacher and learner will probably steer a middle course between these two extremes. The teacher will try to shape and mould what is already present without 'going back to square one', and the learner will incorporate, and make his own, what the teacher is offering.

If one accepts the way of looking at learning that I have attempted to outline in this section then it seems to me necessary to accept that the training (of oneself or others) is more an art than a science. However much information scientific research and theory can supply it will never allow a total knowledge of the learner's cognitive system, because each learner is unique. No matter how much scientific information is available, teachers and learners must still make decisions on a largely intuitive basis. I confess to experiencing some relief that this conclusion may be drawn on theoretical grounds, because if one *had* to rely on research in music education it would be hard to find a consistent and universally applicable set of findings.

Consider, for instance, the question of how to correct habitual errors in performance (such as the execution of a wrong note or a wrong fingering in a passage of music). Buck (1944) has characteristically forthright advice on this point:

> If you work at a passage where the difficulty is the fingering, your only chance is to decide on how you will finger it, and work on it with concentrated thought until it is automatic. It may mean a thousand repetitions. But if, after fifty of them you are careless and and stumble, you have not merely done it wrong for once; you have wiped out all the benefit derived from probably twenty-five of your trials (p. 20).

On this view, the only way to correct error is to play the correct fingering a very large number of times. This is intuitively plausible. However, an extraordinary study by Reitmeyer casts serious doubt on this conclusion (Reitmeyer 1972). In this study, some subjects were asked to indulge in *negative* practice. This involved deliberately practising the error, being aware all the while of the correct fingering. Other subjects practised in the 'conventional' way, playing the correct fingering. The two groups of subjects were then asked to provide repeated correct performances as a measure of the extent to which the error had been corrected and eliminated. Reitmeyer

found that there was no significant difference between the effectiveness of the two techniques.

Without a theoretical framework, such a result is practically uninterpretable, and leads to such weak conclusions as those given by the author, e.g. 'instrumental students and teachers might consider negative practice as an occasional alternative to positive practice'. On the face of it, the result renders Buck's statements false. Yet I would be loath to alter Buck's advice. It is clear that positive practice is *a* road to success, and one which is supported by teaching tradition and intuition. Even if negative practice had turned out to be *better* than positive practice in Reitmeyer's study, I would still be loath to recommend it, since I would imagine that learners would find it very hard to live with, and believe in, such a counterintuitive strategy.

As a cognitive psychologist, I am, of course, fascinated to know how it is possible for negative practice to work. It is possible that repeated attentive *thinking* about the right fingering is more important than actually *playing* the right fingering. This is supported by Neisser's (1983) studies of dart playing. He found that his subjects improved if asked simply to *imagine* themselves throwing darts. In Production System theory, it is what is going on in working memory (or consciousness) that determines the course of learning. Because Reitmeyer's subjects were actively labelling what they played as 'wrong' and another, unplayed, fingering as 'right', we may conclude that production systems picked up only that information labelled as 'right'. We may contrast this case with another outwardly similar case where someone plays the wrong note, but does *not* simultaneously think of the right note in a focused manner. In such a case, it would be *really* extraordinary if there were any improvement. Unfortunately, a teacher cannot easily know whether a learner is or is not thinking of the correct note whilst practising the wrong note. Negative practice is, therefore, an educationally disastrous technique, precisely because an observer cannot check whether it is being carried out effectively. Positive practice has the advantage that the learner *must* be thinking of the correct note in order to play it (unless, of course, he already knows the passage so well that it is automated; in which case there is no learning problem).

The problems that arise when one makes any attempt to derive specific training prescriptions from educational research have been illustrated through this (not atypical) example. This is not to suggest that such research is without value. However, it seems to me that the most useful research is that which offers the musician a general resource which he can use to suit his own purposes rather than a detailed method. One area in which this condition is fulfilled is the development of new technology which offers a musician the opportunity of enhancing the feedback available to him.

For instance, Tucker, Bates, Frykberg, Howarth, Kennedy, Lamb, and Vaughan (1977) describe a computer-based interactive aid for musicians that allows a passage played on the keyboard of an electronic organ to be dis-

played visually in a modified notation that reflects the exact duration of the notes played. With the aid of this feedback, a pianist of concert standard improved his performance of a triple trill quite dramatically within minutes. Similarly, Basmajian and Newton (1974) showed that with visual electromyographic feedback, wind players learned within minutes to suppress or activate specific parts of the buccinator muscle in the cheek. Singers can also be helped in a similar way (Fourcin and Abberton, 1971).

6.4. Assessing musical ability

We finish this chapter by briefly considering 'tests of musical ability'. Within musical cultures where there is an organized pedagogic tradition, achievement in specific musical skills such as performance and theory are measured directly through examination. Apart from the problems caused by 'nerves' and 'stage fright' such examinations seem to fulfil their purpose in a direct and unexceptionable manner. We shall not consider them further here. The purpose of 'tests of musical ability' are rather different. Whilst examinations presuppose intensive preparation of specific materials, tests of ability involve no foreknowledge of test content. Indeed, such tests are invalidated by extensive practice on the particular tasks they contain. This is because of the rationale which underlies their construction.

The argument is that all children within a culture experience a relatively common exposure to, and involvement in, music, at least to begin with. However, because of differences in innate potential, motivation, or experiences at certain critical periods, the 'take-up' of musical knowledge varies from child to child. Thus, even before some children are selected for specialist training, they have come to differ from one another quite widely in the stock of underlying skills and sensitivities they possess. Sometimes these differences are not immediately apparent in the overt musical behaviour of the children. For instance, there may be differences in the ability to listen to and appreciate music. Or again, a child with relatively few musical skills could have received instrumental coaching which provided him with an overt accomplishment not displayed by a child without such coaching who, nevertheless, had many more 'unnoticed' skills rather than the ones which are on the official training agenda. A child who possesses these skills in a measure above those of his age-mates is more likely to make rapid progress under formal training and is more likely to achieve excellence. A child who lacks these skills is unlikely to make such rapid progress, will require more training effort to achieve excellence, and possibly has passed some critical period of development after which it is unlikely that excellence can be achieved.

Without questioning this line of argument, let us look at a few typical situations where such tests might be of use. One example might be the case of a school with a very good choir that gives frequent public performances and broadcasts (such as many English choir schools). Members of the choir

spend many hours a week rehearsing at the expense of other school activities, and the majority of the children selected for training must reach the required level within a relatively short time if the numbers in the choir are to be maintained to take account of the older children who leave the choir every year. Very few potential entrants have had intensive singing experience. After ensuring that candidates can sing simple melodies pleasingly and with good intonation, the choirmaster makes the final selection on the basis of a test of musical ability.

A second example might be the case of an older child, in early or mid-teens, who becomes seriously interested in music after years of relative neglect. He wonders whether he would have a chance of succeeding in a musical career. He attends vocational counselling and is given a test of musical ability. His score is well below the average for his age, and he is advised that he will be unlikely to cross the selective and competitive hurdles that would gain him a place at a music college.

These two examples have in common that they are being used to assist some kind of educational selection. Although the principle of selection can have unfortunate and undesirable consequences, there are benign aspects too. It does a child no good to allow him to embark on a course of training for which he is temperamentally or intellectually unsuited, whatever his current 'wants' might be. Given that some selection is inevitable and possibly helpful, we may ask if and how 'tests' can be used to make such selection as fair and accurate as possible.

First, a test should only be used when there are no more direct signs of achievement to examine. Instrumental or vocal performance which shows technical and expressive mastery provides better evidence of musical ability than any test can do. In both our examples, the sensible teacher or counsellor would have ensured that there was no direct clinching evidence of accomplishment before embarking on testing.

Second, test results should be taken in conjunction with other evidence, formal and informal, where possible. For instance, a child who performs well on a test but does not seem particularly interested in, or excited by, music may still be unsuited to an intensive musical education. It is always possible, for instance, that over-keen parents have discovered the general nature of the tests used, and obtained special coaching for their child on the types of task to be tested.

Third, testing should only be carried out with respect to a particular educational question to be answered at a particular time, not to provide a once-for-all statement about capacity or potential for achievement. In the choir example, the tests used to select those children who, within a few months of testing, would be likely to be able to 'hold their own' in a fast-moving training programme. For the teenager the question was whether he would be able to raise his achievement level to competitive examination standard within a few years. In neither case should relatively poor results

lead to the conclusion that a person is 'unmusical' or 'incapable of musical achievement'. The person concerned is simply judged unlikely to meet *particular* achievement targets within *particular* limited time-spans.

Fourth, the test should be a *valid* measure of musical ability. Validity may be assessed in two ways. A test has 'face' or 'content' validity if it manifestly demands use of the ability it is purporting to test. A test which involves a subject hearing, and then singing back, a short melody has high content validity as a test of musical ability. A test which requires a subject to remember a list of numbers has low content validity. A test may be valid in a second way, however, even when content validity is low. This second type of validity is called 'associative validity' and arises when there are good correlations between a test and some other measure of achievement. One way of assessing associative validity is to see how well one test result correlates with some *other* test of ability. This is often a little circular, because this still leaves one with the problem of assessing the validity of the other test. A better method is to see how test performance correlates with future achievement. If there is a high positive correlation, the test is said to have good 'predictive validity'. Thus, if ability to remember numbers correlated highly with later musical achievement, it would be a valid test of musical ability. The problem with tests that have only predictive validity is that one has to place one's whole faith in the adequacy of the studies which purported to establish the validity. There may be any number of reasons why the conditions which pertained in the validation study do not pertain in a particular testing situation. For this reason, it would seem advisable to use tests which, where possible, have high content validity. If evidence exists of high associative validity, so much the better. However, it is worth saying that it is often quite difficult to obtain really convincing estimates of predictive validity. To obtain such estimates requires a non-selective use of the test with a large population, and a subsequent follow-up study to assess achievement. Ideally the validation study should be carried out in an educational context similar to the one in which the test is being proposed for use. Thus, in our choir school example, the 'ideal' validation would involve the school selecting children for entry to the choir on some basis other than a musical test. Meanwhile, the specific test of musical ability in question would be administered to all the children by a third party, and the results kept secret. All the children would then undergo normal training, and at the end of the training period their achievement assessed by conventional means. Then the test results would be unlocked and their predictive power assessed. In reality, few schools could afford this sort of experiment.

Fifth, the test should be reasonably *reliable*. A test is reliable if the same subject achieves the same score when tested more than once. In practice no test is 100 per cent reliable, and the scores of an individual will fluctuate from testing to testing. Much of this has to do with concentration and other personal factors. A test will tend to be unreliable for a given individual if a

lot of the items are just at the limits of his ability. On a 'good day' he will just succeed at all these items. On a 'bad day' he will just fail. Good test preparation can reduce this problem. A standard technique is to have a series of items of graded difficulty, starting with very easy ones, and moving through to very difficult ones, so that all subjects will find several items that they can always get right, and several that they always get wrong, good day or bad day alike. What will vary from test to test are the scores on the few items which lie around his 'cut-off' point. Because no test is completely reliable, an experienced tester will resist the temptation to make distinctions between people on the basis of small differences in test result. Tests should only be used to place people in broad categories (such as 'top quarter' or 'bottom third'). Even this does not make a test completely fair. Suppose, for instance, one can only take 25 per cent of a given population, and one uses a test as the sole criterion for selection. There is no coherent alternative to simply selecting the highest scoring quarter. This may well mean accepting someone with a score of, say, 62, and rejecting someone who scores 61, even though it is entirely possible that, on another testing, their positions would have been reversed. There is no entirely satisfactory solution to this vexing problem. One flexible and humane response is to abandon rigid quotas and examine the distribution of test scores. Quite often one can find that the scores 'cluster' around certain values, with definite gaps between the scores of different groups. In such a case it would considerably increase the fairness and reliability of the selection to place the 'cut-off' point in the largest convenient gap, even if this meant taking rather more, or rather less, than quota. Another response would involve using test scores as one among several selection criteria, so that 'borderline' cases could be distinguished on some more discriminating criterion.

There are some 24 tests of musical ability documented in the recent literature. Shuter-Dyson and Gabriel (1981) provide a comprehensive description and discussion of all these tests. All of the tests have basic content validity. That is, they all require children to listen to, and make judgements about, short extracts of music. None of the tests require overt musical performance such as singing or beating time. The most common type of test item is a pair of notes, chords, or sequences, which may or may not differ in some respect. The subject is required to say whether the members of a pair are the same or different, or to make a simple judgement about the difference ('which is louder?', 'which is better?', etc.). All of the tests comprise two or more sub-tests, examining different aspects of music. The same types of sub-test occur in many of the tests. One of the most common sub-tests, for example, involves the subject hearing two short melodies of identical length. In the second melody, one note may be changed in pitch from the first melody. The subject has to judge whether the melodies are the same or different, and if different, where the different note lies in the sequence.

Differences between the tests lie in the selection of sub-tests used, the

age-group for which the test has been designed, and the efficiency of the standardization procedures and reliability and validity studies. Several of the tests are not commercially published, and others have gone out of print. The two tests most readily available and most widely used (at least in Britain) seem to be the Seashore Measures of Musical Talents (Seashore, Lewis, and Saetvit 1960) and the Wing Standardized Tests of Musical Intelligence (Wing 1962). For a detailed evaluation of these tests see Sloboda (1984).

Both the Wing and Seashore tests have been designed for use with children of age eight and upwards. As we saw earlier in the chapter most eight-year-olds have an enactive repertoire of songs they have learned from the culture, and which they are capable of reproducing with rhythmic and tonal accuracy. They are beginning to enhance their reflective awareness of the structures and styles that the music of their culture contains. They are beginning to differentiate consonance from dissonance, and to gain a sense of harmonic direction and closure. They also have started to detect high-level 'style' similarities. The period up to the age of 12 or so is, in general, one of rapid and significant changes in musical awareness; and most of the observational and experimental studies reported in the first part of this chapter found wide variation in ability at each age. Unfortunately, both the Wing and Seashore tests were designed long before much of this research was published (Wing 1948; Seashore 1919). If one were designing a new test today it would be only rational to test the very abilities that recent investigators have shown to be developing in middle childhood. Thus the test might include versions of Gardner's (1973) style-sensitivity test, Zenatti's (1969) tonal memory tests, Imberty's (1969) harmonic closure tests, and so on.

