CHAPTER 7

AESTHETIC AGENCY AND MUSICAL PRACTICE: NEW DIRECTIONS IN THE SOCIOLOGY OF MUSIC AND EMOTION

TIA DENORA

7.1 The sociological approach

If psychology is concerned with human behaviour (Sloboda & Juslin, this volume), sociology is concerned with forms of social organization and the relation of these forms to social *action*, by which is usually meant, to paraphrase Max Weber (1978, Vol. 1, p. 4), conduct (real or hypothetical) that is meaningfully orientated in its course and outcome. The scope of material that falls within sociology's compass is wide, and perhaps it is because of its substantive breadth that sociology is a diverse—some would argue, fragmented—field.

Sociologists have traditionally employed a range of empirical strategies and theoretical perspectives, and have tended to engage in a high degree of intradisciplinary opposition such that is probably impossible to speak of 'a' sociological paradigm. For example, some sociologists seek to identify and quantify causes of collective and/or individual behaviour and to predict behavioural trends, while others seeks to understand meanings and meaning systems using ethnographic and qualitative methods of observation. The fissures within sociology are legion—*macro* (concern with large-scale institutions and trends) versus *micro* (focus on interactional process), *quantitative* versus *qualitative*, *structuralist* (focus on social forces and trends) versus *interpretive* (focus on meaning-making activity), to name a few. With that caveat, it is none the less possible to caricature the field by saying that sociology takes as its substantive focus a concern with action, intersubjectivity, the production of culture and knowledge, institutions, organizations and their conventions, and the implications of all these things for the social lives and life chances of individuals.

Whereas some psychologists might suggest that these topics are 'external' to the human organism, some sociologists, particularly those concerned with the sociology of the body, would counter that the nature/culture divide is ripe for dissolution (Birke 1992; Featherstone *et al.* 1991; Haraway 1985), to be replaced with a focus on how organismic features, cultural and material-cultural systems are reflexively linked.

Similarly, Foucauldian-inspired sociologists who have taken inspiration from post-structuralism and post-modern theory often suggest that our images of psychological 'interiority' owe much to post-Enlightenment discourses and discourse practices through which psychological subjects are constituted (Giddens 1991; Law 1994; Smith 1992). Put plainly, interior experience (here understood as the perception and self-perception of that experience) is shaped with reference to conventional, culturally, and historically specific categories that help to articulate and contain that experience. To be sure, these intra- and interdisciplinary conundrums can be explored most interestingly through the topic of emotion; adding music to the equation is even more useful because it allows for core sociological issues that centre around *agency* (here defined as a capacity for, and ability to, formulate action and experience) to be explored and advanced in a focused manner, in particular issues that concern agency's aesthetic and emotional dimension.

To that end, this chapter begins by considering the status of the emotions within sociology's paradigms. It moves from there to a discussion of music's position within sociology and focuses in particular on the changing conception of music's link to social life that has emerged within sociology of music over the past decade. From there, I survey classic works in the sociology of music as these illuminate music as a 'device' for the constitution of subjectivity and emotion in a range of settings. Throughout these discussions, my aim is to demonstrate how new approaches within the sociology of music help to highlight a congenital feature of sociology writ large, namely, the concern with social action, its sources, and its structures.

7.2 The rediscovery of emotion within sociology

There has been a longstanding interest within sociological theory in the emotions. One strand has developed out of Tönnies' (1957) concepts of *Gemeinschaft* and *Gessellschaft*. Tönnies used these terms to distinguish between social bonds built upon communal, emotional, traditional, and personal grounds versus those produced via rational and administrative procedures. The distinction, and with it a concern with the 'feeling' bases of social organization, has persisted and has established itself across a range of sociological perspectives. Max Weber's concern with the affective action (Weber 1978, Vol 1, pp. 24–8), Max Scheler's (1992) concern with the emotional flashes of insight that lead to knowledge (Remmling 1967, p. 33), Vilfredo Pareto's discussion of sentiments and non-logical aciton (Pareto 1963, p. 161), the 'human relations management' of Elton Mayo (Mayo 1933), Charles Horton Cooley's 'looking glass self' and its focus on emotion as the outcome of imaginative co-operation with external images (Cooley 1983), and Randall Collins' treatment of emotion in relation to rational choice theory (Collins 1993) have all highlighted emotion's role in relation to action and social structure.

And yet, despite this interest (and despite the formation of a thriving section on sociology of the emotions within the American Sociological Association), the affective dimension of human social being was, throughout the 1980s, mostly relegated to sociology's periphery. Particularly in the United States, where the discipline was dominated by rational actor models, and an attendant preoccupation with rule following, choice, and free will (Barnes 2000), the sociology of emotions was typically viewed as an off-shoot of 'micro' sociology and so disconnected from structuralist and 'macro' concerns. Within

sociology's dominant disciplinary frameworks, phenomena such as revolution and war, diplomacy, occupations, social and class rivalry, political and economic activity, organizational and institutional behaviour, the rise and fall of social movements, and the exercise of social control were all portrayed as if they took place in passionless corridors, executed by agents who possessed reason but who did not *feel*.

Over the past 5 years or so, more sensitive sociological portraits of action have begun to emerge. With them, the status of the emotions as a topic has been elevated. From a number of subdisciplinary directions has come a new concern with the 'feeling' component of social action. This emphasis can be seen in current approaches to the sociological study of social and political movements and the emerging focus on the affective character of identification with a movement (Melucci 1996*a*, 1996*b*) and 'structures of feeling' as these are entered into, adopted, and adapted in the course of identity politics and movement activity (Hetherington 1998). This emotion renaissance is also evident in new work on political affiliation, for example on the processes by which citizens transfer feelings of 'belonging' from nations to global entities (Berezin 1999). It has been further fuelled by a rapidly growing sociology of the body (Featherstone *et al.* 1991; Turner 1984) and embodied experience (Bourdieu 1998; Williams 1996, 1998).

Thus, sociology is now much more closely affiliated with concerns and topics traditionally lodged within the purview of social psychology. But this trend toward motivation and emotion has simultaneously been linked to sociology's abiding concern with social contexts—situations, occasions, institutions, and organizations—and with the hitherto 'macro' sociological terrain of collective and institutional action. The result is that sociology has begun to eradicate a bifurcation that has been both its hallmark and impediment for more than a century, namely, the distinction between 'micro' and 'macro' levels of analysis. In place of this division, prominent figures within sociology have moved toward a position that brings the feeling component of action—and hence some of the non-rational bases of social order—to the fore. As Alberto Melucci (1996*b*, p. 1) has expressed it:

> Each and every day we make ritual gestures, we move to the rhythm of external and personal cadences, we cultivate our memories, we plan for the future. And everyone else does likewise. Daily experiences are only fragments in the life of an individual, far removed from the collective events more visible to us, and distant from the great changes sweeping through our culture. Yet almost everything that is important for social life unfolds within this minute web of times, spaces, gestures, and relations. It is through this web that our sense of what we are doing is created, and in it lie dormant those energies that unleash sensational events.

The playing out of social change, politics, social movements, and relations of production are experienced and renewed from within this 'web', as Melucci calls it; it is from within the matrix of 'times, spaces, gestures and relations' that these 'larger' things are realized. Put differently, it is on the platform of the mundane and the sensual that the specificity of social experience is rendered and patterns are renewed.

A common thread running throughout nearly all of the recent focus on emotions within sociology has consisted of a focus on the interplay between emotions in lived experience and cultural forms. Inspired by the emphasis within post-structuralist and post-modernist theory on discourse and by the concurrent emphasis on texts and

artefacts as they imply readers, users, and 'subject positions' (particular and conventionally understood emotional stances, styles, or niches), sociologists across a wide range of specialist areas have devoted themselves to the question of how material-cultural and aesthetic media may be understood to provide models or candidate structures for the production and achievement of emotion and feeling within specific social settings. This focus has been clear within areas such as gender and sexuality and its concern with the cultural construction of desire and sexual practice (Jackson 1996, 1999), the study of spoken discourse in real time encounters (Frazer & Cameron 1989), organizational behaviour (Witkin 1995), and the sociology of material culture (Akrich 1991; Latour 1991; Law 1994; Moore 1997; Woolgar 1997).

It is from within this framework that the sociology of music can be seen to interact with the broader sociological focus on emotion. Having undergone significant transformation in the past decade, socio-music studies have moved from preoccupations with music's production to concerns with how it is consumed and what it 'does' in social life. In this regard, developments within the sociology of music merge with developments in the sociology of the arts more widely (Bowler 1994). Recent developments within the field have examined connections between musical consumption and musical experience as a means of producing and sustaining social ordering in real time, over the life course, and with reference to organizational and collective spheres of action. These developments have helped to return the sociology of music to the systematic concerns laid out early on in the area by figures such as Max Weber (1958), T. W. Adorno (1967, 1973, 1976, 1999), and Alfred Schutz (1964)—who is of particular interest because of his focus on music's relation to, and ability to, configure 'inner time' (pp. 172, 174). They have helped to renew the sociology of music's emphasis on fundamental questions concerning music's role as an active ingredient of social formation, its traditional and common sense role as the medium *par excellence* of emotion construction. In short, there is now a place at the top of sociology's table for the study of music.

Such a project involves considerable sweep: it encompasses matters that are usually desegregated—a focus on systems of music production and distribution, on organizational ecology and management, and on subjective experience as it is configured in relation to musical media.

7.3 Music and social structures: the movement toward conceptual symmetry

From the 1970s to fairly recently, the sociology of music and the sociology of culture more broadly have been concerned with how music is *produced*, with its occupational–politics–distribution systems, and with semiotic readings of musical forms. The emphasis was upon music as an object shaped by social relations. What remained tacit was any symmetrical attempt to conceive of music as a potentially dynamic medium, or to consider what music may 'do' in, to, and for the social relations in which it is embedded. Thus, only one half of the equation was present, albeit a crucial half, focusing on how musical works take shape in ways that are enabled and constrained by their cultures and worlds of production. As a result, apart from some notable exceptions discussed below, the matter of musical experience, and music's links to emotion, passion, and energy,

and to the phenomenological and existential features of social life, were all uncharted waters within sociology's paradigm. Even when sociologists considered music consumption, the focus was directed less to the matter of musical experience than to the ways in which tastes, musical values, and listening practices served as symbolic boundaries for status groups and status differences (Bourdieu 1984; Bryson 1997; DeNora 1995; DiMaggio 1982; Lamont 1992; Peterson & Simkus 1992).

As Peter Martin has observed (1995, p. 1), music is ubiquitous in modern societies, yet the significance of music's ubiquity often goes unnoticed within social sciences. In recent years, music's role as an active ingredient of social formation and subjectivity has been restored. Within this 'new' music sociology of emotions, it is possible to conceptualize music as a device for the constitution of emotive action in and across a range of social settings. This concern with *emotion construction* (through musical practice) offers an avenue into sociology's new concerns with the non-cognitive dimensions of agency (e.g. its emotional dimension) and also illuminates the relationship between culture and agency. In the remainder of this chapter, I seek to develop this perspective. I begin, in the next section, with reference to two, originally distinct, strands within the discipline that can be understood to provide the bedrock for more recent work: Adorno's theory of music as a medium of social organization and the more overtly empirical and ethnographic studies of music and lifestyle practice as propounded by Paul Willis in the 1970s.

7.4 Music, emotions, and subjectivity: sociology's classic models

For Theodor Adorno, music was inextricably connected to habits of mind, to social structural organization, and to modes of subjectivity. The music of Arnold Schoenberg, for example, he viewed as able to foster critical consciousness because its material organization went against the grain of musical convention and cliché. Conversely, in the age of 'total administration', music was also a medium that 'trains the unconscious for conditioned reflexes' (Adorno 1976, p. 53). Jazz, Tin Pan Alley, and nearly every other popular music genre was linked, in Adorno's view, to forms of regression and infantile dependency (Adorno 1990).

Adorno's work explores the idea that music interiorizes and is able to instigate forms of social organization in and through the ways that it works on and configures its subject-recipient. Put bluntly, Adorno conceived of music as active, indeed formative, in relation to consciousness. In this regard, his work makes some of the strongest claims on behalf of music's power in any discipline. But because Adorno provided no machinery for conceptualizing music's power empirically, his work is also frustrating; it never operationalizes the claim that music 'trains' the unconscious, nor points the way toward how these matters might be observed at the grounded level of musical practice. Adorno's work remained in the safe haven of theory and semiotic 'readings' of (primarily art music) works; it ventured but little into the realm of empirical analysis and the sphere of music consumption (indeed, Adorno's comments on music reception are mainly devoted to delineating a hierarchy of listener types). In its refusal to go out and look at the world, Adorno's work suffers at times from parochialism (e.g. his views on jazz, his unilateral condemnation of popular culture, and his tendency to prescribe musical taste).

During the 1970s, more empirically orientated work on 'music and society' provided an alternative to Adorno's hypothetical approach. The originally British tradition of cultural studies, ethnographically conceived, was directed at exploring connections between music and lived experience—identity creation, feeling, and the social constitution of embodied action and its parameters. Moreover, these explicitly ethnographic works may be read, with hindsight, to have presaged current developments.

Within the classic studies of young people and their intimate involvement with music, in books such as Paul Willis' *Profane culture* (1978), and Simon Frith's early monographs, *Sound effects* (1981) and *The sociology of rock* (1978), music's social presence was illuminated. Rereading these works with their characteristic focus on the experience of music, it is possible to see music providing a resource in and through which agency, identity, and peer culture are produced. Indeed, these studies can be seen to be compatible with Adorno's concern with music's link, and ability to instigate, social being. But this time, the music–social structure nexus was specified in a manner amenable to observation and in terms of how music was actually consumed and used. Music's structuring properties were understood as actualized in and through the practices of musical use, through the ways music was used and referred to by actors in their ongoing attempts to produce their social situations and themselves.

For example, in his report on the culture of the 'bikeboys', Willis noted that the boys' preferred songs were fast-paced and characterized by a strong beat, a pulsating rhythm. Willis showed how the boys established connections between music and social life. Structural similarities—homologies—between music and social behaviour were forged through the bikeboys' cultural practices and classifications.

Willis's focus was directed at the question of how particular actors make connections or, as Stuart Hall (1980, 1986) later put it, 'articulations' between music and social phenomena and how this process of linking music with forms of social life is part of actors' ongoing constitution of their life worlds and themselves. Although he never described his project as such, Willis's work on the bikeboys and on music's role as part of 'profane culture' more widely served to establish no less than an interactionist version of Adorno's original vision, that is an approach to the question of music's link to subjectivity, to cognitive style, and to actors' ontological orientations. Key, however, was that Willis's approach captured music's social impact as it was achieved by the ways in which actors themselves made 'articulations' or links between forms of music and forms of social life. It drew upon the basic interactionist tenet within sociology that agents attach connotations to things and orientate to social circumstances on the basis of perceived meanings. And it highlighted, through ethnographic description, the way in which social forms of organization are made through reference to aesthetic materials. This focus on the social process of world making (and the role of cultural media in this process) signalled an important shift in focus from aesthetic objects and their 'content' (static) to the cultural practices in and through which aesthetic materials were appropriated and used (dynamic) to produce social life. It simultaneously served to justify the need for 'symmetrical' conceptualizations of the relationship between music and social structure.

The bikeboys' music, as Willis noted, did not leave its recipients 'just sit[ting] there moping all night' (1978, p. 69). On the contrary, it invited, perhaps incited, movement.

As one of the boys put it, 'if you hear a fast record you've got to get up and do something, I think. If you can't dance any more, or if the dance is over, you've just got to go for a burn-up [motorcycle ride]' (1978, p. 73). Willis's work was thus pioneering in its demonstration of how music does much more than 'depict' or embody values. It portrayed music as active and dynamic, as constitutive not merely of 'values' but constitutive of trajectories and styles of conduct in real time. As one of the boys observed, 'you can hear the beat in your head, don't you . . . you go with the beat, don't you?' (1978, p. 72). This insight was germane to more recent developments in the field, for it points to the ways in which music, as it is heard or imagined, may serve to organize or 'configure' its users. Willis showed, for example, how music was implicated in the temporal structure of the bikeboys' evening, how it took them from—or provided the fulcrum for—one state (sitting around) to another (dancing as the music plays) to another (riding as the music plays in memory). Viewed in this way, music can be conceived of as a kind of aesthetic technology, or an instrument of social ordering.

It is precisely this interactionist conception that has been rediscovered by younger sociologists and sociologically minded scholars of music and subjectivity (it also lives on in the recent work of its pioneers; see Frith 1996; Willis 2000). For example, Sarah Cohen was one of the first to call for a renewal of an ethnography of musical practice in her insistence that 'focus upon people and their musical practices and processes rather than upon structures, texts or products illuminates the ways in which music is used and the important role that it plays in everyday life and in society generally' (Cohen 1993, p. 127). Similarly, Georgina Born argued, in her ethnography of IRCAM, that it is necessary to focus on 'the actual uses of technologies [she could just as well have said 'musics'], which are often depicted in idealised, unproblematic, and normative ways' (Born 1995, p. 15). In common with all instruments and technological devices, then, music needs to be understood in terms of its (non-verbal) capacities for enabling and constraining its user(s). Within current sociology, this focus has been directed at how individuals come to appropriate musical forms, and how musical forms feature within social settings as organizing materials of action. How, then, can this idea be developed and how can music's structuring powers be illuminated at the level of social experience? In the remaining sections of this chapter, I present two more examples of recent work concerned with music's role as a resource for the constitution of emotional experience. This discussion should be read in conjunction with the chapter by Sloboda and O'Neill (this volume) on emotions in everyday listening to music.

7.5 Music and emotion work: producing feeling in daily life

One of the most promising trends in current music sociology has been the focus on how music may be used—with varying degrees of conscious awareness by and on behalf of actors as a resource—to construct self-identity and to create and maintain a variety of feeling states. This work clearly connects with pioneering efforts within social psychology (De Las Heras 1997; Neilly 1995; Sloboda 1992, 1999) and ethnomusicology (Crafts *et al.* 1993; see also Becker, this volume). But it also speaks to an explicitly sociological concern with organizational aesthetics and with the social distribution of emotion and conventional notions concerning feeling structures within particular social

settings (for example, matters such as who is entitled to feel what type of emotion, where, when, and how).

The distinctively sociological quality of this concern is its focus on how individuals are produced or produce themselves as social agents with attendant styles of feeling and emotional stature. Thus, from within sociology, emotions are regarded as 'socially constituted' so that the study of music reception and consumption connects with recent discussions within sociology of 'aesthetic reflexivity' (Lash & Urry 1994, Chapter 4) and 'aesthetic agency' (DeNora 1997, 2000; Witkin & DeNora 1997). These terms highlight the consumption of aesthetic media as a means for self-interpretation and self-constitution, for the doing, being, and feeling that is the matrix of social experience. They simultaneously call for an overtly ethnographic turn in the study of aesthetic reception and thus interact with developments in the sociology of media and the plastic arts (Press 1994; Radway 1988; Tota 1997, 1999).

7.5.1 Music as a technology of emotion construction

Two recent studies illustrate this point. The first focuses upon music consumption in France (Gomart & Hennion 1999; Hennion & Maisonneuve 1998), the second on England and the USA (DeNora 1999, 2000). Both draw on roughly 50 in-depth interviews and both have concentrated on music's role in relation to the achieved character of feeling, to the ways in which actors' adoption of emotional stances, subject positions, and states are simultaneously the objects of actors' cultural practices in specific settings. In this regard, these works have begun to pave the way for a new sociology of music and emotions, one that conjoins an ethnomethodological focus (on the procedures and practical activities in and through which social orderings are accomplished in real time and in particular social contexts; Garfinkel 1967; Heritage 1984; Law 1994) with a focus on emotions in terms of how they are crafted and experienced within social situations.

In a piece that compares the love of music with the love of taking drugs, and which draws upon in-depth interviews with music lovers and with drug addicts, Gomart and Hennion (1999) examine actors as they engage in 'techniques of preparation' that produce forms of attachment so as to clarify the mechanisms that produce 'disposition'. In so doing, they shift the focus of their particular theoretical persuasion, 'actor network theory', from action to the study of interaction between people and things, and with this shift they make a concomitant move away from the overly general category of 'action' to the more specific concept of 'event'. They highlight 'what occurs' when, as part of the musical—or narcotic—experience, the self is 'abandoned' or given over to sensation and/or emotion. They are interested in no less than an ethnographic sociology of the production of passion.

With regard to the music lovers, they delineate the various practices involved in preparing for aesthetic experience. For example, Gomart and Hennion describe how their interviewees describe becoming 'ready in one's head' for the ear to hear and the body to respond (1999, p. 232), or how they employ particular listening strategies and rhythms so as to be ready to respond in preferred or expected ways. This process is akin to 'tuning in' or attempting to produce, through fine tuning practices, a signal's power and clarity. Listeners, they suggest, like drug users, 'meticulously *establish conditions* [emphasis in original]: active work must be done in order to be moved' (1999, p. 227).

Listeners are by no means simply 'affected' by music but are, rather, active in constructing their 'passivity' to music—their ability to be 'moved'. The music 'user' is thus deeply implicated as a producer of his or her own emotional response—that is, one who:

> strives tentatively to fulfil those conditions which will let him be seized and taken over by a potentially exogenous force. 'Passivity' then is not a moment of inaction—not a lack of will of the user who suddenly fails to be a full subject. Rather passivity adds to action, potentializes action. (Gomart & Hennion 1999, p. 243)

Gomart and Hennion were attuned to the question of how 'events' of musical passion and emotional response—the being 'taken over' by music—is reflexively accomplished by music lovers. Similarly, DeNora's study deals with music's role in the day-to-day lives of American and British women as they used music to regulate, enhance, and change qualities and levels of emotion. Nearly all of these women were explicit about music's role as an ordering device at the 'personal' level, as a means for creating, enhancing, sustaining, and changing subjective, cognitive, bodily, and self-conceptual states. Levels of musical training notwithstanding, the respondents exhibited considerable awareness about the music they 'needed' to hear in different situations and at different times, drawing upon elaborate repertoires of musical programming practice, and were sharply aware of how to mobilize music to arrive at, enhance, and alter aspects of themselves and their self-concepts. Part of their criteria for the 'right' music was how well it 'fitted' or was suitable for the purpose or situation they wished to achieve, or for achieving a particular emotional state (see the discussion of 'fit' in Sloboda and O'Neill, this volume). For example, as one respondent, Lucy, put it describing how she came to take time out to listen to some of the Schubert *Impromptus* (quoted in DeNora 2000, p. 16).

> I was feeling very 'stressed' this morning 'cause we're in the throes of moving house and its, you know, we're not, we haven't sold our house yet, and it's moving, you know, and, um, so I actively decided to put on Schubert's *Impromptus* because they were my father's favourite—you might want to come along to that again, because Schubert's *Impromptus* have a long history with my life—and I thought, my husband had just gone off to work and I thought well, about half an hour before I come up here [to her place of paid work], I'll just listen to them. So, the speakers are [she gestures] there and there on either side of what used to be the fireplace and I sit in a rocking chair facing them, so I get the sound in between the speakers, and I just sat there and listened [sighs, gentle laughter].
>
> Q. [gentle laughter]
>
> A. But I needed it. It was only ten minutes or so, you know, I didn't listen to them all. I just listened to the bits I wanted to listen to.'

Here, the music's powers to instigate emotion are constituted by Lucy herself; the music's power derives from the ways she interacts with it (Fig 7.1). The *Impromptus*, for Lucy, bear meaning on many levels. Their character as physical sound structures and their relation to a body of musical-stylistic convention is interpolated with, for Lucy, equally important biographical connotations and with a history of use such that the pieces calm her not only because they embody musical calm, but because they restore to Lucy a sense of her own identity. First, for Lucy, the works are associated with comfort; they are bound up with a complex of childhood memories and associations. Her late father, to whom she was close, used to play the piano after dinner and these works,

wafting up the stairs, were ones Lucy used to hear as she was falling asleep. Second, the material culture of listening is also an accomplice, in this example, of music's power to shift Lucy's mood on the morning she describes. Lucy's listening is conducted in a quiet room. She sits in a rocking chair placed between the speakers and so is almost nestled in the, as she perceives it, calm and nurturing music. (The vocabulary of nurturing is Lucy's. As she puts it, music 'soothes me', 'I retreat into music when I can't bear the rest of the world, you know', 'you can go into [music] and have it around you or be in it', quoted in DeNora 2000, p. 42.)

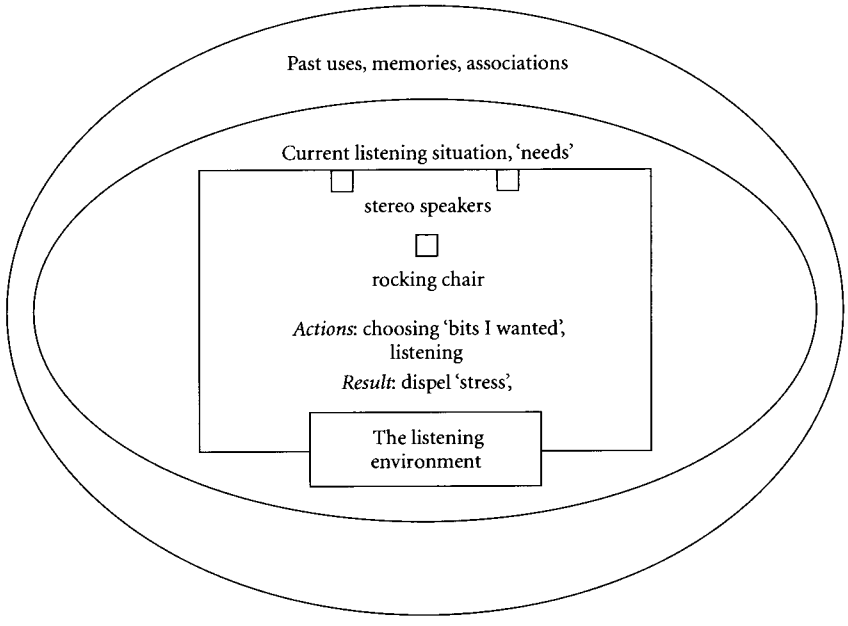

Figure 7.1 Ten to 15 minutes spent with music: 'Lucy' and Schubert's *Impromptus*.

This example typifies the kind of practical knowledge respondents exhibited repeatedly in their accounts of (often tacit) music practices. Through these practices, respondents produced themselves as coherent social and socially disciplined beings. As in the French data reported by Gomart and Hennion (1999), the British and American respondents routinely engaged in various practices of 'tuning in', of producing a musical event that would be capable of 'moving' them, and this production of passivity in the face of music, and its subsequent emotional 'effect' was achieved through an assemblage of musical practices. These included the choice of specific recordings, volume levels, material-cultural and temporal environments of listening (for example choosing to listen in bed, in a rocking chair, in the bath in the evening, in the morning, or while preparing to go out), and the pairing and compiling of musical works, memories, and previous and current contexts of hearing, such that the respondents could often be conceived as—and spoke of themselves as—disk jockeys to themselves (Fig 7.2).

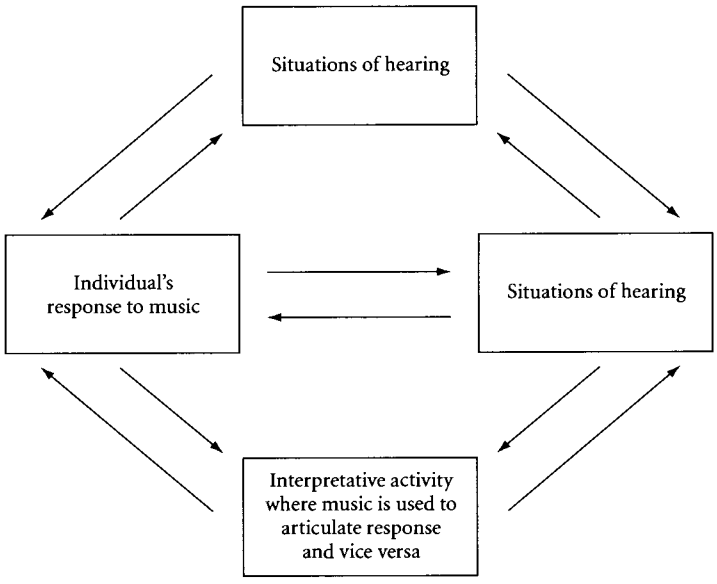

Figure 7.2 The reflexive constitution of emotional states or events through reference to music in social situations.

Thus, in both the French and the British/American studies, music can be seen as a medium or device for achieving 'emotional work'. First coined by Arlie Hochschild (1983) to describe practices within the workplace where workers were required to produce not only material goods or services, but also to produce themselves as types of emotional agents acting under the organizational cultural auspices (and bearing a strong resemblance to Cooley's conception of emotion constitution in his discussion of 'looking glass self', see above), the concept of emotional work has since been adopted more widely within sociology, where emotion is conceived as a 'bodily co-operation with an image, a thought, a memory—a co-operation of which the individual is aware' (Hochschild 1979, p. 551, quoted in Williams 1996, p. 129). Respondents described how they used music both routinely and in exceptional circumstances to regulate moods and energy levels, to enhance and maintain desired states of feeling and bodily energy (e.g. relaxation, excitement), and to diminish or modify undesirable emotional states (e.g. stress, fatigue).

For example, in their own words, the British and American women interviewed by DeNora described how music's specific properties such as rhythms, gestures, harmonies, and styles provided them with referents or representations of 'where' they wish to 'be' or 'go', emotionally, physically, and so on:

Like with my R&B, um, most of the time I listen to it when I'm, you know, trying to relax. I'm gonna sleep, sometimes I'll throw on a few tracks to wake me up, nice 'n slow and then I'll throw on, something else. And then, sometimes, you know, if I'm not really not in that relaxed mood,

I'm like, you know, 'I don't wanna listen to that' and I'll throw something fast on, or, something *fast is playing and I'm like 'that's too chaotic for me right now, I have to put something slow on'.* (Latoya, New York City, quoted in DeNora 2000, p. 49)

Respondents made, in other words, articulations between musical works, styles, and materials on the one hand, and desired modes of agency on the other, and then used music to presage, inspire, elaborate, or remind them of those modes of agency and their associated emotional forms. When respondents chose music as part of this care of self, they often engaged in self-conscious articulation work, thinking ahead about the music that might 'work' for them. And their articulations were made on the basis of what they perceived the music to afford. This perception is in turn shaped by a range of matters. Among these are previous associations respondents have made between particular musical materials and other things (biographical, situational), their understandings of the emotional implications of conventional musical devices, genres, and styles, and their perceived parallels (articulations/homologies) between musical materials/processes and social or physical materials/processes.

With regard to this last issue, the popular music scholar Richard Middleton (1990) has provided a useful bridge between sociology's focus on the articulations actors forge between music and feeling and musicology's focus on the ways in which temporal, rhythmic, and harmonic structures may lend themselves to particular interpretations, and how they may afford or instigate particular responses (see also Cook & Dibben, this volume). Middleton discusses what he refers to as 'exosemantic correspondences' between music and spatial or emotional structures/forms (e.g. slow and quiet: 'relaxed'; minor mode: 'depressed'), and develops semiotic concepts of 'primary' and 'secondary' signification (1990, pp. 220–32). The former refers to music's internal references and relationships, its arrangement of structural elements, and to the ways in which its relationships become terms in which to map, frame, and configure (in this case) emotions: '. . .as this note is to that note, as tonic is to dominant, as ascent is to descent, as accent is to weak beat (and so on), so X is to Y' (1990, p. 223). The latter refers to music's connotative level, its ability to invoke or symbolize images, emotions, and ideas.

While, as Middleton (1990) rightly emphasizes, music's material specificity comes to be implicated in emotion construction, music's capacity to engender emotion is by no means preordained. A characteristic of the perspectives on music and emotions discussed so far is their circumvention of, on the one hand, essentialist conceptions of subjectivity (as if feeling arises from internal processes) and, on the other, the notion that music is a 'cause' of emotional states. By contrast, these 'subject-object' dichotomies are bypassed by considering music as part of—a resource for—the reflexive constitution or working up of emotional states or events (see Fig 7.2). Here, music is not conceived as a 'stimulus' nor does it, *pace* Langer (1942), merely 'resonate' with some pre-existing subjective or mental state to which it exists in parallel. Indeed, this view, of which Langer is an exponent, has been subject to criticism from within sociology by Shepherd and Wicke (1997, pp. 12–14) who, though they endorse the idea that homologies exist or are forged between emotions and musical structures, suggest that the insights from musicology on the ways in which music's structures symbolize emotional structures do not 'stretch to an explanation of the mechanisms through which musical processes and processes of subjectivity are involved with one another' (1997, p. 13). In contrast with

musicological conceptions that confine analytical focus to, for the most part, the musical 'object', most of the sociologists discussed so far tend to conceive of music as providing a *resource* for emotional states and their achievement. Neither a cause nor a parallel of emotional states, music is conceived within sociology as providing a candidate simulacrum, or contrast structure, against which feeling may be formulated in real time. To speak of music in this way is to speak of it as a material against which 'how one feels' may be identified, elaborated, and made into an object of knowledge. One may, for example, say in reference to a musical example, '*this* is how I feel', and thereby grow tense and relax as the music does, when the music does, or in ways that are modelled, often without conscious awareness, on the music. It is here, then, that music's vital, and indeed, moral dimension—as declaimed by classical philosophers such as Plato ('in music that the guardians will build their guardhouse'; Plato 1966, p. 72) and Aristotle ('what we have said makes it clear that music possesses the power of producing an effect on the character of the soul'; Aristotle 1980, p. 24) can be seen: musical structures and representations are drawn, by actors themselves, into the vortex of feeling production; they literally 'get into' action and subjectivity.

In short, recent studies of music in relation to the achievement of emotional states and events points to music's use in real social settings as a device that actors employ for entraining and structuring feeling trajectories. Music is a resource to which agents turn so as to regulate themselves as aesthetic agents, as feeling, thinking, and acting beings in their day-to-day lives. Achieving this regulation requires a high degree of practical reflexivity. The respondents in both the French and the English/American case studies show how actors often perceive their 'need' for this regulation and know the techniques of auto-emotion work. These techniques may be found inadvertently (e.g. something is tried once and 'works' and so is later repeated and thus becomes part of an individual repertoire), or they may be suggested through culture and the media (and so be, at least initially, imitative), or they may be handed down by associates (and so exist as part of group or family culture), or initially encountered in a social setting—all of these technique locations were mentioned by respondents.

The natural history of the processes through which feeling states are identified and 'expressed' (i.e. enacted to self or other over time) is, moreover, a topic to be developed as it concerns the question of how aesthetic agency is configured in real time, as passion is choreographed and entrained. Holding on to this focus, but widening it from the individual experience of culture (and the social regulation of emotion in and through reference to cultural materials) to music's role in relation to the organization of collective action and its emotional component is but the next step within this programme. In the remainder of this chapter, I survey classic and recent work devoted to music's regulatory role in relation to emotional conduct between two actors engaged in intimate conduct, and between more than two actors, using the case of social movement activity.

7.6 Music and emotions in close interaction

Studies of gender and musical taste have long directed their focus to music's connections to love and to courtship. Shepherd and Giles-Davis (1991), for example, have reported on the consumption and use of music by a small number of middle-class

English-speaking teenage girls in Montreal, showing how music provides a kind of template for the formation of sexuality and emotional state. More recently, focus has shifted to the question of how music is actually used during intimate occasions and how it may draw bodies into temporal trajectories (rhythms, pulses, corporeal grammars, movement styles, and feeling grammars). Here, music is viewed as a non-verbal accomplice for particular intimate action forms (DeNora 1997), such that 'who puts what on the record player' as a prelude or backdrop for intimacy is overtly conceived as a question of love's real-time construction and its politics.

Many of the interviewees in DeNora's study (in particular the two younger age groups) described, through a rich series of examples from their daily lives, how they sought to structure both the grammar and style of intimate interaction through musical means and also to reproduce feeling styles and forms by using music that had served as the soundtrack on prior intimate occasions. The typical category for this activity was the concept of 'background' or 'mood' music and the interviewees were unanimous on one point: the music should not be fast paced, loud, or jolting. On the contrary, respondents spoke of how they valued the temporal structures and embodied practices commensurate with a slow pace, with leisured intimate activity. Their responses overlapped with what has already been observed in relation to gender and musical taste (Bryson 1997; Frith & McRobbie 1990; Peterson & Simkus 1992). 'Setting is very important' as one respondent put it, because getting the music 'right' is simultaneously a way of trying to make the action 'right', not merely in the embodied and technical sense, but as a way of prospectively calling out forms of emotional and embodied agency that are comfortable and preferable, that 'feels' right in emotional and embodied terms. (Such agency, of course, includes specific material practices, e.g. a 'light' touch or an 'unhurried' approach, and the music can be perceived as providing 'primary significations' of these things and hence employed as a model or blueprint for action):

> I think, last night, it was really funny, it was like 'mood setting' in a way. Cause, like, he had Enya on, and like, as people call that, 'chick music' [i.e. 'women's' music that young men may choose to play when entertaining women because they think it is what women prefer] . . . and he was trying to produce a relaxed atmosphere and um, I think in a way it does promote physical, or just intimacy in general because it's just like, certain music's more calming and, I remember like I think Stigma or Hyper came on and we were like, 'no no no, we don't want that!' and we like tried to get this piece, like I had him play the *First Night* sound track which I love, and there's like, a love song I, there, that's so beautiful, but everything else is like, 'bu bu de bah' [she sings here a triplet followed by a whole note the interval of a fifth higher than the triplet figure] and I'm like, 'no, no, this is not good' but I do, I think it was just very, it's very calming, very intimacy . . .
>
> Q. So it's part of what creates an intimate atmosphere?
>
> Melinda: Yeah, definitely. I think it's, setting is very important, and like music is a very big part of that. (quoted in DeNora 2000, p. 112)

7.7 Music and collective action: the case of social movements

Outside the sphere of intimacy, music can also be seen to serve as a model for emotional agency. One of the key areas where this perspective has been developed is

within the area of social movements, where new work has sought to draw together the sociology of emotions and the sociology of collective action. Taking inspiration from anthropologist Victor Turner's (1981) concern with 'action paradigms' (cultural materials such as narratives and imagery that may be used in ways that 'emplot' courses of action), Ron Eyerman and Andrew Jamieson (1998, p. 23) have attempted to specify how music may be understood to play an organizing role in the structure of collective action:

> To the categories of action discussed by sociologists we wish to add the concept of exemplary action. As represented or articulated in the cognitive praxis of social movements, exemplary action can be thought of as a specification of the symbolic action discussed by Melucci and others. The exemplary action of cognitive praxis is symbolic in several senses; but it is also 'more' than merely symbolic. As real cultural representations—art, literature, songs—it is artefactual and material, as well. What we are attempting to capture with the term is the exemplary use of music and art in social movements, the various ways in which songs and singers can serve a function akin to the exemplary works that Thomas Kuhn characterised as being central to scientific revolutions: the paradigm-constituting entities that serve to realign scientific thinking and that represent ideal examples of fundamentally innovative scientific work (Kuhn, 1970). The difference between culture and science, however, is that the exemplary action of music and art is lived as well as thought: it is cognitive, but it also draws on more emotive aspects of human consciousness.

As with the examples of individual feeling work discussed by DeNora (1999, 2000) and Hennion (Gomart & Hennion 1999; Hennion & Masisonneuve 1998), Eyerman and Jamieson (1998) describe how music may serve, within the context of social movement activity, as a prescriptive device of agency. Within music's structures, its perceived connotations, and its sensual parameters (dynamics, sound envelopes, harmonies, textures, colours, etc.), actors may 'find' or compose themselves as agents with particular capacities for social action.

For example, Eyerman and Jamieson (1998) describe how Todd Gitlin, a president of the Students for a Democratic Society (SDS) in the 1960s, described the SDS's identification with the music of Bob Dylan ('we followed his career as if he were singing our song; we got in the habit of asking where he was taking us next'; p. 116). In this sense, music may be conceptualized as akin to what Robert Witkin (1974) calls a 'holding form'—a set of motifs that proceed, and serve as a reference point for, lines of feeling and lines of conduct over time. Viewed as such, music plays a role that is similar to that of memory artefacts, as discussed by Urry (1996) and Radley (1990): musical motifs are orientated to for the ways they encapsulate and provide a container for what might otherwise pass as a momentary impulse to act, or a momentary identification of some kind. Holding forms thus provide a touchstone to which actors may return as they engage in collective expressive activity. They are the templates within which agency takes shape and to which actors may refer to renew themselves as types of agents and emotional agents.

Seen in this light, the study of how music is appropriated for emotion work illuminates a fundamental topic within sociology: it provides a way of exploring how social reality, with its forms and relations of feeling, are produced in real time and within specific social milieu. Critical then is the issue that held Adorno and which concerns

music's role in modern societies, the matter of how the aesthetic environments that come to afford agency's production are themselves produced. And so the study of consumption returns full circle to the study of production and dissemination as complementary enterprises. Especially with regard to the public spaces where agency is produced, music's role here has grown massively over the past two decades. If music is a device of social ordering, if—in and through its manner of appropriation—it is a resource against which holding forms, templates, and parameters of action and experience are forged, if it can be seen to have 'effects' upon bodies, hearts, and minds, *then* the matter of music in the social space is, as I have discussed above, an aesthetic-political matter. This is why matters of musical taste have, throughout history and across culture, often been contentious.

7.8 Conclusion

It seems fair to characterize current sociology of music as involved in two projects with regard to the emotions. The first is to produce portraits of music 'in action', that is, ethnographic documentaries of actors' musical practices and of the role these practices play in the production of emotion in real time and specific social settings. The second is to use these ethnographic reports to generate grounded hypotheses of how music functions in social life, what it does, and how it is reflexively implicated in the creation and recreation of social realms, events, and states.

With regard to this second aim, current work on music as a dynamic medium in social life has highlighted music's role as providing a structure or container for feeling, one whose specific properties contribute to the shape and quality of feeling as it is articulated and sustained in real time within and between individuals as part of the fabrication of ongoing social existence. In short, music is a resource for the practical constitution of entities we know as 'selves' and also for emotions and states that we refer to as 'intersubjective'. It is also a resource for the prospective structuring of action and a material that actors may employ as a referent or template as they elaborate and fill in, to themselves and to others, the modes of agency and subjective stances and identities that are structure-in-action. New work in the sociology of music and the emotions has been devoted to revealing music as it 'gets into' and is incorporated into action and to illuminating this process as it is achieved in and through actors' musical practices. This sociology of the 'musical composition' of subjectivity should be distinguished from more general post-structuralist or post-modernist theories of subjectivity and its 'cultural construction' that deal with emotions and subjectivity in monolithic ways and often leave little space for actors' creative and adaptive practices of emotion work. By contrast, the new sociology of music is devoted to a task that far exceeds assertions about music and the subject positions it may place on offer. It is concerned with specifying these matters at the level of action and action's 'heart' where actors are involved in the production of their social 'experience' and also in the mobilization of cultural and aesthetic materials for being, doing, and feeling. Anything less than this cannot address or begin to account for the mechanisms through which cultural materials 'get into' social psychological life and provide building materials of action.

CHAPTER 8

MUSIC AND EMOTION: PERSPECTIVES FROM MUSIC THERAPY

LESLIE BUNT AND MERCÉDÈS PAVLICEVIC

This chapter focuses on the relationship between music and emotion from within what is generally called 'improvisational music therapy' and aims to explore how a music therapist begins to generate and receive patients' emotional responses to the music in music therapy. We do not attempt to duplicate existing literature by reviewing the clinical and research literature of music therapy, nor do we provide an overview of the profession and the various applications of music as therapy. Instead, the chapter is divided into three main sections. We begin with some general background to music therapy and how connections with emotions are observed in clinical practice. Then follows a summary of a study that investigated how music therapists are able to judge the intended presentation of a series of basic emotions by listening to short improvisations played live by colleagues. This hopefully sheds light on the complex range of emotions within the more natural interplay of the patient's and therapist's improvised music. In the final section, we explore this world of co-created music with patients in music therapy by examining recent work on early infant development and elaborating on the connections between the musical and personal in improvisational music therapy using the theoretical concept of dynamic form.

8.1 Some background to music therapy

Music as a therapy provides patients of all ages with an effective means of exploring and communicating a wide range of emotions. As a contemporary discipline, music therapy has developed consistently over the last 50 years, with rapid strides over the last couple of decades in Europe, North and South America, and more recently in the Far East, Australia, New Zealand, and South Africa. Historically, the music therapy profession emerged from work with children and adults where difficulties in communication resulted from profound disabilities or mental health problems (e.g. Alvin 1975; Nordoff & Robbins 1971, 1977; Priestley 1975). A steady profusion of texts during the 1990s indicates how the range of work has developed in various settings: preschool centres and nurseries for children; special schools and units for children with varied learning difficulties; hospitals and special units for adults with learning difficulties, physical disabilities, mental health and neurological problems; hospital units and centres for older

people and for people with visual or hearing impairments; hospices and specialist centres for people living with terminal illness; and the prison and probation service (Aldridge 1996, 1999, 2000; Ansdell 1995; Bruscia 1991; Bunt 1994; Heal & Wigram 1993; Lee, 1995, 1996; Pavlicevic 1999*a*; Wigram & de Backer 1999*a*, 1999*b*; Wigram *et al.* 1995).

Examples of research into the clinical efficacy of music therapy with different populations are reported in these texts, as well as, for example, in the *British Journal of Music Therapy* and the US-based *Journal of Music Therapy*. These journals regularly present the results of both outcome and process-based studies, including, for example, studies on music therapy with preadolescents (Montello 1998), autistic children (Edgerton 1994), adult psychiatric patients (Heaney 1992; Pavlicevic & Trevarthen 1989, 1994), as well as the use of music therapy in paediatric oncology settings (Standley & Hanser 1995). Current research uses a proliferation of research techniques drawn from both quantitative and qualitative perspectives (for a review, see Wheeler 1995). Some researchers consider a qualitative approach as being more in keeping with the nature of music therapy practice (for a review, see Langenberg *et al.* 1996). Others propose that music therapy researchers need to continue using both, with different contexts and questions necessitating different perspectives (e.g. Smeijsters 1997). It is interesting that this debate has evolved out of a context of a more established clinical base, with practice preceding research.

8.1.1 Active and receptive approaches

Psychological responses to music are the bedrock of much that takes place in music therapy. People of all ages with wide-ranging health care needs come to music therapy and make fundamental connections between their emotions and the music that they experience either as active participants or as listeners. In music therapy, we can observe how music can be used to both express and arouse a wide gambit of emotions.

In an essentially active approach, patients are encouraged to articulate their emotions externally by forming musical gestures and structures. This process can be observed most clearly in improvised music making where the roles of composer and performer merge. Here there are also very close connections in the chain of communication between the originator of the music and the recipient. In a receptive approach, various emotions can be aroused while listening to pre-composed music played live by the therapist or on a recording—and this could include recording of previous improvisations.

Further levels of complexity are inherent in music therapy because emotions emerge alongside the facilitating presence of a music therapist who engages with the patient(s) in active musical involvement, by playing music to the patient(s), with the patient(s), or by listening to music together. Any of these scenarios finds a context within individual or group work. The overlapping links between music and emotions, therapeutic relationship, and the various needs of patients are featured in many definitions of music therapy, for example: 'Music therapy is the use of sounds and music within an evolving relationship between child or adult and therapist to support and encourage physical, mental, social and emotional well-being' (Bunt 1994, p. 8).

The complex interactions between the various musical and personal dynamics within music therapy can be illustrated with a quotation from Francis, a musician and patient

who lived with AIDS. His voice is a crucial part of Lee's (1996) extensive case study. Discussing the importance of his music therapy Francis said:

> I feel this is almost like a testament. It is the only expression I have of a spiritual journey. The only time that I feel that I am living and communicating. The only time that I feel I'm living the time I have left is when I am improvising. The rest of the time I'm wondering what the hell I'm doing. Time is a limited factor. When I'm doing these sessions with you I am actually living a moment; I'm actually living with somebody and producing something and revealing myself. When I'm improvising, when we are improvising together, I feel that I am saying something and living—and it's terribly important to me. (Lee 1996, pp. 77–8)

Francis talks here of the importance of living in the present moment of making music (cf. Sloboda and O'Neill, this volume). The music therapy sessions are a means for Francis to gain more understanding about his emotions, and to contribute towards a greater sense of self. It is important that his music is heard not in isolation but in the context of sessions that involve a relationship with the therapist. The quote from Francis relates in several ways to Christopher Small's use of the term 'musicking' (1999, p. 13):

> The act of musicking brings into existence among those present a set of relationships, and it is in those relationships that the meaning of the act of musicking lies. It lies not only in the relationships between the humanly organized sounds that are conventionally thought of as being the stuff of music, but also in the relationships that are established for the duration of the performance between the participants within the performance space.

Small observes how these relationships can model relationships in the world outside the performance space: 'relationships between person and person, between individual and society, between humanity and the natural world and even perhaps the supernatural world' (Small 1993, p. 13). Parallels can be drawn here with therapist and patients in improvisational music therapy: the musical relationship that develops between the players is personally intimate and relationally significant—for both therapist and client. Moreover, it has direct links with patients' lives outside the therapeutic space, offering patients opportunities to explore, extend, and gain meaning into their emotional lives, both within and outside the therapeutic relationship, and to make connections between their individual and social lives.

8.1.2 Musical material in therapy

The range of musical material used to generate a therapeutic relationship is, naturally, context-dependent. One day a music therapist may be facilitating a group improvisation that evolves naturally from a song of emotional significance sung by an elderly patient. The next day may see the same music therapist with a profoundly disabled child working with very elemental sounds or short phrases of music. Here, in addition to the limited musical gestures, any responses and communication of emotions may be via eye blinks, changes in breathing, or subtle shifts in body posture. The therapist's musical and personal response to, and matching of, a patient's musical and personal presentation is in keeping with a well-established principle used in music therapy, namely the 'iso-principle' (Altshuler 1954).

In improvisational music therapy, the improvised music emerging from a session with a group of young children with language problems and limited attention will be

qualitatively different from a session with a group of adults with mental health problems (and will also have different emotional significance). In terms of explaining the efficacy of music therapy, the group of language-delayed children may be so motivated to play the instruments and vocalize that their shifts in levels of excitement, quality of relationship, and emotional experiences and expressions may generalize outside of the sessions into further use of vocal sounds, gestures, and a corresponding rise in self-esteem. Likewise, the group of adults with mental health problems may be able to explore the shifting patterns of relating to one another and to the therapist in music and, with the therapist's help, draw analogies to more personal systems of interaction—both within and outside the music therapy setting.

Each of these scenarios presents a complex and multilayered generating, expressing, and conveying of emotional feelings and is dependent upon the music therapist's capacity to generate, judge, and read emotional responses to the music by patients within therapy. Understandably, the development of attentive listening, awareness, and empathy are some of the core qualities needed to work as a music therapist. But before exploring in more detail the various aspects of emotion in music therapy, we first make a brief detour to explore some of the recent thinking about music and emotion highlighted in this volume. Such thinking is potentially enriching to music therapy thinking and practice.

8.2 Sources of emotion in music therapy

Sloboda and Juslin (this volume) review different sources of emotion in music. There are examples of these meeting points between music and emotion in music therapy.

8.2.1 Associative connections

We are familiar with this connection, the 'Darling, they're playing our tune' notion (Davies 1978), in passive or receptive music therapy. Here, the music is a very powerful trigger that can set off a whole range of associations with specific events and places, memories of certain people, particularly if the experiences or people have been significant in a patient's life. The associations are generally highly individual, making it difficult to predict how different people will associate with different musical repertoires (Pavlicevic 1997). This necessitates much work on the music therapist's part to discover the musical preferences and history of the individual patient. This kind of emotional association is often the focus of work with elderly patients, when music can be used as a kind of reminiscence therapy (Odell-Miller 1995). It is also apparent in hospices and palliative care work where sensitive discovery of a patient's personal musical history is often a starting point of the treatment programme (Aldridge 1999; Lee 1995, 1996).

8.2.2 Iconic connections

Listening to a particular sound or series of sounds, whether improvised or pre-composed, can link musical characteristics to some external musical event or human feeling. For example, a group of children with learning problems can relate a general build-up of loud and fast sounds with a growing storm at sea or some other such high

energy event. Improvising to an external theme provides members of a group in a cancer unit, for example, with opportunities to channel and shift levels of energy, to begin to release deep-set levels of tension and to work together towards a common aim (Bunt & Marston-Wyld 1995; Burns *et al.*, 2001). Such a group may wish to improvise to a given theme or pair of emotions, for example to represent shifts from darkness to light, sorrow to joy, etc. Patients may decide to give a specific feeling-based label to an improvisation after hearing a recording of the piece. Not all patients are comfortable making such connections. Some patients are drawn to the very ambiguous nature of music, preferring to perceive the musical experience as an event in itself. They may acknowledge the emotional power of a musical improvisation or listening experience, but wish to contain the experience within the music and not wish to explore any external associations.

8.2.3 Intrinsic connections

There are many examples in music therapy practice—in both active and receptive approaches—when connections can be observed between the emotional experiences of the patients and both surface and deep structural aspects of the music. For example, we can observe how intrinsic features of the musical structures evoke different emotions in the specific listening approach, guided imagery in music (GIM):

> This does not happen in any simplistic one to one symbolic or causal correspondence between one musical gesture and the creation of an image but in an on-going organic and interactive way. In any series of GIM sessions we can observe similarities between different musical structures and processes and certain structures and processes in the imagery. At the same time of hearing the music the client is also creating an instantaneous link between image and music. It is as if the client is experiencing the music at different levels from the surface to the deep structural, reaching into the music to find the level that matches and resonates with the image. (Bunt 2000, p. 46)

GIM, created by Helen Bonny, involves listening to specifically programmed sequences of recorded music in a deeply relaxed state. The 'traveller' is invited to share the experience and any images or feelings with the therapist/guide (e.g. Bonny & Savary 1973; Bruscia 1995; Clark 1999; Erdonmez Grocke 1999). The images evoked by the music may be visual in nature but also body-based; they may open up a particular pattern of thought or various levels of emotional response. In many ways GIM demonstrates the interaction between the three kinds of connections discussed in this section. A particular melodic detail or surface musical detail may trigger a number of personal associations, memories, and images. Iconic associations may be made between aspects of the music and non-musical events. GIM therapists also witness patients making intrinsic connections between layers of musical expectations and deep structures and the forms and patterns of their internal emotions. The selection of the music used in GIM is indicative of the attention paid to the potential for these kinds of interactive connections.

One of the authors recalls a powerful emotional experience working through Bonny's programme entitled 'peak experience.' The sequence of music is: the 'Adagio' from Beethoven's Fifth Piano Concerto; the 'Et in Terra Pax' from Vivaldi's *Gloria*; the 'Adagio' from Bach's Toccata, Adagio and Fugue in C; the 'In Paradisum' from Fauré's *Requiem*, and the Prelude to Act I of Wagner's *Lohengrin*. A review of the written

transcript of the session indicates how certain moments in the music triggered personal associations, memories, and evoked external images. In addition to these links there were many intrinsic connections. The overall order of the pieces created a mood of expectancy and deepening feelings of awe and wonder. Body-based reactions—changes in breathing, shudders, tension in the stomach, or feelings of lightness, etc.—were closely entrained with the formal aspects of the music—phrasing, changes in pitch, sudden harmonic shifts, shifts in loudness levels, density of the textures, etc. The climactic moments of the Prelude to *Lohengrin* corresponded with the most illuminating and profoundly moving moments of the session, the powerful memory of which has proved long lasting and in many ways transformative.

As a link to the next two sections of the chapter it is worth recalling Bruscia's (1989) useful distinction between 'active' music therapy, generally understood as based on the playing of music—whether pre-composed or improvised—and 'receptive' music therapy, generally understood as listening to music. We have already discussed some receptive approaches and shall now comment further on the use of active music therapy.

8.3 Active music therapy: the example of improvisational music therapy

Improvisational music therapy is a generic term for those approaches in which the act of improvisation is understood as the locus of the therapeutic encounter between therapist and patient, in either individual or group work. Patients in music therapy improvise; the music therapist improvises. The participants in any improvisation make personal variations within the musical forms, the process of deciding what to play and how to shape musical events changing moment by moment. The music therapist values and attends to all the musical communications made by the individual or group member—there is no 'right' or 'wrong' way of playing. In the psychologically and physically safe context of a therapeutic setting, the different forms of improvisation can also help an individual to try out different aspects of relating both within the self (intramusical and intrapersonal) and between people (intermusical and interpersonal) (e.g. Bruscia 1987, 1989). We can view improvisation as a means of negotiating both old and new meanings.

For example, in a group therapy setting with adult patients, instruments such as drums, cymbals, marimbas, xylophones, guitars, and bongos focus the initial musical curiosity of a group of chronically ill patients referred to a music therapy group by the hospital's psychiatrist. The adults begin to explore the instruments and try out the different sounds. The therapist creates an initial sense of security by suggesting an opening improvisation based on a repeating steady pulse. Gradually, members of the group improvise patterns around the pulse. The group members grow in confidence as they explore freer kinds of improvisation. They pass musical messages to one another and play in small groups. The improvisations release a wide range of feelings and verbal exchange takes place in between the improvisations. After a lengthy discussion, the group decides to improvise on a theme, one that moves from despair to hope. Further discussion ensues exploring the emotions brought to the surface during the long group improvisation. A final improvisation adds a sense of closure for the group.

Music therapists respond instantaneously to the sounds that emerge in improvisations. How will the therapist be able to understand the sound gestures? How will the child or adult be able to use the instruments as a direct and authentic expression of different emotions? How can any communications be read, interpreted, and met or engaged in the therapist's authentic music? Can there be any sense of shared meaning? These are some of the challenges that daily confront a practising music therapist. The therapist will also bring to the music therapy room a range of previous experiences, both personal and musical, that will inform how such musical gestures are read. In addition, these gestures will most likely be framed within a particular philosophical, psychological, or therapeutic perspective which could include anthropological, behavioural, cognitive, developmental, humanistic, medical, musicological, psychodynamic, or transpersonal approaches (see overviews by Aigen 1998; Aldridge 1996; Ansdell 1995; Bruscia 1987; Bunt 1994, 1997; Pavlicevic 1997; Ruud 1980). A therapist working within a psychodynamic framework, for example, will be making use of the dynamics of transference and countertransference in understanding the various relationships between the patient and the music, the patient and the therapist, and, in group work, the patient and other patients (see Bruscia 1998; Priestley 1994).

We shall now focus in more detail on aspects of the generating and receiving of emotion through music in the realms of clinical improvisation and in Pavlicevic's development of her theory of dynamic form in music therapy.

8.4 Generating and judging emotion in short improvisations: a small study

A critical aspect to the generating and receiving of emotion in music therapy is the direct experiencing of emotion within the listener/player, as well as the recognition of emotion within the music itself.

8.4.1 Background to the study: improvisation and emotions

Research by Gabrielsson and Juslin (1996) which investigated the connections between the performer's expressive intention and the listener's experience was the inspiration behind a simple classroom exercise to explore the kind of instantaneous observations music therapists make to judge the intended emotional content of short improvisations. We explored how a limited number of emotions—happiness, sadness, tenderness, anger, and fear—were judged. These emotions have been regarded as 'basic' by many researchers (see Sloboda and Juslin, this volume).

Deciding to use short examples of improvised music played live by individual music therapists to the listening groups was an essential feature of this study. Would the music therapists playing the short improvisations be able to communicate the intended emotion? Would the therapists listening to the improvisations be able to judge the correct emotional intention? What musical parameters would the listeners use to decode the emotional expression of each improvisation? Behrens and Green (1993) have pointed out some advantages of using improvisations as compared to pre-composed music in judging the affective content of musical examples. There is no question of familiarity;

the emotional intention of each composer/improviser is known in advance; the length can be controlled, and each presentation can represent a complete musical idea. The use of live, as opposed to prerecorded, examples in our study added additional variables, namely the influence of visual and other non-verbal cues (for example, facial expressions, body movements, posture) in communication of the intended emotion.

8.4.2 Procedure

Two groups of music therapists took part in this study. The first was a group of thirteen music therapy students in their final stages of training, the second a group of eleven music therapy researchers and teachers. The student group was divided into two groups of six and seven and the researchers worked together as one group. The same procedure was used for both the student and researcher groups (referred to as S and R, respectively, in Table 8.1). Descriptions of the five emotions were written on cards and placed face down on a table. Individual therapists from both groups were invited to make a random selection of a card and to improvise freely within the prevailing emotion indicated for a period up to 2 minutes. The improviser could choose from within a wide range of tuned and untuned percussion instruments (e.g. xylophone, drum, cymbal, bells) as well as the therapist's own instrument (e.g. flute, piano). The therapist was asked to spend a few moments trying to access the particular emotion before selecting an appropriate instrument or group of instruments. Some therapists chose also to sing. The improvising therapist then played or sang to the listening group with the intention of expressing the emotion from the card, the title only being shown to the study's convenor.

After each improvisation, the listening music therapists were asked to rate each improvisation for the expression of each emotional state using the scale: 0 = improvisation does not express the state to 4 = improvisation does express the state (the same range as used in the Behrens and Green study). A score was required for each of the five emotions for each musical improvisation since overlaps were expected in decoding certain emotions. For later descriptive analysis, the listeners were also asked to list both musical and other reasons for their judgment of the main emotional state being communicated. There was a total of 26 improvisations (Table 8.1).

8.4.3 Results

The columns in Table 8.1 are used to designate the intended emotional expression of each improvisation and the rows the corresponding adjectives used by the listeners to rate each improvisation. The mean ratings of the respondents are used for each improvisation and total means are tabulated. *F*-tests were used to test for intended expression. The results were highly significant and provide strong evidence that the responses vary between descriptions.

Looking at the mean responses, clearly happy and angry descriptions correspond to happy and angry intended expressions. We can note that there were some overlaps in the ratings of certain emotions, for example sadness/tenderness and angry/fearful. The music therapists also listed the musical parameters and other observations that aided the process of decoding the intended emotions (Table 8.2).

Table 8.1 Mean ratings for each improvisation and group totals

Description	Intended expression				
	Happy	**Sad**	**Tender**	**Angry**	**Fearful**

R, research improviser; S, student improviser; *t*, total mean for each series of improvisations. The bold type indicates the correct judgment of intended emotion.

Table 8.2 Various parameters used by music therapists in decoding basic emotions

Happy
Tempo and rhythm: fast, flowing tempi; lively, skipping, dotted rhythms; firm pulse
Pitch and melody: high pitches, rising melodies
Tonality and harmony: major tonality, clear structured harmony
Timbre, texture and style: bright textures and timbre, much staccato
Loudness level: no major shifts, mainly middle ground
Phrasing and structure: clear, predictable, many short 'flourishes'
Non-verbal communication: smiling, free body movements, foot tapping, bouncing, clapping, upright posture with no apparent tension, a 'twinkle in the eye'
Other: feeling of abandonment, much communication of high levels of energy, meeting cultural expectation of feeling happy

Sad
Tempo and rhythm: slow pulse (absence at times), gentle rhythms
Pitch and melody: wandering, hesitant and unfocused melodies
Tonality and harmony: minor tonality, small intervals, some dissonances, no sustained tension
Timbre, texture and style: sustained, legato, use of single sounds, flat timbre with blurring of sounds, slow vibrato
Loudness level: predominantly soft, small range from *pp* to *mf*
Phrasing and structure: falling phrases
Non-verbal communication: little movement, flat expression, slow breathing, concentration in the eyes, head hanging low
Other: feeling of being unresolved, general look of sadness and introspection

Tender
Tempo and rhythm: gentle, slow pulse, lilting rhythms
Pitch and melody: gradual rise and fall to the melody, frequent glissandi, lyrical
Tonality and harmony: major and minor alternation; use of modes, supportive accompaniment with broken chords and gentle arpeggios
Timbre, texture and style: a light touch and texture, sustained
Loudness level: soft
Phrasing and structure: legato, use of pauses
Non-verbal communication: stillness, enclosed posture, head hanging low
Other: communication of relaxed and reflective state

Angry
Tempo and rhythm: quick tempi, jerky rhythms, sudden changes in rhythmic patterns with accents
Pitch and melody: low sounds, unpredictable or absence of melody, clusters
Tonality and harmony: minor tonality, atonality, feeling incomplete
Timbre, texture and style: fragmented sounds; strident, harsh and percussive timbres
Loudness level: very loud, distorted sounds, strong and forceful
Phrasing and structure: some repetitions, absence of order, shape and form
Non-verbal communication: aggressive body movements
Other: much construed from strong level of energy and shape of opening musical gesture

Fearful
Tempo and rhythm: rapid and jerky tempi and rhythms
Pitch and melody: low sounds, minor tonality or lacking a sense of tonality
Tonality and harmony: random and tense dissonant harmonies, strong chords and clusters
Timbre, texture and style: fragmented, heavy textures
Loudness level: sudden bursts of loud playing building to climaxes
Phrasing and structure: pauses creating feeling of unrest, general lack of organization, no clear pattern or shape
Non-verbal communication: jumpy movements, weighty feeling to the body
Other: cultural stereotypes, e.g. tremolandi; sense of confusion, chaos, hesitation and disconnection; fear read in players' faces

8.4.4 Discussion

Clearly, the music therapists who played or sang these short improvisations were able to communicate the intended emotions to the listeners. The listening music therapists were able for the most part to judge accurately the intended emotional expression. The detailed musical parameters were used almost instantaneously as evidence before selection of the main intended emotion was made: evidence preceding the inference. The improvisers were able to communicate some of the very basic emotions: happiness, sadness, tenderness, anger, and fearfulness. These are very common features of many musical presentations made by patients of all ages. An interaction was observed between tender and sad, alerting music therapists to the need to be particularly cautious in jumping to quick judgments with these and other more than basic emotions. We may describe an improvisation as tender and can pick up the general feeling, but it is hard to be more specific. The students found close links between both sad and tender and between angry and sad. These mixed responses are a feature of the interaction effects of even the most basic of emotions (for further elaboration, see Juslin, this volume). There were also discrepancies picked up when a player appeared to find it difficult to articulate a particular emotion. To some extent, this study was also a judgment on how well each improviser was able to communicate the intended expression.

The musical parameters and other behaviours used to describe how each intended emotion was judged indicate the subtle interaction between musical and other cues. Clearly, visual cues are highly relevant in adding meaning to an emotional gesture. It would be interesting to repeat the exercise with the listeners closing their eyes. Music therapists also often enter into the musical world of their patients by playing music with them. This provides a far closer and resonant means of relating directly with the expression of a specific emotion. The emotion may then be embodied in the joint action of interactive music making. The therapeutic situation also differs from the classroom setting of this study in the fact that a more spontaneous and natural expression of emotions can be observed.

In the next section of this chapter, the concept of dynamic form in music therapy is presented, exploring the personal/emotional and musical/emotional interface in clinical improvisation.

8.5 Dynamic form

8.5.1 Understanding improvisation in music therapy

Explaining the emotional nature of improvisation in improvisation music therapy models (Bruscia 1989) presents complex issues for music therapists and music psychologists because of the musical, psychological, and relational dimensions of the improvisatory act. Music therapists generally understand the spontaneous act of 'improvisation' as being 'more than'—or 'other than'—music improvisation as an 'artistic' event; and as having personal and interpersonal significance. Such improvisation is labelled 'clinical' and is defined by the Association of Professional Music Therapists (UK) as: 'Musical improvisation with a specific therapeutic meaning and purpose in an environment facilitating response and interaction' (quoted in Odell-Miller 1988, p. 54).

At the same time, however, the act of improvisation in music therapy may well draw stylistically from the 'musical' repertoire (for example, the therapist, being a skilled musician, may well use idioms from jazz, blues, modes, boogie-woogie, romantic or baroque music, or free improvisation). This duality of the 'personal' and 'musical' in clinical improvisation has given rise to much debate between therapists, especially with regard to whether or not verbal interpretations of psychological material are necessary, and how words can explain the musical act itself (e.g. Aigen 1999; Ansdell 1995; Pavlicevic 1997; Streeter 1999).

As well as drawing directly from allied theoretical frameworks, as stated earlier, music therapists also describe and explain clinical improvisation using a variety of discourses, including those from behavioural theory (Madsen *et al.* 1968); musicological theory (Ansdell 1997; Lee 1989, 1990); psychoanalytic theory (Brown 1999; Priestley 1994; Robarts 1996; Streeter 1999; Tyler 1998); the medical literature (Aldridge 1996); psychology (Aigen 1999; Bunt 1994; Nordoff & Robbins 1971; Pavlicevic 1997); anthropology (Ruud 1998*a*, 1998*b*); and semiotics (Styge 1999).

8.5.2 A brief scenario

Andrew, a teacher suffering from depression as a result of a family bereavement, arrives for a first therapy session and is presented with a room full of various percussion instruments. He has no formal musical training, and last played music at school. He has been referred to music therapy by his general practitioner, to help alleviate Andrew's depression. At the therapist's invitation, Andrew chooses to play an African Conga drum, and begins to beat it somewhat tentatively, erratically, using both hands in a rather clumsy manner. The music therapist listens closely to what Andrew is playing, and hears the tentativeness in his rhythmic patterns, the dull timbre, the slow and erratic pulse, the uneven dynamic level: somewhere between mezzo-piano and mezzo-forte, with the occasional sforzando thud.

Soon she begins to play with him, on the vibraphone, meeting his playing on the Conga. Even though Andrew's beating is erratic, she can detect some fundamental pulse, which she reflects in her own spontaneous playing. She also matches his dynamic level and reflects aspects of his rhythmic patterns, attempting to establish a therapeutic relationship through musical sounds. Soon after beginning to play with Andrew, the dorian mode comes into the therapist's mind, influenced, perhaps, by an aspect of their joint rhythmic forms which remind her of a folk tune. She begins to improvise in this style, while at the same time continuing to meet Andrew's tempo, rhythm, dynamic level, and so on.

To an uninformed listener, their joint playing might well sound like a 'musical event'. Music therapists, however, are able to distinguish between music therapy improvisation (in which the emphasis is on the interpersonal, emotional communication between the players) and 'non-clinical' music improvisation (in which the emphasis is on the musical content and processes). Indeed, an exploratory study reports that 'blind' music therapist listeners asked to identify music therapy and non-music therapy improvisation are able to identify each of these correctly. Moreover, they report being able to 'hear therapeutic thinking' when listening to music therapy improvisations. In contrast, they describe non-clinical improvisation as being musically driven (Brown & Pavlicevic 1997). But how is

this distinction to be understood? What is its theoretical foundation? The next section offers a brief explanation for understanding clinical improvisation as a personal–relational act between therapist and patient: one that elicits and generates emotion.

8.5.3 The musical as personal

During Andrew's opening moments on the Conga drum, the therapist listens to two things—as one. As a musician, she groups the musical elements of rhythm, pulse, dynamic level, pitch, and timbre, creating a musical event in her listening mind. Based on this, a melody enters her mind in the *dorian* mode, which she begins to play on the vibraphone: this is the 'musical' aspect of the therapeutic event. The other listening is a 'personal' one—and, more specifically, an emotional listening to Andrew. Here, it is the qualities of Andrew's spontaneous playing—that is, the *erratic* pulse, the *tentative* rhythmic patterns, the *dull* thudding of the drum, the *unsustained* dynamic—that reveal Andrew to her as a person (rather than as a musician). When the therapist joins in with his playing, it is with the intention of meeting him directly, as a person (rather than meeting only his music)—through musical sounds. She meets his erratic, tentative, unsustained playing—without, initially, attempting to 'rectify' it in the musical-aesthetic sense—immediately establishing emotional rapport with him. This is the 'interpersonal' and 'musical' duality of clinical improvisation: an event that instantly interfaces musical form and basic expressive qualities. This duality has gained rich understanding by drawing from the psychological literature that has explored the innate musicality of infant communicative behaviour—explored briefly below.

8.5.4 Infant musicality and mother–infant communication: a blueprint for understanding emotion in music therapy improvisation?

Psychological literature on early infant development has shown that newborn infants are neurologically predisposed to identifying, and responding to, contours and rhythms of movements, gestures, and vocalizations in their mothers' gestures, vocal sounds, and facial expression (Malloch 1999; Robb 1999). In addition, they 'tune in' to subtle shifts in vocal timbre, tempo, and volume variations, and with their mothers negotiate and share a flexible musical pulse between them, constantly adapting their tempo, intensity, motion, shape, and contour of their sounds, movements, and gestures in order to 'fit' and to communicate with one another (Beebe *et al.* 1985; Papoušek 1989; Papoušek & Papoušek 1991; Stern 1985; Trevarthen 1993, 1999; Trevarthen & Aitken 1994). Mother and infant develop and share a rich musical 'code' that has interactive significance (Papoušek 1996).

These sensitivities can be understood as an innate susceptibility to 'musical' patterning, which is critical for the infant's biological survival in terms of communicating and expressing fundamental needs such as hunger, distress, discomfort, frustration, and contentment to its mother (or primary caretaker). Thus, infants receive, elicit, and respond to their mothers' movements, gestures, and acts, not as musical or temporal events or 'behaviours' in themselves, but rather, as being *personally* expressive and communicative; that is, as the basis for forming human relationships (Papoušek 1996). Adults too seem to intuitively fine-tune to infants with nuances of rhythm, tempo, and

intonation in 'infant-directed' speech, which contrasts with the 'musical' nuances of 'adult-directed' speech (Trehub & Trainor 1993; Unyk *et al.* 1992). Adults seem to show an innate capacity for enabling and inviting the infant to enter into interactional synchrony with them: that is, as adults we do not need to be 'trained' or to 'learn' how to communicate with babies. The concept of 'interactional synchrony' (Bernieri & Rosenthal 1991; Brown & Avstreih 1989; Condon & Ogston 1966) explains what can be seen as a dance between persons, in which each adapts and shifts eye gaze, head movements, body movements, and vocal sounds in order to personally 'fit' and 'exchange' with the communicating partner (Feldstein & Welkowitz 1978).

Stern's concept of 'vitality affects' (Stern 1985), as well as other mechanisms of non-verbal communication are offered in support of this understanding. Stern explains 'vitality affects' as the qualities of shape or contour, intensity, motion, and rhythm—'amodal' properties that exist in our minds as dynamic and abstract, not bound to any particular feeling or event—enabling us to 'make sense' of the world. Thus, a 'bursting' into tears (or laughter), a bursting watermelon, a musical sforzando, or an athlete's final 'burst' of speed may well share—in our minds—the same 'vitality affects' in terms of intensity, motion, contour, and rhythm. Qualities of, for example, surging, fading away, fleeting, or being drawn out, also underpin the way that we move, talk, gesture, and express feelings, and their presence in our minds enables us to receive the acts and gestures of another as a unified whole—and as carrying emotional meaning.

The concept of 'vitality affects' also explains our capacity to 'recognize', in pre-composed music, what Langer (1942, 1953) calls the 'morphology' of feelings: we hear the swooping, brittleness, tentativeness, and increases in intensity because these very qualities exist in our minds as 'amodal' forms, common both to music and to feelings. From a music therapy perspective, Stern's 'vitality affects' can be understood as being essentially 'musical' in character, realized in clinical improvisation in music therapy (Pavlicevic 1990, 1995, 1997). Because 'vitality affects' are abstract forms that can be expressed through any of our acts (e.g. we may talk, walk, play music, and show anger or joy in a quickly shifting, 'loud', and 'fast' manner), and because 'vitality affects' can be understood as essentially 'musical' in character, then we can consider spontaneous musical acts in music therapy to be personal—as well as musical (for further discussion of 'vitality affects', see Sloboda & Juslin, this volume). But how does improvisation in music therapy 'work' as an interpersonal, emotional event?

8.5.5 Improvisation as an interpersonal event: dynamic form in clinical improvisation

The concept of dynamic form represents this duality of the musical and the personal in music therapy improvisation. Whilst not denying or diminishing the *musical* basis of the therapeutic event in music therapy (after all, clinical improvisation frequently draws from the *musical* stylistic repertoire), dynamic form is grounded in Stern's 'vitality affects'. However, it is more than the direct realization of 'vitality affects' through sound. Rather, dynamic form is at the same time musical *and* relational (or interpersonal) in character. This distinguishes it from Langer's (1942, 1953) morphology of feelings in music, and from the deeply intrapersonal experience of listening to, or performing pre-composed music. Its communicative and relational agility also distinguishes it from free improvisation—which resonates primarily with stylistic and grammatical rules of

music. Dynamic form is elicited within, and as part of, the clinical–musical relationship, using the communicative and expressive mechanisms of basic emotions, that is, those of intensity, contour, tempo, rhythm, timbre, and dynamics. Dynamic form is generated by both therapist and patient, who relate intimately and directly with one another through jointly created sounds (Pavlicevic 1990, 1997, in press). These musical sounds correspond to the mechanisms of 'non-verbal communication', enabling the therapist to 'receive' and directly (and viscerally) experience patients' musical utterances as a presentation of themselves—and also as a presentation of their clinical pathology (Pavlicevic & Trevarthen 1989; Pavlicevic *et al.* 1995). Adult psychiatric patients suffering from conditions that interfere with their capacity to express and communicate emotion—and form relationships with others—portray this collapsed relational capacity in clinical improvisation. Both self and interactional synchrony can be regarded as measures of health with illness and disease occurring when a person becomes out of synchrony—both physically and mentally—with the self and the surrounding environment (Capra 1983; Pavlicevic 1991).

Although clinical improvisation may be heard as musical, the therapist's skill is not solely a 'musical' one, as has been assumed (Schögler 1998). Rather, music therapists' skills lie in their capacity to interface the personal and music in music therapy improvisation; to 'read' music therapy improvisation as an interpersonal event (in the way that mothers and babies read one another's acts not as musical or temporal, but as emotionally expressive and communicative); and to support, develop, and extend the jointly created improvisation according to personal and therapeutic, rather than musical–aesthetic, needs and dictates. It is this direct knowing by one person of the other that enables the therapist to gain a direct experience of the patient, uncluttered by words—and replicating, to some extent, the psychotherapeutic dyad, in which the relationship between therapist and patient is itself the fertile ground for the patient's self-growth and knowing.

If we now return to the opening moments of Andrew's clinical improvisation with the therapist, we can think of each of them as presenting themselves through spontaneously created sounds, using the very ingredients of non-verbal communication—which are essentially musical in character. In the first moments of playing, Andrew portrays aspects of his 'vitality affects' through the musical relationship, using the very modality that directly captures, and portrays to another person, the essence of who he is. However, the jointly created clinical improvisation (once the therapist joins in with him on the vibraphone) elicits much more than this. By joining in with him, the therapist provides the basis for an interpersonal therapeutic relationship, enabling Andrew to express himself, to release deep-seated feelings to which he may, as yet, have no awareness, and to communicate through a powerful, non-verbal, medium: that of music. This musical experience bypasses (and complements) his 'talking' about his feelings—and enables him to gain new insights about himself—which may, or may not, need to be interpreted through words. This direct therapeutic musical event will hopefully enable him to resolve, and be released from, his feelings of loss, and to help him shift from his depressed state (Champion 1992; Pavlicevic 1999*b*). Although, like most music therapy patients, Andrew has no idea about how clinical improvisation 'works', his innate, biological, and neurological preverbal musicality—present from birth—is engaged by the

therapist's clinical musicianship: enabling and inviting his sounds to become personal and interpersonal.

Critical, here, is that not just any musical improvisation will do. The therapist needs to elicit dynamic form between herself and Andrew. Were they simply to play music together, however spontaneously, their focus would be on the sounds, tunes, and rhythms of their music, rather than on playing themselves. Through his depression, Andrew's 'vitality affects' have become narrowed and somewhat stuck: this is revealed in his playing which is erratic, tentative, and somewhat clumsy. His depression means that his experience of the world is slow, cloying, dark, and unshifting. These qualities are experienced directly by the therapist when she plays with him, and she then works with the dynamic form, using clinical techniques to stabilize his beating, extend his tempo, introduce rubatos, accelerandos, diminuendos and crescendos, and so on. This is not in order to make him into a better musician, but rather, to grow his expressive, emotional vocabulary, to 'loosen him up' emotionally, and to help him to access the feelings underlying his depression. At this point, music therapy may (or may not) move into verbal interpretation, with the therapist helping Andrew towards gaining insight into his life, depression, and bereavement. However, many music therapy clients are unable to speak because of their conditions, and even with verbal clients like Andrew, their work might be essentially in the musical event—the gaps between meaning and emotion in clinical improvisation and in words are far from being convincingly explicated in the music therapy literature (Ansdell 1996).

However, a case for the emotional richness of clinical improvisation is made in the final part of this chapter: a transcribed musical excerpt of dynamic form shows, through a brief microanalysis, the interactive mechanisms of communication and relationship between the therapist and client. Neither of their playing can be taken in isolation from the other's—hence the insistence of dynamic form being a feature of their joint playing, rather than of simply the patient's in clinical improvisation.

8.5.6 A musical example

Figure 8.1 shows 19 s of an improvisation by a music therapist (T) with a depressed patient (P) who is an adult amateur musician. The therapist and patient are seated opposite one another with a marimba between them, taking turns to play—hence the one melodic line. The instrument faces the patient, so that the therapist is playing 'upside down'. Although the excerpt shows the two players reflecting aspects of one another's rhythmic motifs (the excerpt has a compound rhythm), melodic line, dynamic levels, and timbre, the duration of the therapist's eleventh statement (T11) is 300 cs, while the patient's eleventh statement of 602 cs is discrepant in duration. This discrepancy exists despite both T11 and P11 comprising ten notes each, and despite the patient's other musical features (i.e. melodic contour, dynamic level, timbre), which clearly show an awareness by the patient of the therapist's preceding statement. The discrepancy is caused by the patient delaying the fourth note of her statement (i) as well as the conclusion of her statement at (ii). The delays within P11 'unbalances' the improvisation, resulting in an asynchronous interaction—this is somewhat perplexing if we consider that the patient is an amateur musician, but not unusual for someone suffering from depression.

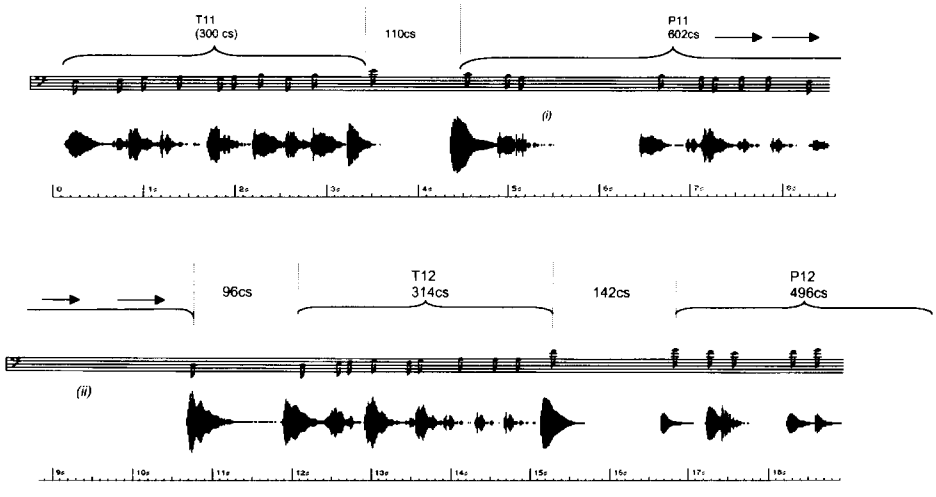

Figure 8.1 Turn-taking on the marimba by a therapist (T) and depressed patient (P).

Other interesting aspects in this brief excerpt are that when the therapist plays again at T12, her statement acknowledges that the patient has reflected some of the material in T11, which encourages the therapist to offer a similar statement to T11 in her twelfth statement (T12). Also of interest is that the patient is contracting her phrase to 496 cs in P12, suggesting some interpersonal responsiveness and flexibility—despite her depression. The therapist's statement at T12 is almost a repeat of her eleventh statement—and this can be understood as her offering the patient a stable and unambiguous musical structure, with predictable rhythm and pulse: a temporal beacon for the patient. Were the therapist to simply reflect the patient's uneven playing, and offer some rhythmic variation in T12, this might have the effect of destabilizing the patient. Instead, the therapist offers the patient a potential relational and communicative environment to expand into, leading, possibly, to a more fluid interpersonal (and personal) expressiveness. Here is dynamic form as an observable, explicit phenomenon with all the mechanisms of interpersonal timing, contour, motion, shape, and phrasing. It is the 'music between' (Ansdell 1995) the therapist and patient that generates and reveals emotion in music therapy—through the therapist's skill at eliciting, and working with, clinical improvisation.

8.6 Conclusion

An emotional response to music is a fundamental aspect of music therapy. It appears as a central link for people of all ages with wide-ranging clinical needs. Music therapists demonstrate the capacity to judge effectively the intended basic emotions of short

improvisations played live. The musical parameters used in their judgments are similar to those used when listening to recorded pre-composed music. Recent work in developmental child psychology, in particular Stern's (1985) 'vitality affects', provides reference points in understanding the subtle interplay between the personal and the musical in improvisational music therapy. Here is perhaps where we have the primary locus of any therapeutic change, in the interpersonal musical relationship built up between therapist and patient. Tuning in to our patients with a focused attention and sense of listening to every emotional nuance being expressed are prerequisites of the work of a vigilant music therapist.[1]

PART III

THE COMPOSER

CHAPTER 9

EMOTION AND COMPOSITION IN CLASSICAL MUSIC: HISTORIOMETRIC PERSPECTIVES

DEAN KEITH SIMONTON

The compositions that constitute the classical music tradition of the Western world probably have many different functions. Yet among those functions is probably some kind of emotional expression or communication. That is, when aficionados of classical music attend a concert or turn on their stereo, they usually expect to be 'moved'. Furthermore, listeners often believe that these emotional reactions are what the composer intended—that the work is a vehicle for emotional communication. As Beethoven once put it, 'Coming from the heart, may it go to the heart' (quoted in Scherman & Biancolli 1972, p. 951).

What makes these expectations somewhat surprising is the fact that classical music constitutes a fairly abstract form of aesthetic expression. Indeed, the concert halls are often dominated by purely instrumental forms—such as the symphony, concerto, quartet, and sonata—in which not a single word or programme gives any clue what the piece is actually about. Moreover, looking at a music score does not help render a classical composition any less abstract. On the contrary, musical notation is far more precise, rarified, and refined than can be found in any other form of artistic expression. Superficially at least, a score has more in common with a mathematical proof than with a painting, poem, or sculpture. This mathematical abstraction even holds for vocal forms, such as opera, oratorio, cantata, and song, where the words to be sung occupy a relatively small space on the page relative to all those meticulously placed symbols indicating pitch, duration, rhythm, dynamics, and other essential features of a composition. No wonder Claude Debussy could claim that 'music is the arithmetic of sounds as optics is the geometry of light' (quoted in *Who said what when*, Anon 1991, p. 252).

These observations thus lead to the following question: how do the abstractions of classical music evoke emotional reactions? There are many useful routes to addressing this issue. One option is to engage in a detailed musicological analysis, such as Leonard Meyer (1956) did in his important book on *Emotion and meaning in music*. Alternatively, one can conduct a laboratory experiment in which the emotional responses of listeners are assessed directly. An excellent example is Krumhansl's (1997) psychophysiological

study of the reactions of college students to musical excerpts from the classical repertoire. These musicological and experimental enquires have contributed a great deal to our understanding of the emotional impact of classical music. Yet they by no means exhaust the available methodological approaches.

Here, in fact, I adopt a distinctive analytical strategy that is far less common than either musicological analysis or laboratory experiments. This approach entails the historiometric study of the composers and compositions that define the classical repertoire. By historiometrics, I mean the adaptation of psychometric methods to examine data about historical individuals (Simonton 1990, 1999*b*; cf. Woods 1909, 1911). In the case of classical composers, these data can include both: (a) biographical information about their lives; and (b) content-analytical information about their works. In a series of articles published since 1977, I have been using this specific technique to study creativity and aesthetics in classical music (e.g. Simonton 1977*b*, 1991, 1995). This research was part of a broader series of studies devoted to understanding the psychology of creative genius. Although this research programme was not directed specifically at investigating emotional expression in music, some of the empirical results might possibly shed a little light on how this phenomenon operates, at least within the classical music tradition.

I begin by describing an objective and quantitative measure of a composition's melodic originality. I then show that scores on this computerized measure have certain aesthetic consequences; consequences apparently consistent with the assumption that the measure gauges something of a composition's 'arousal potential'. These content-analytical scores are next shown to relate to the composer's biography in a manner seemingly compatible with the same assumption. I then conclude with a general evaluation about what this research programme may possibly suggest about music and emotion.

9.1 Melodic originality

The original impetus for this research came from an unexpected direction: the issue of musical style. Those with lots of performing or listening experience with classical music eventually learn to identify the distinctive styles of particular composers. Not only does Beethoven's music sound different in comparison to that of Monteverdi, Handel, Tchaikovsky, or Bartók, but it is even recognizably different from fellow composers of the classical period, such as Haydn and Mozart. But what makes one composer noticeably different from another, even when they both are composing in the same period style?

To answer this question, Paisley (1964) developed an idea taken from those art critics who try to identify the creators of certain unsigned Renaissance paintings. What the critics learn to look for are certain 'minor encoding habits', such as the way a particular painter depicts ears, hands, or stones. Because these objects are rather secondary in importance relative to the composition as a whole, they will often be executed in a mechanical, almost mindless manner. Minor encoding habits have also proven useful in identifying the unknown authors of various literary texts (Holsti 1969). These habits include favourite function words, such as preferred prepositions and conjunctions.

Paisley wished to determine whether classical composers betrayed their identity through analogous encoding habits.

Paisley's (1964) specific solution was to perform a content analysis of the melodies or themes that make up almost any musical composition. Taking the first four notes of each theme, he then determined which combinations of notes were the most common for particular composers. Paisley found that different composers had distinctive ways of constructing their thematic material, and that these encoding habits could be used to predict the identity of the composer of anonymous test samples. Using this technique, Beethoven's work could be easily distinguished from that of other classical composers, including the works of Haydn and Mozart.

If composers can reveal their identity from just the first four notes of their melodies, what else can be learned from the content analysis of their melodic ideas? I decided to develop Paisley's approach to an objective and quantified assessment of an important property of music, namely its melodic originality.

9.1.1 Computerized measurement: two-note transition probabilities

The first task was to obtain a large and representative sample of classical composers. The sampling began with all those whose music could be found in a two-volume dictionary of musical themes (Barlow & Morgenstern 1948, 1950). This dictionary included all the classical music that was recorded up to the middle of the twentieth century. After deleting anonymous compositions and other problematic works, the sample consisted of 15 618 themes by 479 composers (Simonton 1980*b*). This could hardly be called a 'sample' at all, given its size. In fact, according to one study based on performance data, only 100 composers account for 94 per cent of the music that has any place whatsoever in the standard repertoire of classical music (Moles 1968; see also Simonton 1991). So the sample was exhaustive when it came to major composers. In addition, the sample was fairly exhaustive when it came to the principal compositions by the tradition's major figures. For instance, among the 15 618 themes were those coming from *all* of Beethoven's symphonies, concertos, string quartets, and piano sonatas (for a complete listing, see Barlow & Morgenstern 1948, 1950).

Following Paisley (1964), the thematic dictionaries that generated the sample also provided the foundation for the content analysis. For each theme, the dictionaries give the beginning notes, all transposed to a C tonic. In other words, all melodies in the major mode had been transposed into C major, and all those in the minor mode had been transposed into C minor. Although Paisley accomplished a lot with only the first four notes, I decided to use the first *six* notes of each of the 15 618 melodies. These data were all entered into a huge machine-readable data file. The next step was to have a computer calculate the two-note transition probabilities. That is, the first six notes contain five two-note transitions (first to second, second to third, etc.). The partial results of this computerized content analysis are shown in Table 9.1 (for a more complete table, see Simonton 1984, Table 1).

Clearly, some two-note transitions are far more common than others. On the one hand, the dominant–dominant (GG), tonic–tonic (CC), and dominant–tonic (GC) together account for about 17 per cent of all two-note combinations. On the other hand, combinations involving sharps and flats are much more rare—all occurring less

Table 9.1 Two-note transition probabilities from the first six notes of 15 618 classical themes

$P \geq 0.06$: GG (0.067)
$P \geq 0.05$: CC (0.053)
$P \geq 0.04$: GC (0.049) and CD (0.044)
$P \geq 0.03$: CB (0.032), CG (0.032), GF (0.031), EE (0.030), ED (0.030), and DC (0.030)
$P \geq 0.02$: GE (0.029), GA (0.029), EF (0.028), EG (0.026), DE (0.024), BC (0.023), CE (0.022), FG (0.021), FE (0.021), GA (0.021), and AG (0.020)
$P \geq 0.01$: E♭D (0.018), EC (0.016), DE♭ (0.014), AB (0.012), BA (0.011), A♭G (0.011), and DD (0.011)

Probabilities given in parentheses are averaged across the first five two-note transitions (extracted from the more complete listing in Simonton 1984).

than 2 per cent of the time. Moreover, those that do appear, namely E♭ and A♭, are not chromatic, but rather are representative of the minor mode. Truly chromatic notes (those that depart from either the major or the minor mode) are even more improbable, only F# occurring with any frequency whatsoever.

It should be pointed out that the probabilities presented in Table 9.1 were averaged across all five two-note transitions. Slightly different results obtain when the two-note probabilities are calculated separately for each of the five transitions. For instance, two-note combinations involving the tonic and dominant decline in frequency from the first to the sixth note. Thus, over 11 per cent of the time the first transition contains the dominant–dominant (GG) pairing, but this figure decreases to less than 5 per cent by the fifth transition. In contrast, those transitions that involve other notes of the scale increase in frequency. Apparently, when composers first begin constructing a melody, they usually start by defining the theme's key with the most definitive notes of the scale before incorporating the other notes of the diatonic scale, such as the mediant, subdominant, and leading tone.

These latter, transition-specific probabilities were then used to construct a quantitative measure of melodic originality (Simonton 1980*b*). For each of the 15 618 themes, the probability of each of its five transitions was calculated, and then an average taken. The result is a number that represents the mean percentage of times a particular theme's five two-note transitions appear in the entire repertoire. To illustrate, the second movement of Haydn's Symphony No. 94 (the 'Surprise') opens with an extremely simple theme that begins CCEEGG. All of the component two-note transitions are extremely commonplace: the average transition probability is 0.040. A similar degree of predictability is found in the main theme of the concluding movement of Beethoven's 'Waldstein' Sonata, which begins GGEDGC, yielding a mean transition probability of 0.041. By comparison, the opening theme of the introduction to Mozart's 'Dissonant' Quartet commences with AGF#GAB♭, with a mean probability of 0.005. The theme that initiates Liszt's Faust Symphony is even more unlikely: A♭GBE♭F#B♭, yielding an average two-note probability of less than 0.001 (for more examples, see Simonton 1984, Table 3). In any case, given these numbers, a measure of each theme's melodic originality can be defined as one minus the mean probability (i.e. $1-\sum P_i/5$). The higher this number, the higher is the assigned score for melodic originality.

This computerized measure may seem very crude. To begin with, the measure concentrates solely on the melody, thereby completely ignoring instrumentation,

counterpoint, harmony, formal structure, and text (if any). The implicit assumption being made is that 'melody is the main thing', to quote Haydn (Landowska 1964, p. 336). But even with respect to melody alone, the computer-generated score ignores the theme's key, its rhythmic structure, and many other significant features. Instead, the measure concentrates on the relationships between consecutive pitches. Nevertheless, it turns out that this objective and quantitative score is not only perfectly reliable—the reliability coefficient is necessarily unity—but in addition it enjoys enough validity for research purposes.

9.1.2 Measure validation

The melodic originality measure was validated several ways. One very direct validation involved the direct comparison of the measure based on two-note transition probabilities with an alternative measure based on three-note transition probabilities (see Table 2 in Simonton 1984). These two measures correlate so highly that they yield practically the same results (Simonton 1980*a*). Perhaps this should not be too surprising, given that the most likely three-note transitions tend to be made up of the most common two-note transitions (e.g. GGG and CCC). In addition, originality scores based on the probabilities specific to each consecutive two-note transition produce almost the same outcomes as those based upon probabilities that are averaged across all transitions for all 15 618 themes (Simonton 1984). Hence, this gauge of melodic originality is not contingent on the particular operational definition adopted.

Another route to validation was to see if melodic originality correlates with other characteristics of the composition in a manner consistent with expectation. These correlations can be grouped into two categories: general correlates with other characteristics of the composition and those correlates that may more specifically link the measure with emotional expressiveness (Simonton 1994).

General correlations with compositional characteristics

The melodic originality of the themes in a composition is associated with other aspects of that composition. These linkages suggest that the computer content analysis has captured something that has musical significance. In particular, consider the following four empirical findings:

1. Originality is higher for those themes that are also more metrically complex (Simonton 1987). By metric complexity I mean melodies in less common metres, such as 3/2 or 9/8 rather than 2/4 or 4/4 time. Thus, as the two-note transitions become more unpredictable, the beats that contain the corresponding pitches become less simple. This hints that the originality measure might indirectly encompass more compositional effects than just melody alone.
2. Originality is higher for themes from instrumental works than those from vocal works (Simonton 1980*b*). Part of this relation may reflect the superior flexibility of most musical instrumental instruments relative to the human voice (e.g. the virtuoso violin versus a coloratura soprano). But another part may be ascribed to the fact that in vocal compositions, the text has part of the responsibility for communicating content (including any emotional expression).

3. Originality is higher for themes from chamber compositions than those from orchestral compositions, the latter in turn having more original themes than those from theatrical works, such as ballet (Simonton 1980*b*). In chamber compositions, such as sonatas and quartets, largely the thematic material carries the burden of maintaining listener interest. As the instrumental resources increase, as in symphonies, tone poems, and overtures, the opportunities rendered by orchestration can assume more importance in maintaining such appeal and attention. In theatrical compositions, extramusical stimulation becomes prominent as well, such as costumes, sets, and choreography. This renders melodic originality even less necessary.
4. Originality is higher in the outer movements of multimovement compositions than in the inner movements (Simonton 1987). For instance, symphonies and quartets will most often contain four movements: the first usually in sonata–allegro form, the second a slow movement in song or theme-variation form, a third a minuet (or scherzo) and trio, and a fourth that is in sonata–allegro, rondo, or variation form. The first movement contains the themes with the highest melodic originality, followed by the last movement. The middle movement, or movements, features the themes with the lowest melodic originality. Evidently, once the composer has got the listener's attention, originality can relax momentarily, until the intensity picks up again in the work's conclusion.

Specific correlations with emotional expression and impact

Although the melodic originality measure was not designed to tap the emotional content of a composition, two empirical findings suggest that some connection might exist:

1. Originality is higher for themes in minor keys than for those in major keys (Simonton 1987). As is apparent from Table 9.1, transitions containing the notes that define the minor mode have lower probabilities than those from the major mode, which gives minor-key themes their higher originality scores. This fits the subjective experiences of many music listeners, who tend to find themes in the minor mode more exotic, strange, or unusual in some way (Meyer 1956). That impression reflects the greater unpredictability of melodies that necessarily flow by less predictable transition probabilities. Perhaps as a consequence, composers frequently choose the minor mode for emotionally expressive compositions. Representative examples include Chopin's F Minor Fantasia, Mozart's G Minor String Quintet, Rachmaninoff's C Minor Piano Concerto No. 2, or Tchaikovsky's B Minor *Pathétique* Symphony. 'The minor mode is not only associated with intense feeling in general but with the delineation of sadness, suffering, and anguish in particular', observed Meyer (1956, p. 297). Later in this chapter, Meyer's assertion will receive some historiometric support.
2. Scores on the melodic originality measure can be directly compared with the subjective experiences of human listeners. Melodies that score higher in melodic originality should sound more unpredictable, interesting, or complex than melodies that score much lower. Anyone familiar with the themes mentioned ear-

lier should agree that this is the case. The Haydn theme sounds very much like a simple nursery tune (*Twinkle, Twinkle, Little Star*, in its English version), whereas the Mozart theme was so incomprehensible to Mozart's contemporaries (including Haydn) that the quartet which it opens with has been known as the 'dissonant' ever since. More important, one experimental investigation found that the originality scores correspond with subjective assessments of a theme's 'arousal potential' (Martindale & Uemura 1983). The originality scores were calculated using the two-note transition probabilities for themes by 252 composers, with one theme per composer. Naïve listeners then made an independent assessment of the arousal potential of each theme after listening to recordings made by a professional violinist. Those themes that scored higher on the objective measure of melodic originality tended to be those that also scored higher on the subjective measure of arousal potential. In other words, melodic originality predicts whether a theme will be perceived as exciting, stimulating, or arousing. Admittedly, the correlation was only 0.21 ($P < 0.001$), but this coefficient was probably attenuated by two factors. The first factor is that the transition probabilities were based on only 252 themes rather than 15 618. The second attenuating factor is that the variance in melodic originality would probably be truncated, given that only 252 themes by 252 composers were examined instead of 15 618 themes by 479 composers. If this correlation is then taken as the lower bound for the true correlation, it seems reasonable to conclude that, within the entire classical repertoire, those themes that contain more original two-note transition probabilities will be more likely to evoke emotional reactions in listeners.[1]

9.2 Aesthetic consequences

If the hypothesized linkage between melodic originality and arousal potential has some justification, then the content-analytical measure should bear a theoretically meaningful association with: (a) a composition's aesthetic impact on listeners; and (b) changes in aesthetic style within a composer's career and within the history of classical music. The reasons for these expectations will become clear below.

9.2.1 Compositional impact

Research in experimental aesthetics has suggested that the aesthetic success of any work of art is in part a function of its capacity to evoke emotional arousal (e.g. Berlyne 1971, 1974). The arousal potential of a given work is associated with such things as the complexity, novelty, surprisingness, and ambiguity of the aesthetic stimulus. The more complex, novel, surprising, or ambiguous the stimulus, the higher the magnitude of arousal elicited. However, the functional relation between arousal potential and aesthetic

[1] Tuomas Eerola (personal communication, 26 March 1999) informed me that he had found a correlation of 0.93 between the melodic originality measure and an alternative measure of melodic complexity derived from research on music perception. This constitutes another independent validation of the computer-generated scores.

impact is not linear, but rather curvilinear. That is, the relation is described by what has been called the 'Wundt curve' (Berlyne 1971). The most successful works are those that evoke an optimal level of arousal. In contrast, compositions with low arousal potential will prove to be predictable, commonplace, or obvious—and hence boring. And compositions that provoke excessive arousal will induce a state of stress, anxiety, or even fear (e.g. the notorious debut of Stravinsky's *Rite of Spring*). A number of investigations in experimental aesthetics have in fact found curvilinear inverted-U relations between measures of arousal potential and aesthetic preferences (e.g. Kammann 1966; Steck & Machotka 1975; Vitz 1964).

However, most of these experimental studies have used artificial 'art-like' stimuli, which were then rated by college students in somewhat unnatural laboratory conditions (Berlyne 1974). This may help explain why the results are not always consistent with theoretical expectation (e.g. Martindale & Moore 1989). Therefore, it behoves us to ask whether the same Wundt curve can be found under more natural circumstances. In particular, is the aesthetic success of real compositions in the classical repertoire partially determined by the melodic originality of the themes those compositions contain? If this content-analytical measure can really be taken as an approximate gauge of a theme's arousal potential, then scores should predict a composition's aesthetic impact. This is in fact the case for both objective and subjective indicators:

Objective ratings were based on the actual success of the composition in the classical repertoire (Simonton 1980*a*, 1980*b*, 1983). That is, these ratings gauged the frequency that a musical product is likely to be heard in the concert hall, opera house, and recording studio (for a psychometric assessment of such indicators, see Simonton 1998*a*). The relationship between this objective measure and melodic originality is neither linear positive nor linear negative but rather curvilinear. In particular, the relationship is best described as an inverted backward-J curve, as shown in Fig. 9.1 (Simonton 1980*b*). The most popular works are those that have moderate levels of melodic originality, whereas the most unpopular works are those with the highest levels of melodic originality—the pieces with low melodic originality having more middling popularity. This curvilinear function demonstrates that the Wundt curve provides an adequate description of what happens in the real world of music listening. At least, this function holds for the 15 618 themes that define the classical repertoire. The same function has also been shown to hold for the 593 themes that Beethoven contributed to the classical repertoire (Simonton 1987).[2]

[2] Here, as in the rest of this chapter, I am more precisely speaking of *repertoire* melodic originality, that is, the unpredictability of the sequence of pitches when compared with the entire standard repertoire of classical music. Another kind of originality has been defined, namely *Zeitgeist* melodic originality (Simonton 1980*b*). In this case, originality is gauged according to whether a particular theme's construction fits the stylistic norms at the time the work was composed. This distinction is crucial, because the two kinds of melodic originality do not correlate the same way with other variables. For example, the popularity of a composition is a U-shaped function of its *Zeitgeist* melodic originality (Simonton 1980*b*). The most successful works are those that depart (in either direction) from the level of repertoire melodic originality most typical of the day.

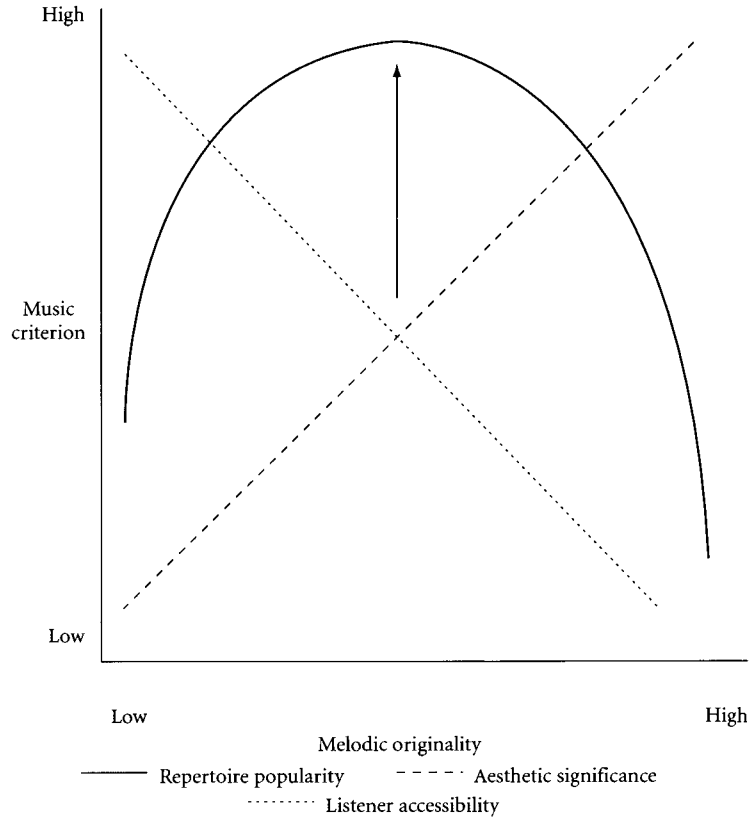

Figure 9.1 The graph summarizes the empirical results regarding how a theme's melodic originality (as computed from two-note transition probabilities) is associated with three musical criteria: objective repertoire popularity (a composite measure of the performance and recording frequency of the composition which contains the theme) and subjective assessments of its aesthetic significance and listener accessibility (according to Halsey 1976). The arrow indicates the explanatory hypothesis that the peak of the curvilinear function might reside where the product of aesthetic significance and listener accessibility may be maximized.