Some of the Wing and Seashore sub-tests approximate quite well to these research tests. Both, for instance contain a test of melodic memory. The Wing tests contain a test for discriminating conventional from unconventional harmonizations, and metrical from unmetrical accenting. Other tests seem more hard to justify. The Seashore tests, for instance, contain a test of pitch discrimination with pitch differences going down to as little as 2 Hz (about one-tenth of a semitone in the pitch range tested). Research we have discussed in Chapter 5.4 shows that many experienced adult musicians are incapable of such fine discrimination, and that assimilation to pitch/scale categories is a more characteristic (and useful) feature of the musical mind. Manor (1950) found a zero correlation between scores on the Seashore pitch test and success at clarinet or trombone playing. A small positive correlation *was* obtained for success at violin playing; a skill where accurate pitch perception is arguably more important than most.

Similarly, the Seashore tests include a loudness discrimination test which requires finer discriminations than many professional bassoonists seem capable of (Patterson 1974).

It is certainly true that a total failure to make discriminations along sound

dimensions such as a pitch and loudness would render musical achievement impossible. However, we are entitled to question the value of extremely fine discriminations below a generous minimum. The thrust of most of the evidence presented in this book is that musical expertise consists in grasping the various levels of structure that exist in musical sequencing. A test of musical ability or aptitude should be demonstrably concerned with such structural skills. On these grounds the Wing test is to be preferred to the Seashore, and seems to produce better validity estimates than the Seashore (Shuter-Dyson and Gabriel 1981). Even so, there are serious technical deficiencies in the presentation of the Wing tests which makes them hard to recommend wholeheartedly (Sloboda 1984). Both tests are somewhat dated, and need re-standardizing for contemporary populations.

Tests of musical ability have never made the same kind of impact on the music teaching profession as have tests in 'core curriculum' areas such as reading or mathematics. It would be interesting to pursue the reasons for this, but here is not the place. It does seem likely, however, that lack of strong and consistent teacher demand is a major factor behind the relative unsatisfactoriness of the music test market. Without such demand it is unlikely that the funds and research impetus will be found to devise a test which serves the musical community really well. This is not to say that an individual teacher or institution will not find a test of musical ability useful in a particular context. However, it would be wise to treat test results with considerable caution. In particular, it would be foolish, and possibly unfair, to make major educational decisions on test scores alone.

7. The musical mind in context: culture and biology

7.1. Introduction

The discipline of psychology occupies a curious and rather precarious position in the world of science. It stands mid-way between the 'physical' sciences such as biology and physiology, and the 'social' sciences such as sociology and anthropology. Within its own boundaries it experiences the tension created by the opposite pulls which the 'physical' and 'social' sciences exert. Thus, there exists a sub-discipline of physiological psychology and one of social psychology. Cognitive psychology occupies a middle position between these sub-disciplines rather as psychology is between the biological and social sciences.

The biological approach to psychology attempts to account for human behaviour in terms of the operation of the brain and nervous system, which is, in its turn, influenced by the genetic constitution of the human organism. It is often 'reductionist' in that it seeks to replace psychological entities such as 'consciousness', 'intentions', 'memories' with combinations of physiological entities and events such as activities in certain brain areas. This approach tends to stress the innate basis of much human mental equipment, the universality of human psychological makeup as a result of shared genetic material, and proposes that many of our basic social conventions and institutions have arisen because they further the survival of individuals within the species, and so have been selected through Darwinian evolution. Critics of this approach point out that cultural and historical variation in human behaviour are very wide; and philosphers have argued with some cogency that the attempt to reduce mental events to brain events fails on conceptual grounds.

The social approach to psychology attempts to account for human behaviour in terms of the social institutions and conventions within which a person develops. On this account, significant behaviour thought patterns are learned through interaction with the culture, and they are specific to the particular culture. This approach stresses the *relative* nature of most human abilities, and their dependence on particular social contexts for their execution. Critics of this approach point out that all humans share a genetic heritage, a common physical environment, and certain cultural constants such as upbringing by adults, language learning, and so on. These factors converge to give rise to psychological universals.

As with most crude dichotomies, each approach states something important about man, but fails to encompass the whole truth. Cognitive psychology occupies a vital pivotal position between the extremes because both 'biologists' and 'sociologists' identify individual human thought and action as the 'given' which requires explanation. The 'neutral' cognitive psychologist attempts to articulate the structure of human thought and action in a way that leaves aside the question of cause—biological or social. For this reason, the typical cognitive psychologist is not concerned to examine a wide range of developmental and cultural contexts. Instead he takes a *particular* stage of behavioural development of an activity within a *particular* culture, and asks the question: how can we best characterize the system that is operating at that time and place? On the whole, I have tried to take a relatively 'neutral' line in this book; although authors such as Sampson (1981) argue that such a stance cannot help but offer implicit support for strong assumptions about the nature of man and society.

Whether or not one accepts such criticism, it is clear that neutrality can be, at best, a temporary strategy which leaves vitally important questions untouched. Biological and social influences must be included in a full explanation of human conduct. Accordingly, this chapter explores a few of the social and biological considerations relevant to musical thought and behaviour.

On the social/cultural side we look at some of the factors which may be responsible for cultural differences in music, and ask whether, none the less, there is any evidence of underlying universal features of music. On the biological side we examine some studies which shed a little light on the neural organization of musical function. We also ask whether there is a biological base for the origins of music in our species. Does music fulfil a biological function, and has it got evolutionary precursors in our immediate ancestors?

7.2. Culture and musical thinking

The musics of the world contain enormous variety. Just what variety has not, perhaps, been fully appreciated until the present century when Western scholars have begun systematically to study and record music of other cultures than their own.

One important approach to the study of the world's music is essentially taxonomic or classificatory. It is a first step in understanding the relation of music to culture. In this approach the musical sounds of a culture are classified in terms of, for instance, the instruments they use, the typical forms found, the scales and tuning systems used, the social contexts in which the music occurs, and so on. Using such information it is possible to build up a comparative 'world map' of music, grouping together those cultures whose musics seem most similar.

To take one example, it seems possible to divide the continent of Africa

into two main musical sub-continents, with the Southern boundary of the Sahara Desert as the approximate dividing line between the two. In Northern Africa, where Muslim influence has been particularly strong, one can discern features of the indigenous music which links it to the music of the Near East. Here the voice is paramount. There is relatively little instrumental music, and instruments are more often used to provide an accompanying drone or rhythm for a vocal line. The music is mainly monophonic and soloistic, and the solo singer uses a particular type of voice production which gives it (to Western ears) a forced nasal quality. Melodies are based on pentatonic (five-note) or heptatonic (seven-note) scales, but are decorated with microtonal shakes. Social contexts for music making include religious ceremonies and festivals, and the recounting of epic poems. The music of Northern Africa is generally seen as part of a larger 'Pan Islamic' tradition which extends as far up as Turkey and Eastern Europe. The Yugoslavian epic songs discussed in Chapter 4 fall into this Pan-Islamic tradition.

The music of Southern Africa has distinctly different charcteristics from Pan-Islamic music. Here music is rarely soloistic but involves groups of people. A fundamental form is the call-response, in which a solo leader sings some short phrase, followed by an answering phrase from a chorus. The music is usually polyphonic, which is to say that there are often at least two independent, but equally important and co-ordinated, things going on at once. Instruments, particularly drums, are very important, and much music has a rhythmic strength and vitality brought about by the repetition of short, highly complex, multi-layered rhythmic patterns, produced by different drummers simultaneously executing their own rhythmic devices. The tonal content of the music seems more accessible to Western ears than that of Pan-Islamic music. Singing is full throated and less prone to microtonal variation. Harmony is common, and typical chords are built from intervals of major and minor thirds, perfect fourths, and perfect fifths. The social contexts for music are many and varied. Practically any social gathering, whether for work, celebration, or religion, is the occasion for group music making. Nearly all music is text-based, with poetic or song structures lying at the core of musical forms. Even purely instrumental music usually derives from a vocal model.

This much simplified contrast between the music of Northern and Southern Africa gives a flavour of the kind of descriptions that ethnomusicologists have been able to give of the world's musics. Of course, there are many more fine distinctions within small regions than this sketch suggests, and Africa contains no less diversity than any comparable area of the world. I have neither the competence nor the space to offer a survey of the world's musics, even at the most general level. There is a large and detailed literature on all aspects of world music. Much of the fundamental research is published in the journal *Ethnomusicology*, but helpful summaries are provided by Kunst (1959), Malm (1977), and Nettl (1964, 1973). Up to date summaries and

bibliographies are provided in *The new Grove's dictionary of music and musicians* (ed. Sadie 1980).

What I wish to do here is go beyond taxonomy to questions of cause. What factors, cultural or social, can help account for the wide differences between musical cultures in the world? I shall focus on a single factor which, although not the only significant one, seem to me to have far-reaching consequences. It is particularly important because it seems to relate particularly strongly to differences between Western Art music (about which this book has mainly been) and other forms. I shall be suggesting that the form of Western music, and the nature of the cognitive skills it supports, are closely linked to the existence of a developed system for notating music. In doing this I draw particularly strongly on the ideas of Blacking (1976) and Shepherd, Virden, Vulliamy, and Wishart (1977). After this I shall turn to the question of the evidence for 'universals' underlying the surface diversity of music.

My aim is to raise a few of the issues which seem to be important for a broader understanding of musical cognition than can be gained from examining only one type of music. Psychologists have not been noticeably interested in music outside their own culture, and there has been little empirical work carried out within the framework of modern psychological thought. In this section I shall be offering some broad, even provocative, general hypotheses, which clearly need refinement in the light of psychologically oriented research. A psychologically informed evaluation of the vast ethnomusicological literature is also needed. It is only the absence of such major achievments that justifies my rashness in dealing with this vast and complex issue at all.

7.2.1. *Music notation as a cultural force*

Many world cultures are, or have recently been, essentially non-literate (or *oral*). That is, they have not used visual notational means of recording details of human transactions. There are many contrasts to be made between literate and oral cultures. I wish to concentrate on four broad proposals about the effects of the availability of notation:

1. The existence of written notation allows lengthy verbatim recall of complex meaningful material.
2. Notation allows proliferation and migration of material so that it exceeds the capacity of any one individual to know it all.
3. Notation encourages the separation of the content of an utterance from its context, and makes it easier for an utterance to be treated as a 'thing in itself'.
4. Notation selects certain aspects of sound for preservation, and, in doing so, both embodies current theory and also tends to restrict the future development of music in certain ways.

First, I will enlarge on these points with reference to language, and then suggest how they may also apply to music. Before doing these things, it is necessary to make some qualifying remarks. Contemporary cultures can be ranged on a continuum from those where literacy is non-existent to those where literacy pervades all aspects of social activity. There are many 'semi-literate' cultures, where literacy exists within restricted classes or situations, and where this has effects which permeate to the oral members of the culture. Even in a predominantly literate culture such as ours there may be individuals who are not literate, but indulge in activity which is supported, directly or indirectly, by the literacy of others. Conversely, individuals who are fully literate can, at the same time, possess significant areas of activity which are essentially oral. Many Westerners are linguistically literate and musically oral. Some musically literate people maintain areas of musical activity, such as jazz or folk music, which are essentially oral. So the literate/oral distinction is not as culturally clear-cut as I sometimes assume for argument's sake.

There is also another complicating factor in the form of new modes of preserving the past, particularly electrophonic and photographic recording. These fulfil many of the functions of notation, but have new properties too. Because these modes of recording are not symbolic, people can use them without acquiring literacy. This tends to increasingly blur some of the distinctions I make, at least when applied to the contemporary scene. With these reservations in mind, we may proceed.

For many people, notation is so important that reality becomes, in many ways, mediated *by* their notations. What can be written down and preserved is *correct* and definitive: man's performance or memory is judged against the written record. In oral culture, present knowledge and memory are the only guides. Disagreements are settled by negotiation, or by recourse to the judgement of respected individuals (D'Azevedo 1962). When members of a literate and an oral culture interact these differing 'world views' can cause mutual incomprehension. Goody and Watt (1963) give a clear example of this (cited in Shepherd 1977):

> Early British adminstrators among the Tiv of Nigeria were aware of the great importance attached to . . . genealogies which were continually discussed in court cases where the rights and duties of one man towards another were in dispute. Consequently they took the trouble to write down the long list of names and preserve them for posterity, so that future administrators might refer to them in giving judgement. Forty years later . . . their successors were still using the same genealogies. . . . However, these written pedigrees now gave rise to many disagreements, the Tiv maintained that they were incorrect, while the officials regarded them as statements of fact, a record of what had actually happened, and could not agree that the unlettered indigenes could be better informed about the past than their literate predecessors. What neither party recognized was that in any society of this kind changes take place which require a constant readjustment in the genealogies if they are to continue to carry out their functions as mnemonics of social relationships.

It is common for many literate people to assume that the life and knowledge of a literate culture is somehow *superior* to that of a oral culture; that literacy adds to man's resources and takes nothing away. It would be more correct to say that literate and oral cultures are *different*, and that there are both gains and losses involved in becoming literate. The advantages are so clear to us that they hardly need spelling out: the increased availability and durability of knowledge, allowing complex and geographically widespread social and knowledge structures to develop. The disadvantages sometimes escape us and need more emphasis. In a completely oral society, gaining knowledge cannot be divorced from the fundamental human interactions of that society. Knowledge is preserved in the very customs and rituals which bind the society together. In so far as the social group is stable, the knowledge it transmits tends to be stabilizing, dependable, and sufficient for life. There is little possibility of a person falling foul of society through failure to know something of importance. The limitation of knowledge to that which is important enough to become enshrined within oral traditions guarantees that each individual knows what he needs.

Literacy, in contrast, involves the possibility that knowledge becomes esoteric and unmanageable. There is so much stored knowledge in a literate culture that it is impossible for any individual to interact with anything other than a small fraction of it. Thus man becomes dependent on other 'experts' to mediate and use knowledge for him. Because written knowledge can be disseminated far from the social context that generated it, the amount of 'useless' knowledge (with respect to a particular individual or group) becomes very large. At best this can mean that a person will waste a lot of time and energy before discovering useful knowledge. At worst it can seriously mislead by supplying knowledge which is simply inappropriate to a person's own situation.

Written notation also encourages us to *distance* ourselves from our words and those of others. When they are captured in permanent form on paper it is easier to analyse, dissect, and treat them as lifeless *objects* distinct from us and our thoughts. In this way, they lose some of their power and immediacy. This has some good consequences. It allows us, for instance, to resist the power of words used for persuasion, seduction, or demagoguery, at least to some extent. But it also encourages the formation of an image of ourselves as *separate* from our words and actions. We see ourselves as observing and acting on the world rather than being part of it.