Subjective ratings were taken from Halsey (1976), who rated thousands of classical compositions on two dimensions, namely aesthetic significance and listener accessibility. Melodic originality was correlated with both of these measures, albeit in opposite directions, as also indicated in Fig. 9.1 (Simonton 1986). Aesthetically significant compositions are those that were deemed sufficiently profound that they could withstand repeated listening. They cannot be fully appreciated in a single, superficial hearing. Such pieces score high on the melodic originality of their thematic material. Accessible compositions, in contrast, can be understood at once, and thereby lend themselves to music appreciation courses taught at schools and colleges. Not surprisingly, works that score high on listener

accessibility tend to score low on melodic originality. Highly unpredictable themes would only interfere with making an immediately favourable impression.

Note that the functions for the objective ratings were curvilinear, whereas those for the subjective ratings were linear and in opposed directions. Do these results contradict each other? I do not think so. Although aesthetic significance and listener accessibility correlate differently with melodic originality, they both correlate in the same positive direction with repertoire popularity. Accordingly, one could argue that the peak of the Wundt curve represents the point that maximizes the joint contribution of aesthetic significance and listener accessibility to repertoire popularity. At low levels of melodic originality, the music is very predictable and thus accessible, but the music is also considered of trivial aesthetic importance. At high levels of melodic originality, the aesthetic significance is not so much in doubt as the ability of listeners to appreciate the composition. At middle levels of originality, the works are still reasonably accessible while at the same time they are above the norm in significance. The vertical arrow in Fig. 9.1 represents the hypothesis that the highest popularity is to be found where the product of aesthetic significance and listener accessibility is maximal.

Interestingly, because low melodic originality is preferred over high melodic originality in terms of repertoire popularity, aesthetic significance appears to have less weight than listener accessibility. On the whole, at least with respect to emotional arousal, listeners would rather be quietly entertained than anxiously provoked.

9.2.2 Stylistic transformations

If the relation between aesthetic impact and melodic originality is mediated by the emotional arousal that highly original compositions evoke, then this relation could be moderated by another basic psychological process: *habituation*. With repetition, the response to an arousing stimulus will often diminish (Berlyne 1971). As a consequence, over time, increasingly higher levels of melodic originality may be required in order to elicit the same optimal level of arousal in music listeners (Martindale 1990; for literary illustration, see Kamman 1966). According to trend analyses of all 15 618 themes by 479 composers, this upward movement manifests itself in two ways (Simonton 1997).

First, composers tend to steadily increase their use of melodic originality as their careers progress (Simonton 1980*b*). Originality is lowest at the beginning of the career, but at once begins to increase. The only exception to this upward growth occurs at around the 56th year of life, where originality tends to reach a peak. After this a modest decline sets in. Beethoven enthusiasts may find the peak at 56 the most intriguing. Beethoven died at that age, which means that he should have been publishing his most original work then, if his career followed the same pattern as 478 other classical composers. A hearing of his Late Quartets suggests that this was indeed the case.

Second, there exists an overall tendency for melodic originality to increase from the Renaissance to the twentieth century (Simonton 1980*b*). This upward trend suggests that each generation of composers feels compelled to produce work that overcomes habituation to a given level of originality, just as predicted by Martindale's (1990) theory of stylistic change. However, just as an exception to the general positive trend was found for composer's careers, so are curious departures found across the history of the classical music tradition. Specifically, superimposed over the positive linear trend are

cyclical fluctuations. Melodies in the Renaissance were highly predictable, but by the time of Monteverdi and Gesualdo, originality had reached a maximum point, with a degree of chromaticism that was to be unmatched for nearly three centuries. After that, themes became more predictable again, albeit not as predictable as during the Renaissance. The trough occurred during the time of the 'classical period'—Haydn, Mozart, and Beethoven—when thematic material would be constructed from basic chords (e.g. the opening of Beethoven's *Eroica* Symphony). With the advent of the 'romantic period', melodic originality increased, most notably with the chromaticism of Chopin, Brahms, and Wagner (e.g. the famous prelude to *Tristan und Isolde*). This trend reached a new height about the time of the First World War. It was this peak that witnessed the emergence of the atonal and serial music of Arnold Schoenberg, such as his *Pierrot Lunaire*. Then melodic originality saw another decline, although again not going as low as the two previous lows. The music of Aaron Copland and Sergei Prokofiev is indicative of this retrogression.

The superimposed oscillation would seem to contradict the basic proposition that arousal potential has tended to increase over time. Yet, if this cyclical pattern is examined more closely, it becomes evident that the momentary declines in melodic originality tend to come during those periods in which composers acquire new ways to increase the arousal potential of their works besides increasing the novelty, complexity, surprisingness, and ambiguity of the thematic material. Rather than augment the magnitude of chromaticism, for example, the composer may have access to novel forms, rhythms, and orchestration. In partial support for this conjecture, not only is melodic originality lower in those forms giving the composer greater resources (as noted earlier), but also the relation between melodic originality and repertoire popularity is moderated by the size of the work (Simonton 1980*b*). The larger the form in which the composer writes, the weaker is the relation between originality and the composition's impact.

In any event, once alternative techniques for evoking emotional reactions become fully incorporated in the repertoire, the composers must again resort to melodic originality as a primary means to overcome the pressures produced by jaded tastes. Furthermore, it is essential to recognize that as the history of classical music unfolds, the troughs in originality get less deep and the crests become more elevated. Hence, the musical history of melodic originality never really repeats itself.

9.3 Biographical antecedents

For a chapter that purports to deal with music and emotion, the results so far may seem a bit cold. Granted, the objective and quantified indicator of melodic originality may indeed correspond with a theme's capacity to stimulate arousal—and that stimulation may shape a composition's aesthetic impact. But emotion in music is often seen as entailing much more than the simple activation of the human sympathetic nervous system. Emotion is also seen as a form of expression, as a means of communicating emotions between a creative artist and an audience. Yet so far we have treated melodic originality as some compositional quality that a composer must manipulate in order to keep listeners from falling asleep—or from running out of the concert hall in disgust or terror.

Fortunately, research using computerized measures has provided ample reason for believing that melodic originality may reflect the emotional state of the composer at the time of a work's composition. For example, the composer's use of melodic originality is noticeably altered when a composition is created during traumatic political events, such as international war (Simonton 1986, 1987; see also Brook 1969; Cerulo 1984). In particular, compositions penned during times of warfare exhibit much greater variation in melodic originality, extremely unpredictable and extremely predictable themes being found in the same work. It is almost as if such highly stressful events polarize emotional reactions, inspiring vast mood swings between resignation and despair, hope and fear. Shostakovitch's notable (and notorious) *Leningrad Symphony* provides a graphic auditory illustration of the magnitude of this polarization of trite and profound.

More significant, however, is the impact of highly personal events in the life of the composer. Below I treat two potential instances of this personal connection: biographical stress and late-life effects.

9.3.1 Biographical stress

Of special interest to any emotional expression hypothesis is the relation between the amount of stress occurring in a composer's personal life and the amount of melodic originality appearing in work created during the same period. If 'music sounds the way emotions feel' (Pratt 1954, p. 296, italics removed), and if stressful events provoke strong emotions, some correspondence between the two should be found. Moreover, the measure of melodic originality would seem to capture some of the attributes of music that contribute to its emotional expressiveness. An excellent example is chromaticism, or the use of notes beside those that define the theme's key. Chromatic notes are often used to express emotions, the unpredictability of the melodic line reflecting the turmoil of our internal emotional state (Meyer 1956). Indeed, this usage is not even confined to the classical music tradition, as the expressive use of chromatic 'blue notes' in blues and jazz illustrates (La Rue 1970).

To test the hypothesized linkage between life stress and melodic originality, I took advantage of an earlier data set that had been compiled for a different purpose (Simonton 1977*a*). The careers of classical composers were scrutinized to determine the factors that affect a composer's output across the lifespan. The particular composers were the ten most eminent according to a large survey of musicologists (Farnsworth 1969), namely, Bach, Handel, Haydn, Mozart, Beethoven, Schubert, Chopin, Wagner, Brahms, and Debussy. Among the potential predictors of compositional productivity was the occurrence of stressful or traumatic events in the composer's life. To obtain a measure of these events, a chronology of such events was first compiled from the extensive biographies available for these illustrious contributors to the classical repertoire. The next step was to convert these raw facts into a quantitative measure of the degree of stress experiences by each composer during consecutive periods of his life. This conversion was achieved by adapting the social readjustment rating scale, which has proven its utility in research on psychosomatic illnesses (Holmes & Holmes 1970; Holmes & Rahe 1967; see also Simonton 1998*b*). Table 9.2 shows some of the biographical events and the weights they were each assigned in the resulting tabulations.

Table 9.2 Biographical stress coding scheme designed for ten classical composers

Legal difficulties: Litigation or lawsuit (30); Detention in jail or exile to avoid arrest (63)

Economic problems: Major loan (20); Trouble with creditors (30); Aversive change in financial state or business readjustment (38)

Educational changes: Change in schools (20); Begin or terminate formal schooling (26)

Vocational changes or problems: Job change (20); Trouble with employer or superior (23); Change in responsibilities at work (29); Begin or end work but not fired or retired (36); Retirement (45); Fired from work (47)

Mobility: City or town of permanent residence changed (30 per move); Nation of permanent residence changed (40 per move)

Interpersonal problems: Duels, fights, and other physical confrontations (10); Argument with friend (10); Disappointed or unrequited love (15); Onset or termination of a reciprocated love affair (30); Death of a close friend (37)

Family problems: Gain of a new family member, including adoption (39); Change in health or behaviour of family member (44); Death of close family member, except children under 3 (63)

Marital difficulties: Marital reconciliation (45); Marriage (50); Marital separation (65); Divorce (73); Death of spouse, unless separated (100)

The points assigned to each life-change stress are given in parentheses.

Given these previously calculated assessments, it was a relatively simple matter to estimate the relation between a theme's melodic originality and the amount of stress the composer had experienced during the period of composition (tabulated in cumulative 5-year periods). The association was found to be positive, even after introducing controls for other confounding factors, such as the composer's age at the time a work was conceived (Simonton 1980*a*). This finding was replicated and extended in a second study that concentrated just on the career of Beethoven (Simonton 1987). Besides replicating the positive association between stress and originality, this investigation tabulated a measure of the lifespan fluctuations in Beethoven's physical health (cf. Porter & Suedfeld 1981; Simonton 1998*b*). This latter measure was also found to correspond to the melodic originality found in Beethoven's compositions. When the composer was experiencing robust health, originality tended to be relatively low, whereas when the composer's health failed, originality was likely to be high. Given that physical illness can be considered a major source of life stress, this finding reinforces what was found for biographical stress. The thematic material found in a composer's works may indeed communicate to the listener the composer's underlying emotional life at the time of their composition.

9.3.2 Late-life effects

Biographical stress and physical illness serve to heighten levels of melodic originality. Yet sometimes certain life events can operate in a contrary manner. This contrast is found in a study conducted of what was called the 'swan-song phenomenon' (Simonton 1989). There has been much speculation about whether artistic creators exhibit a 'late-life' or 'old-age' style (e.g. Arnheim 1986; Münsterberg 1983), and even some empirical evidence suggests that these speculations have captured a grain of truth (Lindauer

1993). Analogous speculations have been advanced regarding supposed last-work effects in classical music (Einstein 1956). So, do late-life compositions exhibit any consistent stylistic shifts? This question was addressed by examining melodic originality in 1919 works by 172 classical composers, and a striking developmental pattern was identified (Simonton 1989). In the years immediately preceding death, a composer's compositions exhibit rapidly declining levels of melodic originality. In other words, the thematic material becomes much more predictable. Significantly, this effect survived statistical control for the composer's age. Hence, the decline is a consequence of the proximity of death rather than old age. Composers who died young, such as Mozart and Schubert, could thus display the same swan-song effects as those who died at relatively advanced ages, like Vaughan Williams and Stravinsky.

But what is the psychological basis for this swan-song phenomenon? One possibility is to dismiss this effect as an example of the mental deterioration that too often occurs towards the end of any person's life (e.g. Suedfeld & Piedrahita 1984). Consistent with this interpretation, not only do the melodies tend to be less original in last works, but in addition the works themselves are of shorter duration on average (Simonton 1989). Even so, this negative interpretation does not seem very compatible with other empirical results: the closer to the composer's death a work appears, the more frequently it is performed in the classical repertoire and the higher the rating it receives in aesthetic significance. Hence, swan songs may be shorter and have more simple melodies, but they are also more successful in terms of popular and critical appraisal!

Given the sum total of these findings, it seems more likely that the lower melodic originality in late works is deliberate rather than negligent. If high originality is associated with highly emotional states, then low originality may reveal low levels of emotionality. For a composer who may feel that the end is quickly and inevitably approaching—as perhaps indicated by terminal illnesses or the frailties of old age—that low arousal state may hint that he has resigned himself to his fate. That resignation, that acceptance then takes the form of powerful and expressive swan songs that communicate the most with the least. This communication of internal peace can itself be considered a form of emotional expression. To get a direct sense of that feeling, we need only listen to the final chorale of Bach's *The Art of the Fugue*, Mozart's *Ave Verum Corpus*, Brahms' Four Serious Songs, or Richard Strauss' Four Last Songs.

9.4 Conclusion

The research just reviewed has many limitations, two of which are especially critical here. First, none of these studies were specifically dedicated to scrutinizing the relation between music and emotion. Instead, their primary purpose was to comprehend more generally the creativity of composers and the aesthetic impact of their compositions. In only one investigation was emotional impact directly assessed, and then only in the rather stripped-down form of 'arousal potential' (Martindale & Uemura 1983). The differentiated emotional states seen in other investigations, such as happiness and sadness, have no direct representation in this historiometric literature (cf. Krumhansl 1997). Furthermore, emotional reactions were mostly introduced as intervening variables to predict or explain the empirical relations between observed variables. Thus, the positive association

between biographical stress and melodic originality was predicted under the assumptions that: (a) stress produces emotional states; and (b) such emotional states influence the composer's melodic creativity (e.g. the use of chromaticism). Likewise, the expected curvilinear relation between melodic originality and repertoire popularity was directly based on Berlyne's (1971) optimal-arousal model of the relation between collative variation and aesthetic preference—and the Wundt curve that it theoretically predicts.

Fortunately, none of the empirical findings contradicted the two-fold supposition that melodic originality both influenced listeners' emotional response and reflected the composer's emotional states. In addition, a strong agreement exists between many of these findings and what Meyer (1956) argued on the basis of a detailed, sophisticated analysis of a select number of representative scores (e.g. the relation between emotion and the violation of melodic expectations). None the less, to make a stronger case for this supposition, these historiometric results should be tied more closely with findings from laboratory experiments. For instance, I have previously suggested using the two-note transition probabilities to construct artificial musical stimuli (Simonton 1984). Experiments can then gauge whether these stimuli influence both physiological responses and subjective appraisals of participants (e.g. as in Krumhansl 1997; see also Scherer & Zentner, this volume). This extension would introduce the experimental controls so obviously lacking in historiometric enquiries.

The second limitation concerns the fact that the correlations between melodic originality and other significant factors are far from perfect. At no time can we say that even a quarter of the variance is accounted for by any one relationship, and more often the effects hover around one or two per cent. Yet we should not expect it to be otherwise. Musical creativity, like other forms of creative behaviour, is a complex, multidetermined phenomenon (Simonton 1999*a*). It probably would take hundreds of variables to fully describe what happens when a composer puts notes on a piece of paper—or when a listener emotionally responds to their performance. In addition, it must be reiterated that the computerized assessment of melodic originality remains only a crude approximation. Composers have a great deal more in their expressive toolkit than the choice of pitches. It certainly makes a difference in emotional impact whether the tempo is adagio or presto, the rhythm regular or syncopated, the dynamics pianissimo or fortissimo, the melody line played on a violin or tuba (cf. Gabrielsson & Lindström, this volume). Indeed, when the current scheme is compared with various alternative content-analytical measures, its simplicity becomes quite obvious (see, for example, Cerulo 1988, 1989). A certain price has been paid to quantify efficiently and objectively so many themes and their corresponding compositions.

All that admitted, the fact remains that the discovered relationships, whatever their limitations, hold for all of the works that dominate the classical repertoire. Certainly, 15 618 themes by 479 composers constitute a far more representative sample than seen in any other investigation, whether musicological or experimental. Therefore, it may be worthwhile to lend serious consideration to the findings that connect the computer-generated melodic originality with a provocative array of variables. Scores on this content-analytical attribute have been empirically linked with various characteristics of classical works, including their key, rhythm, medium, form, and compositional structure. Even more pertinent here, melodic originality seems to bear some connection with a

theme's emotional expressiveness. This latter consequence, however modest, has implications for understanding: (a) how compositions vary in their repertoire popularity, listener accessibility, and aesthetic significance; and (b) how melodic originality changes during the development of a composer's career and during the evolution of musical history. At the same time, the melodic originality of particular themes appears to have some foundation in the life experiences prevailing at the time the works were created by the composer. Stressful and even traumatic events tend to intensify the level of melodic originality in concomitant compositions.

All of these empirical relationships imply that melodic originality, at least to some degree, forms part of the composer's tools for expressing emotion. It seems most likely that more sophisticated methods of assessing the expressive qualities of music will reinforce rather than contradict this conclusion.

CHAPTER 10

THE INFLUENCE OF MUSICAL STRUCTURE ON EMOTIONAL EXPRESSION

ALF GABRIELSSON AND ERIK LINDSTRÖM

The expressive qualities of music have been a matter of discussion by philosophers and music theorists ever since antiquity and, more recently, by music psychologists. Many kinds of expression have been proposed, but expression of emotion is undoubtedly the most frequent. Likewise, most empirical research has focused on emotional expression in attempts to find out, on the one hand, which emotions can be reliably expressed in music (reviewed in Gabrielsson & Juslin, in press) and, on the other hand, which factors in music contribute to the perceived emotional expression. The latter refer to factors in the composed musical structure represented in the musical notation, such as tempo, loudness, pitch, mode, melody, rhythm, harmony, and various formal properties.

While it is a popular conception, and sometimes perhaps true, that composers express their present feelings in their compositions (cf. Cook & Dibben, this volume; Simonton, this volume), a more plausible view is that composers try to use various structural factors in order to achieve certain intended expressions, different in different works, with little or no direct connection to their present feelings. 'A composer . . . knows the forms of emotions and can handle them, "compose" them' (Langer 1957, p. 222). Tchaikovsky, usually considered a very 'emotional' composer, wrote that 'Those who imagine that a creative artist can—through the medium of his art—express his feelings at the moment when he is *moved*, make the greatest mistake. Emotions—sad or joyful—can only be expressed *retrospectively* . . . a work composed in the happiest surroundings may be touched with dark and gloomy colors' (cited in Fisk 1997, p. 157). For further discussion of these questions, see, for instance, Davies (1994, Chapters 4–6; see also Davies, this volume).

The purpose of this chapter is to review empirical research concerning the influence of different factors in musical structure on perceived emotional expression. However, because listeners usually judge perceived expression of composed music as realized in performance, there is a confounding of the properties of the composed structure and properties of the actual performance. As a rule, performance involves various modifications of the notated structure, for instance, variations of tempo, loudness, articulation, intonation, deviations in note timing, etc. (for a review, see Gabrielsson 1999). Perceived expression is thus dependent both on factors in the composed structure and factors in the performance. Only recently have the influence of the latter been subject to systematic

investigations (see Juslin, this volume). Listeners' perception of emotional expression—for instance, to perceive a piece of music as 'happy'—should be distinguished from listeners' own emotional reactions—for instance, to feel happy. Listeners' emotional reactions are treated elsewhere in this volume (Gabrielsson; Scherer & Zentner; Sloboda & O'Neill).

In Section 10.1, we review different methodological approaches to study the influence of musical structure on perceived emotional expression. The results are summarized in Section 10.2, and implications for future research are discussed in the final section.

10.1 Different methodological approaches

Empirical studies of musical expression had a cautious start in late nineteenth century, and it was not until the 1930s that they became more common. Subjects listened to pieces of music or other tonal stimuli and reported the perceived expression by either: (a) free phenomenological descriptions; (b) choice among descriptive terms, adjectives, or nouns, provided by the investigator; or (c) ratings of how well such descriptive terms applied to the music in question. Free descriptions were subjected to content analysis. Listeners' choice among descriptive terms was analysed regarding the frequency with which each term was chosen and regarding intersubject agreement. Ratings were usually analysed by multivariate techniques, such as factor analysis, cluster analysis, and multidimensional scaling in order to find a limited number of fundamental descriptive dimensions. Recently, various techniques for continuous and/or non-verbal recording of perceived expression have been developed.

Stimuli were usually recordings of selected pieces of music. However, before common use of modern sound recording the pieces were performed live by one or more musicians (e.g. Downey 1897; Gilman 1891; Hevner 1935*a*; Rigg 1937). The relationship between the composed structure and perceived expression was studied *post hoc* by analysing the musical scores (e.g. Gundlach 1935; Nielsen 1983) or having musical experts judge the selected pieces with regard to structural properties (e.g. Kleinen 1968; Watson 1942; Wedin 1972*c*).

Studying emotional expression using real music (see Section 10.1.1) means good ecological validity; on the other hand, conclusions regarding the effects of separate structural factors can only be tentative since they are confounded. In contrast to this, there are studies in which the researcher systematically varies one or more structural factors (e.g. loudness, pitch level) in short sound sequences without musical context (see Section 10.1.2). Ecological validity is then limited, but the systematic variation allows more definite conclusions regarding the effects of separate factors. A compromise between these two approaches is to use systematic manipulation of various factors within a musical context (see Section 10.1.3), for instance, to systematically vary tempo, mode, or melodic direction in real pieces of music and thus try to combine the advantages of the before-mentioned strategies. However, some types of manipulation may result in musically unnatural stimuli, thus jeopardizing ecological validity.

10.1.1 Studying emotional expression using real music

Free descriptions and choice among descriptive terms

The earliest reported empirical investigations on musical expression may be those by Gilman (1891, 1892) and Downey (1897). Their subjects listened to live performances on the piano, or piano and violin, of classical music and gave free phenomenological reports on perceived expression. A variety of emotions was reported and some tentative relationships were noted, for instance, descending thirds in an aria by Handel to indicate sadness.

Gundlach (1935) presented 40 musical phrases from different classical compositions to listeners, who were instructed to determine 'what mood or attitude the composer has succeeded in expressing' (p. 628) by choosing one or more out of 17 descriptive terms. From his analysis Gundlach concluded that speed was by far the most important factor for perceived expression, followed by rhythm, interval distribution, orchestral range, loudness, mean pitch, and melodic range.

Rigg (1937) used 20 short phrases played on the piano that were supposed to express either joy, lamentation, longing, or love. Listeners answered the question 'What emotion is suggested to you by each passage?' either by giving free descriptions or by choosing among the above emotion terms plus anger, fear, and disgust. Rigg discussed the advantages and disadvantages of these procedures. With free descriptions, responses may be scattered, but coherence in listeners' responses would be of more significance than if they merely checked terms in a list. With choice among descriptive terms, responses may be nicely bunched and easier to treat but will partly be a product of the given terms. For instance, love was not often mentioned in free descriptions but more frequently chosen when given as an alternative among the emotion terms. Expression of joy was convincingly indicated by the listeners, and some musical characteristics of the joy excerpts were rapid tempo, major mode, simple harmony, staccato notes, and forte dynamics.

Watson (1942) had 20 musical experts mark which out of 15 selected adjectives were appropriate for each of 30 musical examples. They also judged the examples, using a five-step scale, regarding pitch (low–high), loudness (soft–loud), tempo (slow–fast), sound (pretty–ugly), dynamics (no quick changes in loudness–very many changes), and rhythm (regular–irregular), thus enabling a study of the relationships between these factors and perceived expression. For instance, high pitch and fast tempo tended to express happiness and excitement; low pitch and slow tempo, sadness; high loudness, excitement; and small dynamic range, expression of dignity, sadness, and peacefulness.

Ratings and multivariate analysis techniques

In studies by Kleinen (1968), Wedin (1969, 1972*a*), Gabrielsson (1973, Experiments 4–5), and Nielzén and Cesarec (1981, 1982) subjects judged selected pieces of music using a large number of rating scales. The correlations between the scales were subjected to factor analysis in order to obtain a limited number of fundamental factors. These were given similar interpretations in all studies: tension/energy, gaiety–gloom, and solemnity–triviality (Wedin 1969, 1972*a*); intensity–softness, pleasantness–unpleasantness, and solemnity–triviality (Wedin 1972*b*, 1972*c*; in these studies using

multidimensional scaling techniques); tension–relaxation, gaiety–gloom, and attraction–repulsion (Nielzén & Cesarec 1981); gay/vital–dull and excited–calm (Gabrielsson 1973); '*Heiterkeit-Ernst*' (cheerful–serious) and '*Robustheit-Zartheit*' (strong/powerful-soft/tender) (Kleinen 1968).

Musical experts rated the respective pieces of music with regard to structural properties. For example, Wedin (1972*c*) used five-point scales for rating intensity (*pp–ff*), pitch (bass–treble), rhythm (outstanding–vague), tempo (fast–slow), rhythmic articulation (firm–fluent, staccato–legato), harmony (dissonant/complex–consonant/simple), tonality (atonal–tonal), modality (major–minor), melody (melodious–unmelodious), type of music (serious–popular), and style (date of composition).

To avoid listeners' dependence on descriptive terms chosen by the investigator, Imberty (1979) had 80 non-musical subjects freely choose any adjectives which came to their mind while listening to excerpts from Debussy's *Préludes* for the piano. Out of a total of 1063 adjectives, 172 were retained for analysis by correspondence analysis, resulting in a joint representation of the musical excerpts and the adjectives on a number of dimensions. The first two dimensions were *Les schèmes de tension et de détente* (tension vs. relaxation) and *Les schèmes de résonances émotionelles* (positive vs. negative emotions). Imberty went on to construct indices for formal complexity and *dynamisme général* in the used musical stimuli by combining, in various ways, variables as note duration, *intervalle métrique* (duration between two accented notes), density of notes per time unit, loudness, accents, syncopations, and certain characteristics of melodic, harmonic, and rhythmic motives. Using these indices, he claimed that: (a) low complexity combined with average dynamism means formal integration and expression of positive emotions; (b) high formal complexity combined with low dynamism means formal disintegration and expression of melancholy and depression; and (c) high formal complexity combined with high dynamism means formal disintegration and expression of anxiety and aggressiveness. This is one of the few attempts to investigate how emotional expression is influenced by properties of musical form. However, the indices are complex, and require much analytical work and further validation.

With regard to the dimensional structure of emotional expression, the above studies show similar results converging on two main emotion dimensions: valence (pleasantness–unpleasantness, gaiety–gloom) and activity/arousal (tension–relaxation, excited–calm).

Continuous recording of emotional expression

As type and intensity of emotional expression usually vary during the course of a piece of music, researchers may want to use a technique for continuous recording of perceived expression. This may also allow a more detailed study of how factors in the musical structure affect perceived expression. Nielsen (1983, 1987) pioneered the development of such a technique for continuous recording of perceived tension in music. While listening to the music, his subjects continuously pressed a pair of tongs in proportion to the perceived tension in the music—the more tension, the harder the press, and vice versa. The pressures were registered on a polygraph showing 'pressure curves' with waves of heightened tension alternating with periods of relaxation. Tension peaks were mainly conditioned by high intensity (fortissimo), but increased tension could also be

related to ascending melody, increased note density, dissonance, harmonic complexity, rhythmic complexity, and formal properties such as repetition of various units, condensation of musical material, sequential development, and pauses.

Later studies of perceived tension using other response devices include Madsen and Fredrickson (1993), Fredrickson (1997), and Krumhansl (1996). Krumhansl found that tension peaks followed by a rapid decrease occurred at the end of large-scale sections and that judgments of new musical ideas co-occurred with low tension levels. Continuous recording of perceived emotional expression was also studied by Namba *et al.* (1991), Krumhansl (1997), Madsen (1997), and Schubert (1999) using various computerized techniques (for a more extensive review, see Schubert, this volume).

Non-verbal responses

Some methods for studying tension have been mainly non-verbal (e.g. Nielsen 1983), but use of non-verbal responses to indicate emotional expression is rare. Clynes (1977) introduced finger pressure on a so-called *sentograph*—a device for recording the pressure exerted by a finger upon a small disc—to study how subjects expressed different emotions. He found different pressure patterns (sentograms) with regard to duration and dynamics for different emotions (joy, grief, anger, hatred, reverence, love, sex; depicted in Clynes 1977, p. 29 onwards) and then tried to trace corresponding patterns in music (Clynes & Walker 1982). De Vries (1991) had 30 subjects use a sentograph while listening to ten pieces of music and found that sentograms were different for different pieces, and that there were similarities between the sentograms for pieces with a certain emotional expression (anger, grief, joy, love) and Clynes's sentograms for the corresponding emotions. Some evidence in the same direction was found in Gabrielsson (1995) and Gabrielsson and Lindström (1995). (Another example of non-verbal responses—drawings to describe intervals—appears in 10.1.2.)

Specially composed music

Thompson and Robitaille (1992) asked composers to compose short monophonic melodies to express joy, sorrow, excitement, dullness, anger, and peace. Their scores were transformed to sounding music using computer software and sampled grand piano sound. Listeners, moderately trained in music, rated the pieces on corresponding emotion scales. In general they perceived the intended expressions. Analysis of the scores showed that joyful melodies were strongly tonal and rhythmically varied. Sad melodies were slow with implied minor or chromatic harmony. Melodies for excitement were fast, and contained intervallic leaps and high pitches. Dull melodies were tonal in a stepwise motion. Angry melodies were rhythmically complex and with implied chromatic harmony or atonality. Melodies for peacefulness were tonal, slow, and often involved stepwise motion leading to melodic leaps.

10.1.2 Manipulation of structural factors without musical context

Intervals

A distinction must be made between harmonic (simultaneous) intervals (two-tone chords, bichords) and melodic (successive) intervals. Costa *et al.* (2000) used all 12 equal-tempered harmonic intervals (organ sound) contained in an octave, one set in a

low register (geometric mean 185 Hz) and another in a high register (geometric mean 1510 Hz) and had listeners rate them on 30 bipolar scales, reflecting 'emotional evaluation' (e.g. happy–sad, pleasant–painful, friendly–hostile), 'activity' (e.g. tense–relaxed, dissonant–consonant, worried–calm), and 'potency' (e.g. strong–weak, vigorous–languid) in accordance with the three dominant dimensions of meaning according to Osgood *et al.* (1957). High register bichords were rated higher in 'activity' (e.g. more unstable, restless, tense) and in 'potency' (stronger) than low register bichords, and low register bichords were evaluated more negatively than high register bichords. Dissonant bichords were judged as more negative, more active, and stronger than consonant bichords; minor bichords as more dull and weaker than major bichords. Females showed greater polarization of scores and judged bichords as more active and tense than males. Difference in musical experience had no effect. Generally, intervals differed more in emotional evaluation and activity than in potency. Earlier, Maher (1980), using 14 different harmonic intervals in just intonation with triangular waveforms in two sets, one high pitched (geometric mean frequency 500 Hz) and one low pitched (250 Hz), obtained some similar results. High-pitched intervals were rated more happy and powerful than low-pitched intervals. Minor and major second, minor and major seventh, and minor ninth were the most displeasing.

Maher and Berlyne (1982) investigated the perception of 12 melodic intervals, sine-wave intervals in tempered intonation (minor second to octave, rising and falling, with the common 500 Hz geometric mean frequency). Larger intervals were judged as more 'powerful' than smaller ones; minor second was considered the most 'melancholic' interval; whereas octave, fourth, fifth, major sixth, and minor seventh were the most 'carefree'.

Smith and Adams (1999) had South African children listen to six ascending intervals performed on a flute and to represent them in drawings. The thematic content of the drawings was assessed by independent raters and also rated by university students using adjective scales. The primary distinction in the findings was between consonance and dissonance, the latter being associated with unpleasant events, the former with home, family, and stability. Major seventh and augmented fourth tended to be associated with danger and violence, perfect fifth with activity, and perfect fourth with being desolate and old. The octave was perceived as positive and strong, and major third as neutral with no particular meaning. The children's responses were influenced by their level of schooling, race, and living environment.

Earlier, Huber (1923) presented short pitch patterns to musical listeners who were asked to freely describe perceived expression. The reports were classified into: (a) mood impressions; (b) impressions of human character, for instance an elderly man; (c) emotionally coloured announcements, such as a call, question, or request; (d) impressions of movement; and (e) various inner images. Referring to Huber, Langer (1957, p. 231) remarked that 'The entire study shows effectively how many factors of possible expressive virtue are involved even in the simplest musical structure'.

Mode

Heinlein (1928) studied listeners' perception of major and minor chords in all keys, at different intensities and different pitch levels. Musically trained and untrained subjects described the perceived expression, choosing among adjectives such as bright, happy,

joyful (supposed to reflect expression of major mode), melancholy, sad, and soothing (minor mode). None of the 30 subjects got all responses 'correct': there were many sad-type responses to major chords and happy-type responses to minor chords. Loud chords and chords at a high pitch level evoked more happy-type responses than soft chords and chords at a low pitch level, irrespective of mode. Crowder (1984) showed in a reanalysis of Heinlein's data that all but one of the 30 listeners in fact gave more happy-type responses to major chords than to minor chords, that is, in accordance with the conventional association. Crowder (1985) found the conventional major–happy and minor–sad associations in young adults who listened to sine-wave triads in three tonalities and two inversions of each chord. The major–happy and minor–sad associations were also found in many investigations using real music (Hevner 1935*a*; Kleinen 1968; Krumhansl 1997; Nielzén & Cesarec 1982; Peretz *et al.* 1998; Wedin 1972*c*).

Rhythm and tempo

Motte-Haber (1968) had ten rhythm patterns, differing in metre, sound event density, and homogeneity (e.g. uniform or dotted pattern), presented at three different metronomic tempos (ratios 1 : 2 : 4) to listeners, who rated them on a large number of bipolar scales (*Polaritätsprofile*). Metronomically rapid rhythms were rated happier (*fröhlicher*) than slow rhythms. Happiness ratings were strongly correlated with ratings of *subjective* tempo, which was related not only to metronomic tempo but also to sound event density and other rhythm characteristics in interaction with metronomic tempo. Similar relations appeared in Gabrielsson (1973, Experiments 1–3) using other rhythm patterns.

Melodic properties

Gabriel (1978) investigated the perceived expression of 16 short tone sequences, 'basic terms', which music theorist Deryck Cooke (1959) claimed recur with the same expression in Western music from the late Middle Ages up to the twentieth century. For instance, an ascending major triad (1–3–5) with possible insertions of the intervening notes (2 or 4), was said to express 'an outgoing, active, assertion of joy' (Cooke 1959, p. 115). Its counterpart in minor would be 'expressive of an outgoing feeling of pain—an assertion of sorrow, a complaint, a protest against misfortune' (Cooke 1959, p. 122). Gabriel generated the 16 basic terms using sinusoidals, constant tempo, and uniform rhythm. Students listened to these 'reduced' basic terms and had to judge whether Cooke's characteristics were adequate. The result was mainly negative. However, this experiment has in its turn been criticized regarding the choice of stimuli, lack of context, and use of musically untrained listeners (Cazden 1979; Gabriel 1979; Nettheim 1979; Sloboda 1985, pp. 60–4; for a discussion of Cooke's theory, see Cook & Dibben, this volume).

Synthesized tone sequences

Scherer and Oshinsky (1977) investigated the relative importance of several factors by systematic manipulations of synthesized eight-tone sequences (no musical notation was provided, which makes it difficult to judge their musical qualities). The manipulated variables were amplitude variation (small–large), pitch level (high–low), pitch contour

(up–down), pitch variation (small–large), rhythm (even–uneven), tonality (major, minor, atonal), tempo (slow–fast), envelope (round, sharp), and filtration cut-off level (intermediate–high). Psychology students rated the stimuli on three bipolar scales: pleasantness–unpleasantness, activity–passivity, and potency–weakness, and also indicated whether each sequence expressed any or more of the following emotions: happiness, sadness, anger, fear, boredom, surprise, and disgust—the last five rarely or never included in earlier studies of emotional expression in music. Multiple regression analysis was used to estimate the predictive strength of each acoustic parameter on each emotion dimension. Most of the results can be found in Table 10.2 (see below). As seen there, any acoustical variable was associated with many emotions, listed in decreasing order of associative strength, in some cases even with seemingly 'opposite' emotions (e.g. low pitch associated with boredom, pleasantness, and sadness).

10.1.3 Manipulation of structural factors in musical context

Manipulation of several factors

The earliest and still best-known investigations with systematic manipulations of various factors in real music are those by Hevner (1935*a*, 1935*b*, 1936, 1937). She arranged a large number of emotion terms in eight clusters in a circular configuration, an 'adjective circle' (Fig. 10.1). The terms within each cluster were supposed to be close in meaning, and adjacent clusters should deviate slightly by cumulative steps until reaching a contrast in the opposite position. Inspection of Fig. 10.1 suggests an implicit dimensionality similar to that described in Section 10.1.1; in other words, valence (sadness–happiness, cluster II–cluster VI) and activity/arousal (exciting/vigorous–serene/dreamy, clusters VII/VIII–clusters IV/III). The circular configuration is reminiscent of the circumplex model by Russell (1980; see also Sloboda & Juslin, this volume) and may be one of the earliest indications of this conception, earlier than that proposed by Schlosberg in 1941 (cf. Remington *et al.* 2000). Listeners were instructed to mark as many of the terms as they found appropriate for each piece. Hevner selected short pieces of tonal music, but besides the original version she also constructed a variant that differed from the original in: (a) mode, a piece in major mode was also played in minor mode; notated example in Hevner (1935*a*); (b) melodic direction (ascending vs. descending), harmony (simple consonant harmonies vs. complex dissonant harmonies), and rhythm (firm vs. flowing, that is, a firm beat with a chord on every beat vs. a flowing motion in which the chords were broken up); notated examples in Hevner (1936); and (c) tempo (fast vs. slow) and pitch level (one octave or more apart); see Hevner (1937).

Any difference in listeners' choice of descriptive terms between the respective two versions of a piece could then be ascribed to the difference in the manipulated variable. All versions were performed by an experienced pianist, and listeners were hundreds of students, most of them without special musical training. The joint conclusions of several experiments were that variables with the largest effects on listeners' judgments were tempo and mode, followed by pitch level, harmony, and rhythm, whereas melodic direction had little if any effect (Hevner 1937). This order can be seen in Table 10.1, which was Hevner's summary of results from six experiments. It shows the relative

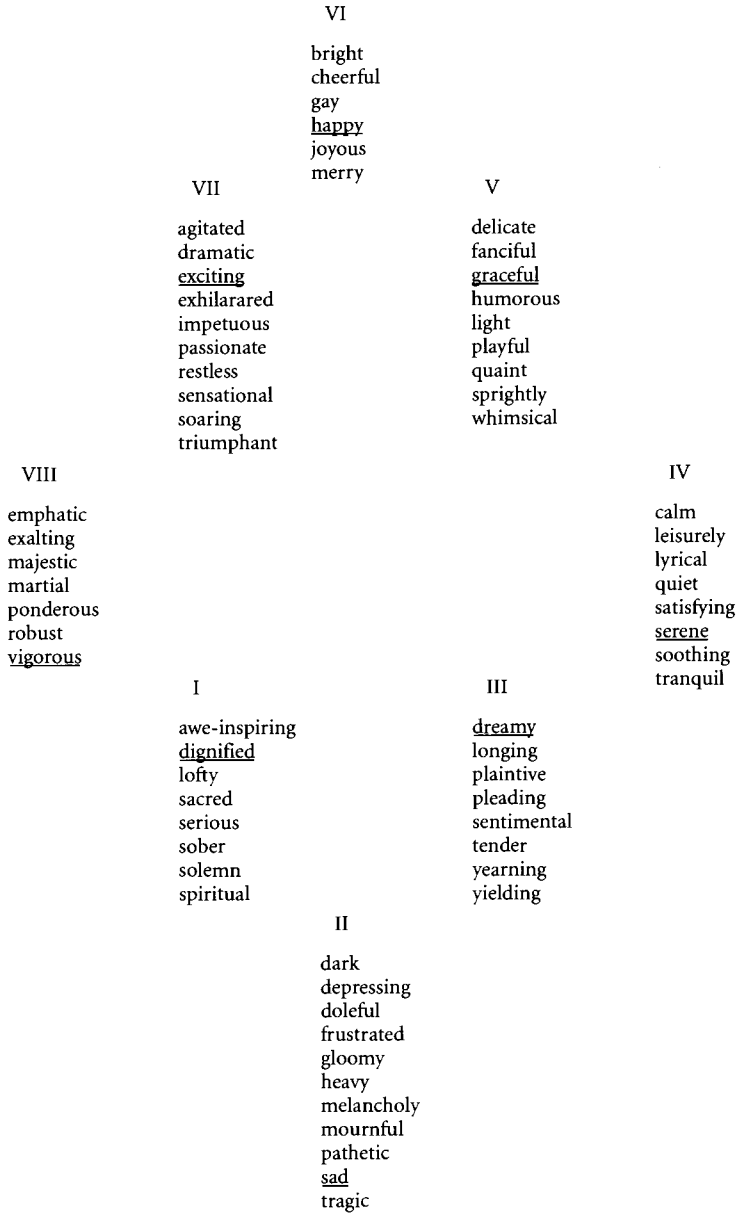

Figure 10.1 Hevner's adjective circle. Adjectives within each cluster appear in alphabetical order. Adjectives used by Hevner (1936, 1937) to represent the respective clusters are underlined (adapted from Farnsworth 1954, p. 98).

weights of each musical factor for each emotion cluster; for instance, minor mode, low pitch, and slow tempo were most important, in that order, for the sad–heavy cluster,

whereas major mode, fast tempo, and simple harmony were most important for the happy–bright cluster.

Hevner (1935*b*, 1937) noted the difficulties of manipulating real pieces of music and still having the manipulated version sound musically acceptable (cf. Behne 1972; Peretz *et al.* 1998, p. 118, footnote). She emphasized the necessity of using pieces with similar emotional expression throughout the whole piece and remarked that the results should only be interpreted in a relative and contextual sense. For instance, although happiness was usually associated with major mode, a piece in minor mode may sound happy due to other factors, such as tempo and rhythm. She warned against drawing too far-going conclusions since results may be dependent on the selected pieces and, above all, since emotional expression usually results from several musical factors in complex interplay. These arguments should be carefully considered by any researcher on emotional expression in music.

Rigg (1939) composed five four-bar phrases supposed to represent two emotion categories: pleasant/happy or sad/serious. They were systematically manipulated regarding tempo, mode, articulation (legato, staccato), pitch level, loudness, rhythm (iambic, trochaic), and certain intervals in an impressively large number of variations. Listeners described perceived expression by choosing first among the above-mentioned alternatives and then among subcategories within each of them (e.g. hopeful longing, sorrowful longing). In a subsequent experiment (Rigg 1940*a*) the same phrases were transposed up or down an octave, to the dominant (a fifth upwards or a fourth downwards), a second down, and a minor second up. Shifts an octave upward made the phrase happier or less sorrowful, and vice versa. There were less effects for the dominant transposition and practically no effect of the smallest transpositions. Finally, Rigg (1940*b*) had the same five phrases played by a pianist at six different tempos, from 60 to 160 bpm (beat = quarter note), and found that the higher the tempo, the more pleasant/happy and the less serious/sad judgments were given. However, one of the phrases, supposed to express lamentation, still sounded sad even at the highest tempo, and for another one, supposed to express sorrowful longing, there was about the same number of happy and sad responses at the highest tempo. Both these phrases were in minor mode and had descending minor or major seconds in the upper voice. Rigg (1964) reviewed the results obtained by Gundlach (1935), Hevner (1935*a*, 1936, 1937), Rigg (1937, 1939, 1940*a*, 1940*b*), and Watson (1942).

Juslin (1997, Experiment 2) used synthesized versions of 'Nobody knows the trouble I've seen' manipulating tempo (slow, medium, fast), sound level (low, medium, high),

Table 10.1 Hevner's summary of results from six experiments (adapted from Hevner 1937, p. 626)

Musical factor	Dignified/ solemn	Sad/ heavy	Dreamy/ sentimental	Serene/ gentle	Graceful/ sparkling	Happy/ bright	Exciting/ elated	Vigorous/ majestic
Mode	Minor 4	Minor 20	Minor 12	Major 3	Major 21	Major 24	–	–
Tempo	Slow 14	Slow 12	Slow 16	Slow 20	Fast 6	Fast 20	Fast 21	Fast 6
Pitch	Low 10	Low 19	High 6	High 8	High 16	High 6	Low 9	Low 13
Rhythm	Firm 18	Firm 3	Flowing 9	Flowing 2	Flowing 8	Flowing 10	Firm 2	Firm 10
Harmony	Simple 3	Complex 7	Simple 4	Simple 10	Simple 12	Simple 16	Complex 14	Complex 8
Melody	Ascend 4	–	–	Ascend 3	Descend 3	–	Descend 7	Descend 8

The numbers indicate the relative weight of each musical factor (left column) for each emotion cluster.

frequency spectrum (soft, bright, sharp), articulation (legato, staccato), and tone attack (slow, fast). Students rated these versions on six adjectve scales: happy, sad, angry, fearful, tender, and expressive. Multiple regression analyses showed that the variance accounted for (R^2) by the manipulated factors was typically 0.78–0.88, except for fearful (0.55) and expressive (0.46). Sharp spectrum (higher partials amplified) and high sound level were the most important predictors for angry; fast tempo for happy; slow tempo for sad; slow tempo, soft spectrum (higher partials attenuated), and legato articulation for tender; low sound level and staccato articulation for fearful; and legato articulation for expressive.

Lindström (1997) constructed 72 versions of 'Frère Jacques' by systematic manipulation of tonal progression (choice of notes affecting latent harmony), rhythm (even notes, 1 : 1, uneven 3 : 1 and 1 : 3 ratios, respectively), melodic contour (original and complex), and melodic direction (original and reversed). Listeners' judgments of emotional expression were most affected by changes of harmonic functions, followed by changes of rhythm and melodic contour. Inspection of interactions and most extreme ratings showed intricate interplay between several structural factors (Lindström 2000).

Peretz *et al.* (1998, Experiment 2) manipulated tempo and mode in synthesized versions of 32 excerpts of classical music and found that these factors affected both normal listeners' and a brain-injured listener's perception of happiness and sadness in similar ways. Moreover, exposition shorter than a second was enough for reliable recognition of these expressions. Kamenetsky *et al.* (1997) compared listeners' ratings of emotional expression in synthesized versions of two baroque and two romantic keyboard pieces. The 'original' version with variations in both tempo and dynamics was rated the most expressive. Removing tempo variations but keeping variations in dynamics reduced expressiveness only marginally, whereas removing variation in dynamics but keeping tempo variations significantly reduced perceived expressiveness.

Balkwill and Thompson (1999) asked two professional Hindustani musicians to perform a short *alap* (improvised opening section) from any raga they wanted to choose to evoke each of four emotions: joy, sadness, anger, and peace. Listening to these performances, Canadian students indicated which of the four emotions was most dominant in each performance and rated the degree to which the respective emotion was conveyed. They also rated the performances regarding tempo, melodic and rhythmic complexity, and pitch range. The recognition of intended emotions was successful except for peace, and data show some confusion between joy and anger and between sadness and peace. Judgments by four experts on Hindustani music showed a similar pattern. On the whole, then, Western listeners were sensitive to intended emotions in Hindustani music. Joy was associated with faster tempo and less melodic and rhythmic complexity; sadness with slower tempo and melodic and rhythmic complexity; anger with timbre of stringed instruments; and peace with slow tempo, flute timbre, and less melodic and rhythmic complexity.

Tempo

Behne (1972) presented ten pieces of recorded music at three different tempos by means of a so-called Springer machine to music students who rated them using bipolar scales. With decreased tempo of the pieces, listeners rated them as more serious (*ernst*)

and complaining (*klagend*). In another experiment, six eight-bar versions of a theme were composed to represent three different basic tempos (slow, midway, rapid) and two levels of harmonic complexity (simple, complex). Each version was then performed at five different tempos by a woodwind trio and rated by 30 subjects. The (complex) results were discussed in relation to conceived tempo, performed tempo, and to melodic and harmonic information density. Hevner's observation that it is difficult to manipulate different factors independently of others in real music was confirmed. The two levels of harmonic complexity were not equivalent across the different tempos: versions with slow original tempo were in fact more harmonically complex than the versions with rapid original tempo at the (assumed) same complexity level.

Mode

Kastner and Crowder (1990) presented 12 short melodies, each of them in major or minor mode, to 38 children from preschool and elementary school. For each presentation they were asked to choose among four pictures of faces: happy, contented, sad, and angry. All children, even the youngest (3 years), showed a reliable positive-major and negative-minor association, not perfect but significantly different from what would happen on chance basis. In similar studies by Gerardi and Gerken (1995) and Gregory *et al.* (1996), the happy–major and sad–minor association was found in children aged 7–8 years and in young adults, but not in children aged 3–5 years. Thus, in all three studies the conventional happy–major and sad–minor association was present in older children, whereas the results for younger children are inconclusive.

Hill *et al.* (1996) studied which of two alternatives—salvation or condemnation—adults associated with a setting either in Ionian mode or in Phrygian mode of a well-known melody from early seventeenth century, variously known as *Herzlich tut mich verlangen* (promise of salvation, reward) or *Ach Herr, mich armen Sünder* (fear of condemnation, punishment), both in settings by J. S. Bach. Adults as well as children judged the Ionian mode more suitable for the 'salvation/reward' alternative and the Phrygian mode more suitable for the 'condemnation/punishment' alternative. The fact that Ionian mode is identical to major mode may have contributed to its association with the 'salvation/reward' alternative.

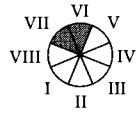
Musical form

Konečni and his co-workers (Gotlieb & Konečni 1985; Karno & Konečni 1992; Konečni 1984; Konečni & Karno 1994) demonstrated that changing the order of movements in Beethoven sonatas and string quartets, randomizing the order of variations in Bach's *Goldberg Variations*, or rearranging the order of different parts in sonata form as in the first movement of Mozart's Sympony in G Minor K. 550 had little or no effect on university students' ratings on various hedonic (e.g. beautiful, pleasing) or emotion-related (e.g. exciting, emotional) scales.

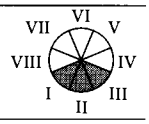
Tillman and Bigand (1996) chunked three pieces by Bach, Mozart, and Schoenberg into (musically adequate) segments of about 6 seconds and then played these either in original or in backward order to university students, who rated them on 27 (mostly) emotion-related scales. There were significant differences among the *pieces* in all scales, but only two significant differences between the two *versions* (original, backward) of

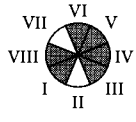
each piece. They concluded that for these subjects musical expressiveness was mainly affected by local structures within the chunks, not by global musical structure. This is in good agreement with the main theme in *Music in the moment* by Levinson (1997).

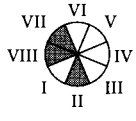
10.2 Effects of separate musical factors

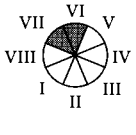


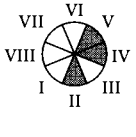
Most of the results from the studies reviewed above are summarized in Table 10.2. The first column contains different structural factors in alphabetical order, the second different levels within each factor, and the third column the corresponding emotional expression according to different studies. Authors' names are abbreviated to the initial two letters of the (first) author and publication year to the two last digits (e.g. He36 = Hevner 1936). Studies are grouped into: (A) early studies using choice among descriptive terms; (B) studies based on multivariate analyses; and (C) later experimental studies; thus offering alternative bases for interpretation of the results. As a rule, the emotions are listed in decreasing order of association with the corresponding factor. Following Rigg (1964), results of the early studies (A) are described in terms of Hevner's clusters designated by Roman numbers and the adjective that Hevner used as a label for each cluster (Hevner 1936, p. 265), with the use of shaded areas in the adjective circle.

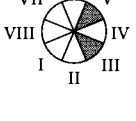




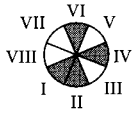


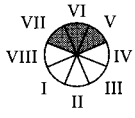


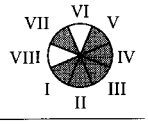


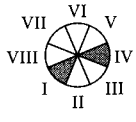


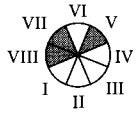
10.2.1. Tempo

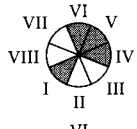


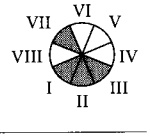


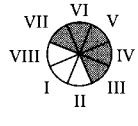


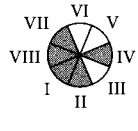




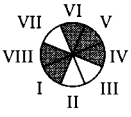


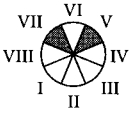


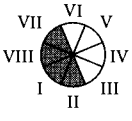


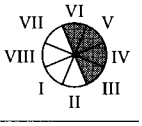


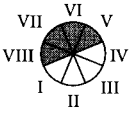
Among factors affecting emotional expression in music, tempo is usually considered the most important (cf. Gundlach 1935; Hevner 1937; Juslin 1997; Rigg 1964; Scherer & Oshinsky 1977). Composers as a rule indicate intended tempo, either exactly—for instance, MM (Mälzel metronome) or bpm (beats per minute) = 100—or with designations such as presto, allegro, moderato, andante, and adagio.

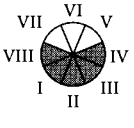












The studies under tempo in Table 10.2 indicate that fast tempo may be associated with various expressions of activity/excitement, happiness/joy/pleasantness, potency, surprise, anger, and fear. Slow tempo may be associated with various expressions of

Table 10.2 Summary of results from reviewed studies. Left two columns indicate structural factor and levels within each factor, middle column the associated emotional expression, right column the corresponding clusters in Hevner's adjective circle. Within each factor studies are grouped into (A) early studies using choice among descriptive terms, (B) studies based on multivariate analyses, and (C) later experimental studies. Authors' names are abbreviated to the initial two letters of the (first) author, publication year to the two last digits (e.g., He36 = Hevner, 1936). See text for further explanation.

Factor	Levels	Emotional expression	Adjective circle (Hevner)
Amplitude envelope	Round	(C) Disgust, sadness, fear, boredom, potency (Sc77), tenderness, fear, sadness (Ju97)	
	Sharp	(C) Pleasantness, happiness, surprise, activity (Sc77), anger (Ju97)	
Articulation	Staccato	(A) VI: gaiety; VII: agitation (Ri39) (B) Intensity/energy/activity (We72c), gaiety (Ni82) (C) Fear, anger (Ju97)	

Factor	Levels	Emotional expression	Adjective circle (Hevner)
	Legato	(A) I: solemn; II: melancholy, lamentation; III: longing (Ri39) (B) Softness (We72c) (C) Tenderness, sadness (Ju97)	
Harmony	Simple/ consonant	(A) VI: happy (He36, Wa42), joy (Ri39; V: graceful; IV: serene; III: dreamy (He36); I: dignified (He36, Wa42), serious (Wa42), solemn (Ri39); VIII: majestic (Wa42) (B) Gaiety, pleasantness (We72c), attraction (Ni82) (C) Relaxation, tenderness (Li97)	
	Complex/ dissonant	(A) VII: exciting (He36, Wa42), agitation (Ri39); VIII: vigorous (He36); II: sad (He36, Wa42) (B) Gloom, unpleasantness (We72c), tension (Ni82, Kr96) (C) Tension (Ni83, Kr96, Li97), fear (Kr97), anger (Li97)	
Intervals	Harmonic:		
	Consonant	(C) Pleasant, 'non-active' (Co00)	
	Dissonant	(C) Displeasing (Ma80), unpleasant, 'active', strong (Co00)	
	High-pitched	(C) Happy, powerful (Ma80), 'activity', potency (Co00)	
	Low-pitched	(C) Sad, less powerful (Ma80, Co00)	
	Melodic:		
	Large	(C) Powerful (Ma82)	
	Minor 2nd	(C) Melancholy (Ma82)	
	Perfect 4th, perfect 5th, major 6th, minor 7th, octave	(C) Carefree (Ma82)	
	Perfect 5th	(C) Activity (Sm99)	
	Octave	(C) Positive/strong (Sm99)	
Loudness	Loud	(A) VII: excitement (Wa42), triumphant (Gu35); VI: joy (Ri39) (B) Gaiety (Ni82), intensity (We72c), strength/power (Kl68), solemnity (We72c), tension (Ni83, Kr96) (C) Anger (Ju97)	
	Soft	(A) II: melancholy (Gu35); V: delicate (Gu35); IV: peaceful (Wa42) (B) Softness (Kl68, We72c), tenderness (Kl68) (C) Fear, tenderness, sadness (Ju97)	
Loudness variation	Large	(C) Fear (Sc77)	
	Small	(C) Happiness, pleasantness, activity (Sc77)	
	Rapid changes	(A) V: playful, amusing; III: pleading (Wa42) (C) Fear (Kr97)	

Factor	Levels	Emotional expression	Adjective circle (Hevner)
	Few/no changes	(A) II: sad; IV: peaceful; I: dignified, serious; VI: happy (Wa42)	
Melodic (pitch) range	Wide	(A) V: whimsical; VI: glad; VII: uneasy (Gu35) (C) Fear (Kr97), joy (Ba99)	
	Narrow	(A) I: dignified; II: melancholy; III: sentimental; IV: tranquil; V: delicate; VII: trimphant (Gu35) (C) Sadness (Ba99)	
Melodic direction	Ascending	(A) I: dignified; IV: serene (He36) (C) Tension (Ni83, Kr96), happiness (Ge95)	
	Descending	(A) VII: exciting; V: graceful; VIII: vigorous (He36) (C) Sadness (Ge95)	
Pitch contour	Up	(C) Fear, surprise, anger, potency (Sc77)	
	Down	(C) Sadness, boredom, pleasantness (Sc77)	
Melodic motion	Stepwise motion	(C) Dull melodies (Th92)	
	Intervallic leaps	(C) Excitement (Th92)	
	Stepwise + leaps	(C) Peacefulness (Th92)	
Mode	Major	(A) VI: happy (He36), joy (Ri39); V: graceful (He36); IV: serene (He36); I: solemn (Ri39) (B) Happiness (Kl68, We72c), attraction (Ni82) (C) Happiness (Sc77, Cr85, Kr97, Pe98)	
	Minor	(A) II: sad (He36); lamentation (Ri39); III: dreamy; I: dignified (He36); VII: agitation (Ri39) (B) Sadness (Kl68, We72c), tension (Ni82) (C) Sadness (Cr85, Kr97, Pe98), disgust, anger (Sc77)	
Pitch level	High	(A) V: graceful; IV: serene; VI: happy (He37), joy (Ri40a); III: dreamy (He37), sentimental (Gu35), pleading (Wa42); VII: triumph (Ri39), exciting (Wa42) (B) Gaiety (Kl68, We72c) (C) Surprise, potency, anger, fear, activity (Sc77)	
	Low	(A) II: sad (He37, Wa42), melancholy (Gu35), lamentation (Ri40a); VIII: vigorous (He37); I: dignified (He37), serious (Wa42), solemn (Ri40a); VII: exciting (He37), agitation (Ri40a); IV: tranquil (Gu35) (B) Serious (Kl68), sadness, solemnity (We72c) (C) Boredom, pleasantness, sadness (Sc77)	

Factor	Levels	Emotional expression	Adjective circle (Hevner)
Pitch variation	Large	(C) Happiness, pleasantness, activity, surprise (Sc77)	
	Small	(C) Disgust, anger, fear, boredom (Sc77)	
Rhythm	Regular/smooth	(A) VI: happiness (Wa42), glad (Gu35); I: serious, dignified, IV: peaceful (Wa42); VIII: majestic (Wa42); V: flippant (Gu35)	
	Irregular/rough	(A) V: amusing (Wa42); VII: uneasy (Gu35)	
	Complex	(C) Angry melodies (Th92)	
	Varied	(C) Joyful melodies (Th92)	
	Firm	(A) I: dignified; VII: vigorous; II: sad; VII: exciting (He36)	
		(C) Sad (We72c)	
	Flowing/fluent	(A) VI: happy; III: dreamy; V: graceful; IV: serene (He36)	
		(C) Gaiety (We72c)	
Tempo	Fast	(A) VII: exciting (He37, Wa42), uneasy (Gu35) agitation, triumph (Ri40b); VI: happy (He37, Wa42), glad (Gu35), gaiety, joy (Ri40b); V: graceful (He37), mischievous (Wa42), whimsical, flippant (Gu35); VIII: vigorous (He37)	
		(B) Happiness, pleasantness (Kl68, Mo68, We72c, Ga73, Ni82)	
		(C) Activity, surprise, happiness, pleasantness, potency, fear, anger (Sc77), happiness, anger (Ju97), happiness (Th92, Kr97, Pe98), joy (Ba99), excitement (Th92)	
	Slow	(A) IV: serene (He37), tranquil (Gu35); III: dreamy (He37), longing (Ri40b), sentimental (Gu35); I: dignified (He37), serious (Wa42), dignified (Gu35), solemn (Ri40b); II: sad (He37, Wa42), lamentation (Ri40b); VIII: excited (Gu35)	
		(B) Sadness (Kl68, Be72, We72c, Ni82), solemnity (We72c)	
		(C) Sadness, boredom, disgust (Sc77), sadness, tenderness (Ju97), sadness (Th92, Kr97, Pe98, Ba99), peace (Ba99)	
Timbre	Few harmonics	(C) Pleasantness, boredom, happiness, sadness (Sc77)	
	Many harmonics	(C) Potency, anger, disgust, fear, activity, surprise (Sc77)	
	Soft	(C) Tenderness, sadness (Ju97)	
	Sharp	(C) Anger (Ju97)	
Tonality	Tonal	(C) In joyful, dull, peaceful melodies (Th92)	
	Atonal	(C) In angry melodies (Th92)	
	Chromatic	(C) In sad and angry melodies (Th92)	

Factor	Levels	Emotional expression	Adjective circle (Hevner)
Musical form	Low complexity + average dynamism	(C) Relaxation/less tension (Ni83), joy, peace (Ba99) (B) Positive emotions (Im79)	
	High complexity (melodic/harmonic/rhythmic)	(C) Tension (Ni83, Kr96), sadness (Ba99)	
	+ low dynamism	(B) Melancholy and depression (Im79),	
	+ high dynamism	(B) Anxiety and aggressiveness (Im79)	
	Repetition, condensation, sequential development, pauses etc.	(C) Increased tension (Ni83)	
	End of large-scale sections	(C) Tension peaks followed by rapid decrease (Kr96)	
	New musical ideas	(C) Low tension (Kr96)	
	Disruption of global form	(C) Little effect (Ko84, Go85, Ka92, Ko94, Ti96)	

calmness/serenity, dignity/solemnity, sadness, tenderness, boredom, and disgust. Which of the different expressions is perceived in each case is highly dependent on the actual context, that is, presence and level of other factors. For instance, although faster tempo tends to increase perceived happiness, other factors may overrule this tendency, such as minor mode and descending seconds (e.g. Rigg 1940*b*; see also Section 10.1.3).

The term tempo may not always have the same meaning, as discusssed in Behne (1972), Gabrielsson (1986, 1988, 1999), and Motte-Haber (1968). Usually, tempo refers to perceived pulse rate. However, sometimes the pulse may be felt at, say, half or double pace. Perceived speed may also be affected by note density (e.g. the number of notes per second) as well as density of melodic or harmonic changes. Interplay between tempo (pulse rate) and note density may occur in an infinite number of combinations, for instance, rapid tone sequences (or high note density) but slow pulse (for examples, see Gabrielsson 1986).

10.2.2 Mode

Major mode may be associated with happiness/joy and minor mode with sadness, at least from 7–8 years of age. Major mode may also be associated with expressions such as graceful, serene, and solemn, and minor mode with expressions such as dreamy, dignified, tension, disgust, and anger.

What expression is perceived depends, again, on the context. For instance, loud chords and high-pitched chords may suggest more happiness than soft chords and low-pitched chords, irrespective of mode. Major mode is not a necessary condition for expression of happiness. An example may be the beginning of the last movement,

'Badinerie', in J. S. Bach's *Second Suite for Orchestra* (Fig 10.2). The theme in B minor with its forward-driving rhythmic pattern is usually played in rapid tempo and can hardly be associated with sadness—the title itself suggests happiness (French: *badinerie*, joke). However, if the same theme were transferred to B major, it may sound even happier (cf. Hevner 1935*b*, p. 202).

10.2.3 Loudness

Loud music may be associated with various expressions of intensity/power, tension, anger, and joy, and soft music with softness, tenderness, sadness, solemnity, and fear. Large variations of loudness (amplitude) may suggest fear, small variations happiness or activity. Rapid changes in loudness may be associated with expressions such as playful or pleading, and few or no changes with sadness, peace, and dignity (cf. Juslin, this volume).

10.2.4 Pitch

High pitch may be associated with expressions such as happy, graceful, serene, dreamy, and exciting, and, further, with surprise, potency, anger, fear, and activity. Low pitch may suggest sadness, dignity/solemnity, vigour, and excitement, as well as boredom and pleasantness (such a 'contradiction' may depend on the context of other factors). Large pitch variation may be associated with happiness, pleasantness, activity, or surprise; small pitch variation with disgust, anger, fear, or boredom.

10.2.5 Intervals

For harmonic intervals, results concerning consonance and dissonance are similar to the corresponding results under harmony (see Section 10.2.7) and concerning high and low pitch level to the corresponding results under pitch (see Section 10.2.4). For melodic intervals, results so far seem rather tentative, for instance, large intervals may be perceived as more powerful than small ones, the minor second as the most sad interval, and the octave as positive and strong.

10.2.6 Melody

Melodic range

Wide melodic range may be associated with joy, whimsicality, and uneasiness, and a narrow range with expressions such as sad, dignified, sentimental, tranquil, delicate, and triumphant.

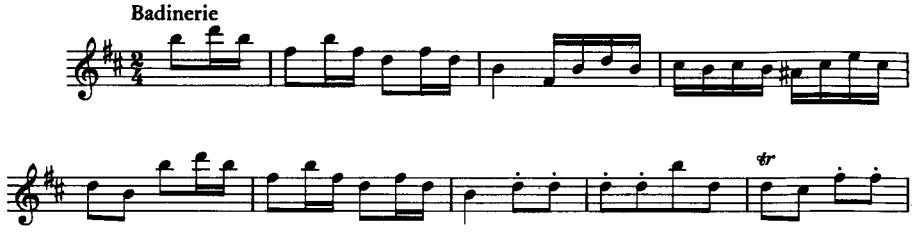


Figure 10.2 Beginning of 'Badinerie', in J. S. Bach's *Second Suite for Orchestra.*

Melodic direction (pitch contour)

Ascending melody may be associated with dignity, serenity, tension, and happiness (but not for children, see Gerardi & Gerken 1995), as well as with fear, surprise, anger, and potency. Descending melody may be associated with expressions such as exciting, graceful, vigorous, and sadness (especially when combined with the minor mode; Gerardi & Gerken 1995) and, further, with boredom and pleasantness. According to Gundlach (1935), Hevner (1937), and Rigg (1939, 1964) melodic direction had no or little importance for emotional expression.

Melodic motion

There is little research on melodic motion except melodic direction. Stepwise motion may suggest dullness; intervallic leaps, excitement; and stepwise motion leading to melodic leaps, peacefulness. Lindström (1997) found that an interaction between melodic contour and rhythm affect judgments of happiness and sadness.

10.2.7 Harmony

Simple, consonant harmony may be associated with expressions such as happy/gay, relaxed, graceful, serene, dreamy, dignified, and majestic; complex and dissonant harmony with excitement, tension, vigour, anger, sadness, and unpleasantness.

10.2.8 Tonality

Composers used chromatic harmony in sad and angry melodies. Joyful, dull, and peaceful melodies were tonal, and angry melodies could be atonal (Thompson & Robitaille 1992).

10.2.9 Rhythm

Regular/smooth rhythm may be perceived as expressing happiness, dignity, majesty, and peace; irregular/rough rhythm, amusement, uneasiness, and anger; and varied rhythm, joy. Firm rhythm may be associated with expressions of sadness, dignity, and vigour, and flowing/fluent rhythm with expressions such as happy/gay, graceful, dreamy, and serene. Terminology varies among authors, which makes comparisons difficult.

10.2.10 Timbre

Tones with many harmonics may suggest potency, anger, disgust, fear, activity, or surprise, and tones with amplified higher harmonics may suggest anger. Tones with few, low harmonics may be associated with pleasantness, boredom, happiness, or sadness; tones with suppressed higher harmonics, tenderness and sadness. Behrens and Green (1993) found sadness best expressed by the singing voice or violin, anger by the timpani, and fear by the violin. With Hindustani music judged by Western listeners, Balkwill and Thompson (1999) found stringed instruments associated with the expression of anger, and the flute with the expression of peace.

10.2.11 Articulation

Staccato may be associated with gaiety, energy, activity, fear, and anger, and legato with sadness, tenderness, solemnity, and softness. Articulation is usually more discussed in connection with performance (Juslin, this volume).

10.2.12 Amplitude envelope

This refers to the type of attack and decay of tones. Sharp envelope (rapid attack and decay) may be associated with anger, happiness, surprise, and activity; round envelope with tenderness, sadness, fear, disgust, boredom, and potency. The shaping of amplitude envelope is usually more discussed in connection with performance (Juslin, this volume).

10.2.13 Musical form

The influence of various aspects of musical form has been little studied. The examples in Table 10.2 concerning the effects of high and low complexity, repetition, condensation of material, and so forth were discussed in Sections 10.1.1 (Imberty 1979; Krumhansl 1996; Nielsen 1983) and 10.1.3 (Balkwill & Thompson 1999). On the other hand, some studies (Konečni 1984; Tillman & Bigand 1996) indicate that various manipulations of musical form may not matter very much (see Section 10.1.3).

10.2.14 Interaction between factors

Perceived emotional expression in music is rarely or never exclusively determined by a single factor but is always a function of many factors (see, for example, Hevner 1935*b*, 1937; Rigg 1964). The influence of a certain factor may depend on how it is combined with other factors, that is, on the interaction between factors. A few examples mentioned earlier were mode × loudness and mode × pitch interactions (Section 10.1.2), and tempo × mode interactions (Sections 10.2.1 and 10.2.2). Possibilities for different types of interactions seem almost endless. Apparent contradictions in results, such that two 'opposite' emotions may be associated with the same structural factor may be resolved by examining interactions with other factors. However, interactions are primarily discussed *post hoc*, and there is practically no planned research regarding interaction between factors (Lindström 2000).

10.3 Some implications for future research

Despite the considerable amount of results summarized above there are still many gaps, uncertainties, and ambiguities regarding the influence of various structural factors on emotional expression. There is no systematic research on how the timbre of different musical instruments affects emotional expression—certainly something that composers pay much attention to. Research on harmony is very simplistic, usually focusing on consonance/dissonance, while there is practically nothing on chords, harmonic progressions, or implied harmony. There is surprisingly little and fairly tentative research on intervals. The study of melody is limited to the effects of range and direction, while melodic motion, that is, the specific sequences of pitches/intervals during the course of

a melody, is almost totally neglected, as is its rhythmic structure. Likewise, the influence of specific rhythm patterns—beyond their degree of simplicity or complexity—is unresearched. Questions concerning how musical form influences emotional expression are touched upon only in a few studies.

However, the most obvious gap concerns potential interactions between different factors. It has been emphasized, again and again (e.g. Hevner 1935*b*, 1937; Rigg 1964), that no factor works in isolation, its effects are dependent on what other factors and levels are present. Music abounds with interactions. To take but one example not mentioned earlier: the expressive qualities of different intervals can hardly be ascertained in a general manner. How a melodic interval is perceived is obviously dependent on in what tempo, in what direction (up, down), in what rhythm pattern, and at what loudness and pitch level the interval appears, not to mention its position within the musical context in question. Analogous examples may be easily found for other factors as well.

Moreover, most factors are studied only regarding two 'extreme' levels—fast or slow tempo, high or low pitch, loud or soft sound, ascending or descending melody, legato or staccato articulation. Intermediate levels are usually neglected, probably on the implicit assumption that their effects may be inferred from results at the extreme levels. Nor are the effects of transitions from one level to another investigated, such as crescendo or diminuendo, accelerando or ritardando, glissando, transition from minor to major mode, from diatonicism to chromaticism, or from thin to thick texture—not to mention combinations of them, for instance, imagine a glissando towards high pitch combined with diminuendo and ritardando.

The last-mentioned examples hint at another neglected aspect: how expressive qualities vary and change in dynamic ways. Most research has focused on one expression at a time: happiness, sadness, anger, etc., and it is recommended that the investigator choose musical excerpts which are homogeneous with regard to emotional expression (e.g. Hevner 1935*b*). However, many of music's most expressive qualities relate to structural *changes* across time which make possible expression of, say, shifting emotions, blending emotions, competing or conflicting emotions.

Going beyond emotions, Langer suggested that, because there are certain formal properties that are similar in music and in human feeling, we may perceive expressions such as 'growth and attenuation, flowing and stowing, conflict and resolution, speed, arrest, terrific excitement, calm, or subtle activation and dreamy lapses' (Langer 1953, p. 27), or 'patterns of motion and rest, of tension and release, of agreement and disagreement, preparation, fulfilment, excitation, sudden change, etc.' (Langer 1957, p. 228). These examples represent complex combinations of perceptual, cognitive, and emotional aspects that elude conventional psychological terminology. They remind us of what Stern (1985) called 'vitality affects', which seem intuitively appealing to the study of musical expression (see also Sloboda & Juslin, this volume). Phenomena like these are little investigated in research; the closest examples are studies on tension and release by means of continuous recording (see 10.1.1). Continuous recording of listeners' judgments is a necessary prerequisite to study these phenomena (for a review, see Schubert, this volume).

Research is also hampered by a lack of appropriate definitions and terminology, both regarding structural factors (e.g. on tempo and rhythm; see 10.2.1 and 10.2.9), and regarding categories or dimensions of emotions (see Sloboda & Juslin, this volume).

Should we try to subsume the hundreds of descriptive words for emotional expression under a few dimensions, such as evaluation, activity, and potency (Osgood *et al.* 1957), or valence and arousal in Russell's (1980) circumplex model? (See Remington *et al.* 2000, for a recent review of the circumplex model.) It seems obvious that this reduction goes too far and cannot capture all possible emotional nuances that we may perceive in music. On the other hand, we may have penetrating phenomenological descriptions abounding with suggestive descriptive terms to the limit of overwhelming the reader. In between, there may be something like Hevner's adjective clusters, although criticized and revised (e.g. Farnsworth 1954), which are still useful and referred to. However, emotions such as anger, fear, surprise, boredom, and disgust were missing and were included only in much later studies (e.g. Scherer & Oshinsky 1977).

In order to ensure both adequate control and ecological validity, future research should aim for an efficient interplay between studies using real music and studies using systematic manipulation of structural factors in as music-like contexts as possible. Many gaps, confusions, and contradictions in the present results may be resolved, slowly but safely, by careful research on the interactions between different factors. Techniques for continuous recording, maybe combined with non-verbal responses, should be used in order to better study perceived expression as a dynamic process. Choice of musical examples should be considerably broadened to overcome the present limitation to Western art (and some popular) music. Connections should be sought to studies of emotional expression in other areas, say, speech and body language, as well as to emotion psychology in general, and, furthermore, to music theory, music aesthetics, and music anthropology.

The real experts are, of course, the successful composers, past and present. They know, somehow, how to manipulate different variables in musical structure to attain an intended expression. This knowledge may be in part explicit, in part implicit, in combinations that are different for different composers. Although we may learn some grains of wisdom from the writings of certain composers—for instance, in the volume edited by Fisk (1997)—on the whole, their knowledge is rarely made available to others except for their students and other close persons. Thus, the mystery of composing music may remain—to the satisfaction of those who want to have some mystery in life left untouched.[1]

CHAPTER 11

MUSIC AS A SOURCE OF EMOTION IN FILM

ANNABEL J. COHEN

Emotion characterizes the experience of film, as it does the experience of music. Because music almost always accompanies film, we may well ask what contribution music makes to the emotional aspects of film. The present chapter addresses this question.

It should be said at the outset that in spite of the integral role of music for film, film music has been largely neglected by the disciplines of both musicology and music psychology until the last decade (e.g. Cohen 1994; Marks 1998; Prendergast 1991). The reasons for the neglect are complex, arising from social, technological, economic, historical, and cultural factors. Some of these factors also account for a parallel neglect by psychology of the study of film perception (Hochberg & Brooks 1996*a*, 1996*b*). Moreover, unlike other types of popular or art music, much music for film has been composed with the understanding that it will not be consciously attended to. Countering this neglect, the present chapter takes a psychological perspective on the sublime and remarkable emotional phenomena produced by music in the context of film. This chapter has the joint intent of supporting the argument that music is one of the strongest sources of emotion in film and of opening doors to further empirical work that explains why this is so.

The chapter is divided into five sections. The first section briefly establishes a context for discussing emotion in music and film. Section 11.2 focuses on music in film, first establishing a historical perspective and then examining the role of music at the interface of the fictional and non-fictional elements of film. It continues with empirical studies of music as a source of inference and then summarizes the functions that music serves for film. Section 11.3 presents a cognitive framework for understanding musical soundtrack phenomena previously described. Section 11.4 considers the role of the composer as the origin of the source of musical emotion for film, whilst conclusions are drawn in the final section.

11.1 Emotion: definitions in music and film contexts

In the present chapter, the term film refers to the narrative dramas characteristic of movie theatres, television, and video with which most people are familiar as a source of entertainment. Music typically accompanies a considerable proportion of the duration of such films. Because of the relative novelty of the empirical study of film music in general, let alone the study of the emotional contribution of music in film, it would be

premature to advocate a particular way of considering emotion in the present chapter. What is more important is to show how various 'music-alone' perspectives on emotion translate in the film context. These perspectives include the contribution of music to emotional meaning (Juslin 1997; Levi 1982), the establishment of general mood (Pignatiello *et al.* 1986), and the experience of genuine, deep emotions (Gabrielsson 1998; Gabrielsson & Lindström 1993; Sloboda 1985, 1992; see also Gabrielsson, this volume).

The film context sometimes permits greater terminological clarity than the music-alone situation. For example, consider the terms 'mood' and 'emotion' which are often differentiated with respect to the presence of an object (e.g. Barrett & Russell 1999; Tan 1996). Whereas both moods and emotions may be regarded as dispositions toward appraising emotional meaning structures and a readiness to respond in a certain manner, moods do not have objects; emotions do. For example, experiencing the emotion of relief requires an object of that emotion, such as a safe arrival after a treacherous journey. Objects are not as evident in music-alone contexts, but, as argued by musicologist Nicholas Cook (1998), in a multimedia context music readily finds an object. The emotional associations generated by music attach themselves automatically to the visual focus of attention or the implied topic of the narrative. Because film content provides the object of emotion generated by music, the film helps to control the definition of the object of the emotion experienced during the presence of music.

Considering music and emotion within the context of film also has the advantage of bringing knowledge from psychological studies of film to bear on questions regarding music and emotion. Based on the emotion theorist Frijda (1986), Tan (1996), for example, addresses the question of the genuine nature of emotions in film, a topic that will be addressed later in this chapter. Thus, research on music and emotion in the film context may benefit from research insights derived from studies of film and emotion. Conversely, our understanding of emotion associated with autonomous music may shed light on emotional processes that occur in the film context. All of this information may contribute to the understanding of both the unique accomplishment of composing music for film and the extent to which music provides an important source of emotion in film.

11.2 Music and cinema

11.2.1 Historical background

Beginnings

From the earliest days of film, music played a part. When silent film was first introduced at the turn of the century, the film projector was anything but silent. Music was therefore enlisted to mask the extraneous noise. While serving the masking function, music also was exploited to illustrate and explain the action (Palmer 1980, p. 549). Kracauer (1960, p. 133) emphasizes that the noise problem of the film projection was relatively shortlived, and yet the importance of music remained. An entire music-for-the-silent-film industry developed to support this function of music (Limbacher 1974; Thomas

1997, pp. 37–40). It included the publication of anthologies of music to represent various emotional settings, an increased demand for pianos in the thousands by small movie theatres that sprang up, and architectural plans for movie theatres that included places for pianists and sometimes other musicians.

Hugo Münsterberg

The first psychologist to direct attention to the new phenomena of film was Hugo Münsterberg at Harvard University (Fig. 11.1). Between 1899 and 1916, he wrote 24 books, one of the last of which was *The photoplay: A psychological study.* In what is regarded as the first book on film theory (Anderson 1997), Münsterberg's views are enlightening. His experience of film was as fresh as a child's although acquired as a highly intelligent adult. His understanding of both introspection and scientific method encourage our confidence in his record of, and insight into, film at that time.

> Yes, it is a new art—and this is why it has such fascination for the psychologist who in a world of ready-made arts, each with a history of many centuries, suddenly finds a new form still undeveloped and hardly understood. For the first time the psychologist can observe the starting of an entirely new esthetic development, a new form of true beauty in the turmoil of a technical age, created by its very technique and yet more than any other art destined to overcome outer nature by the free and joyful play of the mind (Münsterberg 1970, pp. 232–3).

Figure 11.1 Hugo Münsterberg.

He did not live to experience the talking film, but his film experience was not lacking in sound. There were sound effects—he describes a machine, the allefex, 'which can produce over fifty distinctive noises, fit for any photoplay emergency' (Münsterberg 1970, p. 205)—and there was music. In his view, music relieved tension, maintained interest ('keeps the attention awake'), provided comfort, reinforced emotion, and contributed to the aesthetic experience (pp. 204–5).

Münsterberg also used musical metaphor in describing the film experience (e.g. pp. 120 and 128–9). For example, he recounts a narrative cliché of the period, a rapid alternation between three scenes: a jovial boss and his secretary enjoying a private after-hours party in the office, the dismal parents of the secretary awaiting their daughter's return, and the lonely wife awaiting her husband's attention. 'It is as if we saw one through another, as if three tones blended into one chord . . . The photoplay alone gives us our chance for such omnipresence' (p. 105). Yet, to extend his metaphor of the musical chord, it is also music that can represent in rapid succession and perhaps simultaneously the 'emotional polyphony' of these multiple messages.

Possibly because he never experienced the sound film ('talkies'), Münsterberg directed attention to the importance of music within the film and to music as a means of understanding the psychological processes underlying film. He suggested that cinema is more similar to music than to photography and drama, which on the surface are arts that bear a more striking resemblance:

> . . . we come nearer to the understanding of its [film's] true position in the esthetic world, if we think at the same time of . . . the art of the musical tones. They have overcome the outer world and social world entirely, they unfold our inner life, our mental play, with its feelings and emotions, its memories and fancies, in a material which seems exempt from the laws of the world of substance and material, tones which are fluttering and fleeting like our own mental states. (Münsterberg 1970, p. 168–9)

Münsterberg's untimely death (the year of his publication of *The photoplay*) and the coincident advent of behaviourism, focusing as it did on only objectively observable behaviour, may account for the failure of psychological research in film and music to run in parallel with the technological developments associated with these media. Instead, technology developed and its psychological study lagged far behind in spite of having got off to a good start.

The sound film

In 1927, approximately 10 years after the death of Münsterberg, *The Jazz Singer* signaled the advent of the 'talkies' and the demise of the film-music industry. With real voices and sound effects, music would no longer be needed to establish mood and emotional context . . . or would it? To the surprise of many, something was missing without music (Kracauer 1960, p. 138). The screen had lost part of its vitality. As Kalinak (1992, p. 45) says 'when the possibility of synchronized speech and sound effects released sound film from its reliance upon continuous musical accompaniment, it initially rejected music entirely. But the life span of the all-talking picture was brief, the need that music filled quickly reasserting itself'.

Several theorists have commented that music adds a third dimension to the two-dimensional film screen (Palmer 1990; Rosar 1994). Composers also shared this view.

Aaron Copland (1941) stated 'the screen is a pretty cold proposition'. Film composer David Raksin (in Brown 1994, p. 282) referred to Nietzsche's idea 'without music, life would not be worth living'. His statement is extreme (deaf people live worthwhile lives) but paraphrasing the maxim, few hearing people would deny that music contributes to their experience of film.

Since the early days of film, directors have recognized the contribution that film-editing made to the viewer, often referred to as montage. Viewers are typically unaware of the rapid changes in camera angle, the move from close-up to long-shot or from one part of the scene to another and back again. None the less, viewers make sense of the world depicted by these juxtaposed shots. Theories of montage concern the audience's synthesis of juxtaposed information in the film. With the advent of the sound film, Russian director Sergej Eisenstein was among the first to extend the notion of visual montage to sound, and suggested that the listener incorporates the same synthetic process in making sense of the entire audiovisual cinematic presentation.

11.2.2 Music and the diegesis and the non-diegesis

Film theory commonly refers to the fictional, imagined, narrative world of the film as the *diegesis*. In contrast, the *non-diegesis* refers to the objective world of the audience, the world of artefact, of film screens, projectors, proficiency of actors, and technical aspects of the film. In terms of physical reality, music as acoustic vibrations belongs to the non-diegesis. Logically—unless such sound were part of a scene portrayed in a film, as in a film about a musical instrument or the life of a great composer—these sounds of music should *detract from* rather than *add to* the sense of reality of the film. This point was well made in Mel Brooks' comedy *Blazing Saddles* (1974). A sheriff rides out on the desert—with seemingly appropriate music in the background—and meets face to face with the Count Basie Band performing the now inappropriate music *Paris in the Spring*. The fictional (diegetic) and the non-fictional (non-diegetic) realities collide and add to the humour of the scene. It is probably not coincidental that Brooks, the director and screen writer of the film, is also a composer of music, including some film scores, and so he would have been particularly sensitive to this film-score convention.

Thus, the audience selectively attends to only the part of the music that makes sense with the narrative. Selective attention is a common perceptual-cognitive operation. The recently discovered phenomena of 'inattentional blindness' is another example of it in the visual domain of film. Here it has been shown that people rarely noticed or were distracted by impossible visual aspects represented in either a film or in their real-world experience. For example, viewers did not notice that a woman in a film clip began the short scene with a scarf and ended the scene without it (Levin & Simons, 2000). In another study (Levin & Simon, 1998), an experimenter positioned on a college campus solicited directions from unsuspecting subjects. Their conversation was interrupted by two confederates carrying a door. One of the confederates changed position with the experimenter who had initially asked for directions. The conversation about directions then continued. The subject rarely realizes that there were two different people to whom he or she has been conversing. Two facts are important here. First, the visual system is blind to much available information, and this inattentional blindness (cf. Mack & Rock 1998) is equally characteristic of vision in the real and in the film world. Thus, the fact

that audiences extract the emotional information in music and fail to attend to the acoustical aspects might be described as a case of inattentional deafness, a byproduct of the fact that awareness depends on attention, and attentional capacity is limited. A better parallel can be drawn to the role of prosody in speech perception, which shares with music a greater syntactic similarity than the visual examples given. Here patterns of intensity and frequency from intonation systematically provide emotional meaning to a listener, yet the listener focuses on the meaning and is unconscious of this source of information (e.g. Banse & Scherer 1996; Murray & Arnott 1993).

A good example of the role of music as a source of emotion in the narrative is illustrated in the film *Witness*. Here, a young Amish boy is the sole observer of a violent murder in a train station. He is directed to a noisy police station in order to search through a book of photographs of suspects for a match of his memory to the actual perpetrator of the crime. While left unattended momentarily, he wanders toward a display cabinet that holds a photograph of an honoured senior officer in the force. As he views the photograph, Maurice Jarre's music replaces the background sound effects of the police station. The audience realizes that the boy becomes awestruck with the sudden recognition that the photograph of the police officer depicts the person who he saw commit the crime. The audience takes interest in this scene and is concerned now about the implications for the safety of the boy. This is one of the most critical points in the film; without it there would be no further plot. The criminal within the police force would remain unknown and the boy could continue on his trip without a care. Yet it is this crucial moment, a moment that must be comprehended by the audience, to which the unrealistic music is not merely added but is added at the expense of the more realistic, diegetic sound effects. But the audience, caught up in the drama, is unlikely to have noted this departure from reality.

Film-music scholar Claudia Gorbman (1987) has addressed the unconscious perception of music in her book *Unheard melodies: Narrative film music*. Gorbman's perspective is well captured by Jeff Smith (1996, p. 234): 'By veiling the lacks and deficiencies of other discursive structures, film music, according to Gorbman, lubricates the various cogs and pistons of the cinematic pleasure machine'. If anything, departures from reality via music makes an episode 'more real', more vivid, more emotionally relevant. To date, experimental research has not focused on the subtle uses of music in film (such as its replacement of realistic sound as in the *Witness* example). A number of studies, however, have concerned the role of music in generating inferences, and often those inferences are associated with emotional meaning.

11.2.3 Music and inference: empirical studies

Music presumably adds to the diegetic realism while providing non-diegetic, acoustical, information that is completely incompatible with that realism. At the interface of the diegetic and non-diegetic worlds, the use of music in this and in most other film situations is paradoxical (Cohen 1990). To escape the paradox, the analysis of the acoustical information must be regarded as a preattentive step that leads the listener to inferences consistent within the diegetic world of the film. From moment to moment, the audience member extracts information from non-diegetic sources to generate the emotional information he or she needs to make a coherent story in the diegesis. The successful

director and film-score composer provide just the right cues to guide the attentional and inferences processes.

One attempt at understanding the phenemenon of diegetic inference comes from the context of psychological situation models described as 'vicarious experiences in narrative comprehension' (Zwaan 1999, p. 15). Zwaan, for example, has focused on how literature enables readers to 'mentally leap into imagined worlds'. The information provided by the text is sufficient to enable a reader to place himself or herself at a spatial, temporal, and psychological vantage point from which events are vicariously experienced. The perspective is termed a deictic centre.

Magliano *et al.* (1996) extended the approach to the study of film. In their study, music was indirectly examined as one of six operationally defined film factors (such as montage) that might contribute to the psychological definition of the situation. In two experiments, they investigated visual, auditory, and discourse conditions that enable viewers to predict future events while viewing a James Bond movie, *Moonraker*. In experiment 1, participants were instructed to generate predictions while watching the movie. In experiment 2, participants provided think-aloud protocols at different locations in the film. In both experiments, the presence of supporting visual and discourse information led to systematic predictions by the participant. Music significantly cooccurred with other cinematic sources of support such as montage and *mise en scène*, which were found to influence inference processes.[1]

The study by Magliono *et al.* (1996) was not specifically designed to show the influence of music in the film context. Studies that have been so designed have been successful in showing this influence. Such studies typically require more conditions than do comparable studies in music-alone situations, because it is necessary to determine the effects of music alone, film alone, music judged in the context of film, and film judged in the context of music. The studies to be reported have often involved several, if not all, of these different comparison conditions.

In a study by Bullerjahn and Güldenring (1994), professional composers of film music (including Peer Raben, composer for all the Fassbinder films) created a total of five different backgrounds (e.g. crime, melodrama) for the same 10-minute film segment. Both quantitative and qualitative analysis showed that the different soundtracks led to different judgments of the appropriateness of emotional categories (e.g. sad, thrilling, sentimental, vivid), choice of genre (horror, comedy, thriller, crime, etc.), reasons for the actions of the protagonist, and expectations about the completion of the film. In some cases, these judgments and inferences could be attributed to specific aspects of the film. For example, the authors suggested that the final closure of the major chord of one of the melodramatic soundtracks accounted for the presumed reconciliation between the film characters though it is preceded by an argument.

In a series of experiments, Thompson *et al.* (1994) specifically examined the effects of musical closure on perceived closure of a film. In their first experiment, a closed soundtrack ended with a traditional 'perfect' cadence (dominant chord to tonic chord ending).

[1] When music was entered first into the regression equation, it too was found to be a significant predictor of inference, though accounting for only 6 per cent of the variance (J. P. Magliano, personal communication).

The unclosed soundtrack differed only with respect to the final bar, such that the ending was not on the tonic chord. Subjects viewed a short animation accompanied by one of the soundtracks and were asked to rate the degree of closure represented by the clip. Judgments of closure were significantly higher for the condition in which the closed ending was presented. In a second experiment, a professional composer produced closed and unclosed soundtracks to accompany a short film clip produced by one of the experimenters. Closed soundtracks ended on the tonic chord, in contrast to the unclosed soundtracks. The effect of soundtrack closure was strong for only one of the film clips, suggesting that visual factors may take precedence over musical structure in some cases. In a final study, 12 separate soundtracks were composed for 12 clips from a commercial film, initially chosen for their assumed range in degree of closure. The soundtracks were also composed to represent a range of closure, and the degree of closure need not match that of the clip. Participants in the experiment judged the degree of closure of the soundtracks, the clips alone, and the soundtrack and clips together. The influence of independently judged visual and musical closure on judged closure of the film was shown through regression analysis, with a slightly greater contribution arising from visual than musical information. In addition to demonstrating a robust direct effect of musical structure on the feeling of closure of a film narrative, the authors also reported that the role of music was almost completely implicit. When participants were asked for the basis of their judgments, they almost always attributed their judgments to the visual information.

Boltz *et al.* (1991) examined the role of music on inferences in a study that compared music that foreshadowed an outcome versus music that accompanied an outcome. Participants viewed 20 different 3–4-minute clips from feature films and television dramas. Excerpts were selected that ultimately resolved in a happy (positive) or sad (e.g. tragic) way. Music emotionally consistent or inconsistent with these endings (as determined by music-alone ratings) either preceded (foreshadowed) or accompanied the video excerpt. Thus, in some cases the foreshadowing music correctly predicted the mood of the following video event and the accompanying music was congruent with the mood of the video event, and in other cases the foreshadowing music incorrectly predicted the subsequent event and the accompanying music was incongruent with the event. Music accompanying an episode's outcome led to higher recall when the mood of the music and scene were congruent with each other. Conversely, mood-incongruent relations significantly lowered performance to a level comparable to that of the control condition in which no music had occurred. Foreshadowing, however, revealed the opposite pattern. Here, expectancy violations arising from mood-incongruent relations were significantly more memorable than were mood-congruent episodes in which viewer's expectancies were confirmed (Boltz *et al.* pp. 597–8). Boltz *et al.* (1991, p. 602) concluded that their results supported the notion that viewers rely on the emotional expression of music to either generate expectancies about future scenarios or to direct attending toward corresponding aspects of visual activities.

Marshall and Cohen (1988) also observed the ability of music to alter the interpretation of a simple visual presentation. They studied the effects of two different soundtracks on impressions about three geometric forms, a large and small triangle and a circle, in a short animation developed by Heider and Simmel (1944). In their experiment, subjects

viewed the 2-minute animation with one of two soundtracks or with no soundtrack (control condition). They then provided 12 ratings for the film overall and for the three figures. Other groups of subjects rated the music on these same scales. Each of the 12 scales represented a bipolar adjective pair (e.g. fast–slow, nice–awful) and specifically tapped one of the three dimensions of emotional meaning—activity, evaluation, and potency—comprising the semantic differential (Osgood *et al.* 1957). The activity and evaluation dimensions are understood to represent the motivation (arousal) and appraisal (valence) dimensions associated with two-dimensional theories of emotion on which many emotion theorists (Barrett & Russell 1999; Lang 1995; Storm & Storm 1987; see also Sloboda & Juslin, this volume) and music psychologists (Gregory 1998; Madsen 1997; Schubert 1998; see also Schubert, this volume) converge.

In Marshall and Cohen's (1988) study, two musical soundtracks were judged to have approximately the same activity level (measured by averaging responses on scales of fast–slow, active–passive, agitated–calm, restless–quiet). The relative activity levels of the three 'characters' in the film, however, differed for the two different musical backgrounds. For example, the large triangle was judged as the most active under one soundtrack while the small triangle was judged as the most active in the other. Marshall and Cohen (1988) argued *post hoc* that shared accent patterns in the music and in the motion of the figures operated to focus attention on the temporally congruent part of the visual scene, and subsequently associations of the music were ascribed to this focus (Fig. 11.2). A similar accent-pattern/association breakdown in the processing of film and music was proposed by Lipscomb and Kendall (1994, p. 91).

Cook (1998), in his book *Analyzing musical multimedia,* has suggested the generality of Marshall and Cohen's (1988) theory to other multimedia examples in which musical meaning alters the interpretation of events that are at the focus of visual attention. In advertisements for cars, for example, the car takes on both the vitality and the high cultural associations of the classical music in the background. Music does more than echo or provide a counterpoint to a concept already present in the film. Music can also direct attention to an object on the screen and establish emotionally laden inferences about that object.

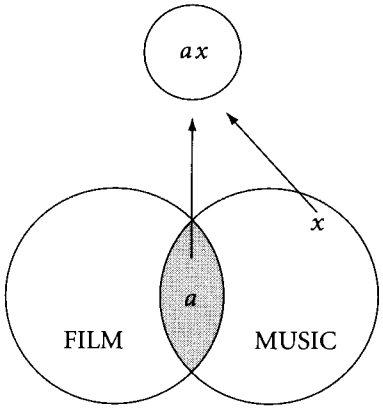

Figure 11.2 Congruence-associationist model based on that depicted by Marshall and Cohen (1988). The total meaning and structure of the music and film are presented by their respectives circles. The overlap in music and film is depicted by the intersection of the circles (*a*). Attention is directed to this area of visual overlap in the film. Other associations of the music (*x*) are ascribed to this focus of attention (*ax*). Thus, music alters the meaning of a particular aspect of the film.

Regarding the ability of music to focus attention, Bolivar *et al.* (1994), following Boltz *et al.* (1991), noted that attention to a visual object might arise not only from structural congruencies but also from semantic congruencies. Hypothetically, for example, a soundtrack featuring a lullaby might direct attention to a cradle rather than to a fish-bowl when both objects are simultaneously depicted in a scene. Subsequently, additional associations from the lullaby would be ascribed to the cradle (and conversely for Schubert's *Trout Quintet*, for those familiar with it). Empirical evidence for the ability of music to focus attention is scant and tends to appear with very simple geometric figures, but has not yet been demonstrated with more complex displays (cf. Lipscomb 1999). Part of the difficulty has been in creation of the materials to study the phenomena; however, rapid advances in the affordability of non-linear editing equipment may make such experiments more practical.

11.2.4 Functions of film music

Cohen (1999*a*) described eight functions of music in a film or multimedia context. First, music masks extraneous noises. Second, it provides continuity between shots, for example, when the camera alternates between close-ups of two people who are presumably looking at each other (cf. Magliano *et al.* 1996, p. 205). Third, as Marshall and Cohen (1988) and Bolivar *et al.* (1994) had argued, and as noted by Münsterberg (1970), it directs attention to important features of the screen through structural or associationist congruence. Fourth, when unassociated with a particular focus it induces mood, as often occurs during the opening credits of a film. The ability of music to induce mood has been supported in several experiments (Pignatiello *et al.* 1986) and is used in music therapy (Albersnagel 1988; Bunt & Pavlicevic, this volume). Fifth, it communicates meaning and furthers the narrative, especially in ambiguous situations (Bullerjahn & Güldenring 1994; Cohen 1993; Kalinak 1992; Levinson 1996). Sixth, through association in memory, music becomes integrated with the film (Boltz *et al.* 1991) and enables the symbolization of past and future events through the technique of *leitmotiv*. In leitmotiv, a particular musical theme is continuously paired with a character or event so that eventually the theme conjures up the concept of the character or event in its absence (Palmer 1980, p. 550). The composer Richard Wagner is typically regarded as the first to exploit this principle in opera. In an insightful article by the composer Saint-Saens (1903, p. 259), entitled 'The composer as psychologist', the author remarks that psychological principles must be responsible for the effectiveness of leitmotiv. Mood-dependent memories can also be cued with the emotions established by music (Eich 1995). Seventh, music heightens the sense of reality of or absorption in film, perhaps by augmenting arousal, and increasing attention to the entire film context and inattention to everything else (cf. discussions of reality status by Preston 1999; Qian *et al.* 1999). Finally, music as an art form adds to the aesthetic effect of the film.

11.3 A cognitive framework for understanding musical soundtracks

Many of the functions of film music can be explained via notions of congruence or association, because these represent two primary ways in which the brain operates:

through innate grouping principles (Bregman 1990) and by learned connections (Cohen 1993), respectively. Cohen (1999*a*, 1999*b*, 2000) presented a capacity-limited information-processing framework that represented the congruence-associationist concepts in a broad cognitive context (Fig. 11.3).

The framework consists of three parallel channels along the vertical axis, each devoted to one of the significant domains of film: speech, visual information, and music. Each channel is hierarchically organized into four processing levels, with bottom-up levels (A and B) meeting the top-down level (D) at level C, the level of conscious attention and

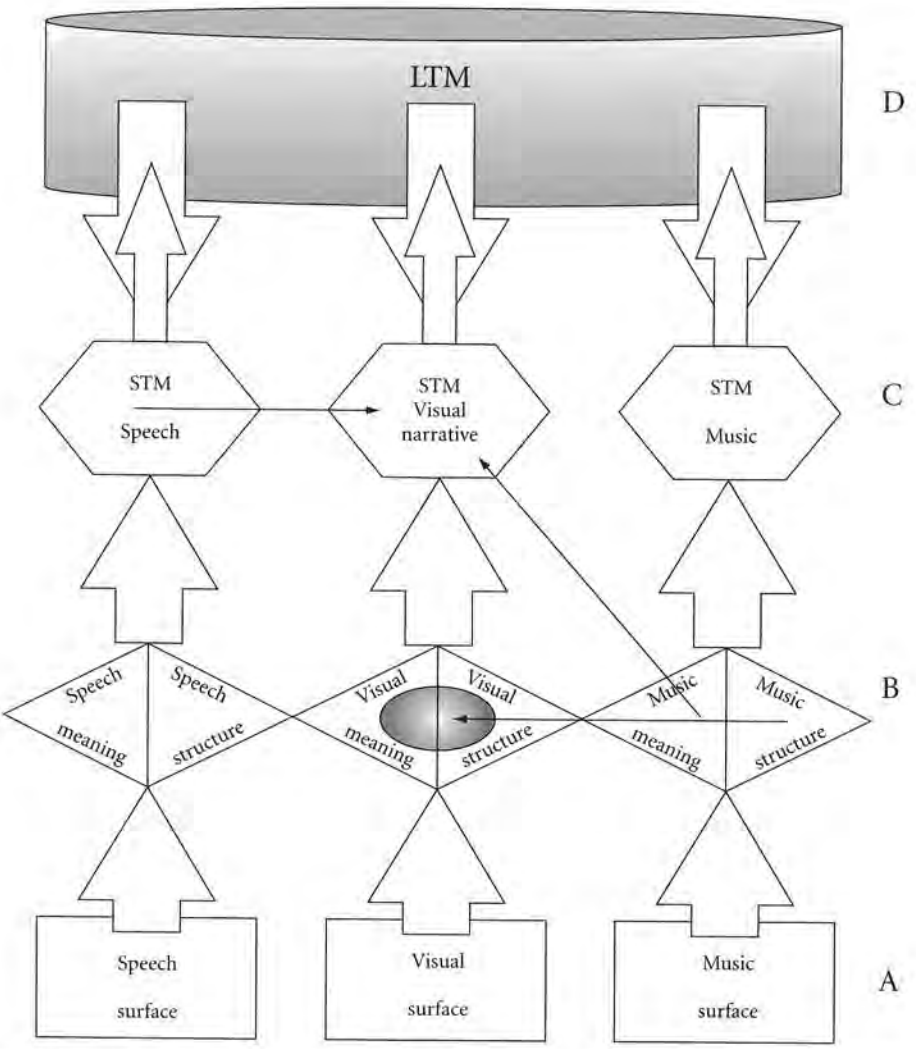

Figure 11.3 Congruence-associationist framework for understanding film-music communication (see text for explanation). LTM, long-term memory; STM, short-term memory.

short-term memory (STM). Environmental sounds (sound effects) have not been included for the sake of simplicity and because of lack of research to date, but their own grammar and complexity calls ultimately for incorporation as a separate channel. Likewise, the visual channel might admit to further breakdowns, for example, animate/inanimate or background/foreground, but this is secondary to the main concepts presented below.

11.3.1 Bottom-up processes: levels A and B

Processing begins at level A with the analysis of physical features of the speech, visual, and musical surfaces into components such as phonemes, lines, and frequencies, respectively. Within each of these domains, at the next level (B), groups of features are subsequently analysed into structural (gestalt-type) and semantic (associationist) information. For music, this means assembly into temporal structures and categorization of cues (e.g. pitch height, tempo, direction) leading to emotional meaning. The outcome of analysis at level B affords the possibility for emergence of cross-modal congruencies, for example, shared accent patterns in audio and visual modalities, to lead preattention to only a portion of the visual information, shown here as the material within the oval in the visual channel.

Cross-modal structural congruence

To further explain the concept of cross-modal congruence, cognitive psychologists have typically applied gestalt principles to visual pattern (e.g. Wertheimer 1939) and later to auditory information (e.g. Bregman 1990; Meyer 1956; Narmour 1991). Rarely are the principles applied to the visual and auditory domains at once. But film music provides the necessity for such application. The simultaneous presentation of music and film automatically elicits bottom-up principles that entail perceptual grouping in both auditory and visual domains. When the auditory information and visual information are structurally congruent (e.g. share temporal accent patterns), the visually congruent information becomes the figure, the visual focus of attention (as originally argued by Marshall & Cohen 1988).

As part of a larger study, Iwamiya (1994, pp. 134–5) showed that judgments of degree of audiovisual matching of four short film clips was lower when the original video and music components were desynchronized by 500 ms (the only delay examined). Thus, gestalt theoretical ideas that are typically applied to visual or auditory domains independently can be applied to conjoint visual and auditory dynamic information. It follows that through innate gestalt grouping processes, music can define the visual figure against the audiovisual background; music can sometimes determine what is the visual focus of attention.

More recently, the gestalt account of the phenomenal sense of 'belonging together' has been seen as a forerunner of the current solution to a general problem in cognition, that of consciousness. Lately, cognitive scientists have focused on the concept of 'binding' to explain how 'the unity of conscious perception is brought about by the distributed activities of the central nervous system' (Revonsuo & Newman 1999, p. 123). It is interesting to note the significance cognitive scientists attach to neural synchronization associated with shared temporal patterning across neural ensembles. Film music that

shares patterns with visual information on the screen, may therefore contribute to attention and consciousness. Indeed, oscillations (cf. accent patterns) below 10 Hz (the typical limit for the film-score composer's click-track) have been proposed as necessary for information integration and the generation of the stream of consciousness characterizing working memory (cf. Revonsuo & Newman 1999, p. 126).

These notions of congruent patterns in perceptual and cognitive psychology relate to those in the film-music literature on sensitivity to, and effectiveness of, synchronized musical and film structures. Kalinak (1992) suggests that it is this synchronization that contributes to the inaudibility of the music. Synchronization masks the real source of the sound (like ventriloquism):

> The vocal track in classical cinema anchors diegetic sound to the image by synchronizing it, masking the actual source of sonic production, the speakers, and fostering the illusion that the diegesis itself produces the sounds. Mickey Mousing [synchronized music and visual accent] duplicates these conventions in terms of nondiegetic sound. Precisely synchronizing diegetic action to its musical accompaniment masks the actual source of sonic production, the offscreen orchestra, and renders the emanation of music natural and consequently inaudible. Musical accompaniment was thus positioned to effect perception, especially the semiconscious, without disrupting narrative credibility. (Kalinak 1992, p. 86)

11.3.2 Short-term memeory visual narrative: level C

Returning to the remainder of the framework of Fig. 11.3, information is transferred to STM at level C. Priority of transfer is given to visual information in the gray oval at level B, which has been selected by cross-modal audiovisual congruence. Not all of the visual sensory information that is potentially available reaches the STM. Also, information of musical meaning from B is transferred not only to a music STM but also to the visual STM. Note that visual STM is referred to as the STM visual narrative. This is a unique aspect of the framework: visual STM is construed as the location of consciousness of the film representation. This decision is supported by the evidence for visual primacy and the typical subservience of audio to vision (e.g. ventriloquism, cf. Driver 1997; see also Bolivar *et al.* 1994; Thompson *et al.* 1994). The concept is that of constructing a narrative from the information gleaned simultaneously from visual, music, and speech sources. The present depiction illustrates how music transports various packages of information, be they structural or semantic, meeting the (diegetic and non-diegetic) goals of a film director and film-music composer for the minds of the audience. The term narrative is in recognition of the aim of the visual STM process to make sense of the visual information using whatever information is at hand. Thus, the emotional meaning of the music is directed here because it is useful in determining the meaning of the visual scene. However, consciousness of this meaning arises only through correspondence with information from top-down processes based in long-term memory (LTM).