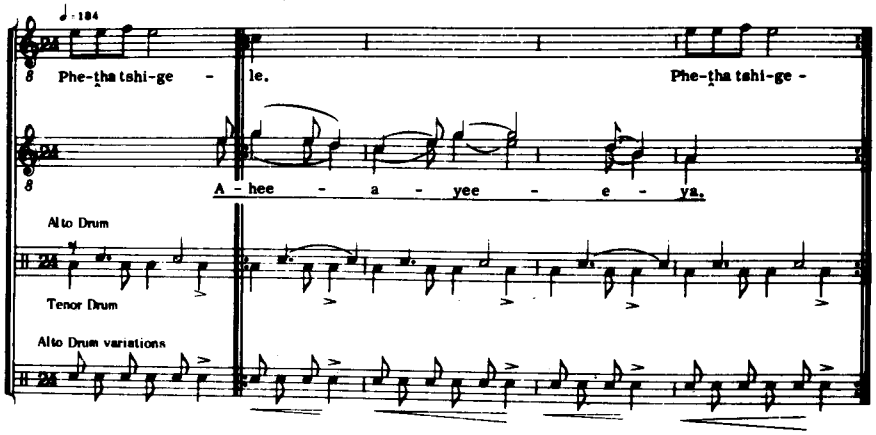
Finally, by *selecting* the aspects of an utterance which are preserved, notation can lead to impoverished communication. Our own alphabetic notation fails to preserve significant information about timing, intonation, voice, gesture—and selects phonetic information for preservation. This can have a profound influence on some forms of spoken language, legitimizing speech where the phonetic element carries more and more of the burden of the communication. In some contexts it may be implied that educated, lit-

erate, speech is grammatically correct, phonetically well-articulated, decontextualized, unsupported by gesture, and smooth in pace and tone, compared to the speech of the oral or the child. The temptation is to make spoken language more and more like its written counterpart, so that the un-notated currency of speech, in all its richness of expression, becomes debased and devalued. The epitome of this trend is to be found, perhaps, in the radio newscaster of whom (at least in Britain) it can truly be said that he supplies no more than what a listener would have learned from reading the text himself. War atrocities and Stock-Exchange fluctuations are reported in the same measured tones.

Having outlined some general aspects of the effects of literacy, let us now see how these arguments might be applied to music. In oral cultures, music is handed on from person to person without notation and so it is, like verbal knowledge, subject to mutation over time. Only the scribe or the tape-recorder can record that change, however. Within the oral culture there is no way of checking that a particular performance is 'the same music' as before, other than through consensus. There is no evidence that oral cultures support any lengthy musical recall that is exact (i.e. *note-for-note* the same as a model). The music is 'recreated' anew at each performance. What we observed to be true of Yugoslav song characterizes most of the lengthy musical products of oral cultures. Although a basic pattern or kernel may be retained, successive performances demonstrate significant differences of detail and elaboration. This is not to say that the members of the culture view the music as fluid or unfixed. There is real and detailed learning of particular pieces of music; but what is learned is inevitably a relatively high-level abstraction from a succession of performances which *are* different in notatable detail. The kind of exact knowledge which we can gain of particular pieces of music through repeated examination of scores or through repeated hearings of the same record is literally impossible in an oral culture.

There are several things to be borne in mind when evaluating this assertion. First, it is not denying the possibility of *all* verbatim recall. Short melodies *can* be easily memorized, and we have some reason to believe that the orally transmitted nursery rhymes and folk songs of our own and many other cultures have changed remarkably little over the years. These usually have a repeating verse structure, and the musical material is rarely longer than 50 or 60 notes. Second, the assertion does not deny the existence of 'prodigious' feats of memory. In oral settings, people do remember very long pieces of music. My point is that it is unlikely that the memory will be a note-for-note replica of a previous performance. In literate cultures we find many accounts of lengthy verbatim recall in cases where the memorizer is not necessarily making use of notation. This does not contradict the general assertion because it seems fairly clear that such achievements rest indirectly on the existence of notation. We may argue that lengthy verbatim recall depends upon the culture being able to provide several exact repetitions of

the same piece of music. Before the advent of modern recording techniques notation would be the only means of providing performers with the opportunity to produce note-for-note repetitions of lengthy works. When such repetitons are available to a listener, then he may begin to develop the representational skills required to achieve verbatim recall. Eventually an individual may get to the point where he can memorize a long work after one or two hearings (cf. Mozart and Allegri's *Miserere*, discussed in Chapters 1 and 5). There is, however, no psychologically plausible account of lengthy verbatim recall which does not rest on a prior history of 'training up' recall ability on shorter pieces which are repeatedly heard.



Third, the assertion is not to claim totally different memory mechanisms for people in oral and literate contexts. The fundamental basis for musical memory, as has been argued throughout this book, is the ability to extract higher-order structure from sequences of notes. In an oral context, the musician uses a stored structure to generate different, but structurally linked, note sequences on different occasions. This ability becomes labelled as 'improvisation' in a literate context. When notation (or recording technology) allows for several hearings of the identical note sequence, then a musician can elaborate his structural memory to provide for exact note-for-note recall. The memory is still *structural* as the experimental evidence reviewed in Chapter 5 shows.

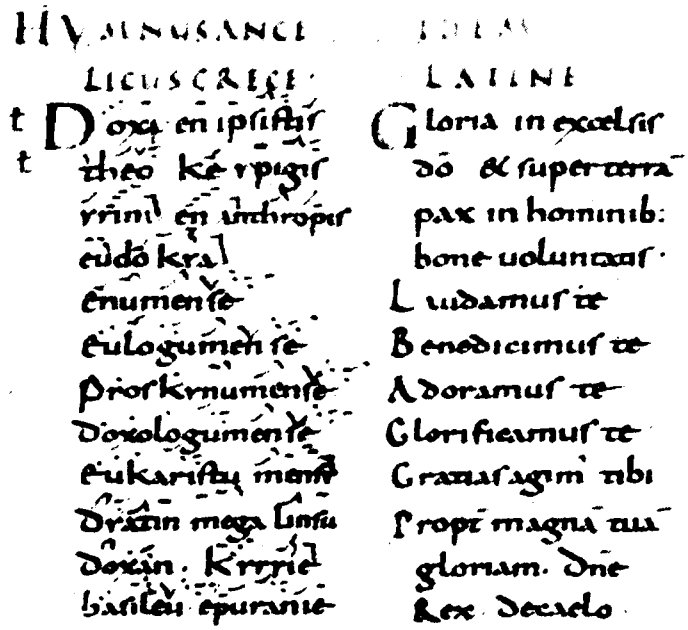
A different, but related, effect of the existence of notation is on the *forms* of music that exist within a culture. One may argue that notation enables the construction of complex and lengthy forms where relationships spanning many hundreds of notes are planned in detail. It also enables the use of devices such as inversion or retrogression, and strict counterpoint. This is because a composer can make detailed records of early events and construct later events by repeated reference to them. In a purely oral context, thematic relations are unlikely to have the almost mathematical exactitude of some notated forms, but to have a looser, although still musically effective, association.

In general the forms of oral music do not match those of literate music in 'architectural' complexity, where multiple hierarchical embeddings can produce long, varied, yet integrated compositions. Rather, we find a preponderance of 'chain' structures where the same kind of short element is repeated, with variations, over and over again. The 'theme and variation' structure that we discussed in Chapter 4 with respect to Western improvisatory performance seems to incorporate fundamental characteristics of oral music, of whatever culture.

It is worth noting that even if notation is necessary for the development of such forms as sonata form, fugue, etc., it certainly cannot be a sufficient condition. There are several cultures with develped notational systems which use very different musical forms to those of the Western classical tradition. We must see notation as only one of a range of interacting influences on the development of form.

In addition, to say that oral music lacks the formal complexity of some Western forms is not to say that it lacks all complexity. Oral music provides all sorts of opportunity for elaboration and detailed craftsmanship. However such complexity tends to be due to elaborations *within* sections rather than relations *between* sections. Consider, for instance, the Venda song (South Africa) given by Blacking (1976) in Example 7.1. It repeats the same short

Example 7.1. South African Venda song. From Blacking (1976) Used by permission of Faber and Faber Publishers, London.



phrase over and over again, yet the rhythmic asymmetries would defeat many a Western performer. The time signature is, in effect, a very fast 5/8 + 7/8 + 5/8 + 7/8, a rhythm which the drummers sustain through a number of possible polyphonic permutations, two of which are given.

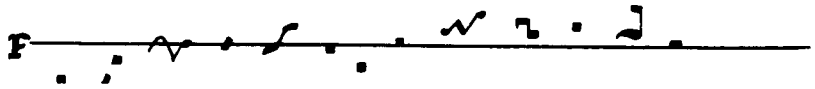
There are at least two different, but complementary, ways of understanding a piece of music. One is through its context, the other is through its content. Both ways of looking at music are available in all situations, but it is possible to argue that notation tips the balance in favour of the content approach, and tends to devalue the context. This is precisely because notation (and sound recording) allow us to examine musical content detached from particular performing contexts. Oral music cannot be detached from its context in this way, and a degree of its 'meaning' is supplied by the context. Without such context we are encouraged to view the music as a 'thing in itself', and to search for what Goodman (1976) has described as 'repleteness', where every noticeable aspect of content is taken to be significant, and *designed* to be significant. We must be careful, however, to make sure that the originator of the music intends it to be replete in this sense. We can 'read too much' into a notated composition, but the danger is exacerbated when we approach oral music with this set, for the oral musician is less likely to have turned every element over in his mind, searching for the *exact* notes to capture his *exact* meaning. There is, of course, nothing inherently wrong in listening to

any music in an analytic way. Intellectual disciplines such as musicology would be impossible without it. There is, however, the danger that such analysis will take one further away from, rather than nearer to, the mind of a musician engaged in oral music, for whom such an analysis would seem inappropriate, even meaningless.

A final important aspect of music notation to observe is that, like language, it *selects* some aspects of sound for preservation and discards others. This has important influences on theoretic conceptions of music and, over the long term, on the nature of music itself. To illustrate this we may briefly survey the development of standard Western notation over the past 1000 years or so. The serious scholar should consult Apel (1953), Cole (1974), Karkoschka (1972), and Read (1974) for full details on this topic. I have written elsewhere at more length on psychological aspects of music notation (Sloboda 1981).

Modern Western notation arises, through a complex chain of developments, from *neumes*, which are first found with frequency in religious manuscripts of the eighth century AD. These were used to notate chants to which fixed prayers were sung in religious communities. Example 7.2 shows

Example 7.2. Ninth century neumatic notation. Photograph from Bibliotheque Nationale, Paris.



one of the earliest examples of neumes from a French manuscript *c.*871. The neumes are written above the Greek text and indicate the approximate shape of the melodic contour (the rises and falls in pitch). Thus, ⟋ denoted a

rise, ∖ a fall and ∨ a fall and a rise. Wishart (1977) comments on neumes as follows:

> The neume did not attempt to mark out what we now have come to regard as individual pitches and units of rhythm, but only shapes and contours of melodic lines customary in current practice, and hence also requiring a complete familiarity with current melodic practice, and an adherence to it before becoming usable.

Neumes were designed without any intention of recording music for posterity or dissemination to other places. Rather they served as mnemonics for recall to people already familiar with local performing conventions. A person faced with neumatic notation alone could not possibly reconstruct the melody notated, even to a first approximation.

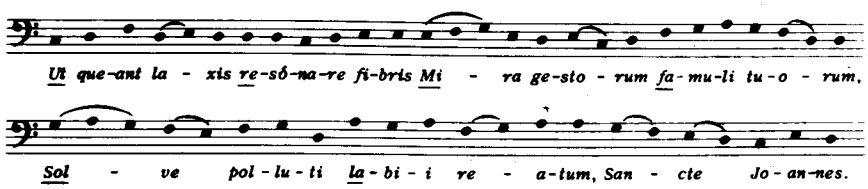
By the twelth and thirteenth centuries, music notation had undergone a series of changes which significantly widened and decontextualized its use. First, symbols became linked to conceptually static entities, 'notes' rather than mobile 'contours'. A note is a sound which remains notionally at the same pitch for the whole of its duration. Second, a means of calibrating the pitch distance between notes was devised by the introduction of stave lines. In the earliest examples, only one line was supplied, identifying a single fixed pitch. In Example 7.3 from the tenth century, the fixed pitch is F below

Example 7.3. Tenth century neumatic notation. From Read (1974).

middle C. It requires some guesswork to decide what the other notes might be. Eventually, however, multiple lines became the rule, as we know them today, with lines and spaces indicating principal melodic pitch levels. Third, aspects of timing began to be notated through the shape of the note symbols. At first, such timing distinctions were fairly crude (e.g. long, short, very short) but gradually the binary subdivision of time units into halves, quarters, eighths, etc., became codified. Whilst notation was linked to chanted texts, timing information was arguably not so important, since the performers were all singing the same text, whose words regulated the timing. The accurate notation of time was, however, crucial to the development of polyphony and instrumental music. An accomplishment such as the performance of a string quartet would be totally impossible were there not accurate means of ensuring synchrony and coordination among the instruments (see Sloboda 1981). Although notation is not the only possible means of promoting synchrony, it has undoubtedly contributed to the rapid development of complex polyphony in Western culture.

For any notational system to work beyond the immediate realm of particular social groups it must become systematic and reliable. This is accomplished mainly by the existence of a small number of finite and discrete

constituents out of which all music can be constructed by combining the constituents. But natural music, particularly that of the voice, is not necessarily made up of discrete elements. Pitch, timing, timbre, loudness can all vary continuously along the various dimensions of sound. Fitting vocal music into the procrustean bed of discrete notation can thus be very unreliable, it would seem. Unreliable, that is, unless the voice actually conforms to the requirements of the notational system by tending towards discrete 'jumps' along the dimensions under its control, particularly the pitch dimension. Within contemporary Western culture it is certainly true that much vocal music aspires to the discreteness that our notational system embodies. Early school training involves emphasis on singing 'in tune' and 'in time', avoiding pitch glides and gross deviations from small whole-number subdivisions in timing. Performed music is thus 'like' notated music in crucial respects. Explications of pitch and time within conventional music theory embody this discreteness through elaborations of concepts of scale, metre, etc. (see Chapter 2). Thus theory, notation, and performing practice form a mutually supporting closed system within which music can be described, notated, transmitted, and understood.