11.3.3 Top-down processes: level D

During bottom-up processing, some preattended information from all channels proceeds to the LTM at D and begins a top-down inference process with the goal of constructing the narrative of the film. Thus, both bottom-up and top-down processes simultaneously generate information that meets at level C, the STM. In order to achieve

consciousness in the STM of material driven by bottom-up processes, matching of this information by inferences generated from the LTM is necessary. The notion of such a matching process is found in theories of conscious attention (Grossberg's 1995 adaptive resonance theory, ART), comprehension (Kinstch 1998, construction-integration), and consciousness (Baars 1997). These theories assume that preattentive processes are sufficient to initiate the inference processes from LTM.[2]

Because everyday emotional experience associated with events is stored in the LTM, inferences based on past experience would include emotion (e.g. how a protagonist would feel in a certain situation). These inferences generated by the LTM matching process accommodate the visual and emotional information from a film, but not the acoustical properties of the musical accompaniment that are the source of the emotional information. This explains why the acoustical aspects of the music are not generally attended to: in the context of the rest of the narrative, the acoustical aspects of the music do not make sense to LTM (where is that background music coming from?) and no hypotheses would be generated easily to include it (unless, of course, music were part of the diegesis, e.g. the portrayal in the film of attending a concert or taking a music lesson).

An example of this attentional and inference process is provided by consideration of a portion of the film *Apollo 13*, the drama based on the dangerous technical difficulties within the spacecraft, Apollo 13, that prevented the planned landing on the moon and threatened a safe return to earth. Toward the end of the film, Apollo 13 hovers over the moon—so near and yet so far. The film depicts the fantasy of one of the astronauts, Jim Lovell (played by Tom Hanks) imagining his dream of having landed, taking several weightless steps, and slowly brushing his gloved fingers across the moon's surface. The audience has no trouble in inferring the anguish, awe, and exhilaration that he would have felt. Thanks to the composer, James Horner, the musical basis for such emotional information is carried by the musical soundtrack. On the other hand, the story gives no reason to predict that a full symphony orchestra is performing outside the spacecraft; hence, the acoustical aspect of the music is not transported to the STM. It is encoded by sensory memory but it is not predicted by inferences derived from the LTM and hence it is unattended to.

Thus, the main phenomenal experience at the STM visual narrative is one of a narrative with visual, verbal, and emotional components (but not music *qua* sound). Once attended in STM, the information about the narrative can itself be stored in LTM and form the basis of new inferences. In parallel, acoustical aspects of the music can be processed at a conscious level (see levels C and D in the music column, Fig. 11.3), as it is known that simultaneous tasks can co-occur (Neisser & Becklen 1975), and there is evidence that background music is remembered (Smith 1996). A similar process is envisioned for speech as well, but this is not the focus of the present chapter.

[2] In Grossberg's (1996) theory, 'when both bottom and top-down signals are simultaneously active, only the bottom-up signals that receive top-down support can remain active . . . Top-down matching hereby generates a focus of attention that can resonate across processing levels, including those that generate the top-down signals. Such a resonance acts as a trigger that activates learning processes within the system. Resonance is also proposed to be a necessary condition for conscious attention'.

11.3.4 Emotion

Emotion cuts through six of the eight functions of film music identified by Cohen (1999*a*): contributing to the narrative's continuity; emotional meaning of events; induction of mood; creation and activation of memory (state dependence, heightening attention to particular events, providing cues in leitmotiv); maintenance of arousal, global attention, and associated sense of reality; and, finally, aesthetic experience. Hence emotion enters at every level of the proposed framework: analysis of structure and meaning, directing emotional meaning to STM, cuing the inference process of LTM, and the matching of LTM and STM representations.

In regard to the nature of experienced emotions generated by music in the context of film, it is useful to consider six criteria of a genuine emotion that Tan (1996) outlined, based for the most part on Frijda's (1986) laws of emotion.[3]

1. *Control precedence.* Music controls emotion response (Thayer & Faith 2000; Thayer & Levenson 1983), hence, like other genuine emotions, emotion created by background music exerts control over the audience member. These effects can result simply from bottom-up analysis of the stimuli, although higher-order learned associations may also play a role.
2. *Law of concern: emotion entails identifiable concern.* When music is combined with other media, the music readily finds an object. Cook (1998) provides clear examples of this with respect to advertising. Marshall and Cohen (1988) explained that music directed attention to an object and ascribed its meaning to that object. Attention is required for concern. Music directs such attention (see horizontal arrow from music to vision at level B in Fig. 11.2).
3. *Law of situational meaning (or stimulus specificity).* Each emotion has a particular 'situational meaning structure', a set of critical characteristics of the stimulus. Characteristics of musical stimuli giving rise to particular emotions have been identified by various researchers (e.g. Juslin 1997; Juslin & Madison 1999; Krumhansl 1997; Rigg 1964), and similarities between these characteristics and visually depicted emotions through gait, posture, and speech intonation have also been noted (for a summary, see Boltz *et al.* 1991; see also Juslin, this volume). Some aspects of the emotional meaning of music transfer directly to film (Iwamiya 1994; Sirius & Clarke 1994; Smith 1999).
4. *Law of apparent reality: the stimulus must represent some reality or other* (see also Tan 1996, p. 67). Music contributes to the sense of reality of the narrative (first demonstrated in the 'talkies' in Steiner's score for *King Kong*; cf. Palmer 1990, p. 28). It accentuates important events. The contribution of only the emotional components of the music to the diegesis has been described in Section 11.2 and explained via Fig. 11.3 (see, in particular, the diagonal arrow between levels B and C).
5. *Law of change: emotion responds to changes in the situation* (see also Tan 1996, p. 56). Music creates an everchanging auditory environment that establishes expectations

[3] But see Russell and Barrett's (1999) practical guide to assessment of emotion in which they claim that films do not induce true emotion, what they refer to as emotional episodes.

and implications, some of which are realized and some of which are violated. As such it is a fertile source of emotion (see also Meyer 1956).

6. *Law of closure: an emotion tends toward complete realization of its appraisal and action tendency, and is relatively immune to outside influences such as conscious control.* Music commands interest, especially in a darkened film theatre, as described by Münsterberg (1970). The emotion generated by music is governed by the tension and resolution established by the music of which the audience is unaware (cf. Thompson *et al.* 1994) and over which one seems to have little control, although this is a matter for further empirical work. Rehearing music reproduces emotional responses regardless of prior expectations (e.g. Jourdain 1997).

Thus, having satisfied the six constraints described by Tan (1996), it can be concluded that music contributes genuine emotional experience in a film. The congruence-associationist framework has provided a perspective for understanding how different aspects of music contribute to this outcome, although much still remains to be explained.

11.4 Emotion and the film-score composer

It is well to say that music is a source of emotion in film, but the ultimate source is the composer. The average theatre-goer appreciates the emotion established by film music but would be hard pressed to compose this music. Whereas many classical composers have created film scores (e.g. Saint-Saens, Satie, Britten, Honegger, Milhaud, Prokofiev, Shostakovitch, Vaughan Williams, Bernstein, Copland, Schuller, and Corigliano), such composition is often regarded as a special talent and preoccupation, exemplified by George Steiner, Miklós Rósza, Erich Korngold, Bernard Hermann, Dimitri Tiomkin, John Williams, Rachel Portman, and Ennio Morricone among others. Composers known primarily for their film music, have also been recognized for classical music composition, for example, Rósza and Korngold.

According to film-score composer Victor Young, the film-score composer is characterized by exceptional exactitude, diplomacy, and patience, in addition to musical training (cited in Karlin 1994, p. 310). Music composition for film differs from music composition for its own aesthetic sake. Typically film music is music produced for the sake of the story. It is constrained by the intent of the director, narrative, time, and budget. Working within these constraints, the composer may be regarded as exploiting his or her metacognition of the operations described in the framework of Fig. 11.3. The composer must know how shared audiovisual accent patterns can focus visual attention, how musical information avoids conscious attention, how mood is established, how musical associations provoke inferences through reinforcement or counterpoint, and how inferences are cued and generated via LTM to further the diegesis.

The composer is usually called upon at the end of the film production (Palmer 1980; Rózsa 1982, p. 191; some exceptions being Eisenstein and Hitchcock classics) and may be shown the film for the first time with recorded music already in place, known as temp tracks. The temp tracks indicate the director's wishes for type and placement of music, and therefore can restrict the composer's latitude considerably. In Henry

Mancini's opinion, familiarity with the temp tracks may bias the director against new insights offered by the composer (Brown 1994, p. 301). The composer's job is to replace the temp tracks with new material that must meet some or all of a number of constraints: to time the music cue to a fraction of a second to coincide with the rhythm of the action of a particular frame of the film, to match or create the mood or spirit of the film content, to use affordable orchestration and rehearsal time, to be unheard (unless the music is part of the diegesis) but be memorable, and to never drown out the dialogue (cf. Burt 1994, Chapter 6; Rózsa 1982, pp. 69, 108, and 110). In spite of these constraints, some composers, such as classically trained John Barry, claim that composing for film can be the ultimate freedom. Within these constraints, the composer can do whatever he or she wants and is assured of exposure.

Composing for film is one way of transmitting musical culture (e.g. Rózsa 1982, p. 205), because, as shown in Fig. 11.3, although the film music serves narrative function, it is also encoded in an information-processing channel devoted solely to music. Exposure to new compositional styles can be an added aspect of the film experience. For a recent example, *The Red Violin* may provide one's first exposure to the work of the contemporary composer John Corigliano. Films provide a major source for transmission of a culture's musical conventions. Thus, composing for film is a two-way street: the composer learns to code music to match the visual and emotional information of a narrative; at the same time, the film provides the composer with an opportunity to represent this emotional information in musically novel and creative ways, often to a large audience.

For a feature film, the composer may be given only a month of intensive work to score an hour of music. This pace is faster than that of a composer of 'music alone' but the genre is often, though not necessarily, redundant and characterized by cliché. The music does not have to stand independently, yet the possibility of (recent expectation for) a lucrative soundtrack album may create a challenge to compose music that lives on its own yet hardly reaches consciousness during the film.

Knowledge of the techniques and technology of film scoring can be acquired formally through courses, books, apprenticeships, or trial and error. The art of film music, however, perhaps more than other forms of music, requires 'taking the attitude of the other' (Meyer 1956, Chapter 1). Specific messages must be communicated in an aesthetic package, but the aesthetic goals may be secondary, unlike composing music alone. Like other skills, such as chess, bridge, music performance, or knowledge of a discipline, expertise in film-music composition may follow the 10-year rule of concentrated practice (Ericsson 1996). A young McGill University student composer, Aaron Hanson, in scoring an 8-minute film for a friend, spoke of the many hours of experimentation that were entailed until he achieved the effects he wanted. Presumably, like learning any language late in life, extensive effort is required to master the syntax and vocabulary. But the film-score language differs from languages learned from scratch in that the grammar of the film-music language is already known implicitly from exposure to music and film-music conventions. The film-score composer must turn that implicit knowledge into explicit knowledge and, in other words, must become an expert of the rules.

Research by Lipscomb and Kendall (1994) corroborates the notion that the professional film-score composer has the knowledge to create a score that uniquely matches a portion of the film. Moreover, the explicit knowledge of the composer is implicitly

shared by the audience. Lipscomb and Kendall (1994) asked participants to select the best fitting of five film scores by Leonard Rosenman for a feature film, *Star Trek IV: The Voyage Home*. One of the scores had been originally composed for the excerpt and the remaining selections were by the same composer but drawn from other excerpts in the film. Confirming the effectiveness of Rosenman's music, the most frequent choice of the subjects was the actual score he had composed for the segment, although not every subject made this choice. Similarly, we recall from research previously reviewed by Bullerjahn and Güldenring (1994), that the professional film-score composer can systematically manipulate the inferences generated by the viewer/listener. Likewise, in the study by Thompson *et al.* (1994), the use of musical closure by the professional composer altered the judged closure in the film.

Some composers may be more suited to film-score composition than others in terms of both personality and motivation (which may play more of a role than talent, as is sometimes the case in regular musical achievement; see Sloboda 1996). The film composer must have a dramatic sense (Rózsa, cited in Brown 1994, p. 278), an appreciation of the visual world of film, and a sensitivity to speech nuances. Unlike many other types of composition, the creation of a film score is a collaborative process. Generally, interpersonal intelligence (Gardner 1993) would be necessary on two fronts: appreciation of the demands of socially shared cognition and the accurate assessment of common ground (Krauss & Fussell 1991), and the willingness to cooperate with the film production team (although the film composer Bernard Hermann was known to be irascible, according to Karlin 1994, p. 270). Korngold describes his positive relations with executive producers and others responsible for the film (cited in Carroll 1997, pp. 298–9) and claims that his artistry was not compromised in film composition. Similarly, Franz Waxman felt 'there was always room for fresh musical ideas in writing for the screen' (in Karlin 1994, p. 307).

11.5 Conclusion

Emotion characterizes the primary experience of both music (Sloboda 1985) and film (Münsterberg 1970; Tan 1996). Music typically plays an integral part of film. Kalinak's (1992, p. 87) argument for the importance of music to the emotional experience in classical narrative film finds support in much of the information presented in this chapter:

> Scenes that most typically elicited the accompaniment of music were those that contained emotion. The classical narrative model developed certain conventions to assist expressive acting in portraying the presence of emotion . . . close-up, diffuse lighting and focus, symmetrical mise-en-scene, and heightened vocal intonation. The focal point of this process became the music which externalized these codes through the collective resonance of musical associations. *Music is, arguably, the most efficient of these codes*, [italics added] providing an audible definition of the emotion which the visual apparatus offers . . . Music's dual function of both articulator of screen expression and initiator of spectator response binds the spectator to the screen by resonating affect between them.

Kalinak's statement regarding the role of music as a source of emotion is a strong one. She has claimed that music is 'the most efficient code' for emotional expression in

film. According to Kalinak (1992, p. 87): 'The lush, stringed passages accompanying a love scene are representations not only of the emotions of the diegetic characters but also of the spectator's own response which music prompts and reflects'. She is arguing that the simultaneity of both the representation and the elicitation of feeling is key. Though her analysis seems correct, more empirical research would be welcomed that compared the relative abilities of music and film to represent and elicit emotion.

That music contributes to the emotional expression and experience of film seems logical, yet surprisingly discussions of emotion in film often ignore music (e.g. Tan 1996). However, Münsterberg (1970) suggested that the psychological processes underlying film were more similar to those of music than to visual art or drama which on the surface might seem more similar. Experimental evidence since then has shown that music influences the interpretation of film narrative and that the music becomes integrated in the memory with the visual information. Music accomplishes other attentional functions through gestalt structural and associationist principles. In addition, the fact that music requires cognitive resources probably plays a role in determining absorption, arousal, and general attention. Music also contributes to the aesthetic experience of the film. More importantly, for present purposes, music in conjunction with film can satisfy Frijda's requirements, as identified by Tan (1996), of a stimulus that can support genuine emotion.

Film-music composition can be regarded as a type of problem solving that exploits knowledge of the musical rules that express and create emotion through specific musical relations. There are many goals that must be satisfied by the film-score composer: providing continuation, directing attention, inducing mood, communicating meaning, cuing memory, creating a sense of reality, and contributing to the aesthetic experience. The ultimate compositional goal is to produce sound patterns that express the emotion consistent with the narrative, the emotion that is jointly recognized and experienced by the audience, binding the spectator to the screen (Kalinak 1992, p. 87). The capacity of music to accomplish the emotional task, arguably far better than the screen itself as Kalinak has suggested, may be based on the ability of music to simultaneously carry many kinds of emotional information in its harmony, rhythm, melody, timbre, and tonality. Real life entails multiple emotions, simultaneously and in succession. Miraculously, yet systematically, these complex relations—this 'emotional polyphony'—can be represented by the musical medium. An example is Korngold's music from the classic film *Sea Hawk* that links romantic love and the spirit of childhood adventure: 'The music for the love scenes still makes an indelible impression with its sweeping heroic lyricism, characterized by arching, repeated rising sevenths that dovetail perfectly with a hypnotic and unforgettable horn call that is redolent of every schoolboy's dream of pirate adventure' (Carroll 1997, p. 254; other examples are provided by Steiner's ability to 'crystallize the essence of a film in a single theme', see Palmer 1990, pp. 29 and 48)

As depicted by the congruence-associationist cognitive framework presented here, and as argued by Cook (1998), music is strong in the representation of emotion in the abstract, and the screen is strong in representing the object to which the emotion is directed. While more research is warranted to further examine the simultaneous contribution of music to emotional meaning, mood, feeling, and absorption, there are sufficient data available now to conclude that music, owing in large part to the explicit

knowledge and skills of the composer, provides one of the strongest sources of emotion in film.[4]

PART IV

THE PERFORMER

CHAPTER 12

THE SUBJECTIVE WORLD OF THE PERFORMER

ROLAND S. PERSSON

'A musician cannot move others unless he too is moved', C. P. E. Bach argued in his treatise on the true art of playing keyboard instruments, 'He must of necessity feel all of the affects that he hopes to arouse in his audience' (1985, p. 152). Famed singer Janet Baker, in an interview published in *The Observer*, stated of musicians in general that '. . . [their] business is emotion and sensitivity—to be the sensors of the human race' (quoted in Crofton & Fraser 1985, p. 112).

Clearly emotions, feelings, and affects are paramount issues to musicians in communicating and understanding music. In fact, the musician's role is so intrinsically tied to the subjective world of emotion that attempts to regard a piece of music, or a performance of it, as in any way detached from a positive emotional experience of some kind, is often frowned upon by musicians. In composer Fredrick Delius' words: 'How can music ever be a mere intellectual speculation or a series of curious combinations of sound that can be classified like the articles in a grocer's shop? Music is an outburst of the soul' (quoted in Crofton & Fraser 1985, p. 49).

The reasons that music has emotional significance, however, are complex and often paradoxical. This is particularly true in regarding the interplay between the dynamics of socially determined criteria for what is considered a piece of music, or a performance, of 'good quality' and the different aspects of music cognition (Persson, 2000). Without the potential to evoke some type of emotional response, however, music as a cultural phenomenon would most probably lose its basically universal appeal (Gregory & Varney 1996).

This chapter outlines exploratory research into the *phenomenology* of emotion in musical performance, which includes performance motivation and generation, as well as the learning and conceptualization process of constructing 'musical meaning'. Most of the material providing the framework for this chapter is based on exploratory qualitative and quantitative research in combination, pursued in a real-world research setting; that is, in a tertiary British music institution (Persson 1993, 1995, 1996, 2000; Persson *et al.* 1996; Persson & Robson 1995; Robson 1993). Data were generated interactively between researchers and musicians as co-researchers, to accommodate the potential conflict between representatives of traditional science and art as reported by, for example, Hurford (1988), Kingsbury (1988), and Persson (1993).

The purpose of the presented research was to seek hitherto untried ways in music-behavioural research to explore the understanding of a limited number of expert

performers' subjectivity. Hence, the results of the research presented here should not be understood as an effort to generalize findings. They are rather the basis for further research and provide an *initial* understanding of how musicians may construe the subjective aspects of musical behaviour.

12.1 Why become a performer?

An obvious first question in seeking to understand the subjective world of the musical performer is to ask what made certain individuals choose a musical career. Nagel (1987), from a largely psychodynamic perspective, has suggested that musicians make such a choice on the basis of gratification of needs, which entails: (a) certain emotion-evoking qualities in the music itself; (b) the potentially positive social feedback of the musical setting: (c) a means to explore devouring and aggressive impulses by the specific motor skills involved in playing an instrument; and (d) a degree of exhibitionism and voyeuristic impulses. However, early relationships, such as the support and encouragement of parents and significant others, also play an important role. One example of this is renowned violinist Ernst Wallfisch (quoted in McDonald 1970, pp. 514–15):

> Music played such a big part in my life from the beginning . . . and I recall much . . . my father was a businessman and an amateur violinist . . . music was his big hobby . . . his circle of friends included many like him and chamber music seemed part of living . . . I can remember as a very small boy all of these people in our home talking, laughing, smoking cigars, and making music.

However, relationships in this context may also be understood as finding certain role models, or 'heroes', who possess certain attractive attributes or qualities, which the developing musician wishes to master or in some way emulate. Drummer Steve Gadd, for example, made several famous jazz musicians his role models (quoted in Boyd & George-Warren 1992, p. 125):

> When I was a young teenager . . . my father used to take me to clubs to hear a lot of organ groups, where the groove got so intense . . . The music was feeling so good you just couldn't sit still. That feeling made you want to be a part of what was creating it . . . I heard a lot of jazz groups like Dizzy [Gillespie], and Oscar Peterson, Max Roach, Gene Krupa, and I loved them all. Can remember listening to Tony Williams and Elvin Jones, listening to things over and over again . . . They touched me so much. You get something from everyone you hear; you try to take it and use it and pass it on.

Motte-Haber (1984), taking a broader theoretical view of what motivates musicians, proposed that achievement motivation, curiosity, self-actualization, the conquering of failure anxiety, as well as the fear of success should all be considered in understanding the basis of motivation specific to learning and mastering a musical instrument. Hallam (1998) puts forward self-determination as an additional variable.

Persson (1993) and Persson *et al.* (1996), in interviewing piano performers, and combining qualitative analyses of open-ended responses with factor-analytical procedures on given variables, relating to different aspects of motivation as found in the literature, established a tentative typology of motivation specific to performance motivation (Table 12.1). Although a small sample of participants ($n = 15$; of whom ten were male and five were female), the musicians were very eloquent in discussing their interest in music and their choice of a musical career.

Table 12.1 Components of musical performance motivation as elicited amongst pianists ($n = 15$). The main motive categories are listed in order of significance (from Persson 1993)

	Type of motivation	Description (and function)
1	Hedonic motive	The search for positive emotional experience
2	Social motive	The significance of group identity and belonging
3	Achievement motives:	
	3a Exhibitionism	A desire to show results of an effort
	3b Independence	The means to achievement are secondary to success itself
	3c Dependence	The means to achievement are important, but do not constitute the ultimate target
	3d Aesthetics	The means also provide the target
	3e Support	Motives are extrinsically provided, mainly by teachers and parents

While motives differed considerably amongst the musicians, they all had in common that their musical pursuit offered, for different reasons, satisfaction. Most participants were therefore motivated primarily by a *hedonic* motive; that is, treasuring music as a means to generate positive emotional experiences mostly for one's own satisfaction. A typical response given by the participants was, for example: 'Mood is a big one for me. You have to be in the right mood, because sometimes you can be sort of in a state where you can't exactly get yourself into how the music should be played. Sometimes you sit down and play as if . . . Ahhhh! [The musician sighs profoundly] You can really *feel* everything in the music' (quoted in Persson 1993, p. 150).

Social motives were also significant in choosing a musical career. It is important to belong to a certain group that has certain desirable attributes with which one identifies. While such identification is occasionally prevented by the so-called 'maestro' function (Persson 1996, 2000), the weight of social motive amongst the musicians interviewed may also suggest that performers are not necessarily the self-sufficient 'lone rangers' that the historical and mythical tradition of the musical maestro often would tempt us to believe (cf. Braudy 1997; Osborne 1990). On the contrary, social identification with a certain musical setting, group, or mentor, as some research has shown, is very important, even a key factor in optimizing musical and artistic development (Manturzewska 1990; Ruud 1997).

Achievement motives, interestingly, tended not to be a priority in the studied group. That is not to say, of course, they do not play a significant role in any career or goal setting. Six types of achievement motivation were identified. Some were exhibitionistic and revealed a desire to show off the results of an effort (cf. Nagel 1987). One informant typically exclaimed, when asked whether he liked being alone on a stage to perform: 'Oh lovely! I enjoy that!' Others were categorized as being independently motivated (where the means to achievement are secondary to success itself):

> . . . basically, it is the attention to yourself, wanting to achieve something. Music is something I enjoy. I have always had this drive in me to do well in whatever I do, so it is not necessarily just music but any other thing . . . I enjoy cooking . . . and I know I do it well because I enjoy it. (Quoted in Persson 1993, pp. 154–5)

However, some participants were categorized as dependently motivated (where the means to achievement are important, but do not constitute the ultimate target of the

musical pursuit): 'I've got this degree. That is motivating for me but I don't wish to be famous by the end of it. I want to do something administrative, which is not so much performance-related really' (quoted in Persson 1993, p. 155).

A few were driven mainly by an aesthetic motive in which the means also provide the target itself. One example of this would be one of the participating performance teachers, who ardently argued that 'Music making is for its own sake, isn't it? You want to feel that you have measured up to what the music demands' (quoted in Persson 1993, p. 266). Well-known violinist Isaac Stern (1979) similarly remarks, in an interview published in *The New York Times Magazine*, that 'somewhere along the line the child must become possessed by music, by the sudden desire to play'.

Finally, some participants felt that the reason they chose a musical career was mainly due to extrinsic motivation. These participants were categorized as displaying a supported achievement motive (where motives are mainly extrinsically supplied by teachers and/or parents). A typical response was the following: 'When you are a child, it is difficult to separate out those [motivational aspects]. I was kind of forced into doing it then, but about the age of twelve I *wanted* to do it' (quoted in Persson 1993, p. 157).

12.2 Determinants of performance generation

Although there are many reasons for embracing a musical career, the importance of being able to control and induce pleasant emotional experience by means of playing appears to be the most fundamental consideration amongst the musicians participating in Persson *et al.*'s (1996) study. If emotions and the phenomenology of experiencing music are paramount to many, if not all, musicians, then, which are more specifically the potential determinants of generating and conceptualizing any particular performance?

The question of what makes a musical interpretation 'artistic' has fascinated the cognitive science of music for some time, and the pursuit of understanding just how performers manipulate musical parameters (e.g. tempo, timbre, dynamics, articulation) to obtain an optimal performance has led to the study of algorithms for computer-generated performances (e.g. Friberg 1991), generative principles as based on motor skills and the nature of their programming (Clarke 1988; Parncutt *et al.* 1997), as well as the nature of specific mental representations (Lehmann 1997). As important as these research efforts are, however, the notions of 'feeling' (the term often preferred by musicians) and 'emotional experience' (the term usually preferred by behavioural science), so important to the musicians themselves, are conspicuously absent from this literature.

While questions have been asked how music, and musicians, communicate emotions to listeners and how music-interpretational intentions are perceived by them (e.g. Clynes 1989; Gabrielsson & Juslin 1996; Juslin 1997, 2000; Ohgushi & Senju 1987; Rapoport 1996; Waterman 1996; see also Juslin, this volume), the question of individual conceptualization and its emotional significance is elusive to a traditional psychological research paradigm, and has therefore rarely been asked. Classical in its field, of course, is Meyer's (1956) treatise *Emotion and meaning in music*, but only recently have attempts been made to address the issue of musical meaning by empirical research (e.g. Sloboda 1998; Watt & Ash 1998).

To understand the nature of motor programming, mental representations, and musical meaning more fully, music psychological researchers also need to ask *why* a performer plays in a certain way but not in another, and by what means—other than motor programming strategies and melodic and harmonic memorization procedures—musicians learn a piece of music as well as recreate it in a performance situation. Although there is some controversy about whether or not emotion and cognition should be regarded as separate systems, it is nevertheless well established that cognition and emotion affect each other in different ways in different circumstances (cf. Lazarus *et al.* 1980; Zajonc 1980). Hence, emotions inevitably play a significant role in learning, conceptualizing, and performing music also (cf. Bower 1992). There is therefore a need for music psychology—and perhaps even more so for music education—to begin to understand 'the emotional frame of mind' that generates recall, certain motor patterns, and communicative potential.

12.2.1 Performers and imagery

In a series of studies, Persson (1993) endeavoured to explore and chart the emotional aspects of conceptualizing music for a performance. A piece of music (Russian composer Reinhold Glière's *Prelude*, Opus 31, No. 1), unknown to all of the 15 participating pianists from a tertiary British music institution, was chosen because of its manifold interpretational ambiguity, and used as a stimulus in the research design. The musicians were all asked to learn and study the piece for 2 weeks, after which it would be performed, recorded, and discussed in an in-depth interview with the researcher. All interpretational clues provided in the score by the composer, including the title of the piece, were erased. Participants were specifically asked to deal with the music in a way that felt appropriate to them, rather than to consider traditional conventions for any given musical style. In other words, musicians were encouraged to break with perceived conventions should they think it necessary to optimize the conceptualization process.

During the period of study, participants were also asked to supply a descriptive title, which they thought suited the piece and their understanding of it. The title then became the point of departure for the interview on how the performers conceptualized the music at hand. Interview transcripts were verified by the participants themselves and were subsequently subject to analysis (for an exhaustive outline of research strategy and analytical models, see Persson 1993). To prompt musicians to elicit a title was believed to reveal something about the process by which they arrived at an individual understanding of the studied music. Seashore (1938), for example, as possibly the only music psychologist who has addressed the issue, argued in his time that musical imagery is *necessary* in all forms of musical memory:

> In vivid musical memory we relive the music. The person who does not have the capacity to do so may recall in abstract terms; such as the musical notation or even the most refined logical concepts of elements in musical performance and musical criticism. But these are only the cold facts. He does not relive the music . . . The non-emotional person can recall the cold facts, but these facts are not the essence of the music, the welling up of musical emotion . . . I have developed a classification of types of musical imagination in terms of which we can readily classify musicians with whom we are acquainted. Basic types in such classification are the sensuous, the intellectual, the sentimental, the impulsive, and the motor. Any given individual may be dominantly one of

these types but ordinarily the personality represents integration of two or more. (Seashore 1938, pp. 168–72)

Not all participants in the study succeeded in finding a descriptive title, and not everyone, as Seashore (1938) would have predicted, was keen on labelling a piece of music in such a way. Following instructions, however, all supplied the piano piece with a title (Table 12.2). Even the reluctant musicians' choices were important to the research, since in spite of their reluctance, they nevertheless had to draw from the musical structure to find something appropriately descriptive. Musical structure is related to emotional response (Sloboda 1991; see also Gabrielsson & Lindström, this volume).

Table 12.2 Participating musicians' descriptive titles, types of titles, and duration of performance ($n = 15$). A denotes student performers and B their teachers (from Persson 1993)

Performer	Chosen title	Type of choice	Duration
A1	By the water's edge	Mood/semblance	2′ 14″
A2	Lazy Sunday by the river	Semblance	1′ 48″
A3	Rain	Semblance	1′ 47″
A4	Soaring	Mood/semblance	1′ 53″
A5	Thoughts	Semblance	1′ 39″
A6	Falling feelings	Mood/semblance	2′ 13″
A7	Portrait of a lost love	Mood	2′ 40″
A8	The typical romantic	Idiom/mood	1′ 39″
A9	Saturday sprinting	Semblance	1′ 06″
A10	Autumn	Mood/semblance	3′ 20″
A11	Coming home	Mood/semblance	1′ 48″
B1	Souvenir de Chaminade	Idiom	1′ 58″
B2	Song without words	Idiom	2′ 22″
B3	Melancholy (tristesse)	Mood	2′ 00″
B4	I wonder why? Warum? Warum? Pourqoui? Pourqoui?	Structure	2′ 13″

Mean performance duration was 2′ 00″.

Titles appear to have been chosen according to mainly four criteria: *semblance* prompted musicians to provide a title in relation to some extramusical association, whereas *mood* made the participants rather focus on their affective response to the music. A musician who appeared to follow a strategy of semblance when learning the music at hand would typically explain his or her choice of title in the following way (quoted in Persson 1993, p. 189):

Sitting by the river, listening to the quiet lap of water. Obviously a warm day! Perhaps going there every day; leisure on the banks, passing dykes, the occasional wildlife here and there . . . well, my descriptive title is rubbish. It is *Lazy Sunday by the river*. The title is rather corny, but—to me—that is what it conjures up . . . It wasn't really telling a story. It was more sort of a scene 'à la Debussy'.

An individual who was categorized as relying mainly on mood would rather respond, for example, in the following representative manner (quoted in Persson 1993, p. 189):

When I read the instruction on the sheet, I thought 'Oh no!', because I remember . . . I could never give pieces and compositions a title. But when I actually started to play [the provided piece], no hassle at all. I was really surprised at the title. I couldn't decide between *Falling leaves* or *Falling feelings*. I wanted 'falling' because I got the impression that the whole . . . The theme is always falling . . . I said falling because I think it is quite a sad piece—melancholy.

Some performers, however, focused on *idiom* when selecting a title as they tried to identify the music stylistically. These participants would argue that the music described nothing but itself. One performer insisted that *structure* was the most significant criterion according to which a title should be chosen. This particular performer argued that there were similarities between melodic phrases and language inflection in several languages, hence her chosen title 'I wonder why? Warum? Warum? Pourquoi? Pourquoi?'.

In further discussions with the participating musicians, the significance of imagery in learning and conceptualizing music was probed. The discussion with each individual was, of course, linked to their choice of title. It would seem that all participants made use of imagery in one way or another in order to construe understanding and meaning, although some would argue that they did not. The analysis of the interviews, however, suggests that learning a piece of music, at least for the occasion staged as part of the research project, most certainly entails a framework of memories that is more extensive than merely relating it to pitch, dynamics, timbre, and the social conventions of interpretation. It also suggests that imagery is used *differently* by musicians.

Participants clearly differentiated between *emotional memory* (associating to anything that might trigger an emotional response, that is also compatible with the qualities inherent in the musical structure) and *memory of an emotion* (recalling a certain emotion, or pattern of emotions, in order to evoke a certain state of mind, which is perceived as appropriate for the piece of music to be studied or performed, and that may, or may not, entail visual imagery; cf. Stanislavsky 1988). The musicians also prioritized one or the other: five participants regarded visual imagery (in terms of emotional memory) as their primary concern in conceptualizing or performing music and memory of emotion was secondary. Eight musicians felt that memory of emotion was primary and visual memory only secondary in importance. Four participants avoided the issue altogether and appeared to feel uncomfortable with discussing music in these terms. However, such a reaction is not to say that these participants did not conceptualize music in a like manner. Their reluctance to discuss and reflect on music in this way is likely, at some level, to be socially determined and to some extent also be influenced by type of personality, as evidenced in participants' sometimes contradictory statements on what they *wished* to do with a particular interpretation and what they felt they *had* to do.

12.2.2 Emotion and self-induction to altered states of awareness

One particularly important finding in the exploratory research on the generation and conceptualization of musical performance was how musicians—some more than others—very consciously manipulated recall of certain memories (emotional memories and memories of emotions) in order to 'get into the mood'. Out of 15 participating pianists, eight acknowledged some sort of self-discovered technique to arrive at a

particular emotional frame of mind for the sake of learning and/or performing. Three musicians were identified as systematically employing what could appropriately be labelled *mood induction* (that is, to remember the sensation of a certain specific emotion without necessarily conjuring up specific imagery). Five musicians, however, used induction by means of *visualization* in order to evoke a particular emotion. The aim of both strategies was to form the basis of their particular understanding of the music at hand. A musician applying mood induction would typically say:

> I find often that to get me into the mood of a piece, say the 'Pathétique Sonata' by Beethoven, and the opening of that, you think something sad. You think *sadly*, not necessarily something that has happened to you, but you think of *the experience of sadness* before you play that chord . . . [it] is a subconscious thing and you are just trying to bring it out' (quoted in Persson 1993, p. 197).

Other performers seemed to combine both mood induction and visualization, depending on circumstance, to attain a certain frame of mind for the performance:

> I very rarely resort to just [the technical]. I don't like that! To me, I'd rather have it musical. [That is], you can see a sense in things; see pictures and images, and feel things. If you're not in the mood for that [music, which you have at hand] you are obviously not going to do justice to it. I suppose being a musician you have to get into the mood of it. (Quoted in Persson 1993, p. 198)

Both approaches are reminiscent of what the musicians of the baroque and classical eras, following the influential 'doctrine of affections' (Bukofzer 1947; see also Cook & Dibben, this volume), then prescribed as a necessity for 'true' performing musicians: 'A musician cannot move others unless he too is moved' (Bach 1985). Thus, performers appear to develop strategies by which they succeed to induce themselves into an 'altered state of mind'. Such a state, in this context, and with the different theoretical schools of thought regarding altered states of consciousness in mind, is best defined broadly, such as done by Ludwig (1990, pp. 18–19), as:

> . . . any mental state(s), induced by various physiological, psychological, or pharmacological maneuvers or agents, which can be recognized subjectively by the individual himself (or by an objective observer of the individual), as representing a sufficient deviation in subjective experience or psychological functioning from certain norms for that individual during alert, waking consciousness. This sufficient deviation may be represented by a greater preoccupation than usual with internal sensations or mental processes, changes in formal characteristics of thought, and impairment of reality testing to various degrees.

These induction strategies are presumably developed intuitively by musicians, as a result of potentially emotion-evoking structures inherent in the music in combination with striving towards hedonic satisfaction (see also Zuckerman 1994). It is known, for example, that music—at least under certain circumstances—is a particularly efficient medium for inducing an altered state of consciousness (Kenealy 1988; see also Becker, this volume). A number of experiments have shown that induction to an altered state is also subject to a learning process (Kamiya 1990; Shore 1990).

Note that performance teachers never discussed such induction procedures during lessons (Persson 1993), which makes it feasible to propose that mastering such induction procedures is mainly a personal and intuitive matter; it develops over time and—because it is natural and so intrinsically tied to the way we perceive and construe music—is probably often taken for granted in teaching performers.

The pivotal significance of the altered state of mind for a creative effort, however, is fairly well documented in the literature on creativity (cf. Krippner 1999), where phenomena such as inspiration (Kneller 1965), imagination (Stein 1974), peak experiences and being cognition (Maslow 1968), flow (Csikszentmihalyi 1988), and play and fantasy (Russ 1993) are in focus. An extraordinary account of this in the realm of musical performance has been provided by Swedish cellist Frans Helmerson (1990, pp. 250–1), when asked to account for how creativity relates to his artistry (translated from Swedish by the author):

> My first point of departure is to evoke the whole [of the piece]. The understanding of the whole is a prerequisite in order to provide the music with a content. It is like assembling the parts in this entire [conceptualization] . . . In other words, it takes a creative process to fit the minute parts of this composition together . . . later in concert I want to—to put it rather solemnly—transcend into a different dimension; one which makes me one with the music. It is a dimension where boundaries between consciousness and intuition are vague and evanescent.

While this 'inspiration-seeking behaviour' certainly could be seen as a social artefact of primarily the romantic era (cf. Persson 2000), the same need for, and use of, the altered state of mind is also found amongst contemporary musicians. Boyd and George-Warren (1992, p. 156), in interviewing 75 popular musicians (such as Eric Clapton, Peter Gabriel, Keith Richards, Ravi Shankar, etc.) regarding their creative process also note, that:

> . . . by completely concentrating on the music they're playing or writing, musicians are able to open themselves up to a peak experience. It is as if an intense concentration can push the conscious mind away from 'self-consciousness' and the unconscious is allowed to filter through. The result can be songs that seem to come from nowhere, the ability to suddenly play a riff that had been too difficult before, or an on-stage 'merging' with band mates.'

12.2.3 Conceptual flexibility

If a performer conceptualizes a piece of music by constructing a type of affective pattern, related to the musical structure, then how stabile is this conceptual structure? Can a musician generate more than one understanding of a certain piece? These questions were also addressed in Persson's (1993) study. Participants were asked to produce two *different* presentations of the given piece and then discuss both. All participants could produce different versions and understandings of the music at hand, but all but one did not. Most argued that they found one conceptualization which they preferred, and that they did not wish to deviate from.

Above all, the content of their conceptual structure was determined by the chosen tempo (see Table 12.2), which has been shown to be the most potent structural factor in music to determine the type of resulting emotional response (e.g. Holbrook & Anand 1990; Rigg 1940; Wedin 1972; see also Gabrielsson & Lindström, this volume; Juslin, this volume). The participants also argued, however, that they could well imagine another conceptualization of the piece featuring different dynamics, tempi, and articulation, but *only* if it was played by someone else!

This response is likely to indicate that a conceptualization is often inflexible and exists within the cognitive confines of what could be functionally termed a *degree of*

tolerance. That is, a musician will often only accept a way of playing a certain piece of music that does not alter the musical parameters to such an extent that they trigger an emotional response different to that which constitutes the way in which they originally construed meaning and understanding in relation to the musical structure. However, there is *some* flexibility in this schema of cognitive-emotional memory structures, the extent of which is likely to be related to personality—and perhaps tolerance for ambiguity in particular (Rogers 1967).

It is possible also that the original conceptualization may change altogether over time in some cases due to accumulated experience and new discoveries that will prompt a musician to re-evaluate 'meaning', thus potentially creating an entirely new schema with a new set of parameters. Pianist Alfred Brendel, for example, argues that:

> . . . as I mold my interpretation and conception I play as instinctively as possible; only later do I attempt to understand what I am doing, why I am doing it. Then I start correcting myself whenever necessary, and from that moment on, I am reassessing my findings as often as I can (quoted in Dubal 1985, p. 91).

In the present research sample, there were apparently limits to a conceptualization, which, when transgressed, prompted the musician to either reject a certain performance or understanding—since it is no longer compatible with the construed 'meaning' of the piece at hand—or construe an entirely new understanding of the music, which takes motivation, effort, and time. However, social context is also likely to play a significant role in determining the degree of tolerance.

It is possible that circumstances and performance tradition *prevented* the participating musicians in deviating from a perceived norm. Although participants knew no details of the piece of music at hand, they still tended to project styles and conventions, typical of the romantic era, onto it—in spite of being encouraged to approach the piece more freely. For example, one performer argued the following in trying to conceptualize the given piece of music in more ways than only one: 'When I think of how my highly respected former piano teacher would have played this, I would know exactly what he would do. I would highly admire that and it would [also] govern what I would do' (quoted in Persson 1993, p. 209). A conservatoire culture is known to often not encourage creative initiatives amongst performers-to-be, but rather insists on conformity and adherence to very elusive rules of tradition and 'authenticity' (Kennedy 1991; Persson 2000; Renshaw 1986).

12.3 Musical reality and its further research

Musicians from all eras, and no doubt in all genres of music, are indeed 'sensors of emotion and sensitivity', and subjectivity is, in a variety of ways, most probably the basis of their musical pursuit. It is thus helpful, both for future research and in understanding the phenomenology of musical endeavours, to term the dynamic nature of this emotional basis from which musicians appear to draw motivation, construe artistic understanding, and generate performances, a *musical reality* (Persson 1995), akin to the Kellyan notion of personal constructs (Kelly 1963).

Musicians, at least as evidenced in the research surveyed in this chapter, do indeed construe elaborate meaning based on intrinsic and mainly hedonic criteria, on extrinsic and contextual demands, and on the triggers of emotional responses inherent in musical structures. Musicians further seem to uphold musical reality, pertaining to a particular repertoire, by means of a monitoring function, presumably optimizing different means of achieving a self-serving satisfaction. Haroutounian (1995) has very appropriately labelled such a function *meta perception*: the perceptual and cognitive process of internally manipulating perceptions with expression.

Needless to say, the subjective conceptualization of music needs further study. The results obtained in the discussed research project, as intriguing and suggestive as they are, are still tentative. Above all, the phenomenological excursion in to the subjectivity of musical performers has generated a number of hypotheses that need testing and further exploration in order to arrive at verifiable cognitive models, and no less important, to facilitate application in an educational setting (Juslin & Persson, in press).

While the existence of a subjective musical reality is certain, its nature and function, also in different contexts, need specific research and a theoretical framework. For example, how does musical reality more specifically relate to choice of repertoire, to determining an interpretation, to how a piece of music is rehearsed, and to the actual public performance of it? There are almost certainly differences, as well as common denominators, regarding how emotions (and by implication also the construct of musical reality) will function in these different situations. It is also quite likely, however, that there are *several* strategies available to musicians that govern musical behaviour in these different settings. This was suggested by one participant, who commented: 'Despite the fact when I'm playing to an audience, I play mainly . . . for recognition . . . [I also play at other times] for a pure love of playing' (quoted in Persson 1993, p. 175). Hence, it is one thing to play to an audience (being under public scrutiny and being assessed as artist) and occasionally another to play for enjoyment (with no sense of external scrutiny and evaluation).

Thus, there seems occasionally to exist a conflict between the internal hedonic motive (the largely self-serving positive emotional experience) and the external demand (i.e. socially imposed traditions and expectations). In some circumstances, however, the different strategies employed in different contexts should perhaps simply be understood, in a Kellyan sense, as *several* coexisting musical realities for the same repertoire, but constructed differently for a variety of performance contexts. If so, there would not necessarily exist a conflict, but the existence of several such coexisting realities would perchance be indicative of adaptive 'survival behaviour' rather than artistic persuasion.

In researching how emotions interact with decisions, choices, rehearsal behaviour, and public performance—and, of course, performance under the pressure of a perceived assessment; real or imagined—therefore, it is probably necessary to consider both possibilities: the potential conflict between self-satisfying hedonism and the imposition of context expectations and assessment, as well as the possibility of several concurrent constructed realities. Their common denominator, however, would be a framework of emotional patterns, motives, imageries, memories, and associations.

A pertinent question is how research into the subjective world of the performer might proceed. I envisage three main thrusts of necessary research efforts.

1. Cognitive functions and neurological correlates need to more solidly, and theoretically, outline the nature of the connection between emotion and musical learning.
2. There are developmental aspects to the notion of musical reality, and research questions need to include possible gender differences. How does musical reality develop over time, in what way, and is there possibly a difference between male and female performers in the way they develop and establish preferences for how to learn? Note that, for example, research on music and cognitive styles has so far not demonstrated that such individual differences have much bearing on understanding musical behaviour (cf. Barry 1992; Heitland 1982). But perhaps an extended research effort into musical performance and personality (regardless of theoretical preference) would (cf. Kemp 1996).
3. Also, given that the notion of musical reality is an appropriate heuristic for future research, one particularly interesting question inevitably emerges: how does musical reality—or rather the capacity to generate effectively an emotionally based conceptualization—relate to musical ability and talent? The understanding of musical talent—or giftedness—has not changed much during the hundred years or so that music has been studied as behaviour. The subjective features, which are presumably part of talent and giftedness, have thus far not been studied at all. Hence, to tie musical reality to the notions of expertise and talent would also seem an important future research effort.

CHAPTER 13

NEGATIVE EMOTIONS IN MUSIC MAKING: THE PROBLEM OF PERFORMANCE ANXIETY

ANDREW STEPTOE

The performance of music induces extraordinarily positive feelings in many players and singers. Participation in a successful and exciting performance often leads to feelings of euphoria, whether it be in a school concert, a piece sung by a village choir, or a public show in a prestigious concert hall. Here is the baritone Thomas Allen (interviewed in the *Independent on Sunday* in 1990) describing his feelings at the end of a performance of *Don Giovanni* in Japan: 'I could have walked over the house tops I was so high'. When the producer came backstage to congratulate him, Allen picked him up and carried him across the stage, 'Oh, I could have run up Mount Fuji!'

The same feelings of joy of creative music making are vividly expressed in a letter written by the 21-year-old Mozart to his father in November 1777. He was playing the organ during a Sunday service in the Court chapel in Mannheim in the presence of the ruler of the state:

> I entered during the Kyrie and played the end of it; and after the priest had intoned the Gloria, I played a cadenza. Because this was all so different from what they are accustomed to here, they all turned round . . . The people had enough to amuse them. Now and then was a pizzicato, and each time I just brushed the keys. I was in the best of spirits. Instead of the Benedictus, the organist has to play throughout. I took the subject to the Sanctus and treated it as fugue. Everybody stood there and stared. The pedal is different from ours; that put me off at first, but I soon understood how it worked. (Quoted in Anderson 1988, p. 370)

Unfortunately, musical performance may also induce negative emotions, including distress and anxiety, which in some individuals can approach extreme levels of terror, impair the quality of the performance, and have debilitating effects on professional and amateur careers.

This chapter discusses musical performance anxiety, outlining the psychological and medical literature on this topic, and touches on issues such as the definition and prevalence of musical performance anxiety, its causes and consequences, and methods of alleviating severe problems. Musical performance anxiety is a complex phenomenon. It is no accident that this chapter began with descriptions of positive feelings, because there are close links between negative and positive feelings in the musical performer.

Indeed, sensations of arousal experienced by most individuals prior to a performance may be disturbing to some, but facilitate a good performance in others. As will become apparent later in the chapter, it has proved difficult to demonstrate that physiological arousal is positively correlated with performance anxiety and that musicians with problems in this area are characterized by excessive arousal. Rather it is the interplay between cognitive processes and physiological activation that is central to musical performance anxiety.

Musical performance anxiety is often regarded as synonymous with stage fright, although stage fright is a phenomenon that occurs in non-musical performers such as actors and public speakers as well. I prefer the term musical performance anxiety for several reasons. Firstly, it refers specifically to the feelings experienced by musicians. Secondly, musical performance anxiety occurs in many settings, and not just on the stage. Stage fright has connotations of distress in front of large audiences, but musical performance anxiety may be elicited in quite intimate surroundings, such as a lesson or an audition. It depends on the evaluative nature of the situation, and not on the presence of an audience. Thirdly, the term 'fright' implies a sudden fear or alarm, while musical performance anxiety may be quite predictable and develop gradually over days prior to an important occasion. Finally, the term has implications for the way in which the music is played, and not just the fear that the performer experiences. Stage fright would be bad enough if it were only a feeling of intense fear. But a major concern for many musicians is that it will have an impact on the quality of the performance, and on their ability to carry out the task of playing or singing accurately and effectively. This feature marks musical performance anxiety out from many other types of situational fear.

The empirical literature on musical performance anxiety is sparse, and relatively few investigators have gone beyond describing the phenomenon into disentangling its elements so as to understand how it develops and is maintained (Brodsky 1996). This chapter will therefore draw on research into related phenomena where appropriate, including stage fright in actors and studies of test anxiety. Other potentially negative aspects of the performer's life will also be briefly discussed, since work stress among musicians appears to be related to performance anxiety.

13.1 Occurrence and experience of musical performance anxiety

Musical performance anxiety is not an all or nothing experience, but a graduated phenomenon. Different musicians encounter it to a different extent, and the same individual may experience varying degrees of performance anxiety on different occasions. Surveys of the occurrence of musical performance anxiety must therefore be treated cautiously, since they typically rely on somewhat arbitrary classifications. The frequency of performance anxiety is also important, since many more musicians will have suffered occasional bouts of severe anxiety than experience them on a regular basis. The best evidence for the occurrence of musical performance anxiety comes from surveys of musicians who are not specially selected on the basis of problems in this area. Obviously, studies of musicians seeking help for difficulties associated with performance anxiety will be biased, and this may lead therapists to overestimate the magnitude of the problem.

Varying estimates of the occurrence of musical performance anxiety have emerged from different surveys, and it is difficult to know whether these are due to genuine variations or differences in questioning. In probably the largest survey published to date, Fishbein and Middlestadt (1988) studied more than 2200 musicians from 48 orchestras in the USA. Nineteen per cent of women and 14 per cent of men indicated that stage fright was a severe problem. Another large survey involving 56 orchestras throughout the world was carried out on behalf of the Fédération Internationale des Musiciens (FIM) in 1997.[1] Seventy per cent of the 1639 respondents indicated that they sometimes experienced such intense anxiety before a performance that it impaired their playing. For 16 per cent, this happened more than once a week. Fity-nine per cent of symphony orchestra players in a Dutch survey claimed to be acquainted with performance anxiety from their own experience, though only 21 per cent described it as intense or very intense (Van Kemenade *et al.* 1995). A survey of more than 300 students in a faculty from the University of Iowa School of Medicine concluded that 21 per cent experienced marked performance anxiety (Wesner *et al.* 1990). Fifty-eight per cent of the members of the Vienna Symphony Orchestra studied by Schulz (1981) indicated that their 'nervous stress' during concerts was high or very high, while 24 per cent also complained of high levels of tension before performances. These surveys indicate that musical performance anxiety is a serious problem for 15–25 per cent of musicians. Some studies have reported higher levels, probably related to differences in exactly how musical performance anxiety was defined, rather than genuine differences in prevalence (Bartel & Thompson 1995; Marchant-Haycox & Wilson 1992). A pattern of slightly higher levels among women than men is seen in several studies, as it is for other forms of self-reported distress (Mirowsky & Ross 1995).

There have been few systematic comparisons of different types of musician within the same study. However, the author and a colleague (Steptoe & Fidler 1987) compared responses from members of the Royal Philharmonic Orchestra, the London Philharmonic Orchestra, and an amateur orchestra, and orchestral instrumental students at the College of Music, using an adaptation of the state scale from the state-trait anxiety inventory (Spielberger *et al.* 1970). The mean scores were significantly higher among students, and were lowest in the professional musicians in the world class orchestras. Does this mean that performance anxiety declines with experience? Not necessarily, because it is possible that more anxious individuals hoping to become orchestral musicians drop out of the profession at an early stage. Alternatively, it is possible that more anxious musicians fail to be employed by prestigious orchestras, leaving a selected sample of less anxious individuals. Unfortunately, no longitudinal studies have yet been conducted that allow the different explanations of cross-sectional results to be teased out.

There are similar difficulties in understanding associations between musical performance anxiety and age. One might expect performance anxiety to decline with age as musicians become more experienced and familiar with different audiences and challenges. On the other hand, success comes with responsibility, and the acclaimed

[1] The FIM survey has not been published in detail. I am grateful to the British Association for Performing Arts Medicine for giving me access to the data.

mature performer may perceive additional burdens in the high public expectations on them. The violinist Nathan Milstein (quoted in the *Guardian* in 1993) recalled how carefree he was when performing in his youth, playing cards or sightseeing during the day before an evening recital. Later in life he was unable to eat lunch and remained preoccupied for several hours before a performance. Highly successful popular musicians and classical musicians, such as Arthur Rubinstein and Luciano Pavarotti, have admitted to extreme nervousness and distress prior to concerts. Perhaps the most celebrated case is that of the great actor Laurence Olivier, who suddenly succumbed to severe stage fright for several years at a late phase of his career (Olivier 1982).

13.1.1 The phenomenon of performance anxiety

Musicians who suffer from performance anxiety describe a wide range of experiences, including fear and terror, trembling, difficulty concentrating, disturbances of breathing, and dry mouth. There is a strong belief among musicians that performance anxiety impairs their playing or singing, and this is corroborated in studies involving objective evaluations. For example, Craske and Craig (1984) had independent judges evaluate the performance quality of piano students divided into anxious and non-anxious groups. Judgments were made from audiotapes recorded when the student played alone, or in the presence of an evaluative audience. Subjective ratings of distress were also collected. Some results are illustrated in Fig. 13.1. It can be seen that the judges' ratings of performance quality were significantly impaired in the audience condition in the anxious group, but improved in the non-anxious group. Subjective distress increased in both groups when an audience was present, but the increase was much larger in the performance anxiety group.

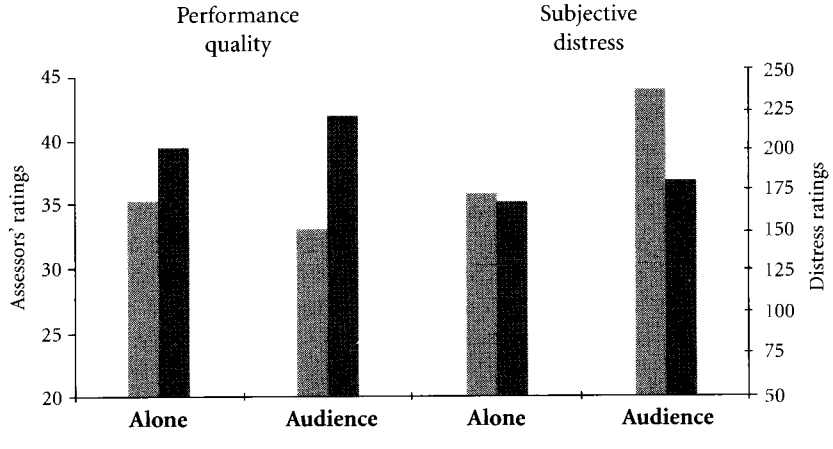

Figure 13.1 Performance quality and subjective distress in anxious (light bars) and non-anxious (dark bars) pianists playing alone or in front of an evaluative audience. Performance quality (left-hand axis) was judged by assessors blind to the pianists' group, and higher scores indicate superior quality. Distress (right-hand axis) was assessed by combining ratings obtained before and immediately after playing, with higher scores indicating greater distress. (From Craske & Craig 1984.)

Musical performance anxiety is a complex phenomenon. By analogy with other work on stress and emotion (Steptoe 1998), it may be useful to separate four distinct elements. These four components are listed in Table 13.1, along with various examples of the ways in which they are manifested. The primary component is affect or feeling, which forms the central experience of performance anxiety for many musicians. It should also be recognized in this context that the moods and emotions evoked by music are not confined to the audience, but may also affect the performer. However, there are other important aspects as well, including cognitive responses or disturbances in information processing, changes in behaviour, and physiological responses.

Table 13.1 The four components of musical performance anxiety

Affect	Feelings of anxiety, tension, apprehension, dread or panic
Cognition	Loss of concentration, heightened distractibility, memory failure, maladaptive cognitions, misreading of the musical score, etc.
Behaviour	Tremor, trembling, difficulty in maintaining posture and moving naturally, failures of technique
Physiology	Disturbances in breathing pattern, perspiration, inhibition of salivation (dry mouth), high heart rate, the release of hormones such as adrenaline (epinephrine) and cortisol, gastrointestinal disturbances

The 1997 FIM survey illustrates the importance of these different elements. Physiological symptoms were frequent before and during performances, with rapid heart beat (67 per cent), sweating hands (56 per cent), and muscle tension (56 per cent) being the most prominent. At the same time, 49 per cent complained that they often lost concentration, and 46 per cent that they experienced trembling and shaking prior to playing. These same four elements are common to many modern conceptualizations of the stress response, which are essentially offshoots of the three system model of fear formulated by Lang and others (Hugdahl 1981).

The various manifestations of musical performance anxiety do not necessarily occur together, and correlations between responses in the different domains are variable (Craske & Craig 1984; Fredrikson & Gunnarsson 1992). One person may show impairment of movement or posture without feeling very upset, while another may experience their principal difficulties in cognitive disturbance. Craske and Craig (1984) showed that concordance between components was greater in more anxious performers, but the correlations between physiological and subjective measures still did not exceed 0.38, suggesting that marked discrepancies remain. Understanding the interrelationships between these domains helps to delineate the core components of performance anxiety.

The framework outlined here and elaborated in the following sections is based on the view that musical performance anxiety is a form of situational stress response. That is, it is similar in some respects to problems such as social phobia or academic examination stress. It should be recognized that this model differs from some approaches that conceptualize performance anxiety as a unique problem related to psychological issues stimulated by performing in front of others. This latter perspective has derived primarily from the psychodynamic tradition. For example, Gabbard (1997) has argued that stage fright can emerge from shame related to genital inadequacy, or impulses that produce feelings of guilt in the unconscious in triumphing over Oedipal and sibling rivals. I

have little sympathy with such views, which lack objective verification, and would argue that bringing musical performance anxiety into the mainstream of stress research has major advantages for understanding issues such as the role of cognitive processes or the relations between physiological arousal and performance quality, while highlighting ways in which performance anxiety can be effectively managed.

13.2 Physiological arousal during musical performance

Perhaps the simplest model of musical performance anxiety is that it is a consequence of heightened physiological arousal. Certainly, the perception of physiological arousal figures prominently in the experience of many anxious musicians, with symptoms such as palpitations, breathlessness, and perspiration that are indicative of sympathetic nervous system activation. Subjectively, many anxious musicians report symptoms of *hyperventilation*—the pattern of dizziness, tremor, and high heart rate due to overbreathing (and subsequent reductions in arterial carbon dioxide levels) that is characteristic of patients with panic attacks (Widmer *et al.* 1997).

The physiological arousal induced by performing in public has also been established objectively. Two types of study have been carried out: (a) those in which physiological monitoring takes place under conditions specially devised and controlled by the investigator; and (b) naturalistic studies in which musicians are monitored during live performances. Thus, in the study by Craske and Craig (1984) described earlier, heart rate was higher during performances in front of an audience compared with playing alone. Fredrikson and Gunnarsson (1992) studied 19 music students, and reported that adrenaline (epinephrine) increased by an average of 139 per cent and cortisol by 66 per cent with performance in front of an audience compared with playing alone.

The classic investigation of physiological activation during live performance is the work by Haider and Groll-Knapp with the Vienna Symphony Orchestra, first published in German in 1971 and in English in 1981. The heart rate and electroencephalogram (EEG) were monitored during rehearsals and live concerts from 24 musicians. String and woodwind players showed similar responses, with a mean heart rate of 93.9 bpm during concerts, reaching an average maximum of 113 bpm. Since the resting heart rate of these musicians was 66.6 bpm, this means that heart rate increases averaged 27.3 bpm. Interestingly, the heart rate difference between rehearsals and concerts was more than 8 bpm, even though the same pieces were being performed. These substantial increases in heart rate confirmed an earlier study of musicians in concert (Schmale & Schmidtke 1965) and the more recent investigation of members of the BBC Symphony Orchestra (Mulcahy *et al.* 1990). Haider and Groll-Knapp (1981) also used EEG recordings to show high levels of cortical activation during concerts.

In the light of these findings, one possibility is that musical performance anxiety is a consequence of excessive physiological activation. The 'inverted-U' association between tension and performance is a well-established phenomenon in the experimental laboratory, and suggests that information processing and behavioural performance improves with arousal to an intermediate stage, but then deteriorates as physiological arousal rises beyond the optimum (Duffy 1962; Näätänen 1973). However, few studies have documented this pattern in performing musicians. Some evidence for such an association

emerged from an interview study I carried out with young professional opera singers (Steptoe 1983). Participants were asked to rank the quality of their performance in five settings: lesson, private practice, audition, dress rehearsal, and public performance. Then, at a different stage of the interview, ratings of emotional tension in these situations were obtained on a nine-point scale ranging from 1 = *extreme tension* to 9 = *extreme relaxation.* I then averaged the emotional tension ratings for each situation, and plotted them against the estimates of performance quality. Figure 13.2 depicts the interrelationship between these measures. It can be seen that the best singing was produced at an intermediate level of tension (in public performances), while the situations associated with greater tension (dress rehearsal and audition) were those in which performance was impaired. The results of this study are consistent with the inverted-U pattern, though they are limited by the use of self-reported measures.

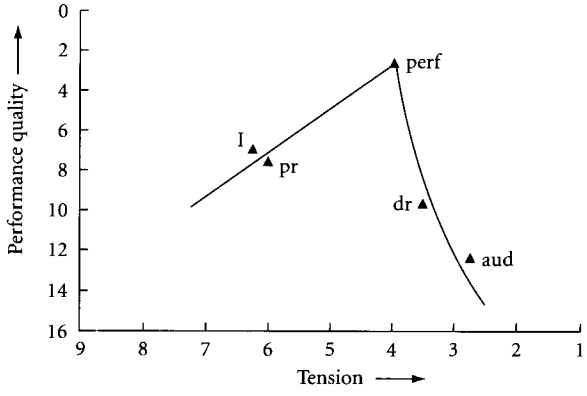

Figure 13.2 The association between self-rated tension and quality of performance in a sample of opera singers, assessed in five situations: private practice (pr), a lesson (l), public performance (perf), dress rehearsal (dr), and in audition (aud). (For details, see Steptoe 1983.)

When it comes to objective physiological measures, there is much less evidence that musical performance anxiety is associated with excessive arousal. In fact, some studies have shown similar levels of physiological activation irrespective of musical performance anxiety. Thus, Abel and Larkin (1990) show that blood pressure and heart rate increased prior to playing in public, but that responses were not significantly correlated with performance anxiety. Similar levels of heart rate and sweat gland activity response in individuals with high and low levels of anxiety were recorded by Craske and Craig (1984), and adrenaline and cortisol response by Fredrikson and Gunnarsson (1992). The only evidence for excessive arousal to emerge thus far is the observation by Fredrikson and Gunnarsson that anxious musicians showed a mean 39.2 bpm increase in heart rate, compared with 22.6 bpm in the less anxious. It is also possible that musical performance anxiety is manifest physiologically, not in general measures of arousal such as heart rate, but in more specific correlates of breathing disturbance associated with hyperventilation (Widmer *et al.* 1997). An interesting result came from the heart-rate-monitoring studies of the BBC Symphony Orchestra (Mulcahy *et al.* 1990). It was found that the increase in heart rate during concerts was paralleled in measures

obtained from managerial and technical staff for the orchestra; even though these individuals were not actually playing music, they responded just as much at a physiological level.

These findings suggest that while physiological arousal may be a necessary condition for musical performance anxiety, it is not a sufficient explanation. Other factors are involved that relate to the cognitive responses to performing, and to perceptions of physiological arousal. However, the results of these objective studies of physiology are also relevant to the issue of the apparently beneficial or facilitatory effects of performance anxiety.

One of the statements that musicians often make about playing in public is that they 'need' stage fright, and that it helps them to perform at the optimum level. This facilitating effect is important, since it may lead musicians not to seek ways of alleviating performance anxiety, because they fear that the quality of their playing or singing may suffer. Some years ago, I interviewed one young professional opera singer whose concern was that she did not get excited enough when performing. She was worried that her lack of 'stress' may have had an adverse effect, giving the impression of little involvement in the music. Her subsequent extremely successful career has given the lie to this fear.

The notion that arousal is facilitative can be understood within a curvilinear model of performance (see Fig. 13.2). However, I would argue that this is not because performance anxiety is beneficial, but because physiological arousal is necessary for a good performance. When musicians say that performance anxiety, or stage fright, is helpful, they may be mislabelling physiological arousal as fear, rather than construing it as an independent entity. Physiological activation may be required for a good performance, but not the negative feelings associated with playing or singing in public. Such empirical work as has been done suggests that facilitating and debilitating aspects of performance anxiety are negatively correlated (Mor *et al.* 1995). The most parsimonious explanation is that the same feelings of physiological arousal are experienced, but while one performer finds these energizing, another perceives them as signs of impending disaster.

13.3 Cognitive factors in musical performance anxiety

The musician playing in public tends to be occupied with task-orientated thoughts. That is, the cognitive apparatus is taken up with thoughts related to effective performance. For the orchestral musician, this will include being sensitive to tempo and dynamic directions from the conductor, the volume of sound in relation to the rest of the orchestra, intonation, the particular challenges of the passage, and so on. A member of a rock band will be alert to the way in which the music is being played by colleagues, to improvisations by others, and to maintaining a regular beat. The singer or instrumental soloist often has added cognitive demands related to remembering the music, the actions on the stage, and adjusting performance to the acoustics of the venue.

A characteristic feature of musical performance anxiety is disruption of task-orientated cognitions. Several types of disruption have been identified. One common problem is *catastrophizing*, or exaggerating in imagination the likelihood and effects of negative events during the performance. For example, singers may find that their breath does not hold out in the way they hoped, or the instrumentalist makes a small error of

intonation. Musicians with musical performance anxiety tend to believe such occurrences will ruin the entire performance, and will lead to loss of control over the situation. Wolfe (1989) observed that anxious musicians were convinced that a small mistake at the beginning of a performance upset them so much that they tended to make even more simple mistakes later on. Catastrophizing also takes the form of fear of collapse, and the concern that the performer will be sick or faint on stage. We have found in both musicians and student actors that there are strong positive associations between catastrophizing and performance anxiety (Steptoe & Fidler 1987; Steptoe *et al.* 1995).

A second form of distraction comes from preoccupation with evaluation by others. Lehrer and co-workers (1990) carried out a factor analysis of thoughts and worries related to musical performance. Various factors emerged, including worry about anxiety and fear of distraction. In addition, concern about the reactions of other people (ranging from close family to critics) was a prominent feature, and was positively correlated with anxiety. By contrast, we have found that more realistic attitudes, such as the belief that the audience wants the performer to play well and will make allowance for slips, are associated with adaptive levels of moderate arousal, and not with severe performance anxiety (Steptoe & Fidler 1987). Concern about the reactions of others may be coupled with very high internal standards and a perfectionist attitude. An analysis of perfectionism in professional performers was carried out by Mor and colleagues (1995). The perfectionism scale included items such as 'one of my goals is to be perfect in everything I do', and 'the people around me expect me to succeed in everything I do'. It was found that perfectionism scores were positively correlated with debilitating performance anxiety, and that more anxious performers also experienced a lower sense of personal control in their lives.

Cognitive responses of this type tend to divert the musician from concentrating on the task itself, thus increasing the risk of errors in performance. Heightened perception of physical signs also contributes; anxious performers may interpret muscle tension or a rapidly beating heart not as a sign of excitement and involvement, but as signalling loss of control and impending collapse. They may therefore become further distracted by trying to keep themselves physically calm. Thoughts about failure during performance have been shown to predict playing below the standards of which the individual is capable of in other situations (Kivimäki 1995).

13.4 Other stresses in the musician's life

Negative emotional experiences among musicians are not restricted to performance anxiety. The musician's life, both during training and their subsequent professional career, is subject to other sources of stress, just as is the case with other types of job. Much of the work on these problems has been carried out in the context of occupational health research.

Parasuraman and Purohit (2000) built on the work of Schulz (1981) to identify five major sources of stress among orchestral musicians. These are issues related to the work environment (air quality, humidity, seating comfort, readability of the musical score, etc.), social tensions (such as conflict within the orchestra, feelings of being undervalued), musical performance anxiety, problems related to artistic integrity (such as

unhappiness about how the music is played, being subordinate to the will of a conductor), and concerns about the technical difficulty of the music. They found that social tension, problems of artistic integrity, and poor working conditions all contributed to job dissatisfaction among professional orchestral musicians. To these might be added worries about job security and the financial viability of music making, and boredom arising from playing the same pieces over and over again. In our own work, we found that the principle sources of stress for orchestral musicians were separation from family, irregular working hours, the monotony of rehearsals, travelling, and uncertainty about regular employment (Steptoe 1989).

The 1997 FIM survey asked orchestral musicians to rate more than 40 potential sources of stress. The ten items that were endorsed as being moderately or severely stressful by the largest proportion of players are listed in Table 13.2. It can be seen that the most common sources of stress for professional orchestral musicians were problems with conductors, conflict with fellow musicians, work environment problems, unsatisfactory rehearsal arrangements, and aspects of playing. However, set against these difficulties are the positive feelings of interest and fulfilment deriving from the sheer pleasure of playing in an orchestra, the variety in the job, and the excitement of performing to audiences.

Table 13.2 Stressful aspects of the musician's life.

	Proportion of respondents who gave a rating of moderate or severe stress
Working with a conductor who saps your confidence	73%
Playing an orchestral solo	73%
Illegible music	65%
Disorganized rehearsal time	65%
Problems with your instrument	63%
Making a mistake when performing	63%
Incompetent conductor	61%
Incompatible desk partner	61%
Having medical problems that affect your work	57%
Playing in a cold hall	55%

Somewhat similar problems are reported by popular musicians playing jazz and rock (Cooper & Wills 1989). The major concerns reported by a sample of popular musicians were the uncertainty of employment, periods of work overload interspersed with underload coming from being obliged to play routine music in unexciting venues, conflicts with fellow musicians, and the lack of clear structures of career development. The concerns of music students run along the same lines (Dews & Williams 1989).

There are, of course, stressful elements in any work environment, and it is not clear whether the problems of musicians are worse than those experienced by other people. Kivimäki and Jokinen (1994) compared orchestral musicians with industrial and clerical workers, and with people in the health care professions. Average levels of job satisfaction were higher among orchestral musicians than all the other groups, primarily because they enjoyed the variety of the work and the skills they could use in their jobs. However, their sense of autonomy or personal control was relatively low. This same

pattern emerged from a comparison of six occupations from a biomedical perspective carried out by Theorell and co-workers (1990). Orchestral musicians felt that they had less autonomy over their work than did all the other occupational groups, including aircraft mechanics, waiters in restaurants, and physicians. Low control at work has been highlighted over recent years as a major source of stress and as a contributor to health risk (Steptoe & Appels 1989).

What is also clear is that these other stresses in the musician's life are not entirely separate from musical performance anxiety. In our own work, we found that musicians with high performance anxiety were more likely to be concerned about other negative aspects of their careers, such as poor financial rewards, social conflict with other professionals, the competitive nature of the job, and uncertainty about employment (Steptoe & Fidler 1987). It is possible that performance anxiety serves to accentuate the individual's perception of other stresses in music making, while these same difficulties may be ignored by musicians who are not troubled with nerves and are able to enjoy their playing.

13.5 Coping with musical performance anxiety

Musicians engage in a variety of informal coping efforts in their attempt to manage performance anxiety. Common methods of coping immediately prior to a performance include deep breathing and muscle relaxation, meditation, immersion in the music, reading, and distraction (Steptoe 1989; Wolfe 1990). Relatively small but none the less worrying numbers report using sedatives and alcohol, while a significant proportion of professional musicians use β-blockers to help them cope with the physical manifestations of performance anxiety. Longer-term methods of coping include thorough preparation and practice, and checking on all aspects of the performance venue (lighting, access, acoustics, etc.).

An apparently paradoxical finding in this literature is that coping has been positively correlated with musical performance anxiety. Lehrer *et al.* (1990) showed that more anxious musicians engaged in more coping efforts, while Steptoe and Fidler (1987) found that anxious musicians were more likely to meditate. The use of distraction techniques has been positively correlated with performance anxiety in student actors as well (Steptoe *et al.* 1995), although Wolfe (1990) observed that musicians who use emotion-focused coping techniques felt greater confidence and competence. The explanation for these associations is not clear. One possibility is that anxious musicians are more likely to engage in deliberate efforts at coping than their less anxious colleagues. The methods of coping may be useful, even though anxiety levels still remain somewhat elevated. A second possibility is that some types of coping are effective, while others are maladaptive. That is, musicians may engage in activities that they think are helpful which do not actually alleviate performance anxiety. Such a pattern is difficult to identify, because methods of coping may be helpful on some occasions but not others. When discussing these issues with musicians, it is striking that efforts at coping may become rather rigid.

A good example is the ritual that some instrumentalists and singers carry out on the day of an important performance. They may, for example, remain silent for several hours, feel they have to eat particular foods or wear certain colours, or insist on arriving at the venue at a specific time. These ritual patterns may develop over months or years

as the musician comes to believe that he or she performs much better when these routines are fulfilled. The problem arises when these coping routines are disrupted. Perhaps an extra rehearsal is unexpectedly called, or traffic problems lead to a change in travel plans. Under these circumstances, the musician who has learnt to rely on an inflexible coping routine may be more disturbed by these occurrences than other performers, leaving them worse off than before.

13.6 Methods of treatment and support

Performance anxiety is not the only serious problem related to health and well-being experienced by musicians. High numbers report pain in their shoulders, backs, arms, and fingers, due partly to overuse and partly to excessive tension. Many wind players experience difficulties in lip control after many years, related to tenderness and inflammation. None the less, performance anxiety is so distressing and intense for some musicians that it seriously impairs their lives and careers. There are a range of popular and self-help guides on managing stage fright, some of which are intended for all types of public presentation (e.g. Ashley 1996; Desberg 1996). The most useful book designed for musicians that I have read is Salmon and Meyer (1998).

Professional support for musical performance anxiety provides two basic approaches: (a) pharmacotherapy; and (b) psychotherapies based on relaxation or cognitive behavioural stress management. Anxiolytic drugs, such as benzodiazepines, have been used to some extent to control performance anxiety, despite side effects and the risk of drug dependence (Lederman 1999). The non-benzodiazepine buspirone has been found to have no beneficial effect on performance anxiety in a small controlled trial by Clark and Agras (1991). Much more popular have been β-adrenergic blockers, originally developed for the treatment of cardiovascular disease. These drugs inhibit the peripheral physiological manifestations of sympathetic nervous system activation, such as rapid heart rate and excessive perspiration. They have been welcomed as peripherally acting drugs that modify the somatic elements of performance anxiety without dulling mental processes.

It is clear that many professional musicians use β-blockers, often without medical supervision. Fishbein and Middlestadt (1988) reported that 27 per cent of musicians in their survey had used β-blockers to help with stage fright, and 70 per cent of these obtained the drugs from informal sources. In the 1997 FIM survey, 20 per cent of respondents had used these drugs over the past year. Musicians who do use β-blockers certainly experience favourable effects, with a reduction in tremor and a greater sense of calm prior to and during performance (Fishbein & Middlestadt 1988).

The scientific evidence for benefits is more equivocal. Liden and Gottfries (1974) compared β-blockers and placebo in a double-blind trial. Musicians' ratings of their own symptoms decreased under both conditions, with no significant differences between them. James and Savage (1984) found no difference in mood ratings prior to performance in β-blockade, benzodiazepine, and placebo groups. However, β-blockers did have superior effects on self-ratings of bow shake and dynamics in string players, and on one of eight ratings of performance quality by professional observers. In another placebo-controlled trial in Switzerland, string players played both with and without an

audience (Neftel *et al.* 1982). Tape recordings of their playing were analysed objectively using a sonograph, which allowed subtle aspects of performance—such as the regularity of trills and vibrato of movements—to be assessed. The heart rate increase when playing in front of an audience was effectively blocked in the active drug condition, and the increase in output of adrenaline was also attenuated by β-blockade. There was evidence from the sonographic analysis that fine motor skills were impaired during performance in front of an audience in the placebo condition, but that these aspects were improved by β-blockade. At the same time, there were no significant differences in self-reported anxiety.

The impression from these and other studies is that β-blockers do indeed reduce physiological activation. Aspects of performance that are critically dependent on fine motor control, such as bow movements and vibrato, may therefore benefit. The impact on anxiety, concentration, and other aspects is less clear. The unsupervised use of such potent medications cannot be recommended.

Psychotherapeutic approaches to musical performance anxiety cover the whole range of talk therapies, only a few of which have been evaluated systematically. Psychodynamic therapies such as psychoanalysis have been recommended (Nagel 1993), but there is no evidence involving controlled trials or standardized measurement concerning their efficacy. The best evidence is for cognitive-behavioural programmes based on the model of stress outlined in this chapter.

There are four core elements of interventions that tend to be effective, either alone or in combination. The first is for the musician to acquire self-assessment skills. It is essential that performers themselves become aware of the sensations, thoughts, and reactions to audiences that they experience when they are playing in public. Without this self-awareness, progress in developing coping skills is likely to be limited. Secondly, most successful programmes include some method of helping musicians reduce or control physiological arousal. This might involve relaxation training, although *biofeedback* (providing participants with information about their physiological function) has been used as well (Nagel *et al.* 1989; Niemann *et al.* 1993; Sweeney & Horan 1982). Music-based relaxation has also been shown to be helpful in this context (Brodsky & Sloboda 1997). Thirdly, cognitive methods are used to challenge the negative thoughts that spring into the anxious musician's mind. For example, Kendrick and co-workers (1982) first elicited negative or distracting thoughts from participants, then taught them to substitute task-orientated and positive thoughts through role play, imagined performance sequences, and verbalizing thoughts out loud. The fourth ingredient is practice at using these skills in the performance setting. Controlled exposure to threatening stimuli is one of the key elements of anxiety management (Noyes & Hoehn-Saric 1998), and the same is true for musical performance. Coping skills cannot be imposed prescriptively since the musician needs to experiment with different approaches before deciding what is most useful.

In a number of randomized trials, methods that involve these elements have been shown to be superior to comparison conditions in terms of reducing anxiety and increasing self-reported confidence, and there is some evidence for favourable effects on objective assessments of comportment and playing (Brodsky & Sloboda 1997; Kendrick *et al.* 1982; Nagel *et al.* 1989; Valentine *et al.* 1995). An additional important factor is the

application of systematic learning and practice methods, such as those described by Reubart (1985) and Salmon and Meyer (1998).

Despite these benefits, it is clear that the average musician does not seek professional help for performance anxiety. In the 1997 FIM survey, for example, only 11 per cent had consulted a psychologist, psychiatrist, or counsellor over the past year, and many of these consultations were probably not for performance anxiety. This represents only a fraction of musicians who complained of performance anxiety. Fishbein and Middlestadt (1988) found that only 25 per cent of musicians in their large survey who experienced severe stage fright had sought psychological or psychiatric counselling. Reluctance to seek help may stem from three factors. The first is that consulting a psychologist or psychiatrist has connotations of mental illness, and musicians quite reasonably do not see their problems in this way. Secondly, there is ambivalence about arousal stemming from the belief that tension is beneficial for a good performance. This may lead to fears that treatment would have an adverse effect on playing. Thirdly, musicians may not be aware of the availability of effective interventions. More positive attitudes may evolve only gradually. In the meantime, advice and strategies for coping with performance anxiety could usefully be incorporated into the training of musicians in conservatories and colleges of music. Self-help materials based on proven techniques also provide musicians with alternatives to formal support (Salmon & Mayer 1998).

13.7 Conclusion

The negative emotions elicited in musicians during performance can be highly aversive, and may lead to the curtailment of promising careers in professionals, and the spoiling of an otherwise enjoyable activity for amateurs. Performance anxiety can be placed within the broader context of stress-related problems, and is not a unique phenomenon limited to actors and musicians. Misconceptions exist about the facilitating role of arousal and the adverse effect of performance anxiety. Promising treatment methods have been devised that are based on cognitive-behavioural stress management. The incorporation of the principles underlying these methods into the training of musicians would almost certainly be very beneficial.

CHAPTER 14

COMMUNICATING EMOTION IN MUSIC PERFORMANCE: A REVIEW AND THEORETICAL FRAMEWORK

PATRIK N. JUSLIN

Music is perhaps the most widely practised and appreciated of all art forms. Part of the appeal of music may lie in its ability to induce and represent emotions (cf. Budd 1985; Davies 1994; Meyer 1956; see also Sloboda & Juslin, this volume). Music is often regarded as an effective means of communicating emotions, and this notion pertains not only to the notated or implied structure of the music, but also to the way it is *performed.* Both empirical research (Persson 1995; Persson *et al.* 1996; Woody 2000) and biographical accounts (Blum 1977; Kennedy 1990; Schumacher 1995; Seckerson 1991) have suggested that many performers conceive of performance in terms of emotions, moods, or scenarios. A quote from one of the leading guitarists in the world, Eric Clapton, may serve to illustrate this point: 'Music . . . it's a form of communication and reassurance of feelings . . . what I get out of music is a feeling that I'm not alone' (Clapton 1998, p. 20).

The last decade has seen a steady increase of studies of how performers communicate emotions to listeners. The goal of this chapter is to: (a) review research on communication of emotions in music performance; (b) outline a theoretical framework suitable for organizing the findings; and (c) consider some implications for future research on music performance.

14.1 The role of the performer

Music might be viewed as part of a communication system in which composers code musical ideas in notation, performers recode from the notation to musical signal, and listeners recode from the acoustic signal to ideas (Kendall & Carterette 1990). The communicative content in music performance includes the performer's *interpretation* of the musical composition, that is, the performer's individualistic shaping of the piece according to his or her intentions (Palmer 1997). Most music performances involve some intention from the performer's side regarding what the music should 'express' to the listeners. Consequently, interpretation involves assigning some kind of meaning to the music (Persson 1995; see also Persson, this volume).

Although there has been much debate on what constitutes the 'meaning' of music, most accounts seem to involve a reference to the emotional impact of music (Budd 1985). It is not surprising, then, that a great deal of research has explored the expressive properties of various musical compositions (Gabrielsson & Lindström, this volume). However, the *performance* is also important in determining the emotional expression of a piece of music. The same notated structure can be performed in a number of different ways, and the precise way it is performed may affect the listener's impression of the music in profound ways. Both anecdotal evidence and empirical research have suggested that performers attempt to convey particular moods to listeners (cf. Persson 1995; Shaffer 1992; Woody 2000). Such expressive intentions may be more common in certain musical styles (e.g. opera, blues) than in others (e.g. serial music). Similarly, they may be more common among some performers (Fig. 14.1) than among others. Still, they occur frequently enough to be of legitimate interest to artists and scientists alike.

The process of interpretation itself is still largely shrouded in mystery. It is often argued that expertise in music performance involves the synthesis of technical and expressive aspects (Gabrielsson 1999; Sloboda 1996), but music teachers tend to spend more time and effort on the former than the latter (Tait 1992). Many music teachers still regard interpretation as 'the thing that cannot be taught'. Others make efforts to

Figure 14.1 Expressive performance: blues guitarist B. B. King in concert. King (1996) explained his relationship to the guitar: 'If I was feeling lonely, I'd pick up the guitar; feel like talking, pick up the guitar; if something's bugging me, just grab the guitar and play out the anger; happy, horny, mad or sad, the guitar was right there. It was incredible luxury to have this instrument to stroke whenever the passion overcame me' (p. 41). 'I started experimenting with sounds that expressed my emotions, whether happy or sad, bouncy or bluesy. I was looking for ways to let my guitar sing' (p. 123). (Photographs by Steve Berman.)

enhance performers' expressive skills by using tools such as metaphors, modelling, or mood induction (see Juslin & Persson, in press).

There are various traditions in musical interpretation, and emotions may enter into the process of developing an interpretation in different ways depending on the tradition. In one tradition, the performer's task is mainly to be 'a faithful carrier of the composer's message' (Sloboda 1998, p. 22). In this tradition, interpretation involves a careful study of the score, perhaps accompanied by consultation with the composer or of historical commentaries. The main factors determining the interpretation are performance convention and inferences about the expressive intentions of the composer.

In other traditions of interpretation, the performer has much more freedom. (This is, of course, particularly true in musical improvisation where the performer is also the composer.) In these traditions, the interpretation may be guided by the performer's own emotions while playing the piece (see Woody 2000). Alternatively, the performer may attempt (explicitly or implicitly) to render the performance with an emotional expression that seems suitable for the piece in question, perhaps enhancing a quality of emotion that is already latent in the piece of music. The performer's judgment of what emotion is suitable for the piece may be guided by his or her own listening to the music or by simple intuition.

In sum, the amount of freedom allowed to the performer in his or her interpretation of a piece varies greatly depending on the musical style and culture. This implies that the relative importance of the performance in determining the emotional expression of a piece of music is likely to vary considerably across different contexts. Although the emotional expression of a piece depends *both* on its composed structure and on its realization in performance, one may, in principle at least, separate the two aspects for research purposes. In fact, such a distinction has formed the basis of a series of recent studies of how performers communicate emotions to listeners. In the following, I summarize the main findings from this research and delineate a theoretical framework suitable for organizing the findings.

14.2 A brief history of the research

Throughout history, there has been plenty of anecdotal evidence concerning the extraordinary expressive skills of particular performers. Performers, listeners, and critics have all testified to the effectiveness of performance in communicating specific emotions to listeners. This can be illustrated by the following quote from the eighteenth-century violinist Francesco Geminiani:

> . . . with regard to musical performances, experience has shown that the imagination of the hearer is in general so much at the disposal of the [performer] that by help of variation, intervals, and modulation he may stamp what impression on the mind he pleases (quoted in Meyer 1956, p. 201).

Claims of this kind are common in the literature. However, anecdotal evidence can be unreliable. Further, in addition to those authors who have made claims about the expressive powers of music, there are others who have argued that music is unable to express anything whatsoever, like Stravinsky (Fisk 1997, pp. 280–1). The extent to which performers can communicate specific emotions to listeners has thus remained an open

question. Given that both performers and listeners regard expressive aspects of performance as important, it may be surprising to learn that research on emotional expression in performance is a fairly recent phenomenon, especially in comparison to research on emotional expression in compositions (Gabrielsson & Juslin, in press).

That this problem did not receive attention earlier is strange. One of the general findings from the early studies of performance was that the performance of a piece of music practically never corresponds to the nominal note values of the notation. In every performance, there are certain 'expressive deviations', or 'systematic variations', from what seems prescribed by the notation. These variations are not random, because performers are able to replicate them with great precision (Shaffer & Todd 1987). This gives rise to a question: what is the *function* of these variations?

One function of expressive variations may be to clarify the structure of the piece to the listener (Clarke 1988; Palmer 1989, 1997; Sundberg 1988). By clarifying the structure, the performer may try to enhance the 'inherent' emotional impact of the musical structure. In this view, then, expressive variations primarily reflect the performer's conceptual interpretation of the structure. However, this explanation has failed to account for all of the variance in musical performances. Repp (1998) analysed 115 performances of a Chopin piece in order to study the individual differences among performers. Based on the results, Repp convincingly argued that individual differences at the phrase level do not arise (mainly) from different interpretations of the musical structure but from different ways of giving 'expressive shape' to one and the same structure. Indeed, a number of researchers have suggested that expressive variations may serve to convey moods to listeners (Gabrielsson 1988; Juslin 1997*a*; Shaffer 1992).

One of the pioneers in music psychology, Carl E. Seashore, argued that 'deviation from the exact . . . is the medium for the creation of the beautiful—for the conveying of emotion' (quoted in Seashore 1937, p. 155). Seashore did not develop any theory to explain how such systematic deviations convey emotions to listeners. However, he did propose a suitable paradigm for exploring this problem. He was interested in the question of how singers express emotions and asked whether there is 'any possibility of a scientific approach' (Seashore 1947, p. 171). He gave the answer himself by describing a study of vocal expression by Fairbanks (1940), one of his colleagues at the University of Iowa. This study required actors to express different emotions in speech, which was later analysed acoustically. Seashore concluded that 'we can exactly parallel this experiment in the field of music' (Seashore 1947, p. 176).

Strangely, Seashore's plea went unheard, and he did not publish any study of that sort himself. Before the mid-1970s, there was not a single study of emotional expression in music performance. By the late 1980s, only two studies on this topic had been published (Kotlyar & Morozov 1976; Senju & Ohgushi 1987). After this modest beginning, however, there was a virtual explosion of studies in the early 1990s (for a review, see Juslin 1999). Most of these studies used the same paradigm that Seashore suggested 40 years earlier.

14.3 The standard paradigm

The paradigm used in most studies of emotional expression in music performance is simple: performers are asked to play a number of brief melodies to express different

emotions chosen by the researcher. The resulting performances are first recorded and then evaluated in listening experiments to see whether listeners can recognize the intended expression. Each performance is further analysed to study what acoustic means the performer used to achieve each emotional expression. (The focus in these experiments has primarily been on *represented* emotion rather than *induced* emotion.) The basic assumption is that because the melodies remain the same in different expressions, whatever effects appear in listeners' judgments or in acoustic measures should mainly be the result of the performer's expressive intention. To have performers play the same piece of music with different kinds of emotional expression might seem 'unnatural' from a musical point of view. However, this design is necessary to secure the internal validity of the experiments: If different emotions are expressed by different melodies, it is impossible to know whether the obtained effects on listener judgments or performance measures are due to the melody, the performance, or some complex interaction between the two. This paradigm is not without its problems, but I will temporarily postpone my critique until later sections (for alternatives approaches to studying emotional expression in performance, see Section 14.7.1).

There are about 30 studies of emotional expression in performance. These studies cover a broad range of musical styles, such as opera, classical music, folk music, jazz, and pop/rock. The emotions investigated have usually included happiness, sadness, anger, fear, and tenderness. A variety of musical instruments has also been included, such as the violin, flute, clarinet, electric guitar, piano, trumpet, drums, synthesizer, and singing voice. Studies have mainly focused on two aspects of the communicative process: (a) the accuracy of the communication; and (b) the code used by performers and listeners.

14.4 Communication accuracy

The first question of interest to any researcher concerned with emotional communication in music performance is whether such communication is at all possible. It can seem odd to talk about 'accuracy' in the context of music, but most performers are probably concerned about whether their interpretation of the music is perceived in the intended way by listeners. Thus, the extent to which a performer and a listener agree on the expression of the performance can be seen as a measure of the 'accuracy' of the communication. In a pioneering study, Kotlyar and Morozov (1976) asked ten opera singers to sing phrases from various pieces of music in such a way that they would communicate joy, anger, sorrow, and fear to listeners. Musically trained listeners were asked to judge the expression of each performance. The results showed that the listeners were highly successful at recognizing the intended expression.

Since then, many studies have confirmed that professional music performers are able to communicate particular emotions to listeners (Behrens & Green 1993; Gabrielsson & Juslin 1996; Gabrielsson & Lindström 1995; Juslin 1997*a*, 2000; Juslin & Madison 1999; Ohgushi & Hattori 1996*a*; Sundberg *et al.* 1995). However, these studies have also revealed marked individual differences in *encoding* (expression) and *decoding* (recognition) accuracy, consistent with the results from studies of other non-verbal communication channels (Buck 1984; Wallbott & Scherer 1986). Studies of amateurs have

indicated that they have a lower accuracy than experts, but that their accuracy can be improved by appropriate feedback (Juslin & Laukka 2000).

Few studies have reported the decoding accuracy in a manner that makes more precise estimates possible. However, Juslin (1997*b*) used a forced-choice format in order to make the results comparable with the results from studies of vocal expression. Juslin found that decoding accuracy was 75 per cent correct, or about four times higher than what would be expected by chance alone. This suggests that, at least under ideal circumstances, the accuracy of communication of emotion via musical performance may approach the accuracy of facial or vocal expression (cf. Ekman 1973; Scherer 1986). The examination of error distributions shows that certain pairs of emotional expressions are confused more frequently than others. For instance, sadness and tenderness expressions are typically confused with each other, whereas sadness and happiness expressions are rarely confused. On the whole, though, the communicative process is robust.

One objection to this finding could be that the accuracy of the communicative process is boosted because of the response formats used. In most studies, listeners made their judgments by means of forced-choice or adjective ratings, methods which offer only a limited number of response options. To address this problem, Juslin (1997*c*) investigated the generalizability of decoding accuracy across response formats using a *parallel enrichment procedure* (Rosenthal 1982). That is, quantitative data from forced-choice judgments of musical performances were augmented by qualitative data from free labelling of the same performances. The two methods converged on the conclusions that: (a) communication was reliable regardless of the response format; and (b) what could be communicated reliably was the basic-level emotion categories, but not specific nuances within these categories.

14.5 Code usage

The early studies were primarily concerned with investigating whether performers are able to communicate emotions to their listeners at all. However, if we want to study communication as a process, we must also consider its mechanisms, particularly the code used by performers and listeners. Accordingly, researchers have tried to describe the means by which performers express specific emotions (Baroni & Finarelli 1994; Gabrielsson & Juslin 1996; Gabrielsson & Lindström 1995; Juslin 1997*a*, 1997*b*, 2000; Juslin & Madison 1999; Rapoport 1996).

14.5.1 Expressive cues, emotion categories, and emotion dimensions

One main finding from this line of research is that the performer's expressive intention affects almost every aspect of the performance; that is, emotional expression in performance seems to involve a whole set of *cues*—or bits of information—that are used by performers and listeners. A summary of the code usage established in studies thus far is presented in Fig. 14.2. Included are the five emotions (happiness, sadness, anger, fear, love/tenderness) that have been studied most extensively. These emotions represent a natural point of departure since all are regarded as typical emotions by lay people (see Shaver *et al.* 1987; Shields 1984) and have been postulated as so-called 'basic emotions'

by scientists (Plutchik 1994, p. 58). The same emotions have also occurred (some more than others) in the expression marks of musical scores (e.g. *festoso, dolente, furioso, timorosi, teneramente*).

Figure 14.2 combines *categorical* and *dimensional* approaches to emotional expression to illustrate that the code allows performers to communicate both graded signals (e.g. level of activity) and categorical signals (e.g. happiness). Each emotional expression is placed at an approximate point in a two-dimensional emotion space constituted by *valence* and *activity level* (cf. Russell 1980). The placement of each emotional expression in the emotion space is partly based on the results from a study in which participants rated the valence and activity of 400 emotion terms (Whissell 1989). These positions of the emotional expressions are further supported by a cluster analysis of listeners' ratings of various emotional expressions reported in Juslin (1997*b*). Figure 14.2

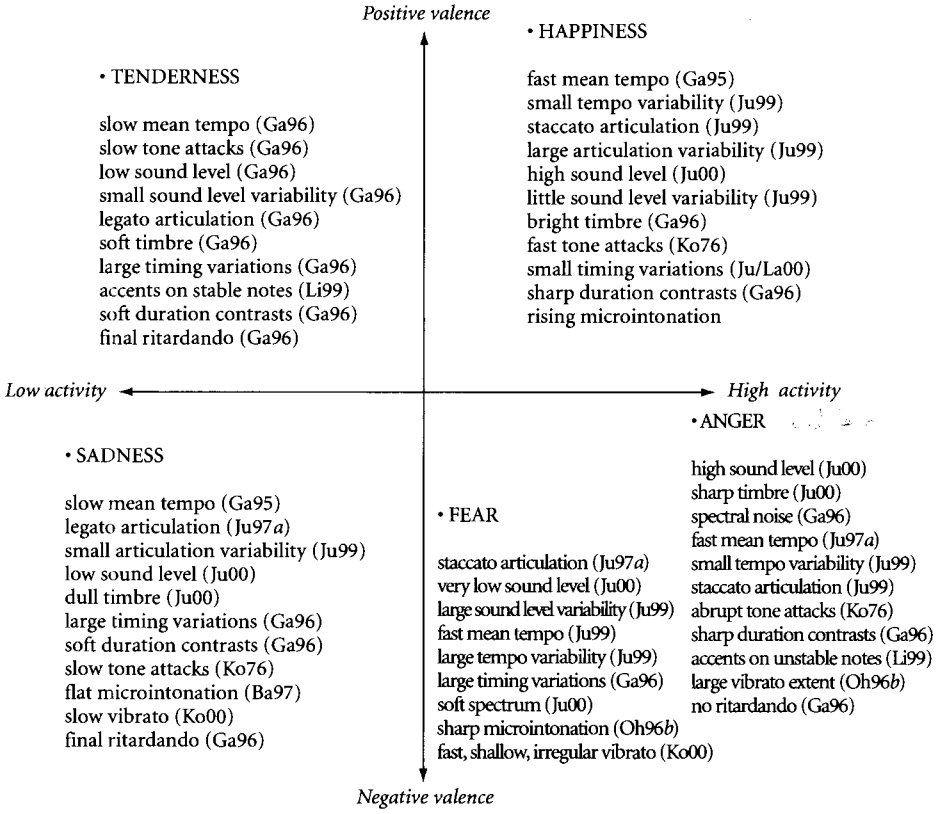

Figure 14.2 Summary of cue utilization in performers' communication of emotion in music. (One representative study is cited for each cue. Authors' names are abbreviated to the initial two letters of the first author (and the second author if needed for clarity), and the publication year to the two last digits, e.g. Ko76 = Kotlyar & Morozov 1976.)

shows that happiness and tenderness expressions are both positive, whereas only happiness is high in activity. Similarly, both anger and sadness expressions are negative, whereas only anger is high in activity.

As seen in Fig. 14.2, the expressive cues include tempo, sound level, timing, intonation, articulation, timbre, vibrato, tone attacks, tone decays, and pauses. Both the mean level of a cue and its variability throughout the performance may be important for the communicative process. For example, sadness expressions are associated with slow tempo, low sound level, legato articulation, small articulation variability, slow tone attacks, and dull timbre, whereas happiness expressions are associated with fast tempo, high sound level, staccato articulation, large articulation variability, fast tone attacks, and bright timbre (for a more detailed review, see Juslin 1999). Although Fig. 14.2 is limited to a few seemingly 'static' emotion categories, it is easy to imagine how the emotional expression can be gradually altered during the course of a performance, along the two emotions dimensions.

Some of the cues described in Fig. 14.2 may be common knowledge to most performers, whereas other aspects, such as those having to do with the *microstructure* (e.g. timing) of the performance, are less obvious. The number of cues available depends on the instrument used. In addition, the cue utilization is not completely consistent across performers, instruments, or pieces of music (Juslin 2000). Notably, even children (4–12 years old) seem to be able to use some of these cues to express emotions in song. For instance, they use a fast tempo and a high sound level in happy expressions, whereas they use a slow tempo and a low sound level in sad expressions (Adachi & Trehub 1998).

The positions of the emotional expressions in the emotion space in Fig. 14.2 suggest that certain cues may have a larger influence on certain emotion dimensions than others. Thus, for instance, tempo, sound level, and articulation seem to be especially important for the activity level, whereas timbre (e.g. the amount of high-frequency energy in the spectrum), perhaps in combination with sound level, seems to be especially important for emotional valence. In the latter case, intermediate levels of sound level and high-frequency energy are associated with positive emotions, whereas more extreme levels (e.g. very high or very low sound level) are associated with negative emotions. This hypothesized two-factor structure can, of course, be tested in future research, using listening tests with synthesized performances.

As suggested by Fig. 14.2, research to date has primarily focused on the expressions of a set of 'basic emotions' (Sloboda & Juslin, this volume). However, it is interesting to speculate whether 'secondary' or 'complex' emotions may be developed from these expressions. Many emotion researchers believe that such emotions constitute 'mixtures' of more basic emotions. For instance, it has been proposed that pride involves the combination of happiness and anger (Plutchik 1994, p. 61). Judging from Fig. 14.2, the expression of pride would then presumably involve some kind of compromise among the cues used to communicate happiness and anger, although perhaps with a slightly lower activity level (cf. Whissell 1989).

Performance analyses have shown that performers may use a number of cues to express specific emotions. However, these analyses do not show that listeners actually *use* the same cues in their judgments. To test the validity of hypotheses derived from performance studies, it is therefore necessary to conduct listening experiments with

synthesized and systematically varied performances. Such experiments have mostly confirmed that listeners make the same associations between cues and emotion categories as performers do (Juslin 1997*b*; Scherer & Oshinsky 1977; see also Bresin & Friberg 2000; Juslin *et al.*, in press).

In addition to the results with regard to relationships between acoustic cues and emotion categories, Juslin (1997*b*) reported findings on how acoustic cues contribute to the perceived 'expressiveness' of the performance. Juslin manipulated the tempo, sound level, articulation, timbre, and tone attacks of synthesized performances in a factorial design, and asked listeners to rate the expressiveness of the resulting 108 cue combinations. The single cue combination that was most expressive according to listeners had the following characteristics (with cues in order of predictive strength): legato articulation, soft spectrum, slow tempo, high sound level, and slow tone attacks. This raised an interesting question: Is this how performers should play in order to be judged as expressive by listeners? It may be noted that the most expressive cue combination was highly similar to the cue combination that expressed sadness and tenderness best according to the listeners. This seems to suggest that there is a close connection between sadness/tenderness and expressiveness. This result was confirmed by a cluster analysis of the listeners' judgments, which showed that the ratings of sadness and tenderness correlated more strongly with the ratings of expressiveness than did the ratings of happiness, fear, or anger. It is worth noting in this context that so-called 'separation calls', associated with social loss, are believed to elicit strong sympathetic responses in listeners (Plutchik 1994, p. 331). This could perhaps explain why listeners find performances with a sad expression particularly expressive.

14.5.2 The importance of musical time: expressive contours

Most studies thus far have focused on cues that remain 'fixed' during the performance or on 'summary measures' (e.g. mean, standard deviation) of cues that do vary. However, from an intuitive point of view, it would seem that much of music's expressiveness lies in patterns of *changes* in cues during the course of a performance. Frick (1985) used the concept 'prosodic contours' to refer to dynamic patterns of voice cues over time found in vocal expressions. In music, this corresponds to continuously changing patterns of tempo, articulation, and sound level throughout the performance (examples of patterns of articulation for different emotions are presented in Fig. 14.3). In this chapter, I will call these patterns *expressive contours*. Are such expressive contours involved in the communicative process?

Preliminary evidence that expressive contours are really involved in the communicative process was obtained in a study by Juslin (1997*b*). This study included two kinds of stimulus. The first consisted of a set of musical performances of 'Nobody Knows' on the electric guitar, made with different expressive intentions (e.g. sadness, happiness, tenderness). The second kind of stimuli consisted of synthesized performances of the same melody, in which the same emotional expressions were simulated on the basis of hypotheses from previous performance analyses. The 'human' performances included expressive contours, whereas the synthesized performances included only cues that were 'fixed' throughout the whole performance. Both kinds of performance communicated the intended emotions with high reliability.

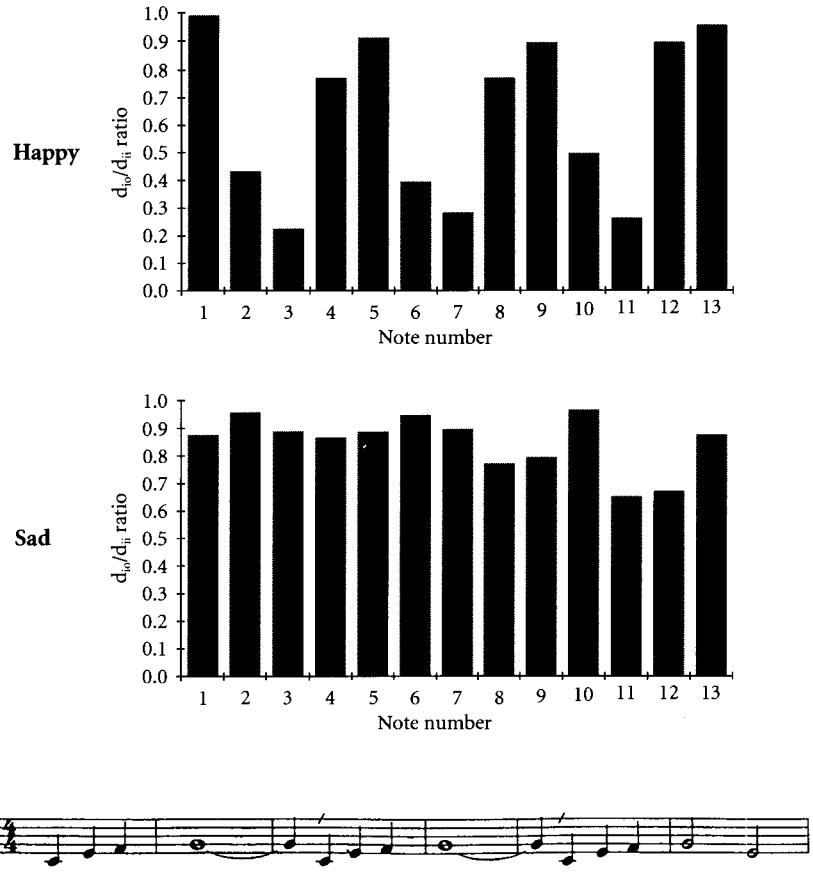

Figure 14.3 Articulation patterns for happy and sad performances of 'When the Saints' on the electric guitar (unpublished data from Juslin 1997*a*). The duration from the onset of a tone until the onset of the next tone (d_{ii}) and the duration from the onset of a tone until its offset (d_{io}) were used to calculate the d_{io}/d_{ii} ratio, i.e. the articulation. Articulation close to 1.0 may be referred to as legato, whereas articulation below 0.5 may be referred to as staccato.

To study the relative importance of expressive contours, Juslin played the performances backwards and then asked listeners to decode the intended emotional expression. Playing the sequences backwards changed the expressive contours (i.e. patterns over time) but preserved the summary measures (e.g. tempo) of the performances. The results showed that the human performances suffered from this manipulation (i.e. decoding accuracy was reduced), whereas synthesized performances did not. This suggests that human performances depend, at least to some extent, on the use of expressive contours. However, this study did not provide any clues about what expressive contours were used by listeners.