Although notation helped cement theory and practice over the ages, it would, I believe be wrong to assume that pre-notated vocal music had no qualities of discreteness in the pitch and other dimensions. At any stage of history, a notational system used in performance would have to be perceived as providing a relatively good fit to current practice before it would be accepted by performers. We know that discreteness exists in contemporary oral cultures, although it is often blurred through a greater freedom in the use of microtonal and microrhythmic embellishment. Above all, we know that, since prehistory, musical *instruments* have possessed the precise qualities of discreteness that conventional notation codifies, at least in the pitch domain. A plucked string issues a single unchanging pitch. A set of pipes or strings offers a set of relatively fixed pitches, and music played on such instruments must, of necessity, be confined to this set. To notate instrumental music with discrete pitch symbols is not a procrustean operation. It very closely mirrors the sonic state of affairs. In so far as we can assume that the sounds of fixed pitch instruments would influence the vocal practice of oral musicians, we have good reason to suppose that instruments have provided a continuous force towards discreteness in vocal practice.

We may also note that early theories of harmony were based on discrete pitch intervals, and that theoretical notations employing alphabetic conventions were used by Ancient Greek and Chinese writers. However, we should not, perhaps, make too much of this, because until the late Middle-Ages music theory based on the properties of vibrating strings and air columns, as codified in the writings and notations of philosophers, had almost nothing to do with the actual practice of making music. It would not have occurred to philosophers to use their notations and theories to record con-

temporary musical *practice*. We know almost nothing about what Ancient Greek singers and instrumentalists actually did from the writings of these theorists. This is also true of early medieval writers such as Boethius (*c*.480–524) who taught that performers and composers were 'separated from the intellect of musical science'.

What makes the later development of notation in medieval Europe so different is that it was rooted in *practice*, drawing theory, so to speak, in its wake. Furthermore, it arose in a religious context where instruments were frowned upon (although such instruments as the organ became gradually acceptable from the eighth century on: Caldwell 1978). Instrumental music was almost entirely secular—the province of the essentially oral laity—and it did not begin to be notated until long after stave notation was widely accepted.

The acceptance of stave notation seems to rest largely upon the work of Guido of Arrezzo (*c*.1000–50). It is he who is generally credited with the completion and systematization of the four-line stave still used for plainchant notation today (Hoppin 1978). Guido was fully aware of the importance of the need that his own system filled. He was able to 'produce a perfect singer in the space of one year, or at the most in two' whereas previously 10 years of study had yielded 'only an imperfect knowledge'. With his system, singers could now read and perform a melody they had never heard before. As well as perfecting the four-line stave system, Guido was also responsible for devising the 'sol-fa' mnemonic for singers. This is a way of remembering the pitch relations between notes on the stave by referring back to notes in a well-known melody The melody he chose was the hymn to St John the Baptist, '*Ut queant laxis*' (Example 7.4). This hymn 'spells out' a six-note

Example 7.4. Plainsong hymn to St. John the Baptist. From Hoppin (1978).

scale, *ut–re–mi–fa–so–la*. The system, with minor modifications is still in use today, although the archaic '*Ut queant laxis*' has been replaced with more appropriate contemporary songs (as immortalized in Rogers and Hammerstein's *Sound of Music*).

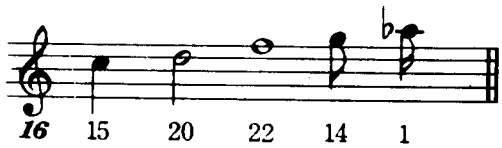
Guido's system rapidly spread through Europe, and soon, all chants of the Roman liturgy had to be notated within his system. That not every existing chant fitted into this system easily is suggested by the fact that some chants underwent significant rewritings and transpositions over the years which can be seen as attempts to 'bring them into line' (Hoppin 1978).

The notational system perfected by Guido paved the way for the emergence of a new breed of musician, the sight-reader (see Chapter 3, section 2). This is the performer who uses notation to give a reasonably polished performance of music without prior rehearsal. He does this through his intense familiarity with the notational system. With advances in printing techniques and resultant increases in legibility, sight-reading reached its apotheosis in the present century.

One should emphasize that the selectivity of music notation does not *force* performance practice to be restricted to what is notated. Even with standard Western notation, performers still have considerable interpretational latitude (see Chapter 3), and one requires much more than the ability to read music to give a culturally acceptable peformance of a Beethoven sonata. What our notation does is to fix a level of detail at which we are prepared to say that anyone providing a performance in accord with the notation has provided a performance of *that* piece, and no other. Thus, the most idiosyncratic and ill-informed performance of a Beethoven sonata is still *that* sonata. This would not be true of someone attempting to provide a performance of Gregorian chant from early neumatic notation. The notation is just not specific enough. Modern notation is normative in a way that early neumatic notation could not be. This does not, however, prevent modern notation being used for purposes where it is *not* normative, and where it significantly underdetermines performance (e.g. the baroque ground bass).

Although notation has supported positive developments, it has its negative aspects too. Wishart (1977) argues that the sterile 'dead end' of twelve-tone music was due to a constriction of the musical imagination by the categories implicit in the notational system:

> In its constant search for new modes of expression, the Western classical music tradition was . . . constrained by its very concentration upon relationships of a limited set of thus notatable 'pitches', to extend the notatable field of harmonic relationships to the limit. The final step into a 12-tone and thence 'integral', serial technique, rather than being a 'liberation' from this restricted set tonality, must be seen in historical perspective as the final total capitulation to the finitistic permutational dictates of a rationalized analytic notation system, and the gateway to much sterile rational formalism . . . More subtle uses of pitch, such as sliding inflections, which can vary over an infinitude of possible speed, interval of sliding and curvature of the slide . . . were not amenable to this finitistic approach.



The freedom from sterile and formal music has been made possible, not so much through new notational systems, as through the opportunity now afforded to composers to bypass notation entirely and compose directly into sound with the assistance of electronic machines. This is partly because it is difficult to see how *any* notational system could cope with things like sliding inflections reliably; and partly because the fixed 12-tone system has become enshrined in conventional instrument technology. One cannot do pitch glides on a piano.

I have suggested that the selectivity of music notation reinforces the tendency to view musical elements as falling into discrete categories, a tendency which is, in any case, encouraged by the existence of discrete pitch instruments. We may still be entitled to ask, however, *why* it is that man has favoured fixed pitch instruments for his music. It has recently been argued (e.g. Balzano 1980; Pressing 1983) that discreteness in both the pitch and time dimensions are essential if music is to serve certain communicative functions. We shall see, in the following discussion, that much music in both oral and literate traditions shares basic characteristics, in view of which we must conclude that even such potent cultural forces as notation are not all-important in determining the nature of music.

7.2.2. *Musical universals*

We have examined one factor which can contribute towards cultural variation in music. There are, of course, many other such factors. For instance, not all cultures support the existence of musician 'specialists' such as composers, instrumentalists, etc. This can have a profound influence on the type of musical activity that takes place. Is it possible that, despite all such factors, there are some underlying features which typify most music? If there are, then these might be related to some universal cognitive basis for music which transcended individual cultures. We have already suggested the possibility of primitive auditory grouping strategies playing a part in the way that music is heard (Chapter 5.2). Another possible set of universals arises in connection with the use of the pitch dimension in different cultures.

A very large number of cultures contain, both in theory and practice, the notion that music takes place with respect to fixed *reference* pitches. These pitches need not be fixed for all time, but are usually fixed for the duration of a single piece of music. In many cultures, the principal reference pitch (or pitches) are maintained throughout the music in the form of a (usually instrumental) 'drone'. Even where drones are absent, we can usually see that certain pitches are 'privileged', in that the music often returns to them, and circles round them. Ethnomusicologists sometimes represent this feature by deriving a *weighted scale* for a given piece of music. This orders the principal pitches in ascending sequence, and associates with each pitch a notated duration which roughly reflects the number of occurrences of that note in the piece. Example 7.5 for instance, gives the weighted scale associated with a particular Aboriginal song (Malm 1977). It shows that there are five principal

Example 7.5. Weighted scale notation. From Malm (1977).

notes, with F occurring most frequently, and A flat occurring least frequently.

Thus, although tonality, as we know it, is by no means universal, the notions of scale and tonic have formal analogies in most cultures. One of the influences on the development of fixed discrete points along the continuum is, as we have argued earlier, the existence of instruments which are either of permanently fixed pitch (e.g. the *metallophones* such as gongs, bells, and xylophones) or else which can be tuned, but which offer a fixed set for the duration of a single performance (e.g. the stringed instruments such as harp, sitar, or guitar). Moreover, within most of these scales the *octave* appears to be a particularly privileged interval. The disposition of pitches repeats within each octave, and the octave frequently appears as an interval in polyphonic music. It is particularly common to find the principal reference pitch being reinforced by voice or instruments at several different octaves. In addition, intervals close to our perfect fifth and perfect fourth appear in the polyphony of most cultures.

The similarities do not end here, however, because it seems that the subdivisions of the octave into scale steps follow common principles in most cultures. First, the number of subdivisions is always moderately small. Miller's (1956) 'magic number seven plus or minus two' would encompass most of the world's scales. Particularly common are five- and seven-note scales. In fact, the term *octave* derives from the fact that, in a seven-note scale, the eighth note marks the start of the repetition of the scale pattern at a pitch with a frequency of approximately double that of the first note. A second similarity is that practically no scale divides the octave up into equal ratio steps. In other words, scales are almost never found where the pitch intervals between adjacent notes are the same for each and every pair. Rather, scales are composed by selecting from a number of smaller (often notionally equal) steps, but in such a way that there are different numbers of steps between some of the adjacent scale members. Thus, our own diatonic major scale selects seven notes from a nominal equal-interval 12-note chromatic scale (Fig. 7.1). The Indian *Sa-grama* scale is derived from a theoretical 22-interval *sruti* scale (Fig. 7.2).

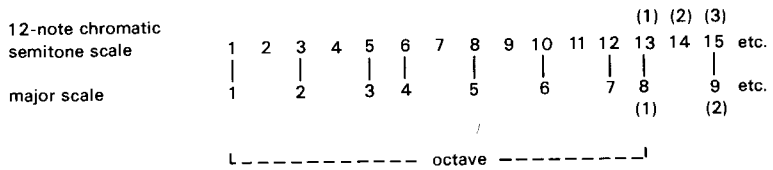


Fig. 7.1. Octave subdivision of the diatonic major scale.

The ubiquity of this unequal interval principle leads one to ask whether it serves some fundamental psychological purpose. It has been suggested earlier (Chapters 2 and 5) that one consequence of this unequal distribution is to allow a listener to 'get tonal bearings' on hearing a subset of the notes of a

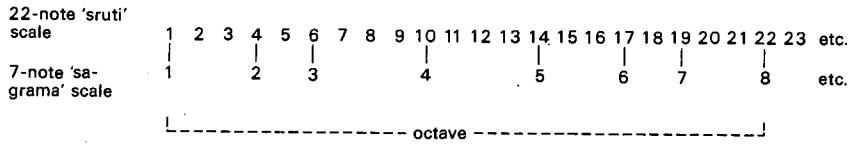

Fig. 7.2. Octave subdivision of the Indian sa-grama scale.

scale, without any necessary explicit marking of the tonic by repetition or priveleged performance treatment. For instance, in the case of a major scale, the interval separating notes four and seven (six semitones) is unique. No other pair of notes is separated by this interval (the *tritone*); and so a listener hearing a melodic sequence such as 4–7–8 in a major scale can identify the last note played as the tonic. In the Indian *Sa-grama* scale, the interval between notes three and five is similarly unique (eight *sruti*), at least in theory.

Shepard (1982) argues that it is this property of uneven spacing which

> enables the listener to have, at every moment, a clear sense of where the music is with respect to such a framework. Only with respect to such a framework can there be things such as motion or rest, tension and resolution, or, in short, the underlying dynamisms of tonal music. By contrast, the complete symmetry and regularity of the chromatic and whole-tone scales means that every tone has the same status as every other. The fact that for such scales there can be no clear sense of location, and hence of motion is, I believe, the reason that such scales have never enjoyed wide or sustained popularity as a basis for music.

It has been further argued (e.g. Balzano 1980) that the burden of the musical significance of a scale rests, not in its precise tuning, or in the degree to which perfect whole number frequency ratios are represented between its members (e.g. 3:2, 4:3, etc.), but in the configuration that the scale takes up by virtue of selecting its members from a larger set of notionally equal steps. Although 'perfect' intervals have been *historically* important in the development of scale systems, scales achieve much of their psychological significance through configurational properties which Balzano has captured in terms of group-theoretic notions borrowed from mathematics. As he points out,

> When we look at the Just, Pythagorean, and Equal Temperament tunings of our familiar major scales, it is evident that there is an important sense in which they all work in substantially the same way: we don't have to learn to compose or hear separately for each one. The ratios, which are different in all three tuning schemes, do not really address this fundamental commonality.

The evidence we have already reviewed on categorical perception (Chapters 2 and 5) shows that precise tuning of intervals is without psychological consequence in many situations. What Balzano has done is to formalize the level of description at which we can see that all the various tunings of the major scale are doing the same (group theoretic) job. It is only possible for a very limited number of other scales to perform the same functions.

One function of a scale, as we have argued, is to give a listener a sense of *location* by virtue of the different intervallic relations that hold between the various members. If this was the only function of a scale, then the 'best' kind of scale would be of the type illustrated in Fig. 7.3 where intervals between

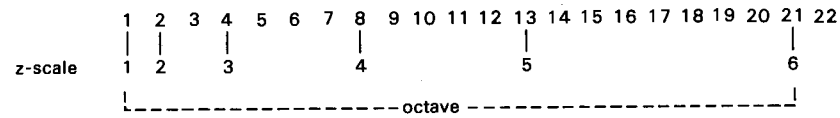

Fig. 7.3. Octave subdivision of the 'Z' scale.

adjacent notes are all different, and most non-adjacent intervals are different too. We can arbitrarily name this scale, based on a 20-fold division of the octave, the Z-scale. There are other properties of scales like the major scale, however, which the Z-scale does not share. Perhaps the most important of these is the special relationship that holds between the twelve major scales generated by starting on each note of the chromatic scale in turn. Each scale shares all but one of its notes with the scale that starts on its fifth degree. The fourth note of the old scale is sharpened to form the seventh note of the new scale; and by recursively performing this operation round the 'circle of fifths' one can generate all the major scales. This allows concepts of scale- or key-relatedness to enter music. G major is *close* to C major because it shares all but one note. F sharp major is *remote* from C major because it shares *only* one note. The Z-scale does not have this property. There is nowhere that one can start a Z-scale which causes an overlap of all notes but one with another Z-scale. One can see, intuitively, that the large number of different intervals makes that impossible. The major scale contains only two types of interval between adjacent notes, tone and semitone; and it seems that this property is crucial.

Balzano (1980) has demonstrated that there is a restricted set of artificial scales which share crucial group-theoretic properties with the diatonic major scale. These scales require the octave to be subdivided into 12, 20, 30, or 42 equal intervals, or any larger number given by the formula $n(n-1)$. Each of these subdivisions yields one, and only one, scale type with the desired properties. For the 12-fold division, that scale is the diatonic major scale. For the 20-fold division, that scale is the nine-note scale given in Figure 7.4. Its closest relation is generated by starting on the fifth degree and sharpening

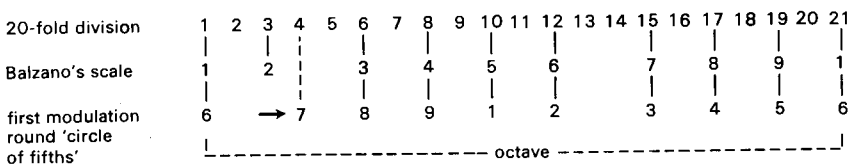

Fig. 7.4. Octave subdivision of Balzano's (1980) nine-note scale.

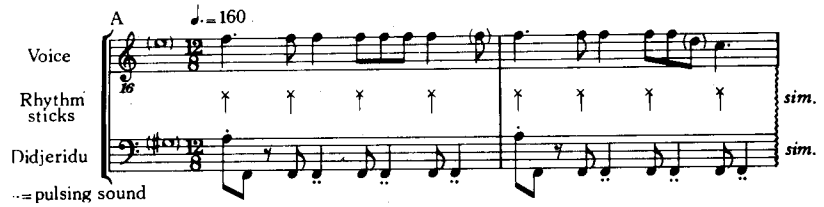
just one note (the second note of the old scale). Applying this operation recursively yields all 20 possible scales of this mode. Note that there are only two different intervals between adjacent notes, 2/20 or 3/20 of an octave. It is a general feature of Balzano's scale set that the two intervals which are found between adjacent notes are separated in size by just one subdivision of the octave. So, the eleven-note scale derived from a 30-fold subdivision of the octave has adjacent intervals of either 2/30 or 3/30 of an octave. The 13-note scale derived from a 42-fold subdivision of the octave has adjacent intervals of either 3/42 or 4/42 of an octave. As the size of the subdivisions becomes smaller, the absolute and relative difference between these intervals becomes smaller. It is much easier to discriminate between a tone and a semitone than between the analogous intervals in the other scales of the set. It can be argued, therefore, that the 12-fold division is psychologically optimal; and although Balzano advocates the experimental use of the other microtonal scales in computer music, it is perhaps not surprising that there is little evidence of these other scales having been developed in the world's cultures.

The considerations on which Balzano bases his formulations are essentially algebraic. Traditional formulations of scale structure have been essentially acoustic, pointing to the natural occurrence of some scale intervals in the harmonic series. The 12-note chromatic scale can be seen as the single system which satisfies both algebraic and acoustic constraints, and to which music therefore, in some sense, tends. Three observations support the centrality of the diatonic scale:



1. Many pentatonic scales are based on a subset of the full diatonic scale, and so can be converted to a diatonic scale by the addition of two further notes.

2. Far from being a recent Western invention, the diatonic scale can be traced back to the most ancient tuning systems so far deciphered from archaeological records (Kilmer, Crocker, and Brown 1976; cited in Shepard 1982).

3. Even in cultures where the octave is *theoretically* divided into other than 12 parts, practice often diverges from theory in the direction of a 12-fold system. Thus, for instance, although we have seen that Indian music theory postulates a 22-fold division of the octave in its *sruti* scale, contemporary music practice seems to be based on a 12-fold subdivision of the octave though each has a fairly wide range of tolerance as to the actual pitch (Jairazbhoy 1971). It is important to remember that many excellent Indian performers have no overt knowledge of, or interest in, music theory (Malm 1977).

We now move from the pitch domain to a consideration of possible musical universals in the temporal domain. Just as reference pitches seem universally important, so do reference *times*, important moments in relation to which other sounds are organized; and, just as many cultures maintain the reference

pitch in awareness through the use of a drone, so many cultures maintain reference times in awareness through the use of instruments marking out a regular pulse or metre. The simplest pulse involves a series of equally spaced sounds, such as is provided by a clock ticking, but in nearly every culture, such a basic pulse becomes elaborated through intermediate detail. Example 7.6 shows the first two 'bars' of an Australian Aboriginal song given by

Example 7.6. Opening of Aboriginal song. From Malm (1977).

Malm (1977). Here we see that the rhythm sticks provide a basic unadorned pulse. The didjeridu is, however, doing something more complex. It synchronizes with each beat of the rhythm sticks, but adds a second 'pulsing' sound after each beat, which has the effect of subdividing the beat, marking its passage by an asymmetric disposition of sounds (the long 'pulsing' sound marks the end of the beat, the shorter sound the beginning). Through such asymmetry, a sense of *location* within the beat is created. Such ascribing of location is given the general name of *accenting*, and it is crucial to the music of nearly all cultures. Differentiation through accenting can be achieved in a variety of ways. For instance, the time subdivision can be symetrical, with asymmetry in terms of pitch or dynamic pattern. This can also be seen in the didjeridu part of Example 7.6. Every fourth pulse of the rhythm sticks is marked by a pitch change in the didjeridu, thus creating a superordinate pulse, which justifies the positioning of the bar-lines in the transcription.

Thus, a hierarchy of reference times can be created, since a superordinate pulse can itself form the basis of a yet higher grouping. In Javanese Gamelan music, for instance, the fundamental time unit is the *gongan*. Each *gongan* is marked by the sounding of the largest gong in the ensemble. The *gongan* is divided into two equal halves by the sounding of the *kenong*. Each *kenong* is divided into two equal halves by the sounding of the *kempul*. Each *kempul* is divided into two equal halves by the sounding of the *kethuk*. Each *kethuk* may then be further subdivided (a *kethuk* corresponds very roughly to a bar in Western music, so a *gongan* is an eight-bar unit).

When a pulse unit at some level is subdivided asymmetrically in time, we usually talk of the subdivisions as forming a rhythm, or rhythmic pattern. Just as scales are usually made up by selecting pitch intervals asymmetrically from a larger set of small equal intervals, so rhythmic patterns are made up by selecting time intervals asymmetrically from a larger set of small equal time intervals; and in the same way that scales tend to repeat at the octave,

so rhythmic patterns tend to repeat in such a way as to mark off time into equal segments.

One of the simplest rhythms of many musical cultures is the *dactyl* (a long interval followed by two short ones). In Western music, this is notated as a minim followed by two crotchets, and signifies the selection of the first, third, and fourth of four equal underlying beats for marking. When this figure is repeated over and over in an *ostinato*, most listeners hear the long note as strongly marking (*accenting*) the beginning of the next four-beat grouping. On the whole, in Western music, the underlying and repeating sequence of equal time units (metre) from which rhythmic patterns are derived tends to contain small even numbers of units. The dactyl requires a four-unit metre, but six and eight are also very common. Furthermore, rhythmic asymmetries are often constructed on a principle of binary subdivision of the metrical unit. Thus, we can conceive of the dactyl as being constructed by subdividing the four-unit metre into two equal halves containing two beats each. The first half is then 'filled' by a single note, whilst the second half is further subdivided into two equal 'quarter notes'.

In some other cultures (e.g. Southern Africa and India) we find more complex rhythms. First, the number of beats contained within the metrical unit can be large and uneven. In Indian music, *tala* of between seven and sixteen beats are common. Second, subdivisions are frequently not made on a principle of binary subdivision. When the number of beats is odd, binary subdivision is impossible; but even when there are an even number of beats we often find non-binary subdivisions. Consider, for instance, the rhythmic pattern of the drum parts in Example 7.1 (South African Venda song). The pattern repeats every twelve beats, but the effect of the two long notes (crotchets on the lowest stave) is to create an unequal subdivision of five plus seven.

The ability of rhythm to give a listener a fine-grained sense of temporal location within the metrical unit through asymmetric subdivision of time units suggests that, in some sense, complex rhythmic structures perform the same kind of cognitive functions that are supported by diatonic tonality in our culture (Pressing 1983). Regardless of how far this analogy can be pursued, it is certainly true that scale and rhythm perform the same essential function, that of dividing up the pitch and time continua into discrete and re-identifiable locations, on which backdrop all the essential dialectical activities (tension–resolution, motion–rest) can flourish.

Finally, these fixed points provide cues for synchrony, so that musicians can organize their behaviour with respect to what others are doing. A universal feature of polyphonic music is the temporal and pitch co-ordination of the parts. Without reference points, it would be impossible for people to make the necessary anticipatory and planned adjustments to bring their behaviour into co-ordination with others, and thus make musical behaviour the structured *social* phenomenon that it is the world over.

7.3. Biology and musical thinking

7.3.1. *The neural organization of musical function*

On 9 October 1959 the distinguished Russian composer V. G. Shebalin (1902–63) suffered a severe stroke. When he recovered consciousness he was suffering from a partial paralysis which affected the right side of his body. He also suffered severe disturbance in speech function, which remained with him to the end of his life. He found it hard to understand, produce, or reproduce speech. About a year after his stroke, for instance, when asked to repeat three short sentences: 'The moon is shining. The house is burning. The dog is barking', he replied: 'The moon is shining . . . and the house . . . no . . . I really don't understand.' In trying to describe his compositional history he offered:

> An oratorio is descended . . . it was a long time ago . . . that is a kind of spiritual . . . oh . . . gradually it became . . . it was extended . . . and then . . . and now . . . gradually . . . ah . . . it became very different . . . how may I say . . . I have to recall . . . oh . . . nothing . . . I have thoughts . . . no . . . it is too difficult . . .

Reading and writing were also disturbed, although not so badly.

Despite these severe difficulties (as Luria, Tsvetkova, and Futer 1965, report) he continued to work as a composer.

> He worked hard with his pupils, listening to their compositions, analyzing and correcting them. He spent a considerable time over his own creative work. While aphasic, he finished compositions which he had started to write before he was taken ill, and he created a series of new compositions which other musicians considered to be up to standard, and which did not significantly differ from the compositions of his earlier years.

Of his Fifth Symphony, composed in 1962, Dimitri Shostakovitch said, 'it is a brilliant creative work, filled with highest emotions, optimistic and full of life. This symphony composed during his illness is a creation of a great master.'

How is it possible that a man's verbal ability could disintegrate, leaving his musical intellect unchanged? A large body of evidence has now been amassed to support the view that intellectual functions are localized in different areas of the brain, so that damage to one area may only disrupt a proportion of normal intellectual functions. Post-mortem examination of Professor Shebalin revealed massive damage in the left temporal and parietal regions of the brain, but not elsewhere. Such damage is often associated with language disorder, and sensorimotor defects on the right side of the body.

In order to discuss this issue in more detail, it is necessary to outline a few basic neuroanatomical facts. The human brain (and body) is divided into two roughly symmetrical halves. Each half of the brain receives nervous input from, and issues nervous commands to, one side of the body. However, for reasons which are not well understood, there is a 'crossover' of nerves

going in and out of the brain, such that nerves belonging to the right side of the body connect with the left brain, and nerves belonging to the left side of the body connect with the right brain. We say that nervous organization is essentially *contralateral* (literally 'opposite sided').

The part of the brain which seems most deeply implicated in learned cognitive skills is the cerebral cortex which, in man, is the largest part of the brain. The cortex surrounds the rest of the brain like a thick cap, but it is divided down the midline into two cerebral *hemispheres*. Although the two hemispheres are to a certain extent capable of independent operation, they are connected by a fat bundle of nerve fibres called the *corpus callosum*. When this is intact, information can be transferred from one side of the cortex to the other. In most animals, each cerebral hemisphere seems to do roughly the same job. In some higher mammals, however, especially man, there is now incontrovertible evidence that each hemisphere is, or becomes, specialized to some degree. For most people (the 90 per cent or so who are unambiguously right-handed) the mechanisms controlling language behaviour seem to be primarily concentrated in the *left* hemisphere, and those controlling spatial orientation and other non-verbal skills seem to be concentrated in the *right* hemisphere.

There are several converging sources of evidence which support this conclusion:

1. Studies of people with brain damage show that left-hemisphere damage is often associated with language disorder (as in the case of Professor Shebalin), whereas right-hemisphere damage rarely causes significant language disruption.
2. By temporarily anaesthetizing one or other hemisphere, one can selectively disrupt different intellectual functions. For instance, Gordon and Bogen (1974) found that left-hemisphere intervention caused speech disturbance whilst right-hemisphere disturbances caused disruption of singing.
3. One can observe asymmetries of various sorts in the gross electrical activity of the brain which alter according to the task being carried out. For instance, McKee, Humphrey, and McAdam (1973) took electroencephalograph (EEG) recordings from points on the scalp above the temporo-parietal regions of both hemispheres. They took recordings whilst subjects carried out various musical and linguistic tasks. The left hemisphere was more active during the linguistic tasks than during the musical ones.
4. When linguistic or non-linguistic input is restricted to one ear, then linguistic material is better processed if it is presented to the right ear (left hemisphere), and non-linguistic material such as music is better processed if presented to the left ear (right hemisphere). A well-used technique is that of 'dichotic presentation' in which two different stimulus sequences are simultaneously presented to the two ears (e.g. Kimura 1964, 1967). When the two messages are speech sequences then the message reaching the right ear

tends to be better perceived. When the two messages are musical sequences then the pattern tends to be reversed, with the left ear doing better.

The literature on hemispheric specialization is very large, and is growing all the time. Recent general introductions to the area are provided by Springer and Deutsch (1981), and Kinsbourne and Smith (1974). Reviews of the literature with particular respect to music have been provided by Benton (1977), Damasio and Damasio (1977), Gates and Bradshaw (1977), Marin (1982), Shuter-Dyson and Gabriel (1981), and Wyke (1977). Rather than attempt to review this large, and not altogether homogenous, body of research, I will confine myself to a critical examination of a few of the most noteworthy findings in the area, those that seem to have particular relevance for the arguments that we have been pursuing in the rest of the book.

The first point to make is that music is not a single, monolithic, capacity which either exists in an individual or does not. Musical skill has many, logically independent, sub-skills which may, therefore, be anatomically independent as well. A region of a cerebral hemisphere is a very big place in neural terms, and even if it were possible to assert that music was 'in' a part of the right hemisphere, it would still be pertinent to ask whether different components of the skill were in different anatomical locations *within* that region. Psychologists have been particularly alerted to the possibility that very specific sub-skills can be considered as functionally and anatomically distinct by finely analytic work carried out over the last decade or so on people with language disorders caused by brain damage (see Coltheart, Patterson, and Marshall 1980). It has been known for many years that a person may suffer receptive disorders of language without production being affected, and *vice versa*. The recent research goes beyond this in demonstrating that disruption may be confined to a specific *part* of a single skill like reading. Thus, for instance, a person may be able to read familiar concrete nouns, but have the greatest difficulty with connectives and other function words (e.g. 'and', 'which', 'that', etc.). This is important psychologically, because it shows that the mechanisms by which content and function words are understood must be, to some extent, functionally distinct.