Further evidence that expressive contours may be of importance comes from a study by Juslin and Madison (1999). They used a combination of analysis and synthesis

afforded by the possibility to 'resynthesize' human performances by means of computer technology. This method was used to investigate the relative importance of timing patterns in communication of emotions through musical performance. Juslin and Madison gradually removed different expressive cues (tempo, dynamics, timing, articulation) from piano performances played with various intended expressions (anger, sadness, happiness, fear) to see how such manipulations would affect a listener's ability to decode the emotional expression. The results indicated that: (a) removing the timing pattern yielded a decrease in listeners' decoding accuracy; (b) timing patterns alone were capable of communicating at least some emotions with better than chance accuracy; and (c) timing patterns were less effective in communicating emotions than were tempo and dynamics. The results further indicated that timing patterns (defined as sequences of inter-onset intervals) were particularly important for fear expressions, whereas articulation patterns were particularly important for happiness expressions. This study demonstrated that listeners indeed can use timing patterns to decode the emotional expression of a performance. However, the results did not reveal what it is in the timing patterns that provides the listeners with emotional information.

One way of exploring what it is in the expressive contours that provides the emotional information is to rely on listeners' continuous ratings of expression in performance. In recent years, researchers have increasingly been developing methods for describing the moment-to-moment changes in listeners' emotional responses to music (for a review, see Schubert, this volume). Most of the attempts have involved the use of different pieces of music. However, Sloboda and Lehmann (in press) have applied continuous response methodology specifically to performance. They focused on how music performers use various strategies to enhance the emotional intensity of a performance. Ten expert pianists were required to perform a Chopin prelude as if in a concert. The resulting performances were recorded and the performers were interviewed concerning their interpretations of the piece. Finally, musically trained listeners were asked to rate the concurrent level of perceived 'emotionality' in each interpretation by moving a mouse pointer on a continuous response computer interface.

The results indicated that the different interpretations of the piece gave rise to different profiles of perceived emotional intensity, and that at least some of the differences among the interpretations could be explained in terms of the expressive devices used by the performers. The performers used devices related to timing, dynamics, and asynchronies between melody notes and bass notes (e.g. delaying a note, lengthening a note, changing the dynamic range). Most of the expressive devices occurred at the beginnings of musical phrases. But can such devices be used by listeners to decode different emotions?

One possible answer is provided by research on how notated structure and performed structure *interact* in producing an emotional expression. In a recent study, Lindström (1999) manipulated a brief melody ('Frère Jacques') concerning tonal progression, rhythm, melodic contour, and melodic direction. The resulting versions of the melody were rated by listeners on emotion scales. On the basis of these ratings, Lindström chose 16 versions of the melody that could be regarded as 'good' or 'less good' exemplars of specific emotions (e.g. anger). Then, he asked professional pianists to play the different versions of the melody to express four different emotions (happiness,

sadness, anger, tenderness) to listeners. The performers were asked to 'think aloud' throughout the preparation of the performance.

Two findings were of particular interest. First, there was a 'compensation tendency' in the performances, such that the performers used more 'extreme' variations in the performance to achieve the intended expression (e.g. happiness) in those versions of the melody that were 'less good' exemplars of the intended emotion. Second, the results showed that the performers accentuated different features of the melodic structure depending on the intended expression. Thus, for example, if a certain note in the melody structure was seen as particularly 'happy', then the performers emphasized this note (e.g. via accents in timing, dynamics, articulation) in happiness expressions, but de-emphasized it in sadness expressions. However, the general pattern of cues was the same as in previous studies, which suggests that it is mainly the local aspects of the performance that are affected by particular melodies, whereas overall cues (e.g. mean tempo, mean articulation, mean sound level) are used pretty much the same regardless of the particular melody (see Juslin 2000). In sum, it seems that, depending on the intended expression, different parts of the melodic structure are emphasized. This might explain how listeners can arrive at judgments of the expression on the basis of expressive contours.

This section has shown that there are a number of acoustic cues that performers can use to communicate emotions to listeners. But many studies have shown that cue utilization is inconsistent both across and within performers. Similarly, listening experiments have shown that cue utilization is inconsistent both across and within listeners (cf. Juslin 1998). This presents something of a puzzle: how can the communicative process be so reliable if the cue utilization is inconsistent? To explain the characteristics of the communicative process, we need a theoretical framework.

14.6 A theoretical framework: the functionalist perspective

One explanation of the scarcity of studies of emotional expression in music performance prior to 1990 might be a lack of relevant theories. This has led to a neglect of expressive aspects of performance in both research and education. One candidate for a useful theory would seem to be Clynes' (1973, 1977) 'sentic' theory, in which he argued for the existence of biologically pre-programmed spatiotemporal forms, or *essentic forms*, for the communication of specific emotions. Unfortunately, independent attempts to replicate these spatiotemporal forms have yielded mixed results (e.g. Gorman & Crain 1974; Nettelbeck *et al.* 1989; Trussoni *et al.* 1988).

The only elaborated theoretical framework aimed specifically at performance aspects has been presented by Juslin (1995, 1997*a*). Juslin suggested that researchers should adopt a *functionalist perspective* on emotional communication in music performance. This involves the integration of ideas from research on emotion and non-verbal communication with Egon Brunswik's (1956) *probabilistic functionalism*. This framework provides useful questions, hypotheses, and ways of interpreting results. The functionalist perspective is concerned with three aspects of the expressive code: (a) its origin; (b) its description; and (c) its improvement. The following sections focus on the first two of these aspects. For a discussion of applications for music education, see Juslin and Laukka (2000) and Juslin and Persson (in press).

14.6.1 Origin of the code

The fact that performers are able to communicate emotions to listeners is something that requires an explanation: What is it that makes this possible? What is the origin of the code used by performers and listeners? According to the functionalist perspective, the key to this problem lies in considering the *functions* that communication of emotions has served—and continues to serve—in social interaction (e.g. Darwin 1872). Although music performance may be a recent addition to the human behavioural repertoire, it must still be constrained by psychological mechanisms that have been shaped by evolution (Juslin 1998). Evolutionary considerations may be particularly relevant for emotional communication, because animals also communicate emotion, for instance, via acoustic signals (e.g. Plutchik 1994, Chapter 10). Accordingly, Juslin (1998) has argued that communication of emotion in music performance reflects two factors: (a) brain programmes; and (b) social learning. Each of these factors will be discussed below.

Brain programmes

The first factor hypothesized to govern emotional expression in performance is innate 'brain programmes' for vocal expression of emotion. Studies of both monkeys and humans with brain lesions have investigated the neurological 'substrates' underlying spontaneous vocalizations of emotion (e.g. Jürgens & von Cramon 1982; MacLean 1978; Panksepp 1982; Penfield & Roberts 1959; Ploog 1981, 1986). These studies have yielded evidence of 'brain programmes' that function to initiate and organize 'pre-wired' vocal expressions. Electrical stimulation of particular brain structures in the amygdala and the hypothalamus produces vocalizations that observers cannot distinguish from natural expressions. In humans, at least, these 'pre-wired' vocal expressions can also be executed at will for communicative purposes, thanks to brain structures in the anterior cingulate cortex. Such 'brain programmes' might explain the reported cross-cultural agreement in encoding and decoding of vocal expressions (Frick 1985). There is further evidence that both encoding (Shapiro & Danly 1985) and decoding (Borod *et al.* 1998) of emotion through voice prosody is handled by the right hemisphere of the brain.

What, then, does voice prosody has do to with performance of music? According to the functionalist perspective, music performers are able to communicate emotions to listeners by using the same acoustic code as is used in vocal expression of emotion. The notion that there is a close relationship between music and the human voice has a long history (Helmholtz 1954; Kivy 1989; Rousseau 1986; Scherer 1995; Sundberg 1982). However, it seems unlikely that this link can explain all of music's expressiveness. I have thus suggested that the hypothesis that there is an iconic similarity between vocal expression of emotion and musical expression of emotion applies mainly to those aspects of the music that the performer can control during his or her performance, such as tempo, loudness, or timbre (Juslin, in press). Neuropsychological evidence suggests that certain aspects of music, such as timbre, share the same neural resources as speech, whereas others (e.g. tonality) draw on neural resources that are unique to music (Handel 1991; Patel & Peretz 1997). Further, the same brain hemisphere (the right) seems to be involved in perception of emotion in music and speech (Borod *et al.* 1998; Bryden *et al.* 1982).

In addition, whereas previous formulations of the link have been vague and speculative, the functionalist perspective specifies the actual neurological substrates responsible for these similarities, and leads to research that provides empirical evidence in favour of this hypothesis. Juslin (1999) carried out a systematic review of the code usage in vocal expression and music performance. The results revealed a number of similarities in code usage. For example, vocal expression of sadness is associated with slow speech rate, low voice intensity, low intonation, and little high-frequency energy in the spectrum of the voice (Juslin & Laukka, in press; Scherer 1986). The same acoustic cues are used to communicate sadness in musical performances (cf. Fig. 14.2).

Juslin also argues that encoding and decoding of emotions proceed in terms of a limited number of 'basic' emotion categories (cf. Ekman 1992; Izard 1977; Johnson-Laird & Oatley 1992; Oatley 1992), which provide decoders with the maximum information and discriminability (Ross & Spalding 1994). To be useful as guides to action, expressions are quickly decoded in terms of just a few categories of emotion related to such fundamental life problems as danger (fear), competition (anger), loss (sadness), and cooperation (happiness). It may be noted that even in the first months of life, infants are able to differentiate prototypical vocal expressions in infant-directed speech, and to respond adequately to their categorical messages (Papoušek *et al.* 1990). Indeed, infants may be able to decode vocal expression of emotion even earlier than they are able to decode facial expression (see Oatley & Jenkins 1996, Chapter 6). There is also evidence of categorical perception of emotion in vocal expression in adults (e.g. de Gelder & Vroomen 1996). This supports a conceptualization of the perception of emotion from acoustic stimuli in terms of basic emotion categories.

A related finding is that neurophysiologist and ethologist Ploog (1981, 1992) and his co-workers have managed to identify a limited number of vocalization categories in squirrel monkeys. (Note that the neurological substrates involved in vocalizations are rather similar in monkeys and humans.) The vocalization categories are associated with important events in the monkeys' lives, and include warning signals ('alarm peeps'), threat signals ('groaning'), desire for social contact signals ('isolation peeps'), and companionship signals ('cackling'). It seems plausible that vocal expressions deriving from 'brain programmes' discovered in humans have served—and still continue to serve—similar communicative functions (Panksepp 1982).

It is possible to speculate that vocal expressions associated with the 'basic' emotion categories gradually became meshed with music that accompanied related cultural activities. There is evidence that people can accurately categorize songs of different 'emotional' types (e.g. mourning, love, war, lullaby) that come from diverse cultures (e.g. Eggebrecht 1983). Moreover, there are similarities in the acoustic code used in such songs in different cultures; for example, mourning songs usually have a slow tempo, low sound level, and soft timbre, whereas festive songs have a fast tempo, high sound level, and bright timbre (Eibl-Eibesfeldt 1989). Thus, the acoustic code used by performers today may be linked—in functional ways—to important cultural activities of the past (Gregory 1997; see also Becker, this volume).

Social learning

The second factor governing emotional expression in performance is social learning or specific memories. This is a life-long process that begins with the socialization of

emotions. Certain aspects of music performance (e.g. those not shared with vocal expression) may be completely governed by cultural influences. Others—although based on innate mechanisms—are 'modulated' by experience. This modulation of the code begins with the early interaction between mother and infant (or even earlier, through 'biochemical imprinting' during the prenatal stage). When mothers talk to their infants, for example, if they want to calm their infant, they reduce the speed and intensity of their speech and talk with slowly falling pitch contours. If, on the other hand, mothers want to express disapproval towards some unfavourable activity they use brief, sharp, and staccato-like contours (Papoušek 1996). Thus, as Papoušek argues, the origins of expressive skills in music cannot be easily separated from the earliest stages of emotional communication.

The shaping of the expressive code continues throughout life, along with accumulated experience. Performers learn links between expressive cues and extramusical aspects (e.g. body language, biological motion) through analogies (cf. Sloboda 1996). In the professional career, the code is modulated by advice from music teachers, performance conventions, and the use of metaphors. This second factor of social learning, reflecting cultural influences, could explain: (a) the individual differences among performers; (b) why the cue utilization is inconsistent; and (c) why there are cultural differences in cue utilization. However, Juslin (1999) assumes that the 'core' of the expressive code is provided by the first factor—innate brain programmes for vocal expression. This could explain why expressive skills are often regarded as 'instinctive'.

Predictions based on the functionalist perspective that have received empirical support include: (a) that there are similarities in cue utilization between vocal expression and musical performance (Juslin 1999); (b) that basic emotions are easier to communicate than other emotions (cf. Gabrielsson & Juslin 1996; Gabrielsson & Lindström 1995; Senju & Ohgushi 1987); (c) decoding of emotion from music is quick (Peretz *et al.* 1998); (d) decoding of emotion from music performance is largely independent of musical training (Juslin 1997*a*); (e) that even children, 3–4 years old, are able to decode such basic emotions as happiness, sadness, anger, and fear in music with better than chance accuracy (see Cunningham & Sterling 1988; Dolgin & Adelson 1990; Kratus 1993; Terwogt & van Grinsven 1988); and (f) that listeners are able to decode basic emotions with accuracy better than chance even from single voice tones (Konishi *et al.* 2000).

One more prediction is that there should be cross-cultural agreement regarding some aspects, at least, of music's expressiveness. A common hypothesis is that there is universal recognition of emotions from vocal expression. For instance, Frick (1985) reviewed a large number of cross-cultural studies of vocal expression of emotion and concluded that 'there is little evidence for . . . cultural differences in the prosodic communication of emotion' (p. 414). If, as I have claimed, there are many similarities in cue utilization between vocal expression and music performance, we would expect to find some degree of cross-cultural agreement in listeners' judgments of emotional expression in musical performances. Thus, Juslin (1997*b*, p. 248) proposed that 'some aspects of music (e.g. tonality, melody, and harmony) are relatively more culture-specific, whereas other aspects . . . are more culture-independent (because they are based on nonverbal communication of emotion)'. This notion was subsequently turned into a formal model by

Balkwill and Thompson (1999). While few studies have explicitly aimed to address this issue, there is evidence of cross-cultural similarities in performers' utilization of cues from studies in India (Balkwill & Thompson 1999), Russia (Kotlyar & Morozov 1976), Italy (Baroni & Finarelli 1994), Japan (Ohgushi & Hattori 1996*b*), Sweden (Juslin 1997*a*), and Germany (Langeheinecke *et al.* 1999). These studies suggest that cues like tempo, sound level, and timbre are used in a similar manner in different cultures. When it comes to cross-cultural studies that involve other cues (e.g. harmony), there are larger cross-cultural differences (Gabrielsson & Juslin, in press).

The discussion so far has mainly been concerned with the origin of the acoustic code used in the communication of emotion in music performances. However, to truly understand the virtues and limitations of the communicative process, it is also necessary to describe the nature of the code in more detail. The following section describes a conceptual tool that may be useful in describing the essential characteristics of the communicative process.

14.6.2 Description of the code: the lens model

Juslin (1995, 1998, 2000) suggested that the communicative process be described in terms of a modified version of Brunswik's (1956) well-known 'lens model' (Fig. 14.4). This model is meant to illustrate how music performers *encode* specific emotions by means of a number of *probabilistic* (i.e. uncertain) albeit partly redundant *cues* in the performance (e.g. tempo, sound level, timbre, articulation). The emotions are *decoded* by listeners who use the same cues to judge the emotional expression. The cues are probabilistic in the sense that they are not wholly reliable indicators of the intended expression. Listeners thus have to *combine* the cues in order to arrive at reliable judgments of the expression. Brunswik's (1956) notion of *vicarious functioning* may be used

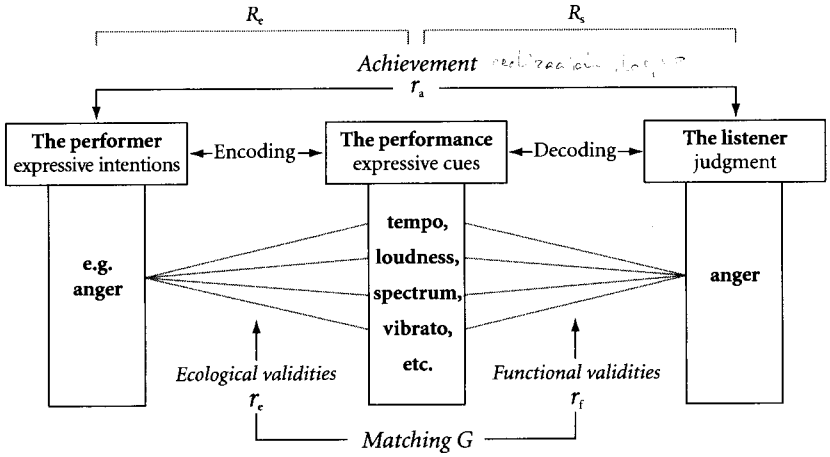

Figure 14.4 A Brunswikian lens model for communication of emotion in music performance (adapted from Juslin 1995).

to describe how listeners use the partly interchangeable cues in flexible ways, sometimes shifting from one cue that is unavailable to another that is available.

Intercorrelations between cues partly reflect how sounds are produced on instruments. For example, hitting a string harder on the electric guitar generates a tone with increased sound level, but it also generates more high-frequency energy in the spectrum of the tone. However, intercorrelations between cues may also reflect how performers use the cues to accomplish different expressions (e.g. the use of high sound level and fast tempo in both anger and happiness). Empirical studies have confirmed that the cues in performances are probabilistically related to both performers' intentions and listeners' judgments (see Juslin 1997*a*, 1997*b*, 2000), and that there are cue intercorrelations (Juslin 1997*a*; Kratus 1993). Studies using synthesized music performances that are varied in a systematic manner have suggested that the performance cues contribute independently—in an additive fashion—to listeners' emotion judgments, as evidenced by a lack of interactions among the cues (e.g. Juslin 1997*b*). Notably, this is consistent with findings from studies of the vocal expression of emotion, which involve many of the same cues (Ladd *et al.* 1985). However, it stands in contrast to the findings from studies that manipulate aspects of the melodic structure (see Gabrielsson & Lindström, this volume).

The redundancy of the cues reduces the uncertainty of the communicative process. On the other hand, it also limits the information capacity of the communicative channel, because the same information is conveyed by many cues. In Brunswik's own words, the system aims at 'smallness of error at the expense of the highest frequency of precision' (1956, p. 146); such a system leads to 'compromise and falling short of precision, but also the relative infrequency of drastic error' (1956, p. 145). It is easy to see how a system for communication of emotions with this characteristic could have survival value. It is ultimately more important to avoid making serious mistakes (e.g. mistaking anger for joy), than to have the ability to make more subtle discriminations between emotions (e.g. detecting different kinds of joy). The characteristics of the present communicative system can thus be partly explained by evolutionary pressures of the past (Juslin, 2001).

A 'Brunswikian' conceptualization of the communicative process in terms of separate cues that are 'integrated'—as opposed to a 'Gibsonian' conceptualization in terms of more holistic 'higher-order variables' (Gibson 1979)—seems to be supported by studies of the physiology of listening. Handel (1991) points out that speech and music use similar perceptual mechanisms, and that the auditory pathways involve different neural representations for different aspects of the acoustic signal (e.g. timing, frequency) that are kept separate until later stages of analysis. Perception of both speech and music requires the integration of these different representations. (Of course, the question of exactly which acoustic cues are relevant and how they should be defined is an empirical matter.)

In the lens model, the relationship between the performer's expressive intention and a cue in the performance (e.g. articulation) describes the *ecological validity* (r_e) of that cue (Fig. 14.4). Ecological validity is a measure of the validity of that cue in predicting the performer's intention. The *functional validity* (r_f) of the same cue is indexed by the relationship between the cue and the listener's judgment. Functional validity is a measure

of the validity of the cue in predicting the listener's emotion judgment. *Achievement* (r_a) refers to the accuracy of the communication, as measured by the relationship between the performer's intention and the listener's emotion judgment. Finally, *matching* (G) refers to the extent to which ecological and functional validities are 'matched' to each other—that is, whether the performer and listener share a common code (the measurement of each of these quantities is described below).

The Brunswikian lens model has a number of important implications. First, we cannot expect perfect communication accuracy. If cues are only probabilistic, it means that accuracy can only be probabilistic. Second, to understand why the communication is successful or not in a particular situation, researchers need to describe both encoding and decoding in terms of the same concepts. Third, because the cues are intercorrelated to some extent, many different cue utilization strategies can lead to a similar level of accuracy (cf. Dawes & Corrigan 1974). There is a virtue associated with the redundancy of the communicative process: because there is no pressure toward uniformity in cue utilization, performers are able to communicate basic emotions successfully without compromising their unique styles of playing.

One problem in analysing cue utilization is that the strategies used by performers and listeners are largely *implicit* in nature (Juslin & Laukka 2000; Sloboda 1996). Therefore, we need to somehow externalize their expressive strategies. One useful approach to this problem may be to use multiple regression analysis (MRA) to describe the complex relationships between: (a) the performer's expressive intention and the cues (ecological validities); and (b) the listener's judgment and the cues (functional validities). MRA is a data-analytic method flexible enough to handle the complexity of the communicative process (e.g. multiple cues, uncertainty, intercorrelations among cues). MRA also permits us to describe performers and listeners in terms of similar concepts, so that their *cue weights* (i.e. the extent to which they rely on particular cues) can be compared (for details on how this is done, see Juslin 2000).

As demonstrated by Juslin (2000), MRA models of performers and listeners can be mathematically related to each other by means of the *lens model equation* (LME). The LME was originally presented in an influential article by Hursch *et al.* (1964) in the context of studies of human judgment. In such studies, the goal was to relate the judge's cognitive system to a statistical description of the judgment task (Cooksey 1996). However, the LME can also be used to describe communication of emotion in music performance.

The LME (eqn 14.1) embodies the fact that communication accuracy, or achievement (r_a), is a function of two additive components. The first component is usually called the *linear* component because it represents that component of the achievement which can be attributed to the linear regression models of the performer and the listener. The linear component shows that achievement is a function of *performer consistency* (R_e), *listener consistency* (R_s), and *matching* (G). Performer consistency refers to the multiple correlation of the performer model (i.e. performer's intention and cues), whereas listener consistency refers to the multiple correlation of the listener model (i.e. listener's judgment and cues). Both indices reflect the extent to which the regression models fit the cue utilization and are usually interpreted as measures of consistency, or

predictability, of the cue utilization. If $R = 1.0$, then the cue utilization is perfectly consistent. Matching (G) is a measure of the extent to which the beta weights of performers and listeners are 'matched' to each other; that is, whether they use the same code. This index is obtained by correlating the predicted values of the performer's regression model with the predicted values of the listener's regression model. The resulting correlation is interpreted as the extent to which the performer's beta weights and the listener's beta weights would agree if both regression models were perfect (i.e. $R_e = R_s = 1.0$).

$$r_a = G R_e R_s + C\sqrt{(1-R^2_e)}\sqrt{(1-R^2_s)} \quad (14.1)$$

If the communication under study is unsuccessful, we may ask whether this is because: (a) the performers use a different code than the listeners (indicated by a low G value); (b) the performers apply their code inconsistently (indicated by a low R_e value); or (c) the listeners apply their code inconsistently (indicated by a low R_s value). These three factors set the upper limit of achievement (Hursch *et al.* 1964). By analysing each of them separately, it becomes possible to see how the communicative process could be improved (Juslin & Laukka 2000).

The second component of the LME is usually called the *unmodelled* component of the communicative process. It includes both unsystematic and systematic variance not accounted for by the linear component. This includes effects of inconsistent cue utilization, order effects, distractions, memory intrusions, omission of relevant cues, or *configural cue utilization* (i.e. the use of particular patterns of cue values). $(1-R^2_e)$ and $(1-R^2_s)$ refer to the residual variance of the regression models of performers and listeners, respectively. C—or *unmodelled matching*—represents the correlation between the residuals of the performer's model and the residuals of the listener's model. If C is high it indicates: (a) a common reliance on cues in the performance not included in the regression models; (b) chance agreement between random model errors; (c) cue interactions common to both models; or (d) non-linear cue function forms common to both models (Cooksey 1996). However, research indicates that the unmodelled matching of the cue utilization is relatively small in music performance (Juslin & Madison 1999).

Analyses based on the lens model paradigm have generated a number of findings. First, linear regression models provide a good fit to the cue utilization, explaining approximately 70–80 per cent of the variance in expression and judgment (see Juslin 1997*b*, 2000). Second, achievement seems to depend mainly on the extent to which the cue utilization of the performer is 'matched' to the cue utilization of the listener (at least as regards professional performers; amateur performers may also differ with regard to the consistency of their cue utilization) (Juslin & Laukka 2000). Third, cue utilization is more consistent across different pieces of music than across different performers. That is, performers use pretty much the same code regardless of the melody, but there are considerable individual differences between performers. Fourth, two performers can communicate equally well despite slight differences in their cue utilization (see Juslin 2000). Finally, it has been shown that the lens model paradigm can be used to improve performers' expressive skills through so-called 'cognitive feedback' (Juslin & Laukka 2000).

14.7 Implications and directions for future research

Viewing emotional communication in music through a Brunswikian 'lens' has a number of important implications. First, previous studies have tended to focus on either performance or perception. The Brunswikian lens model provides the tool for an ultimately more interesting enterprise: how to *relate* performance to perception. Each of the two aspects can only be fully understood in relation to the other. Second, future studies should consider a whole set of cues to deal with the complete code used and thereby permit both performers and listeners to show their capacity for vicarious functioning. Third, future studies should analyse sufficiently large samples of performers, listeners, and pieces of music to allow for a greater generality and the use of multivariate methods, such as MRA. This recommendation parallels Brunswik's own insistence that we should deal with the phenomenon under study 'on an adequate level of complexity' (1952, p. 1). Lens modelling is an attempt to capture the relationships among *subjective* intentions or judgments and *physical* characteristics of music performances, and can therefore be conceived of as 'emotional psychophysics'.

14.7.1 Limitations of previous research

There are a number of limitations of previous research, which provide incentives for further research. First, studies of emotional communication in music performance have mainly been conducted in the laboratory. For obvious reasons, scientists have striven to obtain internally valid results using experimental methods. However, it is now high time to bring the research from the laboratory into the 'field'. We still have limited knowledge about how performers communicate emotions to listeners in real life. How reliable is a performer's communication under realistic conditions? Ways of getting closer to 'ecologically valid' settings might be to analyse existing recordings of performances (Rapoport 1996; Siegwart & Scherer 1995) or to observe performers, from the preparation of a piece to the actual performance in a concert.

Second, the research summarized in this chapter has largely rested on the assumption that the encoding process proceeds more or less independently of the musical structure, but this assumption may be questioned. Performers usually modulate their cue utilization to suit specific compositions, hence there is some inconsistency in cue utilization across different pieces of music (Juslin 2000). Future research should focus on the *interaction* between the composed structure and the performance in determining the expression of a piece of music. The studies of emotional expression in performance in the 1990s measured performance effects separately from structural effects. Now, after 10 years of research, we may be ready to start considering composition and performance together; to study the complete process. One way of doing this could be to expand the lens model further to also include cues associated with the structure of particular pieces, such as rhythm, mode, melodic contour, and tonal progression.

A number of researchers have raised the question whether performances recorded under laboratory conditions produce very different results than performances recorded under natural conditions, such as a concert (Rapoport 1996). Because we lack data on this issue, the jury is still out. However, it seems plausible that similar patterns of effects will be found in realistic settings, but that the effects will be smaller. One reason for this

may be that performers often have to coordinate their own playing with that of other performers. This places constraints on their freedom of expression. In addition, the social dynamics within orchestras or bands may influence the expression of the music in ways that merit further research (Davidson 1997).

Only a few studies have explored emotional expression in natural music performances. Siegwart and Scherer (1995) investigated emotional expression in opera singing by analysing existing recordings by famous artists. They reported that: (a) different interpretations elicited significantly different listener ratings of emotional expressiveness; (b) voice samples differed substantially with respect to acoustic cues; and (c) listeners' judgments could be successfully predicted on the basis of the acoustic cues. These are important results, because they suggest that the effects reviewed in this chapter are not confined to the laboratory.

14.7.2 Directions for future research: the case of emotion induction

Thus far in the chapter, I have primarily been concerned with how emotion is *represented* in music performance. This simply reflects the fact that most studies to date have investigated representation of emotion—perhaps because *induction* of emotion is more difficult to study. In everyday life, however, the question of why particular performances of music manage to induce strong emotions in listeners is just as important. In this section, I suggest some ideas with respect to how expressive performances might induce emotional reactions in listeners. These ideas are admittedly speculative, but may serve as directions for future research.

First of all, it is possible that the expression of a performance may arouse emotions in listeners through a process of so-called *emotional contagion*, which has been defined as 'the tendency to automatically mimic and synchronize facial expressions, vocalizations, postures, and movements with those of another person and, consequently, to converge emotionally . . .' (Hatfield *et al.* 1994, p. 5). There is a large amount of evidence that people easily 'catch' the emotions of others when watching their facial expressions or hearing their vocal expressions, presumably through some kind of 'motor mimicry'. The fact that certain aspects of emotional expression in music are highly similar to vocal expression of emotion suggests that we get emotionally aroused by the voice-like aspects of musical performances (Juslin, in press).

One objection to this theory could be that most performances do not sound very much like vocal expressions, at least superficially (Budd 1985, Chapter 7; see also Davies, this volume). Why, then, should we react to performances as if they were vocal expressions? One explanation may be that emotional expression is processed by simple, automatic, and independent 'brain modules', which react to certain features in the stimulus (Fodor 1983). Such modules do not 'know' the difference between vocal expression of emotion and other acoustic expression but will react in the same way as long as certain cues (e.g. high speed, loud dynamics, fast attack, many overtones) are present in the stimulus (Juslin, in press). Evidence that we indeed react emotionally to performances of music as we do to vocal expressions comes from studies that use facial electromyography and self-reports to measure emotions (see Hietanen *et al.* 1998; Lundqvist *et al.* 2000; Neumann & Strack 2000; Witvliet & Vrana 1996; Witvliet *et al.* 1998). This modular view of perception of emotion in music is supported by evidence that processing of information about

emotion is largely implicit (Niedenthal & Showers 1991), that judgments of emotion in music are quick, and that researchers have obtained brain dissociations between judgments of musical emotion and of musical structure (Peretz *et al.* 1998).

A second way in which a particular performance might arouse emotions in its listeners involves the fact that emotional reactions often occur when musical expectations are violated in some way (Meyer, this volume). It is easy to imagine this happening with regard to music performances. Meyer (1956, p. 206) suggested that expressive variations in a musical performance may serve an aesthetic function by 'delaying an expected resolution', or otherwise 'creating psychological tension'. It should be observed that such effects may be achieved in different ways. For instance, a performer may enhance listeners' emotional responses to the music by emphasizing notes that are of particular 'significance' in the composition, thereby enhancing violations of musical expectations that are already latent in the structure. Support for this idea has been obtained in recent studies (e.g. Sloboda & Lehmann, in press).

However, a performer can also arouse emotions in listeners by performing in a manner that deviates from stylistic expectations with regard to the performance of a certain structure. In this case, the deviation does not serve to enhance significant aspects of the structure, but rather to create psychological tension through deviations from performance conventions. It should be noted that the most 'extreme' performances of classical music are often made by the most well-known performers (cf. Sloboda 1998). In some cases, expressive devices of a performance may have a direct impact on the physiological processes of the listener. Harrer and Harrer (1977), for example, have claimed that it is possible to 'drive' the pulse rate of a listener by dynamic changes in volume (e.g. the crescendo or decrescendo of a rolling drum beat). Moreover, sudden syncopations in a musical performance may be capable of producing premature heart beats. The use of such effects by music performers has been described in the vast literature on rubato. For instance, the famous virtuoso violinist Niccolò Paganini (1782–1840) is known to have used tempo rubato to great effect (Hudson, 1994).

14.8 Conclusion

In this chapter, we have seen that performers can communicate specific emotions to listeners by using a number of probabilistic but partly redundant cues in the performance. The relative importance of the performance for the expression of the music is likely to differ depending on the performer, genre, and piece of music—ranging all the way from the faithful rendition of a piece of avant-garde music to the heartbreaking, improvised solo of a blues number.

The vicarious functioning of cues allows performers to simultaneously communicate emotions to listeners in a universally accessible manner and develop a personal expression. This communicative system therefore constitutes the happy marriage of the general and the individual, of the biological and the cultural. The communicative process is fairly robust but has a limited information capacity, ultimately leaving it to the listeners to specify the precise 'meaning' of the music. The phylogenetic roots of the communicative system can explain its powerful impact, and also why many performers regard emotions as 'the essence of musical communication' (Persson 1995, p. 60).

The subtle emotional nuances of music may seem a distant cry from the evolutionary framework of 'basic emotions' that I have described in this chapter. But I would argue that, ultimately, the real force of music's expressiveness—if not its uttermost subtlety—resides in such roots. In writing about the origins of music, Rousseau (1986, p. 65) said:

> . . . how far from understanding the power of their art are those many musicians who think of the potency of sounds only in terms of their air pressure and string vibrations. The more they assimilate it to purely physical impressions, the farther they get from its source and the more they deprive it of its primitive energy. In dropping the oral tone and sticking exclusively to the . . . harmonics, music becomes nosier to the ear and less pleasing to the heart. As soon as it stops singing, it stops speaking. And then, with all its accord and all its harmony it will have no more effect upon us.

Thus, the music that touches us the most does not necessarily come from someone who 'plays and sings with the grace of a God', but from someone 'bold enough to act as a messenger of the heart' (Schumacher 1995, p. 314).[1]

PART V

THE LISTENER

CHAPTER 15

MUSIC AND EMOTION: DISTINCTIONS AND UNCERTAINTIES

LEONARD B. MEYER

I have the gall to divide this chapter into only *two* parts:[1] 'Distinctions' and 'Uncertainty'. The first section considers conceptual/terminological problems having to do with music and emotion, and provides the background and terminology for the matters considered in the second part. The distinctions made in Section 15.1 do not pretend to constitute a coherent argument but are connected by the succession of topics discussed. Section 15.2, the core of the chapter, is concerned with the role of uncertainty in human experience generally, and in musical/aesthetic experience in particular.

15.1 Distinctions

I begin by proposing a number of distinctions because, despite its empirical outlook and methodology, the psychological analysis of human emotional experiences—causes and responses—as well as humanistic theory have lacked conceptual specificity and precision. This is evident in the range of behavioural states considered 'emotional'. To take a representative example, Klaus Scherer (1994, p. 31) writes that some terms for emotions 'highlight the physiological, as in the case of "aroused" or "tired." Some are quite cognitive, like "bewildered" or "curious".'

It seems curious, however, to consider 'curious' or 'tired' as being emotions. Such 'states of being'—of awareness (e.g. 'that's an interesting idea') or of feeling (e.g. 'I'm hungry')—are not generally classed as emotions.[2] But are not feelings of sadness, joy, anger, etc., which *are* considered emotions, similarly states of being? So the question is: what are the necessary and sufficient psychological and/or physiological conditions for considering a state of being—a feeling—an emotion?[3]

[1] Since my role is supposed to be that of the 'resident humanist', I have taken the liberty of playfully paraphrasing the first sentence of Caesar's *Gallic wars*: 'All Gaul is divided into three parts'.

[2] If tiredness is disturbed or curiosity thwarted, emotion may be evoked; but the 'evoking agent' is the disturbance, the thwarting, and the uncertainty this produces, not the tiredness or the curiosity.

[3] In the course of thinking about these matters, a possible distinction occurred to me: namely, that states of being such as curiosity, hunger, fatigue, cold, etc. depend upon conditions *internal* to an individual, while love and hate, fear and anger, etc. also include conditions *external* to an individual.

Though, to the best of my knowledge, there has been no satisfactory answer to that question, we go on using the concept of emotion and distinguishing different kinds: love and hate, fear and courage, etc. We conceptualize and classify our experiences of the inner as well as the outer world because envisaging and choosing, which lie at the heart of human behaviour, occur primarily in terms of such classes rather than individual instances. So this part of the chapter attempts to distinguish some of the kinds of relationships involved in the interaction between music and emotion.

15.1.1 Emotional states versus emotional processes

States

Delineation and association: statistical parameters. As a rule, the terms used to characterize emotions denote what I will call emotional 'states'. When listeners or critics describe music as sad, happy, angry, elated, and so on, they are referring to such states. In music, such states are essentially delineated by the action of what I have called the 'statistical' parameters. These aspects of sound vary in *amount* or *degree*—for example, register (lower–higher), dynamic level (louder–softer), speed (faster–slower), continuity (gradual–abrupt), and so forth. Although the configuration of parameters delineating an emotional state fluctuates, state-defining parameters such as register, speed, and dynamic level remain relatively constant over moderate-sized segments of music. And it is this constancy that makes *naming* possible. Indeed, when subjects in psychological experiments identify emotions their answers are, for the most part, based on the disposition of statistical parameters. Put negatively, one cannot imagine sadness being portrayed by a fast forte tune played in a high register, or a playful child being depicted by a solemnity of trombones.

The identification and naming of states is a result of the association of different dispositions of statistical parameters with feelings characteristically evoked in natural or cultural *circumstances*. That is, we deem a passage to portray 'love' or 'anger' or 'jealousy' not because of knowledge of physiological responses or psychological constraints, but because of awareness of, and often empathy with, the feelings and behaviours that occur in particular sociocultural contexts.[4] Thus we recognize the sadness expressed in Macbeth's 'Tomorrow, and tomorrow, and tomorrow' speech because we know the circumstance in which it is delivered—that is, Macbeth's learning of his wife's death. In addition, of course, his feelings are communicated by the repetition of the word 'tomorrow', which in this context signifies sadness and depression, by his performance (slow, soft tone of voice, etc.), and his physical behaviour and facial expression.[5] If this view

[4] This calls attention to a methodological question: namely, when listeners record their responses to music by, say, pressing buttons or naming emotions, or when psychologists measure the physiological changes (in blood pressure, pulse rate, etc.) of listeners, what do the 'results' represent? Often it seems unclear whether the answers are a result of the subjects' *recognition* of the 'state' delineated by the music or of their own affective *response* to the musical patterning? In this connection, see Sloboda (1992).

[5] Though overt behaviour may be the result of an innate response, behaviour is usually influenced by cultural convention. This is the case because behaviour almost always acts as a sign that is implicative

has merit, then observed behavioural circumstances play an important role in the identification and classification of emotional states.

Classification. It is sometimes supposed that our understanding of the world begins with the peculiarities of the individual—person, work of art, landscape, and so on. But, though experiences of phenomena may be peculiar, the peculiar is almost always qualified by, and comprehended in terms of, a conceptual class. This is one of the reasons why understanding and responding to different styles of music depends on learning. For it is largely learning that enables composers, performers, and listeners to internalize the norms governing musical relationships and, consequently, to comprehend the implications of patternings, and experience deviations from stylistic norms.

Just as we classify the phenomenal world into physical and biological realms, styles of music into classic and romantic, folk and jazz, and phrase relationships into antecedent-consequent, so we classify emotions. In most cases, the classifications are fuzzy. They are so because the classes are abstractions from individual, though similar, relationships and experiences. And one of the problems with abstractions is the tendency to treat them as though they possessed a set of objective properties independent of context and culture. But unlike tuberculosis, the biological nature of what we conceptualize as emotional experience has not been ascertained.

Nevertheless we classify emotions. We do so for the same reasons that we classify and categorize the world in general: because to choose effectively, it is necessary to imagine the probability of coming events (whether the behaviour of people or of musical patterns), and such imagining invariably entails classification. One manifestation of the need to classify is our proclivity to give 'to airy nothing/A local habitation and a *name*' (Shakespeare, *A midsummer night's dream*, V. i, emphasis added).[6] Put prosaically—because they threaten our sense of predictive power, nameless phenomena are highly disturbing.

Awareness of, and responding to, the class of some phenomenon need *not*, however, involve conscious conceptualization or naming but rather recognizing and experiencing the relationships presented—that is, knowing how the kind of patterning *works*. The point is important because, as mentioned above, conscious classification and explicit naming tend to undermine uncertainty and weaken emotional response. Something akin to 'the suspension of disbelief' (discussed below) seems at work here. That is, because enjoying music is a matter of experiencing the tension of syntactic and native processes as well as the fluctuations of statistical parameters, listeners generally avoid

(both to the individual and to others) of probable subsequent behaviour. Put in evolutionary terms, emotional behaviour was evidently preadapted for communication. There is a need for careful cross-cultural studies of emotional representation. Are the emotional states classified and represented in Western culture differentiated and recognized in non-Western cultures? If so, are they similarly represented?

[6] The fundamental importance of categorization (classification) was the subject of studies that appeared in *Science* (Vol. 291, 12 January 2001) after this essay was written. The result relevant for this essay is summarized in the section, 'This week in science': 'Categories are the fundamental building blocks of nearly all higher level cognitive functions' (p. 207).

consciously classifying and naming kinds of relationships, techniques, or strategies. Just as a reader enjoys a poem not by 'watching the metaphors go by', but by responding to the relationships implicit in the comparisons, so experienced listeners respond to the implicative tension of a gap-fill melody or an antecedent-consequent phrase without conceptualizing its relational class.

Mapping versus relating. The conceptualization of feelings as phenomena independent of experiential context has led to a search for the neurological basis of emotion. However, although the areas of the brain that respond to some order of stimuli have been located and mapped, neurologists have yet to explain the nature of *relationships* within or between such areas.

The situation is not unlike that of the astronomers of ancient Greece who were able to map the heavens with considerable precision, but could not *explain* the relationships between the stars, planets, and the like. Neurological studies seem in a comparable position with respect to the mind. The brain has been mapped, and the areas that respond to different kinds of stimuli have been located; and, as with the Greeks, various areas have been given appropriate names. But while the parts of the brain that respond to specific musical stimuli have been identified, the neurological nature of the relationships between such stimuli remains a mystery. For example, the places in the brain that respond to the pitch A (440) and the C# above it, and those stimulated by the pitch E (660) and the G# above it, can be identified; but why both intervals are perceived as belonging to the same relational class (i.e. major third) remains to be explained.

Processes: native and syntactic

As observed above, emotional states fluctuate in intensity; and human empathy with the action of the music begets analogous feelings in listeners.[7] But like other fluctuations (e.g. in temperature, energy, or the stock market) changes in intensity or amount do not give rise to processes—that is, to changes involving *functionally differentiated relationships.* And, as argued in Section 15.2 below, crucial facets of the emotional experience of music lie in the realm of processes rather than that of states.

Two kinds of musical processes, 'native' ones and 'syntactic' ones, need to be distinguished.[8] Both are subject to the cognitive constraints of the mind and the physical ones of the body. Syntactic processes, however, also involve learning the norms of a particular

[7] Some emotional states require more contextual specification than others. For instance, musical representations of grief and joy, anxiety and calm are readily recognized by competent listeners (see, for example, Gabrielsson & Lindström, this volume; Juslin, this volume); but, because their recognition is more context-dependent, emotions such as jealousy and disgust are more difficult to represent in music alone. Consequently, their representation is, I suspect, relatively uncommon and when it occurs it tends to be accompanied by a text—a vocal part or a programme.

[8] In *Style and music* (Meyer 1989), I emphasized the different roles of syntactic and statistical parameters in creating musical relationships. As will be clear from what follows, though I am keeping the term 'statistical parameters', I now want to use the concept of *process* in connection with syntactic and native relationships. Although implicit in my earlier work, the implication-realization relationship was first made explicit in *Explaining music* (Meyer 1973), Chapters VI–VIII. The relationship has since been thoughtfully analysed, extended, and modelled by Eugene Narmour (1990).

musical style. As a result, native and syntactic processes almost always complement one another in the shaping of musical experience. Those based on the syntax of a style tend to be quite specific, but are historically and culturally circumscribed. Native processes, on the other hand, are less specific. But, as limitations common to humankind, they are essentially universal.[9]

The very existence of sound entails the use of the statistical parameters. Consequently, native and syntactic processes are invariably coordinate with, and qualified by, the action of statistical parameters. Responses to these parameters are also native, rather than learned. But because they are essentially matters of amount, statistical means do not give rise to functional differentiation. Rather what they involve is the *continuation* of prevalent action.

There is, however, an important exception: when amounts—whether of information or redundancy, of speed or intensity of stimulation—become excessive in relation to human cognitive capabilities, the native implication is change rather than continuation. The question is: to what? Because relationships of amount are without specific implications, the probability of the 'what' is uncertain. And when uncertainty is strong, almost any kind of change is welcome. A prolonged crescendo may *end* in silence or a jazzy fox trot, in a soft tremolo or a trumpet fanfare. Whatever the case, the proper term for such termination is indeed 'end', *not* close.

Processes, on the other hand, are functionally differentiated. For instance, the parts of the first phrase of Harold Arlen's 'Somewhere Over the Rainbow' perform different functions. The melody begins with an upward skip of an octave, a 'gap' (native process), whose physical effort implies the relaxation of the following conjunct descent, the 'fill', whose specific pitches are governed by tonal syntax. The fill also involves gradual reduction in physical tension through diminished motor emphasis, lower volume, increased rhythmic regularity, and simplification of texture. This 'abatement' implies ending. And in a tonal piece such as Arlen's, syntax transforms an end into a close. In addition, to 'make assurance double sure'(Shakespeare, *Macbeth*, IV. i), the final pitch of the fill constitutes a return to the first structural tone of the melody.

Like the gap–fill pattern just discussed, many native processes are manifestations of the gestalt principles of pattern perception: for example, once begun processes tend to continue to a point of stability or clear articulation; the mind tends to improve shapes, making them simpler—more regular and complete. Cognitive constraints also result in other native processes: for example, rapid note-succession is associated with high registers and small size; long, slow note-succession is associated with low registers and larger sizes;[10] as mentioned earlier, very high levels either of redundancy or of information imply change; and, as discussed below, forceful motor emphasis tends to weaken the effect of syntactic process.

[9] Preoccupied with the evident individuality of different cultures, ethnomusicologists have, it seems to me, neglected the influence of shared, 'native' constraints on the development and organization of the musics of different cultures.

[10] The interrelation among size, speed, and place seems a universal in all realms of being: the physical, biological, social, and perceptual. In this connection, see Schmid *et al.* (2000).

Although syntactic and native processes often complement one another in shaping musical experience, they are essentially independent variables. Thus, while an abatement process generally implies closure, closure could easily be thwarted by syntax—for instance, by an open-ended rhythmic pattern or a non-closural harmony. Or to take a converse case, potential syntactic closure can be undermined by a process whose regularity natively implies continuation. The need to weaken the momentum of a marked continuity process explains why, when a perfect cadence is preceded by regular motion by fourths and fifths, the chord on the second step of the scale is usually inverted (vi–ii6–V–I). Strong syntactic closure is possible because the 'native' continuity process is broken by the first inversion rather than a root-position ii chord.[11]

In other cases, though not congruent, processes may work together to shape experience. Such complementary interaction is evident in the duet of Aida and Radames, 'O terra, addio' at the end of Verdi's *Aida*. Because the initial gap (native) of a major seventh (G♭ to F) strongly implies a fill, the following rise to G♭ functions not only as a poignant, yet delightful, resolution to the tonic (syntactic), but also as an escape tone that descends to D♭, which begins the fill (native).

While syntactic and native processes may complement one another, the relationship of process to amounts is not complementary. Though the statistical aspect of music is a necessary condition for both kinds of processes, its action is inversely related to theirs. That is, the more compelling the action of statistical parameters, the less effective the processes which, as we shall see, shape emotional experience. When, however, syntactic and native processes are primary, statistical parameters tend to be subservient.

15.1.2 Implication

The distinctions between emotional states and emotional processes suggest that different kinds of relationships evoke and shape different facets of musical experience. The statistical parameters beget the physical–somatic conditions which, through empathy, characterize emotional states in the primal present. Syntactic and native processes not only beget physical empathy with music, but generate mental arousal that, directing attention to what is still to come, gives rise to implication.

Implication versus causation

Both syntactic and native processes generate implications—guesses (feelings) about how present patterns will be continued and perhaps reach closure. But because 'What's to come is still unsure' (Shakespeare, *Twelfth night*, II. iii),[12] implications are never more

[11] The desire to enhance closure also accounts for why, instead of continuing directly to the tonic, a descending melodic line (e.g. from the fifth of the scale) often moves from the second to the third step of the scale before closing on the tonic.

[12] I have used quotations from, and references to, Shakespeare's writings throughout this essay not only because I happen to know his works quite well, but because their variety and pertinence so often illustrate (with little qualification) points I want to make.

than *probable.* Consequently, it is important to distinguish implication from causation. As I put the point in *Style and music* (Meyer 1989, p. 96):

> The possibility of alternative consequences . . . may help to account for the difference between implication and causation. For though both involve 'if–then' relationships, causation is a special case in which the antecedent (cause) is a sufficient condition for the consequent (effect). Consequently, alternatives are not possible. The difference in our understanding of the two concepts is reflected in ordinary language. Though it seems entirely proper to assert that 'X *implied* Y, but Y did not occur,' it would seem illogical to assert that 'X *caused* Y, but Y did not occur.'

Implication: native and syntactic processes

Native as well as syntactic processes can give rise to implications. As observed earlier, the implication created by a gap such as the one that begins 'Somewhere Over the Rainbow' is the result of a native process. At the beginning of Mozart's Piano Sonata in A Major (K. 331), however, a *learned* syntactic process generates the implications that link the antecedent to the consequent phrase. Similarly, an antecedent 'when clause', such as begins Shakespeare's Sonnet 'When to the sessions of sweet silent thought', implies a consequent closure:

> But if the while I think on thee dear friend
> All losses are restored and sorrows end.

Notice that in both music and language, the 'suspense' created by syntactic or native processes is short range, as compared with 'referential' suspense—for example, about finding the culprit in, say, a detective story. Thus, while the implications of the deceptive cadence at the beginning of Beethoven's Piano Sonata in E Flat, Opus 81a ('Les Adieux') are reactivated during the movement, suspense is experienced locally. And this is also true of language. One cannot, for instance, imagine the implicative tension (suspense) of a 'when' clause at the beginning of a chapter lasting until its close.

Not all implications arise from the presence of orderly processes. As discussed in Section 15.2, some result from the human antipathy to disorder. For instance, whether resulting from unpredictable change or incomprehensible redundancy, uncertainty leads listeners to anticipate the advent of stability and order. Thus insistent repetition (coupled with harmonic instability and a gradual crescendo), such as occurs early in the development section of the first movement of Beethoven's Sixth Symphony (mm. 151ff.), leads listeners to anticipate change. The question is to what extent the expectation of change is a result of culturally acquired goal-directed proclivities; after all, marked beat redundancy does not seem to imply change in contemporary popular music.

15.1.3 Emotional expression and emotional experience

The nature of emotional expression versus emotional experiences (and related matters) has been widely discussed in the psychological literature. Accordingly, I have chosen: (a) to offer an early instance (*c.* 1604) of the distinction between expression and experience; and (b) to call attention to a kind of emotional response seldom considered in the psychological literature.

Expression versus experience

Seems, madam! Nay, it is; I know not 'seems.'
'Tis not alone my inky cloak, good mother,
Nor the customary suits of solemn black,
Nor the windy suspiration of forc'd breath,
No, nor the fruitful river in the eye,
Nor the dejected havior of the visage,
Together with all forms, moods, shows of grief,
That can denote me truly. These indeed seem,
For they are actions that a man might play;
But I have that within which passeth show,
These but the trappings and the suits of woe.
(Shakespeare, *Hamlet*, I. ii)

Connotations and recollections

What is usually meant by an emotional response to music is a response made by acculturated listeners to the relationships that shape auditory experience. But, as is well known, an emotional response may be evoked not primarily by the sound patterns presented, but by allusions that those patterns are understood to make to other compositions (e.g. a Bach chorale), to music associated with a cultural activity (e.g. a waltz or a funeral march), or to sounds in nature (e.g. of the wind or of an animal). In these cases, it is not the patterning of the music *per se* that evokes emotion, but the *connotations* that it has for different listeners.

A related kind of response, which I call 'nostalgia' emotion, is not the result of a culturally shared reference. Rather, depending on the experience and susceptibility of a particular listener (coupled with the specific circumstance), emotion may be evoked by any sound whatsoever—from the soft sound of waves on the shore, to the singing of birds in the trees, to the rather crude music of 'The Old Grey Mare, she ain't what she used to be many long years ago', to which I marched during basic training 'many long years ago' (in 1943).[13]

15.2 Uncertainty: 'puzzles the will'

15.2.1 Evolution, choice, and culture

Evolution and choice[14]

Although evolution unquestionably influenced human behaviour through the direct action of biological constraints, what most significantly shaped human behaviour and

[13] It is important to recognize that emotional responses to the 'remembrance of things past' is dependent on the context of the act of remembering. Music that moves us in the concert hall or at a memorial service will probably be without affect in an elevator or a supermarket.

[14] I begin the first part of Section 15.2 with a paraphrase of the end of the last chapter of *The spheres of music* (Meyer 2000). I have included it not only because it constitutes the context for my concern with uncertainty, but because I believe it offers an account of how evolution affected human cultures that is significantly different from those proposed by neuropsychologists and sociobiologists.

gave rise to human cultures was not the presence but the absence of adequate innate constraints.[15] It is because evolution resulted in such an animal that human cultures became indispensable. This aspect of evolution is summarized by biologist François Jacob (1982, p. 61):

> In lower organisms behavior is strictly determined by the genetic program. In complex metazoa the genetic program becomes less constraining, more 'open' . . . This openness of the genetic program increases with evolution and culminates in mankind.