Using such an analytic approach it has been discovered that language function is not entirely confined to the left hemisphere, even in fully right-handed people. For instance, it seems that the right hemisphere can understand words and simple sentences provided that such understanding can be signalled by non-verbal actions, such as obeying a command, pointing to, or picking up a named object.

One of the major problems in studying the effect of brain damage on musical skill is that the level of skill prior to damage can be very varied, and is often unknown; whereas most people have a high, and verifiable, level of linguistic skill prior to damage. The most informative musical cases are those where the patient was a professional musician before receiving brain damage. Here we can be fairly sure what skills were present prior to damage. Thus, a

case like that reported by Wertheim and Botez (1961) is of particular interest. The patient they studied was a professional violinist known to have perfect pitch before brain damage. He developed right sensorimotor disturbances consistent with left hemisphere damage, and experienced difficulties in receptive aspects of language functioning. Some aspects of music function remained undisturbed. These included:

1. Reproduction by singing or violin playing of single pitched notes.
2. Pitch discrimination down to intervals smaller than a semitone.
3. Noticing differences between pairs of melodies or chords.
4. Detection of tonal violations in melodies.
5. Naming of single written notes.
6. Identification of major and minor scales.

Other aspects were disturbed. These included:

1. Loss of perfect pitch (i.e. the ability to name pitches).
2. Inability to recognize familiar pieces of music, or to identify composer and/or style.
3. Inability to identify melodic intervals.
4. Inability to reproduce rhythmic patterns.
5. Inability to read note sequences.
6. Errors in singing familiar melodies.
7. Errors in copying and transcribing music.

The pattern of disorders does not admit of easy explanation, but Marin (1982) suggests that the pattern is compatible with preservation of simple perceptual abilities (pitch discrimination, pitch reproduction) along with some highly overlearned and automated knowledge structures (the major and minor scales, basic tonal progressions) together with the loss of recognition and identification of musical sequences, particularly where some lexical operation (such as naming) is required.

This patient shows a very different profile of disorders to Professor Shebalin, who seems to have suffered no musical loss at all. It turns out that Shebalin is rather unusual in the clinical literature. There exist only about twelve reported cases of language disorder in musicians which is unaccompanied by musical disorder. More commonly, both language and music are affected, especially when damage occurs to the left hemisphere. There is also a small group of documented cases where musical disorder (primarily of a receptive nature) is unaccompanied by noticeable language disruption. In these cases, brain damage is usually in the right hemisphere.

We see, therefore, that although right hemisphere damage nearly always disrupts musical functioning in musicians, left hemisphere damage often disrupts it too. It is, therefore, oversimplistic to say that music is 'in' the right hemisphere. What the complex, and somewhat unsatisfactory literature on

brain damage does at least show is that musical skills are just as dissociable and separately disruptable as are language skills.

For further insight into the neural organization of musical skill we turn from studies on brain-damaged patients to a series of studies on normal intact subjects. The line of enquiry I wish to focus on was initiated by Bever and Chiarello (1974). In their experiment they used two groups of subjects. 'Musicians' were those who had been attending music lessons for at least five years, and were currently playing or singing. 'Non-musicians' were those who had received less than three years of music lessons and had not been musically active in the last five years. The subjects were all right-handed. They listened to a tape of specially prepared melodies, and were asked to say whether each melody had occurred before in the sequence. Half the subjects had the melodies presented to the right ear (left hemisphere) and the other half had them presented to the left ear (right hemisphere). Bever and Chiarello found that non-musicians performed best when the melodies went to the left ear. This confirmed the 'traditional' view that music is processed in the right hemisphere. The musicians, however, showed exactly the reverse pattern of results; they performed best when the melodies went to the *right* ear.

Bever and Chiarello attempted to account for these results by recourse to the widely held view (first proposed by Hughlings-Jackson, see Taylor 1932) that the left hemisphere is specialized for 'analytic' and 'sequential' processing, whilst the right hemisphere is specialized for 'holistic' or 'global' processing. On this view, the 'crossover' of laterality in music recognition occurs because the musicians adopt a analytic strategy whereas the non-musicians adopt a holistic strategy. The terms 'analytic' and 'holistic' are rather broad in their connotation, but their application to music has been taken to relate to such distinctions as that between processing the contour of a melody and processing the precise pitch intervals of which the melody is composed (see Chapter 5.3), the former being a holistic process, the latter being analytic.

The work of Bever and Chiarello has stimulated a spate of experimental studies looking at the way in which musical ability and experience, processing strategy, and stimulus material, interact to give different patterns of hemispheric differences. It seems that the left hemisphere advantage is not confined to musicians. People who score highly on a test of musical aptitude tend to show left hemisphere advantage, regardless of training (Gaede, Parsons, and Bertera 1978), as do non-musicians who consciously adopt an 'analytic' strategy in a music perception task (Peretz and Morais 1980). It would be fair to say that the literature does not yet provide a fully coherent picture of hemispheric asymmetry in musical function. The differences between left and right ear scores, although statistically significant, are often very small, and they are highly sensitive to the nature of the task, the stimulus material, and subject strategy. In addition, experimenters have by no means tapped the whole range of musical activities, concentrating on the recognition of small

changes in chords or brief melodic sequences. For all these reasons, although the analytic–holistic distinction seems a current 'best bet' as an explanation of left–right differences in normal subjects, the picture is by no means complete.

Marin (1982) argues cogently that the study of the neurological bases for music will not advance substantially until the categories and distinctions between musical activities made on psychological and music-theoretic grounds are taken seriously by researchers. Too often tests are devised on the basis of methodological convenience rather than with precise and well-grounded musical considerations in mind. Traditional distinctions between, for example, receptive and productive skills, are just not fine-grained enough to tell us, for instance, whether the phenomenon under study operates at the phonological, syntactic, or semantic level (Chapter 2).

What we can see clearly, even in this rather incomplete picture, is that various sub-skills of music have a certain degree of neural independence. There is little evidence for a single 'music centre' in the brain. Furthermore, the brain areas responsible for music seem to have a partial, but incomplete, overlap with those responsible for language. We should, therefore, not be surprised if the behavioural and cognitive analogy between music and language (Chapter 2) is, whilst compelling, not complete. Music, if not a totally distinctive neural function, almost certainly employs a distinctive configuration of neural resources.

7.3.2. *The origins and functions of music*

The principles of evolution and natural selection propounded by Darwin continue to play a central role in theories of biological development (Dawkins 1976). Darwin proposed that man's music evolved from the vocalizations of sub-human primates like the apes (Darwin 1874, Chapter XIX) which served as 'emotional' signals. Correct though Darwin's general theory may be, his explanation of musical evolution is far from satisfactory. For one thing, the vocalizations of apes seem to be involuntary patterns, having more in common with human behaviours like laughing, crying, and screaming, which survive very distinctively in humans as something quite different from music. For another, ape vocalizations do not share any of the organizational qualities of human music. They are not based on scales or rhythmic patterns, as are all human forms, and they do not show any of the the planning or purposiveness that characterize other areas of ape behaviour such as locomotion and manipulation of objects. If apes have an intellect, there is little evidence that their vocalizations are at its service. It is for this reason that attempts to teach chimpanzees a vocal language have been such a dismal failure. Only when chimps were taught a manual sign-language was any modest progress made (e.g. Gardner and Gardner 1969).

Darwin's notion was that the most musical (i.e. pitched) sounds of apes were produced by the male during courtship, and that correspondingly man's earliest music was in the form of love songs. Modern ethnological studies force

us to reject both parts of this notion. The call cries of most primates are signal calls expressing 'all is well', 'I am here', 'danger', and variants of these (Marler 1965; Petter and Charles-Dominique 1979; Williams 1980). Williams reports that 'monkeys and apes in fact have no specific sex-calls, and there is no reason for assuming that the ancestors of primitive man serenaded their prospective mates.' Secondly, the most primitive songs about which we know are not concerned with personal love or sexual relations. The poetic songs of the Aborigines, for instance, express the feelings of men and women as members of the community rather than as individuals. Even when fertility is celebrated, it is seen in its wider role of sustaining the natural and social order.

A major function of primate calls seems to be 'group cohesive' (Petter and Charles-Dominique 1979). Calls are used so that members of a social group can locate one another, and indicate their motivational state. It is possible to argue that primitive human music has analogous group cohesive functions. For instance, Blacking (1976) reports that a Venda person can often know exactly what a distant group is doing by the song they are singing. Songs and dance rituals serve to unite and define social groupings. This analogy between apes and men is, however, by no means exact, and fails by itself to account for the temporally organized nature of human music. It seems as if some specifically human tendency to create and notice organized patterns, hierarchies, and sequences, has overrun and overhauled almost every type of behaviour 'inherited' from non-human primates.

Comparing man to his nearest biological neighbours, it has seemed to many that, despite observable similarities, there is an unbridged 'quantum leap' between the highest achievements of apes and what every normal human being can achieve as a matter of routine. Of course, in standard theory, evolution does proceed by discrete leaps, each leap being occasioned by a genetic mutation in an individual. However, simply to state this theory does not provide a satisfactory explanation of any given case. We have no idea if it is possible that a single mutation (or a manageably small number of them) could turn an ape-like creature into something resembling a man. Furthermore, in the case of music, it is not at once clear how musical behaviour makes for better adapted individuals that are more likely to survive; and this, of course, is a precondition for any mutation to be selected for transmission to future generations. This puts music in a special case apart from language and other 'practical' skills whose survival values are numerous and obvious.

Does man *need* music? If he does, then deprivation should be harmful in some way. We know, for instance, that sleep is necessary to humans, since continued deprivation of sleep causes physical and psychological ill effects. On this count music is very unlike sleep. People can go without music for very long periods without suffering noticeable ill effects. Perhaps, however, this is to take a too naïve approach. There are several activities (such as sex)

which are vital for the continuance of the species, but which can be refrained from by individuals without any apparent personal harm. Music may be like this, necessary to the species, but not to any particular individual.

If this is an appropriate line of argument, then the 'unit' for a deprivation experiment might need to be a whole culture. Cultures without music do not, in fact exist, but it seems hard to imagine why lack of music should be harmful to a civilization like our own. We may argue, however, that modern cultures have outgrown the *need* for music, and it is in primitive non-literate cultures that music is of major survival value. Society requires organization for its survival. In our own society we have many complex artefacts which help us to externalize and objectify the organizations we need and value. Primitive cultures have few artefacts, and the organization of the society must be expressed to a greater extent through transient actions and the way people interact with each other. Music, perhaps, provides a unique mnemonic framework within which humans can express, by the temporal organization of sound and gesture, the structure of their knowledge and of social relations. Songs and rhythmically organized poems and sayings form the major repository of human knowledge in non-literate cultures. This seems to be because such organized sequences are much easier to remember than the type of prose which literate societies use in books. It would, perhaps, be an exaggeration to say that there was no logical alternative to music as a mnemonic device. It does seem to me, however, that there are very few things which 'natural' peoples could congenially do with their speech that did not tend towards what we understand as music. They can move their bodies and modulate the timing of their speech. When this is done in an organized way, *rhythm* is created. They may modulate the pitch of the voice. When this is done in a organized way, *melody* and some form of *tonal structure* is created.

We began this book with the observation that music is emotionally appealing to almost all people, and ventured the view that its appeal came *through* its structure, so that there was an inescapable cognitive component to the act of musical appreciation. We have explored the nature of these cognitive structures and processes in some detail through the seven chapters of the book. I have tried to present as complete as possible a picture of what is known about human musical cognition, without too much speculation, but with an eye to the considerable gaps in our knowledge. Perhaps I may be allowed to end on a note of pure speculation with respect to the fundamental question which, in many ways, must motivate all scientific enquiry into music. This question is, of course, *why* does music pervade human culture?

Even though humans have an intellect which, in some respects is very powerful, they do not find it easy to evaluate the long-term effects of their actions, or to predict which course of actions will lead to the most desired result in a complex situation. This is why the development of scientific thinking has been one of the most important steps in human development. It allows a method for arriving at such evalutions by the application of logical

thinking and controlled observations of the world. However, long before the development of scientific method, people were notably successful at mastering their environment. They achieved success precisely through the kinds of mental processes which we can now formally defend as being effective ways of modelling and conceptualizing events in the world. They used these processes, not primarily because they had emerged through a rational process of calculation, or through trial and error, but because it was *appealing* to behave in that way. Evolution had supplied a natural propensity to behave in adaptive ways. This included a propensity to use language and music. Music is indeed of immense benefit as a mnemonic aid, but evolution did not implant a rational awareness of this fact in the human mind. Rather, it supplied a *motivation* for music, so that it became enjoyable and 'natural' for people to indulge in it.

Society has now changed, so that we have many more powerful mnemonics than music available to us. Our instincts and motivations, however, change more slowly. We still enjoy music, and thank goodness we do. Detached from its mundane origins, it can now serve as a vehicle for a whole range of aesthetic and transcendent experiences. Two words of caution are necessary, however. Because our instincts for music are rooted in the conditions that prevailed in the infancy of humanity, the *forms* that were available to early people have a primal and inescapable influence. In particular, it is the *voice* and the human body in rhythmic movement which form the motivational mainspring of music. If music departs too far from this mainspring, it will cease to have deep meaning and power for us. Contemporary musicians have, I believe, already come to realize that the unfettered development of electronic music leads to sterility and lifelessness. Electronic instruments must always be constrained by the parameters of 'human' music making, enhancing and enriching these parameters rather than striking off in arbitrary directions.

The second, final, point is more sombre. For all its achievements, our Western society has a degree of precariousness about it. It is all too easy to construct scenarios which would entail the destruction of the delicate balances which preserve our complex social arrangements. In such a situation, those of us who survived would find ourselves in a world where the artefacts of our present society would, by and large, have disappeared. The resources that we carried around in our heads would, once again, form the mainstay of our attempts to survive. Songs and poems would become vital mnemonic and cohesive tools for the construction of a new society, and musical skill would, indeed be a skill for survival. It is not, therefore, simply a task of disinterested scientific curiosity to come to a better understanding of musical skill. Music is a fundamental human resource which has played, and may well play again, a vital role in the survival and development of humanity.

Yugoslavia, epic poetry of 141–2

What are the mental processes involved in listening to, performing, and composing music? What is involved in 'understanding' a piece of music? How are such skills acquired? Questions such as these form the basis of the cognitive psychology of music. The author addresses these questions by surveying the growing experimental literature on the subject. The topics covered will be of interest to psychologists as windows on to a human cognitive skill of some complexity that is only now beginning to receive the attention that has been given to such skills as language. The book will also be of relevance to musicians who are seeking to understand the psychological bases of their skills. The author does not simply review existing research, but takes a critical look at what has been achieved in the subject, introducing such topics as composition and musical skill in non-literate cultures. He draws freely on his own knowledge and experience as a practising musician as well as a psychologist to provide an overview that is scholarly and also accessible to the general reader.

Dr Sloboda is a Professor in psychology at the University of Keele; he is also a pianist and the director of a chamber choir.

. . . the clarity of Sloboda's writing and his numerous suggestions for further research will make the book essential reading for anyone, student or researcher, interested in how minds and music interact.
Nature

Viewed overall, Sloboda's book deserves loud applause, for its content, for its frankness in dealing with speculative issues largely ignored by other workers, and especially because it brings with it a new kind of approach. *New Scientist*

Sloboda's book must be an essential purchase for all those with an interest in the psychology of music . . . *British Journal of Psychology*

A wholly admirable book which may yet re-establish the place of music psychology in civilized society. *Music and Letters*

List of Contributors xi
Preface xiii

1. The Perception of Musical Tones
R. A. Rasch and R. Plomp

I. The Psychoacoustics of Music 1
II. Perceptual Attributes of Single Tones 6
III. Perceptual Attributes of Simultaneous Tones 14
IV. Conclusion 21
References 21

2. Exploration of Timbre by Analysis and Synthesis
Jean-Claude Risset and David L. Wessel

I. Timbre 26
II. Timbre and the Fourier Spectrum: The Classical View 26
III. The Shortcomings of the Classical Conception 29
IV. Attack Transients 29
V. Complexity of Sounds: Importance of Characteristic Features 30
VI. Instrumental and Vocal Timbres: Additive Synthesis 30
VII. Cross Synthesis and Voice Synthesis 34
VIII. Additive Synthesis: Percussion Instruments 37
IX. Substractive Synthesis 39
X. Acoustic Modeling as a Synthesis Technique 41
XI. The Importance of Context 42
XII. Analysis-Synthesis as Fitting Acoustic and Perceptual Models to Data 44
XIII. The Use of Analysis-Synthesis Models of Timbre 45
XIV. Timbral Space 47
XV. Conclusion 49
Appendix: Signal Representations and Analysis-Synthesis Processes 50

Preface

We shall advance to our conclusions by strict demonstration.
Aristoxenus: *Harmonic Elements*

The above words were written by Aristoxenus of Tarentum (ca. 320 B.C.) in the course of arguing that musical phenomena can be understood only through scientific investigation of human processing mechanisms. Reasonable as this view may seem to modern psychologists, it ran counter to the prevailing theoretical stance, based on Pythagorean doctrine, which has profoundly influenced the study of music throughout history. Most characteristic of this stance is a strong distrust of the evidence of the senses, together with the belief that music ought to be investigated by contemplation of numerical relationships alone. As Anaxagoras (ca. 499–428 B.C.) put it: "Through the weakness of our sense perceptions we cannot judge truth." And later as Boethius, the leading music theorist of the Middle Ages and a strong follower of Pythagoras, wrote in *De Institutione Musicae:* "For what need is there of speaking further concerning the error of the senses when this same faculty of sensing is neither equal in all men, nor at all times equal within the same man? Therefore anyone vainly puts his trust in a changing judgment since he aspires to seek the truth."

There are several good reasons that such a rationalistic position should have been adopted at the time and should have persisted for so long. One reason was a lack of understanding of the nature of sound. One can see that the inability to characterize a physical stimulus should have inhibited development of theories concerning how this stimulus is processed. A related problem was the lack of stimulus control, which made experimentation difficult. Another problem was the lack of mathematical techniques appropriate for the study of probabilistic phenomena.

These factors considered, it appears as no coincidence that the last decade has seen a sudden flowering of interest in the empirical study of music on the part of both psychologists and musicians. The nature of sound is now well understood, and the required mathematical techniques have been developed. Recent advances in computer

technology have enabled investigators for the first time to generate complex sound stimuli with versatility and precision. It has thus become possible to explore such issues as auditory shape analysis, attentional mechanisms in music, the organization of memory for musical information, and so on, with the stimulus control required for tight experimentation. Researchers have been able to build on conceptual frameworks recently developed in other branches of psychology and in music theory. This same technological development has led composers to experiment with the computer as a compositional tool. In so doing, numerous questions in perceptual and cognitive psychology that are of both practical interest to composers and theoretical interest to psychologists have been raised. As a result of this developing interest on the part of both scientists and musicians, we are experiencing a rapid expansion of work in the area of musical processing; and perhaps more importantly, collaboration between musicians and scientists is a rapidly growing phenomenon.

The purpose of this volume is to draw together the diverse and scattered literature on musical processing that has accumulated particularly over the last decade. The work is intended as a reference source for all those interested in music and the way it is processed by the listener and the performer. It is also intended as a reference source for perceptual and cognitive psychologists, who will find in the study of music much that is of general interest to their fields. The volume may also be used as a text for courses in the psychology of music.

The volume opens with a chapter on *The Perception of Musical Tones*, by Rasch and Plomp, which surveys the classical psychoacoustical literature on tone perception, focusing on characteristics of particular relevance to music. The attributes of pitch, loudness, and timbre are examined, as are psychoacoustical phenomena that occur when tones are presented simultaneously, such as beats and roughness, combination tones, and consonance and dissonance. The authors also provide a useful summary of research methods in psychoacoustics.

Timbre perception is examined in depth by Risset and Wessel in *Exploration of Timbre by Analysis and Synthesis* (Chapter 2). The authors address several issues that are of importance both to perceptual psychology and to contemporary music. For example, How is it that we can identify the sound of an instrument regardless of its pitch or loudness? What types of information can be discarded in the synthetic replication of a sound without distorting perceived timbre? How are the timbres of different instruments perceptually related? By investigating such questions it has proved possible to modify timbres in intriguing ways, for example, to extrapolate a timbre beyond its instrument register or to create a sequence of timbres that progress regularly from one instrument type to another. As the authors note, this field of research is likely to have a profound impact on the development of new music.

Johan Sundberg's chapter on *The Perception of Singing* (Chapter 3) examines some closely related issues. For example, How are we able to hear a singer's voice against a loud or orchestral background? How do we manage to identify sung vowels even though these differ markedly from those in speech? Why do we perceive singing as a set of discrete pitches even though the fundamental frequency events are not discrete? These and other questions are expertly evaluated.

Consider what happens when we listen to a live performance by an orchestra. The mixture of sounds that reaches our ears is produced by many instruments playing in parallel. Somehow our auditory system is able to sort out this mixture of sounds, so that we may choose to listen to a particular instrument or to a particular melodic configuration. What are the mechanisms whereby such groupings are achieved? To what extent are they under voluntary control? These questions are explored in *Grouping Mechanisms in Music* (Deutsch, Chapter 4). It is also shown that under certain circumstances the listener may perceptually reorganize what he or she hears, so that striking illusions may occur. When this happens, the listener's perceptions may not accord with the intentions of the composer.

As implied in Berlioz's statement "There is no such thing as music in the open air," the enclosed space of the concert hall contributes much to the aesthetic quality of music, through the complex sound reflections to which it gives rise. Experiments on the subjective effects of different sound fields are reviewed by Rasch and Plomp in *The Listener and the Acoustic Environment* (Chapter 5). The results of such studies have important practical implications for the design of concert halls.

The next two chapters in the volume are concerned with temporal aspects of music. In Chapter 6 on *Rhythm and Tempo* Paul Fraisse thoroughly surveys a field which he has so ably pioneered, including a review of his own classical contributions. This chapter is complemented by an in-depth study on *Timing by Skilled Musicians*, by Sternberg, Knoll, and Zukofsky (Chapter 7). As the authors write, "During ensemble rehearsal and performance, players must judge, produce and imitate beat fractions. It is plausible that because of the requirement that players 'keep together,' performing experience would cause the three functions to become at least consistent with each other and probably accurate as well. Neither of these expectations was borne out by our experiments." The results of this unique study are particularly valuable; such eminent musicians as the composer and conductor Pierre Boulez and the violinist and conductor Paul Zukofsky were employed as subjects. Based on their findings, the authors propose an information-flow model of timing which also has general implications.

The next four chapters are concerned with abstract structures formed by pitch relationships in music. The large majority of musical cultures employ scales. In Chapter 8, *Intervals, Scales, and Tuning*, Burns and Ward explore the perception of musical scales in detail, focusing on the interval as the basic building block. The authors argue that the use of a small set of discrete pitch relationships in music is probably dictated by inherent limitations in our ability to transmit sensory information. Such limitations probably also account for the phenomenon of categorical perception of musical intervals, the evidence for which is thoroughly reviewed. Arguments for different tuning systems are explored, and the authors conclude that patterns of intonation used by musicians are primarily a function of their acquired ability to reproduce learned interval categories.

The *Processing of Pitch Combinations* (Deutsch, Chapter 9) examines how pitch information is internally represented at different levels of abstraction. At the lowest level, local features such as intervals and pitch classes are represented, as are global

features such as contour. At the next higher level, such features are combined so as to give rise to perceptual equivalences and similarities between larger sets of pitches. At a yet-higher level, pitch information is mapped onto a set of highly overlearned alphabets and is retained in the form of hierarchies. A distinction is drawn between musical abstractions that result from passive "bottom-up" processes and those that are the result of hypothesis testing or are "top-down" in nature. The final section of the chapter is concerned with memory for pitch at these different levels of abstraction.

The internal representation of musical hierarchies is explored in an elegant collaborative study by Rosner and Meyer on *Melodic Processes and the Perception of Music* (Chapter 10). The authors argue, following Meyer's earlier theoretical work, that melodies often appear to be hierarchically structured in such a way that the type of patterning exhibited by a given melody differs from one hierarchical level to the next. The authors further hypothesize that "melodic patterns are classified by listeners, as well as music theorists, in terms of the organization of the highest level on which significant closure is created by the parameters that shape musical relationships." Using a concept identification task, the authors found that musically untrained listeners did indeed classify melodies in accordance with theoretical expectations.

The question of how pitch relationships within a musical system can best be represented has traditionally been the main focus of music theory. In his provocative *Structural Representations of Musical Pitch* (Chapter 11) Roger Shepard proposes that pitch in our tonal system be represented as a double helical structure requiring an embedding space of five dimensions. In arguing for this model, Shepard draws on recent empirical findings from psychology and psychoacoustics, as well as on considerations from tonal music.

The next four chapters consider musical ability from different points of view. In *Musical Ability* (Chapter 12) Rosamund Shuter-Dyson describes and critically evaluates different tests of musical ability. Various questions are then explored. For example, How does musical ability correlate with other intellectual abilities? How does musical ability develop with age? To what extent is musical ability a learned phenomenon and to what extent does it depend on training? Cases of exceptional musical ability are also described. This chapter should serve as a particularly useful reference for music educators.

The question of how the ability to process melodic information develops with age is explored in detail by Dowling in *Melodic Information Processing and Its Development* (Chapter 13). Dowling argues for a developmental sequence that begins with the infant's ability to match pitches and distinguish such gross features as contour, progresses to the young child's ability to recognize tonal scales and discriminate key changes, and arrives finally at the adult's ability to detect small differences in interval size. Dowling proposes that the same hierarchy of melodic features is manifest in adult musical behavior.

One intriguing example of unusual musical ability is the possession of absolute pitch. Ward and Burns discuss this phenomenon in depth in Chapter 14 (*Absolute Pitch*). Why is it that a few people possess absolute pitch, whereas most people do not? Is it innate, or is it acquired through experience, perhaps at a critical age? Is it an ability that tends to

disappear through a process of unlearning? A detailed study of the processing capacities of one listener with absolute pitch is also presented.

Chapter 15 (*Neurological Aspects of Music Perception and Performance*) was written by Oscar Marin with two aims: first, to characterize the types of deficit in music perception and performance that are associated with damage to the nervous system and second, to use this information to elucidate the neuroanatomical basis of musical function in the normal case. Marin emphasizes that music is a highly complex function, so that simplistic views of how it is represented are bound to prove incorrect. This chapter also includes a discussion of the relationship between the neuroanatomical substrates of music and those of speech.

Instrumentalists will find Sloboda's *Music Performance* (Chapter 16) of particular interest. Sloboda emphasizes the importance of abstract structural representation to understanding how music is performed. Deviations from accuracy in expert performers can often be explained as serving to communicate musical structure to the listener. Experiments involving sightreading, memorization, and improvization are discussed with this theoretical framework.

Konečni's contribution on *Social Interaction and Musical Preference* (Chapter 17) stresses the important role played by music in everyday life. As the author writes, "a thorough understanding of aesthetic behavior cannot be achieved without examining how it changes as a function of its immediate social and nonsocial antecedents, concurrent cognitive and resultant emotional states." Furthermore, "both subtle and major changes in social behavior may occur as a function of listening to music." A set of laboratory experiments documents these arguments.

In the final chapter of the volume, *New Music and Psychology*, the composer and music theorist Robert Erickson presents a thoughtful evaluation of the relationship between the two disciplines. Erickson also outlines several questions raised by contemporary music that can usefully be approached using the methods of experimental psychology.

I am grateful to Michael Jordan for compiling the index, and I should like particularly to thank E. C. Carterette for his invaluable contribution in organizing the volume.

I. THE PSYCHOACOUSTICS OF MUSIC

A. Introduction

The aim of research in music perception is to explain how we respond subjectively to musical sound signals. In this respect it is a part of psychophysics, the general denomination for scientific fields concerned with the relationship between the objective, physical properties of sensory stimuli in our environment and the subjective, psychological responses evoked by them. If the stimuli are of an acoustic nature, we speak of *psychoacoustics*. Psychoacoustics can be of a general, theoretical nature; it can

ISBN 0-12-213560-1

also be applied to a certain class of auditory stimuli, such as music and speech. This chapter is devoted to *musical psychoacoustics*.

The most important topics of musical psychoacoustics are the subjective properties of musical tones (pitch, loudness, timbre) and the phenomena that occur when several tones are presented simultaneously, which is what usually happens in music (beats and roughness, combination tones, consonance and dissonance). We will focus our discussion on these topics. However, before we deal more extensively with them, some attention must be given to the methodology of psychoacoustics and to the frequency-analyzing power of the ear, a capacity that is fundamental to its perceptual functioning.

B. Methodology

Psychoacoustics is an empirical or, rather, experimental science. Observations from daily life and informal tryouts may be starting points for psychoacoustical knowledge, but the core of the scientific content is the result of laboratory investigations. In this respect it is an interdisciplinary field of research. Contributions have been made both by experimental psychologists and by physicists and acousticians.

A *psychoacoustical experiment* can be described most simply in a stimulus–response scheme. The *stimulus* is the sound presented to the subject. The experimenter requires the subject to give a *response*. The experimenter tries to discover the relationship between stimulus and response characteristics. Both stimulus and response are observable events. The subject is considered a "black box" that cannot be entered by the experimenter. Psychoacoustical research is often carried out without an attempt to explain the experimental results functionally in terms of sensory processes. Such attempts are made in research that is labeled *physiological acoustics*, a part of sensory and neurophysiology.

Our ears are very sensitive organs. Because of this, very accurate control of the stimulus variables is required in psychoacoustical experiments. Sound pressure level differences of less than 1 dB, time differences of a few msec, and frequency differences of less than 1 Hz can have a profound effect on the subjective response to a stimulus. It is impossible to obtain well-controlled psychoacoustic stimuli by manual means, like playing tones or chords on a musical instrument. The precision of the ear in distinguishing fine nuances is much greater than our ability to produce these nuances. As a rule, psychoacoustics makes use of electronic audio equipment that can produce sound stimuli according to any specification. In recent years it has become feasible to run the experiments under computer control. The computer can also be used for storage and analysis of stimuli and response data. Most problems concerning the production of the stimuli in psychoacoustical experiments may be considered solved. After the sound stimulus has been produced, it must reach the subject's eardrum with the least possible distortion. Usually high-quality headphones are used unless the spatial effect of the listening environment is involved. Background noises should be reduced, if not eliminated.

It is possible to have the subject describe his perception verbally. However, this response is often insufficient because our sensations allow much finer distinctions than our vocabulary does. Moreover, the use of words may differ from subject to subject. Because of this, in psychoacoustics most results are derived from responses made on the basis of a certain perception without direct reference to the perception itself. For example, if we have to indicate in which of two time intervals a sound has occurred, the response is a time indication based on an auditory sensation. A great deal of inventiveness is often required of the experimenter in designing his experimental paradigms.

The procedures used most often in psychoacoustical experiments are choice methods and adjustment methods. A single presentation of a sound event (one or more stimuli) to which a response must be made is called a *trial*. Using *choice methods*, the subject has to make, for each trial, a choice from a limited set of well-defined alternatives. The simplest case is the one with two alternatives, the *two-alternative-forced-choice* (2AFC). The insertion of the word "forced" is essential: The subject is obliged to choose. He must guess when he is incapable of making a meaningful choice.

For example, let us assume that the investigator is studying under what conditions a probe tone can be heard simultaneously with another, or masking sound. Each trial contains two successive time periods marked by visual signals. The masking sound is continuously present; the probe tone occurs in one of two time periods, randomly determined. If the probe tone is clearly detectable, the subject indicates whether it was presented in the first or in the second period. If the tone is not perceived at all, the subject must guess, resulting in an expectation of 50% correct responses. The transition from clearly detectable to not detectable tones is gradual. It is reflected by a gradual slope of the so-called *psychometric curve* that represents the percentage of correct responses plotted as a function of the sound pressure level of the target tone. The sound pressure level that corresponds to a score of 75% correct responses is usually adopted as the threshold for detection.

In order to arrive at an accurate estimate of the threshold, the experimenter varies sound pressure level of the tone for the successive trials. In the *constant stimuli* method the experimenter presents the tones according to a fixed procedure. The method of constant stimuli is time consuming because a number of trials are definitely supra- or infra-threshold and, therefore, do not give much information. Another class of choice methods, called *adaptive methods*, makes a more efficient use of trials. The experimental series is started with a certain initial value of the stimulus variable. One or more correct responses, depending upon the experimental strategy adopted, result in a change in the stimulus variable that makes it harder for the subject to make a correct choice. If the subject makes one or more false responses, the experimental task is facilitated. In this way, the value of the stimulus variable fluctuates around a certain value, which can be defined to be the threshold for perception.

Besides choice methods there is the *adjustment method*. The subject controls the stimulus variable himself, and he uses this control to find an optimal value. This method is not always feasible. The adjustment method is suitable for stimulus var-

iables that allow an optimal quality in perception: the best pitch for a tone in a musical interval, the most comfortable loudness, the greatest similarity or dissimilarity, etc. The optimal adjustment behaves like a stable equilibrium between lower and higher, both suboptimal, adjustments. Adjustment methods have the advantage that the results can be derived directly from the adjusted value, and do not have to be derived indirectly from the psychometric curve.

C. The Ear as a Frequency Analyzer

Only by the ear's capacity to analyze complex sounds are we able to discriminate simultaneous tones in music. *Frequency analysis* may be considered the most characteristic property of the peripheral ear. The cochlea is divided over its entire length into two parts by the basilar membrane. In 1942 Von Békésy was the first to observe, with ingenious experimentation, that at every point along its length this membrane vibrates with maximum amplitude for a specific frequency. This finding confirmed the hypothesis, launched 80 years earlier by Helmholtz, that the cochlea performs a frequency analysis. Sound components with high frequencies are represented close to the base; components with low frequencies are represented near the apex of the cochlea. The frequency scale of the sound is converted into a spatial scale along the basilar membrane.

This capacity of the ear means that any periodic sound wave or *complex tone* is resolved into its frequency components, also called *partials* or *harmonics* (see Fig. 1). In mathematics the analogous procedure of determining the sinusoidal components of a periodic function is called *Fourier analysis*. In contrast with the theoretically perfect

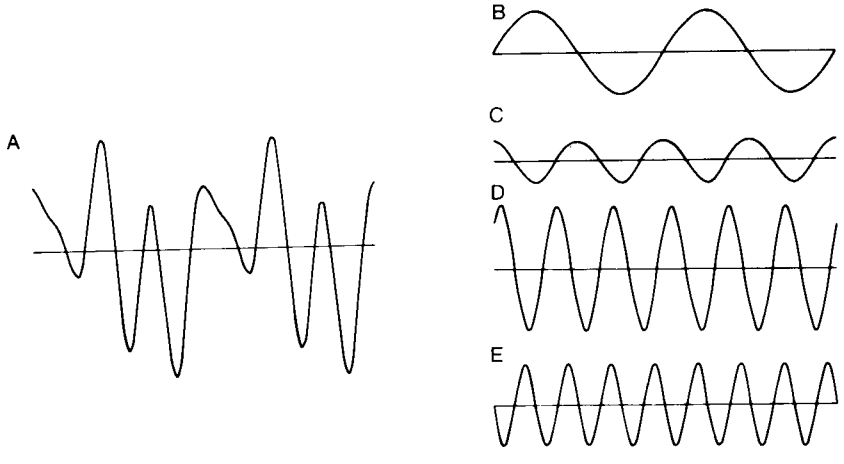

Fig. 1. The wave form A, a complex tone, is in fact the sum of the simple tones B-E. This is an illustration of Fourier's theorem that every vibration of frequency f can be analyzed mathematically into a series of sinusoidal vibrations with frequencies f, $2f$, $3f$, etc. These sinusoidal vibrations are called the harmonics.

Fourier analysis, the frequency-analyzing power of the ear is limited: Only the lower harmonics can be analyzed individually.

There are many ways of studying the extent to which the ear can separate simultaneous tones. Only two approaches will be considered here. The first method investigates how many harmonics (with frequencies nf, $n = 1, 2, 3, 4$, etc.) can be distinguished in a complex tone. This can be done by using the 2AFC procedure: The listener has to decide which of two simple (sinusoidal) tones—one with frequency nf, the other with frequency $(n \pm \frac{1}{2})f$—is also present in the complex tone. The percentage of correct responses varies from 100 for low values of n to about 50 for high values of n. Experiments along these lines have shown (Plomp, 1964) that, on the average, listeners are able to distinguish the first five to seven harmonics.

A quite different approach involves measuring the minimum sound pressure level necessary for a probe tone to be audible when presented with a complex tone. This is the so-called masked threshold; by varying the probe-tone frequency, we obtain the "masking pattern" of the complex tone. In Fig. 2 such a pattern is reproduced. The masking pattern of a complex tone of 500 Hz reveals individual peaks corresponding to the first five harmonics, nicely demonstrating the limited frequency-analyzing power of the ear.

The usual measure indicating how well a system is able to analyze complex signals is its bandwidth. The finding that the fifth harmonic can be distinguished from the fourth and the sixth means that the mutual distance should be a minor third or more. This distance constitutes a rough, general estimate of the bandwidth of the hearing mechanism, known in the psychophysical literature as the *critical bandwidth* (Fig. 3). A detailed review (Plomp, 1976) revealed that the bandwidth found experimentally is dependent on the experimental conditions. The values may differ by a factor of two.

In the lower frequency region (below 500 Hz) critical bandwidth is more or less constant if expressed in Hz. That means that musical intervals (frequency ratios) larger than the critical bandwidth at high frequencies may fall within the critical bandwidth at lower frequencies.

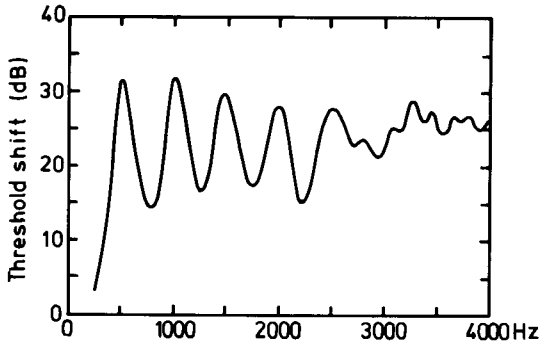

Fig. 2. Masking pattern of a complex tone consisting of the first 12 harmonics of 500 Hz (based on Plomp, 1964). Only the first five harmonics are analyzed by the ear.

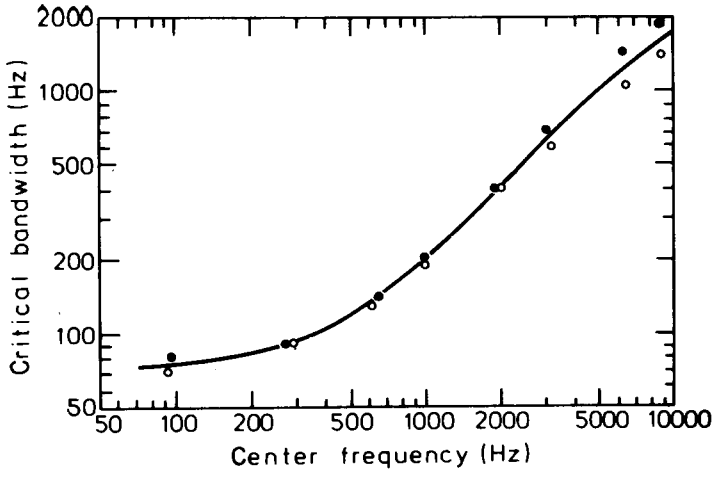

Fig. 3. Critical bandwidth as a function of frequency. This curve is a rough approximation only.

II. PERCEPTUAL ATTRIBUTES OF SINGLE TONES

A. Pitch

Pitch is the most characteristic property of tones, both simple (sinusoidal) and complex. Pitch systems (like the diatonic-chromatic and the 12-tone system) are among the most elaborate and intricate ever developed in Western and non-Western music. Pitch is related to the frequency of a simple tone and to the fundamental frequency of a complex tone. The frequency of a tone is a property that can usually be controlled in production and is well preserved during its propagation to the listener's ears.

For our purposes, pitch may be characterized as a *one-dimensional* attribute, i.e., all tones can be ordered along a single scale with respect to pitch (but see Chapters 8, 9, and 11, this volume). The extremes of this scale are *low* (tones with low frequencies) and *high* (tones with high frequencies). Sometimes tones with different spectral compositions (timbres) are not easily comparable as to pitch. It is possible that the clearness of pitch varies, for example, as a result of important noise components or inharmonic partials, or that the subjective character of the pitch varies, for example, when comparing the pitch of simple and complex tones. There are a number of subjective pitch scales:

1. The *mel* scale (see Stevens, Volkmann, & Newman, 1937). A simple tone of 1000 Hz has a defined pitch of 1000 mel. The pitch in mels of other tones with another frequency must be determined by comparative scaling experiments. A sound with a pitch subjectively twice that of a 1000 Hz tone is 2000 mel; "half pitch" is 500

mel, etc. Since there is no unambiguous subjective meaning of "a pitch half as high" or "double as high," the mel scale is a rather unreliable scale. It is not used very often.

2. The *musical pitch* scale (i.e., the ordinary indications C1, D1, . . . , C4, . . . , A4, etc.). These indications are only usable in musical situations.

3. The physical *frequency* scale in Hz. In psychoacoustical literature the pitch of a tone is often indicated by its frequency or, in the case of complex tones, by its fundamental frequency. Since the correspondence between frequency and pitch is monotonic, frequency is a rough indication of our pitch sensation. It must be realized however, that our perception operates more or less on the basis of a logarithmic frequency scale.

Pitch in its musical sense has a range of about 20 to 5000 Hz, roughly the range of the fundamental frequencies of piano strings and organ pipes. Tones with higher frequencies are audible but without definite pitch sensation. Low tones in the range of 10 to 50 Hz can have the character of a rattling sound. The transition from the perception of single pulses to a real pitch sensation is gradual. Pitch can be perceived after very few periods of the sound wave have been presented to the ear.

Simple tones have unambiguous pitches that can be indicated by means of their frequencies. These frequencies may serve as reference frequencies for the pitches of complex tones. The pitch sensation of complex tones is much more difficult to understand than the pitch of simple tones. As was discussed, the first five to seven harmonics of a complex tone can be distinguished individually if the listener's attention is drawn to their possible presence. However, a complex tone, as heard in practice, is characterized by a single pitch, the pitch of the fundamental component. This pitch will be referred to as *low pitch* here. In psychoacoustical literature this pitch is also known under a variety of other terms, such as periodicity pitch, repetition pitch, residue pitch, and virtual pitch. Experiments (Terhardt, 1971) have shown that the pitch of a complex tone with fundamental frequency f is somewhat lower than that of a sinusoidal tone with frequency f. The existence of low pitch of a complex tone raises two questions. First, why are all components of the complex tones perceived as a perceptual unit; that is, why do all partials fuse into one percept? Second, why is the pitch of this perceptual tone the pitch of the fundamental component?