It seems reasonable to suggest that the growth of cognitive capacity was coordinate with the development of consciousness. And consciousness is aroused when choice is required. Indeed, it seems possible that the growth of consciousness was partly a result of the increased importance of choice. That is, as animal intelligence increased so did the apprehension of differences—of kinds and relationships—in the phenomenal world. This change may well have been accompanied by a diminution of the role of instinct in animal behaviour.[16]

Increased apprehension of kinds and relationships led to the invention and production of usables (from cradles to coffins), to a concomitant increase in the number of conceptual categories, and to a burgeoning of behavioural options. The consequences of these developments were momentous because the proliferation of conceptual categories and behavioural possibilities makes choosing at once inescapable and burdensome. In philosopher Peter Singer's words: 'Our ability to be a participant in a decision-making process, to reflect and to choose, is as much a fact about human nature as the effect of the limbic system on our emotions' (1981, p. 42).

The necessity of choice is a universal that lies at the very heart of the human condition. It constitutes a basis for both ethical and aesthetic judgments. In ethics, as in the law, individuals are culpable only if the behaviour in question can be shown to be a result of choice. In the arts, forgeries are banished to the basement because the relationships reproduced were not created—not *chosen*—by the forger.[17]

Choice

A number of interrelated conditions combine to facilitate effective, propitious choosing: the presence of constraints limiting options; the ability to envisage the consequences of alternative choices; concepts of hierarchical structuring; and the power to realize one's choices.[18]

Constraints. Without controls limiting the number and ordering the priority of alternative behavioural possibilities, human beings would be caught in distressing indecision—

---

[15] Since writing this passage, I discovered that Clifford Geertz (1973, pp. 45–6) made much the same point in *The interpretation of cultures.*

[16] Put the other way around: as the power of instinct waned, choice became the main basis for human behaviour, and with the necessity of choice came the burden of uncertainty.

[17] See 'Forgery and the anthropology of art' in *Music, the arts, and ideas* (Meyer 1994), Chapter 4.

[18] Because it is not involved in the process of choosing, but in the realization of choices, 'power' is not allotted a separate heading under 'Choice', but is considered below—especially in Section 15.2.2.

an uncertainty that is not only time-consuming, but a source of unwelcome psychological tension. Growing out of and complementing innate constraints, cultures provide the learned, behavioural controls without which human beings could not choose, function, or, indeed, survive.

A single example from the history of music serves to illustrate this point. The abandonment of common-practice tonality by some early twentieth-century composers spawned so many compositional options that limitations were necessary to make choosing feasible. From this point of view, the invention of the twelve-tone method was a response to the need for constraints limiting options. This was the necessary condition for the advent of serialism; the sufficient condition for the constraints actually devised was largely a result of nurture—specifically, of the cultural belief that similarity begets unity.[19] Put succinctly, if too simply: the native need for compositional constraints created the 'problem'; cultural concepts provided a 'solution'.

Envisaging, culture, and stability. In order to choose intelligently, the various options available in a particular natural or cultural context must be comprehended and the probable consequences of each envisaged.[20] The need to envisage in order to choose is evident everywhere in human culture—from soothsayers to scientists, from astrological imaginings to the interpretation of dreams, from poll-taking to fortune-telling, from economic forecasting to the postulation of predictable historical processes. Similarly, faith in the existence of an established, unchanging order or, alternatively, in change that occurs in an orderly way is appealing because it seems to assure the possibility of successful envisaging.[21]

Indeed, all our institutions, laws and customs, as well as styles of art, serve to stabilize the conceptual-behavioural environment for the sake of effective envisaging and successful choosing. And the same is true not only of theories (including even those about chaos), but of styles of behaviour, whether in the arts or in culture generally. Conversely, the insane are institutionalized because we are uncertain about how to act in the face of 'irrational'—that is, frighteningly *un*predictable—behaviour.

Hierarchies: functional versus continuous. One mode of conceptualization that serves to stabilize our understanding of relationships in the realms of both nurture and nature is that of hierarchic structuring. Because the term 'hierarchy' has been used to refer to

[19] In this connection, see the Webern and Krenek quotations in *Music, the arts, and ideas* (Meyer 1994, p. 263). The nature of aesthetic unity has been an enduring concern of artists and aestheticians since Greek times. But the intensity of that concern and the nature of its conceptualization are culture-dependent. Thus, the belief that similarity produces unity appealed to romantic composers, because their repudiation of conventional constraints led to a significant increase in the number of available choices, and the variation and transformation of an existing pattern (motive, harmonic progression, etc.) facilitated compositional choice by limiting options. The role of similarity in creating unity is considered below, in note 36.

[20] Envisaging entails making inferences (based on both native and learned constraints) about the implications of a particular patterning or about the probable course of events in a specific set of circumstances.

[21] Thus, despite manifest differences in belief and method, science and religion have a common goal: namely, to stabilize the perceptual/cognitive world for the sake of explaining, envisaging, and choosing. In other words, both realms are ultimately ways of minimizing unwanted uncertainty.

different kinds of relationships, it seems important to distinguish between two basic types: (a) functionally differentiated hierarchies; and (b) continuous (functionally undifferentiated) ones.[22]

Because their *functional differentiation* specifies relational processes, biological organisms (plants as well as animals), cultural institutions (governmental, educational, industrial), most temporal art works (novels and dramas, sonata forms and rondos), and man-made machines (submarines to space ships) tend to enhance the stability of the behavioural environment. Wealth, power, and celebrity; geological, biological, and technological change; and the fluctuations of climate and populations, all form continuous hierarchies whose elements are related to one another not in terms of function, but of *amount*—for example, of wealth or power; strength, speed, or intensity.[23] In the absence of functional constraints, it seems doubtful whether statistical hierarchies foster stability and enhance the ability to envisage and choose successfully.[24]

15.2.2 Uncertainty

A critical corollary of the imperative of choice is the human abhorrence of uncertainty—for instance, the uncertainty surrounding death, which is undoubtedly a crucial reason for the prevalence of religion and for the correlative belief in an after-life. These are the focus of lines from Hamlet's famous 'To be, or not to be' soliloquy:

. . .the dread of something after death,
The undiscover'd country from whose bourn
No traveler returns, puzzles the will
And makes us rather bear those ills we have
Than fly to others that we know not of?
(Shakespeare, *Hamlet*, III.i)

[22] The difference between functionally differentiated and continuous hierarchies is analogous to that between the functioning of syntactic/native processes and the action of statistical parameters. This difference is exemplified by that between the closure created by a functionally differentiated syntactic progression (e.g. from subdominant to dominant to tonic) and that created by 'tonal centring' through the repetition of a pitch, etc. (as, for instance, in the first movement of Béla Bartók's Piano Sonata). After this section was written, one of the readers called my attention to Lawrence Zbikowski's (1997) essay on 'Conceptual models and cross-domain mapping'. That essay also distinguished between two kinds of hierarchy. The first, 'chains of being', is comparable to my 'continuous hierarchies'; but his second type does not seem to consider the role of functional differentiation.

[23] Whether a hierarchy is functional or continuous does not depend on the *kind* of phenomenon, but on the level being scrutinized. For instance, although social history constitutes a continuous hierarchy on the highest level of change, change on lower levels (e.g. of a particular political event) may be governed by functional constraints, and the same can be said of, say, the history of sonata form versus the form of a particular sonata-form movement.

[24] This does not gainsay the fact that statistical change may seem implicative: for instance, the gradual intensification of dynamics, increase in frequency, and shortening of duration may be understood to imply arrival at some kind of goal. But whatever 'arrival' (articulation) occurs necessarily involves either significant repetition of the tonicized pitch (see note 22) or a significant change in other parameters—for instance, a lengthening of the final sound, a change in orchestration, dynamic level, or register.

Here an apparent paradox arises. On the one hand, uncertainty is anathema to humankind.[25] For this reason, as noted above, we devise ways of reducing uncertainty both in the 'out-there' world and in our personal lives. On the other hand, in the arts and in other 'playful' activities such as sports, games, and gambling, we actually relish and cultivate a considerable amount of uncertainty.

Belief, empathy, and aesthetic experience

The paradox is possible not only because of what Coleridge called 'the willing suspension of disbelief',[26] but more importantly because of a *positive* belief in the competence, integrity, and creativity of the artist and, above all, in the significance of works of art. Such positive belief is indispensable for man-made aesthetic experience (as distinguished from the experience of beauty in the natural world), because it is a necessary condition for the empathy on which perceptual engagement and affective response depend.[27]

The importance of such belief is evident in the ability of criticism to affect the responses of listeners. For instance, the negative reception of avant-garde music was, at least in part, a result of critiques that undermined audience empathy by suggesting that the choices of composers were the result of system-based calculation or of random chance, rather than of 'inspiration' and 'inner feeling'. On the other side, consider this stunning, if preposterous, instance of the power of positive belief to produce a favourable response in an audience. In a book review, 'Fascinating rhythm', David Hajdu writes: 'In 1971, Ravi Shankar, the Indian virtuoso, performed at New York's Madison Square Garden. After hearing a few minutes of Shankar's ensemble, the audience of some 20 000 roared in approval. "Thank you," Shankar replied. "If you appreciate the tuning so much, I hope you will enjoy the playing more."'[28]

The empathy that belief begets is not solely cognitive. Almost always it involves physical behaviour—an inner performative empathy, a kind of imitative identification, with the qualities and patterns of the music.[29] Lack of motor empathy, for example, seems to

[25] Uncertainty is evidently also anathema to other animals. Elizabeth Pennisi (2000, p. 577), for example, writes that: 'Although baboons are considered quite aggressive primates by nature, violence tends to be much more prevalent when the troop's structure is unstable . . . if the troop members don't know one another, or if the hierarchy is disturbed, say, by the loss of the top male, the rush to establish rank results in scuffles that subside when everyone knows his or her place.' In short, instability, lack of familiarity, disturbance of social structuring—all create uncertainty which, in turn, begets violence.

[26] *Biographia literaria*, Chapter 14. The 'willing suspension of disbelief' is an important factor in the ability of audiences to re-experience implicative relationships—to 'make believe' that they are experiencing anew.

[27] In addition to being a source of aesthetic enjoyment, music has, since its beginnings, served to foster social cohesion—through the evocation of empathic sharing in religious and secular ceremonies, attending to or participating in theatrical performances, and marching or dancing together.

[28] *New York Review of Books*, Vol. 47, No. 12 (20 July 2000), p. 41.

[29] Many years ago (Meyer 1956*b*), I argued that belief was essential for the success of music therapy. More recently, studies described in the *Harvard Men's Health Watch* (September 1997, p. 6) have demonstrated the importance of belief for longevity and more general well-being. In addition, it seems likely that belief plays a significant role in the placebo effect (see Enserink 1999).

have played a significant role in the negative aesthetic and hence emotional response to avant-garde music, while motorically accessible musics (from Bach to rock) have found ardent audiences. Indeed, I suspect that often contemporary music has failed to find favour with concert audiences, not primarily because it tends to be dissonant, but because it is difficult to empathize with and experience motorically—not just the lack of rhythmic regularity, but such motor-related problems as the prevalence of large descending skips and intervals such as augmented fourths.

The roles of belief and empathy (physical as well as cognitive) help to explain why the uncertainty experienced in relation to works of art, games, and sports differs significantly from that evoked by 'real-life' circumstances.[30] Indeed, in the temporal arts, the arousal and resolution of uncertainty is an essential basis for aesthetic-emotional experience. Because patterns imply alternative possible continuations and realizations, implication invariably involves some degree of uncertainty—uncertainty about *what* will happen, *when* it will happen, and *how* it will happen.[31] Consequently, to paraphrase *Hamlet* again: like sorrows, uncertainties 'come not single spies/But in battalions' (Shakespeare, *Hamlet*, IV. v).

It is important to recognize that uncertainty entails at least an inkling of patterning. Because either too little or too much information precludes the perception of even a modicum of order, neither is compatible with uncertainty. That is, unless there is some degree of order, whether presumed or inferred, there is nothing to be uncertain *about*. And because even a bit of order tends to be implicative, uncertainty is so as well.

The succession of states

The role of uncertainty has unfortunately been neglected in the study of the emotional response to music. Neglect has probably occurred because emotional 'states' such as love, anger, and hate are, as mentioned earlier, experienced, classified, and named in terms of the particular real-life circumstances with which they become associated.[32] But uncertainty itself is not 'circumstantial'. And, because it can be coupled with and qualify many states of being or feeling, uncertainty is not thought of as an 'emotion'. However, although not a nameable, circumstantial state, uncertainty is a necessary, though perhaps not sufficient, condition for the emotional experiences and behaviours of human beings.[33]

What I am suggesting, then, is that states of feeling (e.g. love, contentment, hunger, fatigue) become emotional experiences when they are at least tinged by uncertainty. As

[30] Another reason for this difference has to do with our relationship to 'roads-not-taken'. In the arts and other pleasure activities, 'roads-not-taken' constitute a source of experiential enrichment. In real life, on the other hand, an abundance of alternatives tends to be disturbing and perplexing.

[31] At times, implications are realized remotely and may, as a result, be recognized largely in retrospect. That is, we did not experience uncertainty when the pattern was presented earlier, but realize subsequently that we *might* have done so.

[32] I suspect that the neglect of uncertainty was, ironically, a result of the psychological and cultural craving for the control that *naming* (separate emotions) provides.

[33] This account represents a modification of that given in Meyer (1956*a*, p. 16 ff.).

observed earlier, although being 'curious' is not in itself an emotional experience, it may become so if the behavioural inclinations (the needs or goals) associated with it are thwarted. And this appears to be the case with other goal-directed needs—from the need for food to the need to choose. *Qua* feelings, they are states of being. They become emotional experiences or responses when thwarting creates uncertainty about appropriate courses of action.

Seen thus, uncertainty is the result of ignorance—ignorance about how past and present patterns will be continued, eventually reaching stability and closure. In other words, uncertainty is always more or less goal-directed, implying (perhaps unconsciously) resolution to the security of knowing.

Since uncertainty is a function of the amount of information the mind is required to process, if there is so little information that patterning is impossible, the result is a sense of powerlessness and hope-based uncertainty is abandoned. Perhaps this is why during the Vietnam War it was found that, deprived of any stimulation whatsoever, prisoners became mentally deranged. Stimulus overload (too much information), which may be a matter either of amount, or speed, or both, is almost as disturbing as stimulus deprivation. Hence audiences tend to be alienated, when (what for them is) an excessive amount of information in a piece of contemporary music precludes patterning and, consequently, a sense of control.[34]

At the end of *Emotion and meaning in music* (Meyer 1956*a*) and subsequently in *Explaining music* (Meyer 1973), I grappled with the problem of accounting for the succession of emotional states presented in a piece of music. Much later, in 'A universe of universals' (Meyer 2000), I argued that no necessary, inherent order governs the succession of emotional states or referential subjects presented in a piece of music.[35] We accept such successions because the uncertainty and lack of cognitive control created by intervening instability make the return to mentally manageable patterns satisfying. In short, it is the uncertainty–resolution (or, correlatively, the implication–realization) process, not similarity of melodic, rhythmic, or tonal pattern, that unifies the succession of emotional states presented in a piece of music.[36]

As emphasized in Section 15.1, we conceptualize and understand phenomena not in terms of individual instances, but in terms of *classes*. And classification plays a critical role in our sense of cognitive control and power.

[34] If the amount of information is inordinately increased, the result is a kind of cognitive white noise.

[35] A particular succession may, of course, be the result of a programme conceived by the composer, or devised by critics or listeners to account for a succession not linked together compositionally by the tension of syntactic uncertainty. This, together with the diminished sophistication of the audience, may help to account for the increased use of programmes during the nineteenth century.

Also, in order to enhance expressivity, there tended to be an increase in the instability and tension of putatively stable passages. As a result, the difference in degree of uncertainty between presumably stable and unstable passages diminished. When this occurred, the relatively weak level of uncertainty could not unambiguously link successive emotional states.

[36] As observed in note 19, the belief that similarity begets unity became aesthetic doctrine during the nineteenth and early twentieth centuries. But a moment's thought makes it evident that the more

Power

When it involves loss of control, uncertainty may also become associated with feelings of angst and terror. This perhaps partly explains why rapid tremolos, which cannot readily be processed by either mind or body, are associated with angst and terror. As in the startle reaction, shockingly unexpected stimuli engender anxiety and fear of the unpredictable and the inexplicable. Writing about the situation in Kosovo, Mark Danner observed that random, indiscriminate violence is more effective than orderly extermination: 'Imposition of terror, *the more "indiscriminate", the better,* breeds fear . . .'[37] Briefly: total uncertainty is unbearably painful.

So too is the frustration created by the impossibility of action. This may help to account for the weeping which seems to come from strong feeling, often evoked by emotion-laden associations and memories, that can find no expression in action. Feelings of hopelessness—an inferno resulting from the inability to choose and hence to act—give rise to strong emotion. For instance, when we recognize that an important goal cannot be realized—that hope must be abandoned—feelings often result in weeping.[38] The action that might-have-been is, as it were, transformed into tears.[39]

This is the source of what I have called the emotion of 'nostalgia'. A personal experience exemplifies this kind of response. At a performance of Verdi's *La Traviata*, when Germont began to sing 'Di Provenza', I began to weep, not only because my father

alike two patterns are, the more they seem separate—the case, for instance, with the motivic repetitions in the Scherzo of Beethoven's Symphony No. 7 (e.g. mm. 37–40 and 49–52). Confusion occurs because unity is equated with *uniformity*.

Unity, however, involves the functional connection of phenomena that differ in some significant respect; uniformity involves connection through similarity of substance and/or pattern. Thus, although the grains of sand on a beach are essentially alike, it would surely seem strange to say that the beach was unified. Similarly, while it is proper to characterize a musical ostinato or a word repetition (such as Macbeth's 'Tomorrow, and tomorrow, and tomorrow') as uniform, it would be wrong to say that they created unity. Whether in music, or in literature, or in biological organisms, unity results not from similarity, but from functional differentiation.

[37] 'Endgame in Kosovo', *New York Review of Books*, Vol. 46, No. 8 (6 May 1999), p. 8.

[38] As Sloboda (1992, p. 37) observed, weeping would seem to be a unambiguous manifestation of emotion. Yet it has been strangely neglected in the psychological literature about music. I can think of two (not mutually exclusive) reasons: (a) because, like uncertainty, weeping is circumstantially variable; and (b) because it is difficult to know whether the tears are a result of acculturation or personal experience.

[39] If weeping comes from within, laughter comes from outside us, from the incongruities of the outside world (in this connection, see note 3). Even when we laugh at ourselves, it is the out-there, 'other' self that we laugh at. Laughter (e.g. at jokes) exemplifies a related facet of uncertainty. Initially, as with any process, we are uncertain as to how stability and closure will be reached. To heighten the tension of uncertainty, the first part of the process is usually elaborated. The tension of patent, though usually playful, delay is resolved by a 'punch-line', and we laugh: first, because of the relief that comes with *knowing* and second because, though apt, the outcome is surprising and amusingly incongruous.

especially loved that aria, but because evoking memories of 'days beyond recall', and beyond empathic reciprocity, made my present powerlessness apparent.[40]

Risk-taking and culture

Uncertainty can also be associated with what appears to be the opposite of frustration: namely, the thrill and exhilaration of risk-taking. For what sky-diving and the virtuoso performance of a challenging cadenza, or adventurous mountain-climbing and daring modulations to a distant tonality, have in common is the thrilling uncertainty of risk-taking and the illumination of self-discovery.[41] The pleasure of, and empathy with, risk-taking is, however, dependent on the belief of all concerned (composer, performer, and audience) in the existence of expert control.

Risk-taking is in turn related to the heroic. To appreciate, and empathize with, the uncertainty of risk is to move toward and experience something of the heroic. And though it seems *passé* (and a bit theatrical), Samuel Johnson touched on an important facet of human behaviour when he observed that:[42]

> Were Socrates and Charles the Twelfth of Sweden both present in any company and Socrates to say 'Follow me and hear a lecture on philosophy'; and Charles, laying his hand on his sword, to say 'Follow me and dethrone the Czar'; a man would be ashamed to follow Socrates . . . The profession of soldiers and sailors has the dignity of danger [of risk-taking]. Mankind reverence those who have got over fear, which is so general a weakness.

But in contemporary culture there has been a significant decline in the valuing of personal honour, the heroic, and the risk-taking associated with them. Hayden White (1973, p. 232) relates the ironic mode of much twentieth-century thought to 'the passage of the age of heros and of the capacity to believe in heroism'.[43] And, according to Admiral Arthur, commander of the American naval forces during the Gulf War, even in the military 'We now have people being taught how to be cautious, not how to be bold' (Schmitt 1995). Construed in terms of the subject of this chapter, tolerance for the tensions of uncertainty has been considerably reduced. One reason for this reduction is

[40] Needless to say, not all crying is 'nostalgia-generated'. Infants cry because of unrealized needs—for food, affection, nappy (diaper)-changing, etc. But certainty can, without forcing, also be considered an unrealized need—the need for power, for confidence in our ability to act.

[41] Thus, Garry Wills observed that Robert Kennedy 'courted danger, climbing mountains, shooting rapids. What he was looking for was his true self, so long repressed, so totally held in the service of others' ('Waiting for Bobby,' a review of Ronald Steel's *In love with night: The American romance with Robert Kennedy* published in the *New York Review of Books*, Vol. 47, No. 2, 10 February 2000, p. 20).

[42] Said by Samuel Johnson in 1778 and quoted in Harry G. Summers Jr., 'The men of Company E' (a review of *Band of brothers* by Stephen E. Ambrose published in the Book Review, *New York Times*, 6 December 1992, p. 11). It could be argued that fear is basically a kind of uncertainty.

[43] Also see J. B. Freeman's 'Dueling as politics: Reinterpreting the Burr-Hamilton duel' (*William and Mary Quarterly*, 1996, pp. 289–318), discussed in Gordon S. Wood, 'An affair of honor' published in the *New York Review of Books*, Vol. 47, No. 6, 13 April 2000, pp. 67–8.

that risk-taking, honour, and the heroic are *individual* endeavours that are incompatible with egalitarian, mass culture.

But perhaps the most important reason for the changes taking place in our culture is the altered attitude toward history itself.[44] As the future-oriented perspective prevalent since the Renaissance has weakened, there has been a trend away from risky goal-directed action, in both life and art. This seems evident in the complacent *present*ational character of much minimalist music. Paradoxically, this is also the case with 'bing-bang' popular music whose aggressive force implies no future goal, but rather calls for compliance NOW.[45]

Further thoughts about uncertainty

Narratives and plots. Uncertainty is of vital importance in the aesthetic process of moving from the insecurity of ignorance to the security of knowing. This process, which Aristotle referred to as the 'reversal' of the action in a drama, is at the core of all plots. And this calls attention to the difference between a narrative and a plot.

Most histories (evolution, political, economic, and intellectual), as well as many literary and musical genres (novels and dramas; sonata forms and song cycles), are narratives.[46] But not all narratives are plots. A narrative succession is transformed into a plot when uncertainty is experienced in terms of an imagined goal. One of the problems with many narrative interpretations of music is that they are based on passages that present stable emotional states and referential associations. The result is a succession of largely separate vignettes rather than a plot in which uncertainty reaches resolution in stability.

Here another paradox arises. The human need to envisage leads us to conceptualize the world as being more or less predictable. But continual succession without functionally ordered structure (as in cosmology, evolution, and human history) creates the uncomfortable uncertainty of *un*ordered endlessness. As a result, we tend to transform what are essentially fluctuating continuities (narratives without goals) into plots. To put the paradox succinctly: the uncertainty created by pattern instability begets functional differentiation, which reduces the uncertainty produced by an unarticulated succession of emotional states.

Finally, I suspect that the psychological desire to transform narratives into plots is one reason why we tend to anthropomorphize phenomena. That is, anthropomorphism not only provides conceptual means for envisaging and choosing, but provides goals that change potentially endless successions into implication-realization patterns—that is, into plots with potential for closure.

[44] The end of historic optimism is discussed in the 'Postlude' to the second printing of *Music, the arts, and ideas* (Meyer 1994).

[45] Although my aesthetic predilections are obvious, my concern is not with making value judgments, but with trying to understand and explain some of the changes taking place in contemporary culture.

[46] Though implicative, sonnets (as illustrated above) are not narrative—nor are limericks. Both are like propositional 'arguments'. In music, the closest form to 'pure' narrative is the theme and variations which, like high-level histories, are potentially endless successions.

Motor action, deviation, and implication. Because it implies virtually automatic continuation, marked motor regularity and strong emotional process tend to be inversely related. And because rapid tempos are usually coordinate with forceful motor action, speed and emotion also tend to be inversely related. For instance, in the opening section of Bach's Brandenburg Concerto No. 2, rhythm, tempo, and (implicit) dynamics evoke strong motor empathy, but only minimal emotional tension.[47]

This suggests why forceful motor action is incompatible with richly implicative processes: namely, because emphatic motor action tends to minimize the imagining of alternative implications—that is, other continuations.[48] For the same reason, however, forceful motor action can be important in the generation of surprise: that is, we are most easily and forcefully surprised when we are *un*aware of the possibility of alternatives.

Mention of surprise reminds us that implications and uncertainties can be recognized, though not experienced, in retrospect. This occurs when the regularity of a pattern and its context make continuation seem highly probable. Then if an abrupt change occurs—as, for instance, in the slow movement of Haydn's 'Surprise' Symphony (No. 94)—we realize that we *should have been* less complacent about the implications of the earlier patterning. Conversely, we may in retrospect recognize that a present pattern is, in fact, the realization of an implication not noticed in a prior process.

In general, not just forceful motor action, but any pattern or behaviour that seems predictable—is stylistically normal and cognitively coherent—reduces uncertainty. By disturbing such predictability, deviation (surprise, delay, etc.) may evoke uncertainty and emotional experience.[49] In short, some degree of regularity (stability) is a necessary condition for an emotional response to music; the sufficient condition is, as I suggested 'many long years ago', the uncertainty created by some degree of deviation.[50]

Intensity, control, and emotional experience. As observed earlier, the intensity of uncertainty is variable, depending both on the patterning of events and what is believed to be the importance of their goal(s). In general, as the number and strength of implied alternatives increases so does uncertainty;[51] and the same holds for the richness of their

[47] Again, the distinction between an emotional state and an emotional process is critical. Although Bach's opening creates feelings of forceful, confident power, it does not, as I see it, give rise to marked emotional process.

[48] Because they tend to preclude awareness of possible alternative continuations, overly rapid tempi also obscure the relational richness potential in performance.

[49] Briefly, in 'life' we try to conceptualize the world so that it seems regular and predictable. In the arts, on the other hand, we devise regularities as a base for the deviations that, by creating uncertainty, beget emotion and shape aesthetic experience.

[50] In *Emotion and meaning in music* (Meyer 1956*a*), I argued that deviation, whether one present in the composer's score or one created by the performer, tends to evoke emotion. But I failed to see that deviation does so because it is a source of uncertainty.

[51] Janet M. Levy (1995) distinguishes the multiple meanings (implications) that beget uncertainty from ambiguity which 'gives rise to two or more specifiable meanings' (p. 152).

imagined consequences, both proximate and remote.[52] Thus, when it is said of a novel that 'the plot thickens', what is probably meant is that uncertainty has increased. In music, the degree of uncertainty that is pleasant and enjoyable depends not only on musical relationships, but, as suggested earlier, on the beliefs of the audience about the historical importance and aesthetic value of the music being played. Beliefs are a prerequisite for empathy, and empathy for attentive perception and sensitive response.

The degree of uncertainty appears to be the basis for the distinction made by psychologists between 'pleasant' and 'unpleasant' emotions.[53] This is, I suspect, because intensity influences the sense of control experienced by the listener. Put differently, emotions are felt to be pleasant, even exhilarating, when associated with confidence in the power to envisage and choose; they are experienced as unpleasant when intense uncertainty precludes the sense of control that comes from the ability to envisage with confidence.

Finally, the aesthetic importance of uncertainty lies not only in the shaping of emotional *processes*, as distinguished from the evocation of emotional *states*, but in the articulation of musical structure. When the tensions of instability are resolved to the cognitive security of stable patterning, functional relationships have at once articulated and unified musical structure.

I am, appropriately, uncertain about how to end this essay—and that makes me somewhat sad. Yet, at the same time and for the same reason, I feel glad—glad because connecting puzzled uncertainty with emotion *seems* to confirm my basic argument.[54]

[53] Anxiety needs to be distinguished from uncertainty. Unlike uncertainty, anxiety occurs when governing constraints are not known and cannot be inferred from the perception of overly complex stimuli. Consequently, anxiety is not implicative but endures, fluctuating in a persistent present. However, because of our beliefs about its special nature, aesthetic experience seldom gives rise to anxiety; it does so only when all sense of order and hence the possibility of cognitive control is lost.

CHAPTER 16

EMOTIONAL EFFECTS OF MUSIC: PRODUCTION RULES

KLAUS R. SCHERER AND MARCEL R. ZENTNER

It is an ancient, and very pervasive, idea that music *expresses* emotion. Apart from the copious literature to this effect contributed by composers, musicologists, and philosophers, there is also solid empirical evidence from psychological research, reviewed in chapters of this book (e.g. Gabrielsson & Lindström, this volume; Juslin, this volume), that listeners often agree rather strongly about what type of emotion is expressed in a particular piece. It is also a pervasive belief that music can, at times, actually *produce* emotion in listeners. The distinction between perception and production is related to the distinction between cognitivism and emotivism proposed by philosophers in their analysis of emotion in music (e.g. Kivy 1989). Whereas 'emotivists' hold that music elicits real emotional responses in listeners, 'cognitivists' argue that music simply expresses or represents emotions. Our view is that it would be premature to prejudge the issue and that both positions may be perfectly appropriate depending on a number of factors outlined below. Our purpose in this chapter is to provide a formalization of the processes whereby music produces emotional effects in the listener that go beyond the cognitive inference of what the music can be said to express. In addition, we review the pertinent evidence to date and suggest ways in which future research might investigate these processes in a systematic fashion. We state at the outset that our discussion and the review of the available evidence are largely based on Western classical music, thereby restricting the generalizability of our claims to other kinds of music and other cultures.

Our attempt at a formalization of emotional effects of music will consist in defining the affective changes that music is supposed to produce in the listener and to identify the determinants of the listening situation (features such as the musical structure of the piece listened to, the interpretation by the performer, relevant state and trait characteristics of the listener, and the respective context). An important issue for discussion will be the relative weighting of the different determinants and the type of their interaction in producing the affective outcome. We follow the senior author's attempt to define the emotional meaning of music in analogy to Bühler's Organon model of language, postulating composition, expression, perception, and production *rules* to model the different facets of emotional meaning (Scherer, 2000*d*). In this context, the term *rule* is used to denote a certain regularity or lawfulness of the effects discussed that can be expressed in concrete predictions or hypotheses. It is not excluded that these rules can be integrated into attempts at computational modelling of the underlying mechanisms (in fact, we consider this a highly desirable option), but we do not feel that the current state of the

art provides the necessary precision in specifying the model parameters and the input and output variables that would be required to pursue this aim. Thus, the term *rules* and the pseudo-mathematical formulas to formalize them suggested below are used in a purely descriptive sense in this chapter.

A formalization of the process by which music generates emotion requires, first of all, a definition of what exactly is to serve as the *output variable*, that is, the type of emotional or affective state that is supposed to be produced by music. This is necessary since much of the confusion in the literature is due to a lack of conceptual clarity concerning the hypothetical constructs involved. Scherer (2000*a*) has suggested a design feature delimitation of various affective phenomena, reproduced in an adapted form in Table 16.1. In view of the lack of agreement in the field, we have not attempted to identify the characteristics of *aesthetic emotions*, particularly relevant to music, either as a separate category or as a subcategory of the types proposed. This is a task that remains to be accomplished in future work. We will consistently apply the distinctions suggested in Table 16.1 in this chapter, both in classifying the literature to be reviewed (which at times requires one to speculate what an author meant or what a study measured) and in formalizing mechanisms and discovery procedures. In particular, we will try to distinguish affective preferences, moods, and emotion episodes, all of which might be produced by music. Clearly, any attempt to demonstrate that these different types of states are induced by music requires that the defining characteristics of the respective state are operationalized and measured.

The next step is to operationalize the *input variables*; that is, to specify in greater detail which aspects of listening to a piece of music are involved in the inference and/or induction of emotion (for a more detailed example of such an analytical approach, see Dowling & Harwood 1986). We will distinguish structural, performance, listener, and context features, presuming that these features can, individually or in combination, produce the different affective states described above.

Structural features

We subdivide structural features of music—that is, all those qualities of a composer's score that a good performer needs to respect—into segmental and suprasegmental types. *Segmental features* consist of the acoustic characteristics of the building blocks of musical structure: individual sounds or tones as produced by the singing voice or specific musical instruments. In some ways one may presume that such individual sounds correspond to the isolated affect vocalizations that may lie at the source of speech and music. The use of 'Ah' and 'ahimé' in baroque operas illustrates what has been called the domestication of 'brute' affect vocalizations (Kainz 1962; Wundt 1900; for a review of this literature, see Scherer 1994). The closest equivalent in instrumental music is the individual tone, interval, or chord. The acoustic structure of such individual tone segments, corresponding to phones in speech, is described by duration, energy (amplitude), pitch (fundamental frequency), and timbre or harmonic structure (spectral composition) of the complex wave, as well as the energy and pitch envelopes and microchanges in timbre over the duration of the sound. In sound or tone sequences, this acoustic information can be aggregated, yielding measures of central tendencies (mean, median) that, in relatively homogeneous sequences, can be described as the

Table 16.1 Design feature delimitation of different affective states (adapted from Scherer (2000*a*))

Design feature / Type of affective state: brief definition (*examples*)	Intensity	Duration	Synchronization	Event focus	Appraisal elicitation	Rapidity of change	Behavioral impact
Preferences: evaluative judgments of stimuli in the sense of liking or disliking, or preferring or not over another stimulus (*like, dislike, positive, negative*)	L	M	VL	VH	H	VL	M
Emotions: relatively brief episodes of synchronized response of all or most organismic subsystems in response to the evaluation of an external or internal event as being of major significance (*angry, sad, joyful, fearful, ashamed, proud, elated, desperate*)	H	L	VH	VH	VH	VH	VH
Mood: diffuse affect state, most pronounced as change in subjective feeling, of low intensity but relatively long duration, often without apparent cause (*cheerful, gloomy, irritable, listless, depressed, buoyant*)	M	H	L	L	L	H	H
Interpersonal stances: affective stance taken toward another person in a specific interaction, colouring the interpersonal exchange in that situation (*distant, cold, warm, supportive, contemptuous*)	M	M	L	H	L	VH	H
Attitudes: relatively enduring, affectively coloured beliefs and predispositions towards objects or persons (*liking, loving, hating, valuing, desiring*)	M	H	VL	VL	L	L	L
Personality traits: emotionally laden, stable personality dispositions and behavior tendencies, typical for a person (*nervous, anxious, reckless, morose, hostile, envious, jealous*)	L	VH	VL	VL	VL	VL	L

VL = very low, L = low, M = medium, H = high, VH = very high.

dominant acoustic structure of the sound sequence. This process of aggregation is straightforward for some acoustic variables (e.g. pitch) and rather difficult for others (e.g. timbre). However, even in the more difficult cases approximations can be found (e.g. a rough aggregate measure of dominant timbre might be the mean proportion of the energy above 1 kHz).

Segmental effects on emotion inference or induction are expected to be relatively stable and universal, with the exception of random error, over all types of listeners and

performance conditions. Generally, such effects are mediated by evolutionarily evolved iconic signalling characteristics, based on physiological changes in affect vocalization and relatively independent of individual or cultural differences (cf. also Rosar 1994).

Suprasegmental features consist of systematic configurational changes in sound sequences over time, such as intonation and amplitude contours in speech. In music, comparable features are melody, tempo, rhythm, harmony, and other aspects of musical structure and form. While iconic coding also plays an important role (e.g. with respect to tempo, rising/falling contours), suprasegmental features seem to carry emotional information primarily through *symbolic coding*, as based on a process of historically evolved, sociocultural conventionalization (see Kappas *et al.* 1991; Scherer 1988; Sloboda 1992).

Performance features

These refer to the way in which a piece of music is executed by performer(s). Both the stable *identity* (physical appearance, expression, reputation) and *ability* (technical and interpretative skills) of the performer, as well as transient performance-related variables referred to here as *performance state* (interpretation, concentration, motivation, mood, stage presence, audience contact, etc.), may have a major impact on the perception and induction of emotion. The effects of performance features can be based on both iconic and symbolic coding.

Listener features

Listener features are based on the individual and sociocultural identity of the listener and on the symbolic coding convention prevalent in a particular culture or subculture. They can consist of interpretation rules (e.g. musical systems) that are shared in a group or culture, or of inference dispositions based on personality, prior experiences, and musical talent. These factors can be summarized into *musical expertise*, including cultural expectations about musical meaning, and *stable dispositions* unrelated to music, such as personality or perceptual habits. In addition, transient listener states such as motivational state, concentration, or mood may also affect emotional inference from music (cf. Cantor & Zillmann 1973). In the case of listener features, we suggest a third type of meaning-conferring coding—*associative coding*—in addition to the established semiotic distinction between iconic and symbolic coding. By this we mean the fact that segmental, suprasegmental, and performance cues can be associated with emotional content in an individual's memory due to learned associations and conditioning.

Contextual features

These refer to certain aspects of the performance and/or listening situation. Thus, the *location* of a performance and/or a listening situation may be a concert hall, church, open-air site, car, or recording studio. The dominant material surrounding the listener/performer may be wood, glass, stone, metal, or cement. In addition to the location, the particular *event* may be a wedding, a funeral, a ball, or the celebration of an outstanding achievement. The music may be transmitted through loud-speakers, headphones, or

without any technical support. The music may be heard without interruption or it may be disturbed by the sirenes of an ambulance or the coughing of a concert visitor. We submit that all these features can have an influence on the acoustics, the ambiance of the location, or the behaviour of the audience, which in turn may lead to different emotional effects due to objective features of the situation or subjective perceptions of the listeners.

16.1 Production rules

16.1.1 Predictions

We suggest that an emotion that is actually experienced by a listener while listening to music is determined by a multiplicative function consisting of several factors:

Experienced emotion = Structural features × Performance features × Listener features × Contextual features,
where
Structural features = W_1 (Segmental features) × W_2 (Suprasegmental features),
Performance features = W_3 (Performer skills) × W_4 (Performer state),
Listener features = W_5 (Musical expertise) × W_6 (Stable dispositions) × W_7 (Current motivational / mood state),
and
Contextual features = W_7 (Location) × W_8 (Event).

We postulate multiplicative rather than additive functions because it is unlikely that any of the constituent factors in and of themselves, in the absence of other factors, can lead to marked, reliable emotional effects. Furthermore, it seems intuitively reasonable to assume that some listener features (e.g. musical expertise) will strongly interact (in the statistical sense of conveying special strength or significance) with specific structural or performance features. Finally, we submit that the different factors carry different weight. In fact, the order in which the variables are listed above follows the results of a study in which experienced listeners, many of them experts, were asked to rate the extent to which each of the major factors listed above was perceived to influence musical emotion induction (Scherer *et al.*, in press). Clearly, more exploratory studies are needed before more subtle predictions can be made and tested.

After this initial formalization of the output and the input variables involved in emotional responses to music, and the formulation of certain predictions, we now turn to what we call *routes*, that is, particular mechanisms whereby emotion may be generated by music. We distingish: (a) *central routes* (i.e. implicating the central nervous system (CNS) in emotion generation); and (b) *peripheral routes* (based on direct effects on the peripheral, i.e. the somatic and autonomic, nervous systems (SNS and ANS) with ensuing proprioceptive feedback to central areas). In Sections 16.1.2 and 16.1.3 below, we will briefly describe these different routes and some of the underlying mechanisms. Section 16.1.4 describes the evidence to date.

16.1.2 Central route production

Appraisal

A parsimonious premise is that musical stimuli provoke emotions in a similar fashion to any other emotion-eliciting event. Thus, the mechanisms described by emotion psychologists may be also applicable to the study of emotion induction via music. There is an emerging consensus that emotion elicitation and differentiation is best understood by assuming a process of event evaluation, or appraisal, that models the way in which an individual assesses the personal significance of an event for its well-being on a number of critieria and dimensions. This process of evaluation is demonstrated in the upper portion of Fig. 16.1: an object or event is evaluated by a specific person, with respect to a number of criteria or dimensions concerning the implications of the event for needs, goals, or values of the individual and his or her ability to cope with the consequences of the event. The result of this appraisal process is an emotion, which is then expressed or externalized in physiological symptoms and, particularly, in motor expressive movements in the face, body, and voice. In this theoretical tradition, the type of ensuing emotion and the patterning of the physiological and expressive responses are seen as dependent on the specific profile of appraisal results on the pertinent criteria (see Scherer 1999; Scherer *et al.*, 2001; for alternative models of emotion differentiation, see Scherer 2000*a*). This appraisal process may occur in a rudimentary, automatic fashion at lower levels of the CNS (mostly the limbic system), especially for evolutionarily 'prepared' stimuli, or in a more elaborated and more effortful process involving the cortical association regions of the CNS as well as the lower centres (see Leventhal & Scherer 1987; Teasdale 1999; van Reekum & Scherer 1998).

The automatic, lower-level appraisal route to emotion elicitation has been well described by Öhman and his colleagues (Öhman 1988) who have suggested that a number of stimuli (e.g. snakes and spiders) can be processed by the lower centres of the brain in an extremely short period of time, outside of awareness, without any apparent

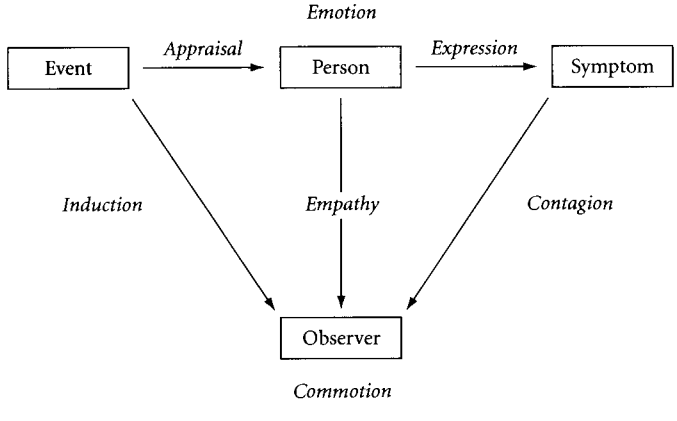

Figure 16.1 Model of 'normal' emotion induction via appraisal (upper part) and mediated 'commotion' due to empathy or other mechanisms of emotional communication (lower part) (based on Scherer, 1998).

implication of cortical association areas. This research group has demonstrated that facial expressions of fear may have the same effect (Dimberg 1988). While empirical evidence for humans is lacking, one can assume that vocal expressions of emotions comparable to alarm calls in primates (see Jürgens 1988) may be similarly 'prepared' stimuli with respect to immediate, low-level meaning assignment. In consequence, musical stimuli sharing the acoustic characteristics of such fear vocalizations (sudden onset, high pitch, wide range, strong energy in the high frequency range) may be appraised by evolutionarily primitive but extremely powerful detection systems and may provoke, like pictures of spiders or facial expressions of fear, physiological defence responses (see Öhman 1988).

Similar low-level detection mechanisms can be demonstrated for the appraisal criteria of suddenness/novelty and intrinsic pleasantness (e.g. Scherer 1984, 1988). While the results of such rudimentary evaluation processes may not be emotions in the fully-fledged sense, as defined in Table 16.1, they may nevertheless produce positive valence reactions with respect to preferences or other types of affective phenomena short of fully-fledged emotions. There is some evidence that musical sounds can generate strong suddenness/novelty and, in particular, intrinsic pleasantness evaluations.

For example, Zentner and Kagan (1996, 1998) examined the hypothesis of an innate preferential bias favouring consonance over dissonance by exposing 4-month-old infants to consonant and dissonant versions of two melodies. Consonance and dissonance were created by composing the dissonant version in parallel minor seconds, the consonant version in parallel thirds using only two (synthetic) voices (for details regarding the stimuli, see Zentner & Kagan 1998). It was found that infants looked significantly longer at the source of sound and were less motorically active to consonant compared with dissonant versions of each melody. Further, fretting and turning away from the music source occurred more frequently during the dissonant than the consonant versions. Because no relation was found between infants' previous exposure to music (as assessed by questionnaire) and their behaviour in the experiment, the authors suggested that the human infant might possess a biological preparedness that makes consonance more attractive than dissonance. This tentative conclusion is not only consistent with perceptual work on infants' responses to consonant and dissonant intervals (e.g. Schellenberg & Trehub 1996), it is also supported by animal work which demonstrated a preference of consonant over dissonant chords in albino rats (Borchgrevink 1975).

It should be noted that similar automatic evaluation processes can occur for auditory stimuli that are not themselves evolutionarily prepared but that have been conditioned to such stimuli. Thus, LeDoux (1996) has convincingly shown that sounds conditioned to electrical shocks are processed by direct projections from the thalamus to the amygdala in rats (eliciting preparatory neuroendocrine and peripheral responses), before more extensive processing via the auditory cortex and the association areas occur. Similarly, pieces of music that have been consistently associated with evolutionarily prepared (or other powerful, unconditioned stimuli) can be evaluated at very low levels of the brain and evoke emotional responding.

One interesting issue that, so far, has not been much explored in the psychology of emotion, is that, either as a part of intrinsic valence detection or as a separate

mechanism, there may be automatic evaluation of aesthetic qualities. Thus, it cannot be excluded that there are some universal criteria of beauty that are evaluated automatically on the basis of visual and auditory stimulation and give rise to an affective response (see Etcoff, 1999). This is certainly the case for the schematic level of appraisal where learned aesthetic preference may play a powerful role.

The capacity of musical stimuli to elicit emotion via processes of higher-level appraisal are virtually unlimited. The appraisal criteria or dimensions suggested by appraisal theorists in particular concern the goal conduciveness/obstructiveness of an event, the individual's potential to cope with the consequences, as well as socionormative and self-ideal norms or standards, (for a summary, see Scherer 1999). Very simply put, appraisal theory predicts that if I have to listen to music that I tend to abhor and that in addition disturbs my concentration on an important task at hand (obstructiveness with respect to desires and goals), I will experience anger or aggravation if I believe it is possible to get the music to stop eventually, and desperation or resignation if I feel powerless.

It can reasonably be argued that music plays only a secondary role in this example, easily exchangeable with any other disturbing stimulus. Future work in this area will need to pay much greater attention to motivational constructs that are specific to music. Why do people listen to music? Why do they go to concerts? Why are some pieces chosen over others? These are the kinds of motivational urges that need to be taken into account when assessing goal conduciveness or obstruction in appraisal processes antecedent to emotions produced by music. More detailed discussions of this point can be found in the chapters by Sloboda and O'Neill, DeNora, and Gabrielsson (this volume).

The evaluation of the compatibility of a stimulus event with external standards (norms, cultural values) and internal standards (personal values) as part of emotion antecedent appraisal is highly relevant for emotion elicitation via music. There seem to be prescriptions specific to culture and/or historical periods as to what is aesthetically pleasing or beautiful and what is to be rejected as a violation of 'good taste' (e.g. Farnsworth 1969; Kenyon 1991; see also Lynxwiler & Gay 2000, for an interesting recent example). Throughout musical history, the social norm or standards criterion has been involved in powerful emotional reactions towards 'modern' music, which was seen as violating established standards of morality and decency. The well-known scandal provoked by the première of Igor Strawinsky's dissonant and polyrhythmic *Sacre du Printemps* or by the première of Edgar Varèse's surreal *Deserts*, both in Paris, are just two particularly drastic examples of strong emotional reactions to the perceived disregard of established standards.

Appraisal processes, then, are one possible route by which emotion may be generated by music. Before turning to other potential mechanisms of emotion production, let us mention certain limitations with this explanatory approach. First of all, the appraisal dimensions pertinent to an evaluation of music may only be in part the same as the dimensions implicated in the generation of everyday emotion. In fact, it has often been claimed by theorists that music does not seem to present stimulus antecedents that are usually implicated in emotion appraisal (e.g. Budd 1985; see also Davies, this volume; Sloboda & Juslin, this volume). Methodologically, examination of this route faces particular challenges, one of which is the microanalysis of specific appraisal processes that

continously precede emotional changes in *real time.* Appropriate methods for such sophisticated analyses do not exist and have yet to be invented.

Memory

Another central route that is well established as a mechanism of emotion induction is imagination or recall from memory. In these cases, a strong emotional reaction that an individual has experienced in the past resurges in memory, spontaneously or triggered by a specific cue, or is evoked due to an experimental instruction to vividly imagine the event. It has been suggested that expressive and physiological reaction patterns to emotion-inducing events are stored in memory together with the experiential content (Lang 1979; Lang *et al.* 1980). In consequence, it is often claimed that recall of past emotional experiences from memory and imagination can evoke similar emotional reactions as in the original experience. The empirical evidence for such memory-induced resurgence of expressive and physiological reactions is still scarce (but see Contrada *et al.* 1991; Dalton 1998; Tarrant *et al.* 1994) except for clinical evidence from the area of post-traumatic stress disorder (Pitman *et al.* 1999; van der Kolk 1997).

Music, like odours, seems to be a very powerful cue in bringing emotional experiences from memory back into awareness. This is not surprising, for two reasons: first, music is quite a pervasive element of social life and accompanies many highly significant events in an individual's life—religious ceremonies, marriage, burial rites, dancing, and other festivities, etc. Thus, there are many associations between musical elements and emotionally charged memories. Second, music, like odours, may be treated at lower levels of the brain that are particularly resistant to modifications by later input, contrary to cortically based episodic memory (e.g. LeDoux 1992).

Empathy

In the two routes described above, emotion elicitation was based either on the occurrence or the remembering of an event of major significance to the individual. However, emotions are sometimes elicited by just *observing* another person being affected by an event that is very important to him or her but not necessarily to us. Examples are pity with someone afflicted by malfortune or shared joy with someone who has succeeded beyond expectation. The lower part of Fig. 16.1 illustrates three possible origins of such 'commotion' (for further detail, see Scherer 1998). The arrow to the left marks a 'normal' case of emotion *induction* via appraisal: we evaluate the event that has produced the emotion in the person we observe and evaluate it in a similar fashion, with similar results. Even if we are not directly affected by the consequences of the event (e.g. an unreasonable action by a third person), we may evaluate the injustice or unreasonableness in exactly the same fashion as the person that is directly concerned and react equally with anger or irritation (possibly without knowing the reaction of the person concerned). The middle arrow illustrates the mechanism of *empathy.* Here the assumption is that we directly identify with the person concerned and feel 'with' her or him. The process of empathy requires sympathy—were we to dislike the person in question, we might actually feel the opposite emotion (e.g. joy over our enemy's anger). Finally, the right arrow illustrates a mechanism often called *emotional contagion.* Here, the essential feature is the observation of the motor expressions of the person concerned,

possibly without any knowledge of the event that caused the reaction. The assumption is that the sheer observation of strong motor expressions can produce similar muscular innervations in ourselves. This process, generally called 'motor mimicry' (Eisenberg & Strayer 1987), has been at the centre of a theory of emotional inference suggested by the German philosopher and psychologist, Lipps (1909). He argued that understanding the emotions of others occurs through *Einfühlung* (empathy), which is based on our mimicking, at least in a rudimentary fashion, the expressive patterns we see in the other (in other words, a contagion, at least of the expressive movement).

Why are these mechanisms of interest to the issues at hand? The link becomes clear when we try to extend the model in Fig. 16.1 to the situation of mass media communication such as film or TV. Assume that you are watching a character in a movie who is experiencing a very sad event, like the loss of a lover. In this case, there is no objective event, only the idea of an event that is the imaginary cause of the actor's acted feelings and the consequent expression manifestations. Assuming that the motor mimicry effect underlying contagion does not require an authentic experience, we presume that the viewer may still reproduce some of the features of the observed expression, albeit in a very weak and rudimentary fashion. In addition, it is not impossible that one will feel empathy, even though we know the emotion of the actor to be prescribed by the script. How else can we explain the tears shed in movie theatres? And, finally, we may even evaluate the imaginary event and be affected by this virtual appraisal. The adaptation of the emotion model to theatre or mass media-generated emotions is shown in Fig. 16.2 (for further detail, see Scherer 1998).

One can argue that listening to expressive music is very close to this example. Rather than an actor playing out a script, we have a musician performing a musical score. We may expect that the expressive movements in the music will lead to some kind of contagion, for example, a certain rhythm producing synchronized movements of the body. This mechanism will be described in greater detail below, because

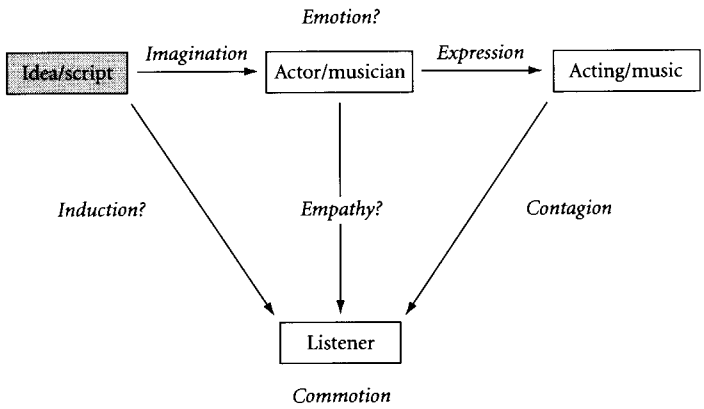

Figure 16.2 Adaptation of the commotion model in Fig. 16.1 to the case of listening to emotionally expressive musical performances, based on the suggestions concerning emotion communication in the mass media in Scherer (1998). Grey shading indicates the potemtially virtual nature of ideas/scripts.

it may occur on a peripheral rather than a central level. However, there may also be a kind of empathy with the emotion presumed to be felt by the performer that may be construed in our imagination through an underlying 'idea' that is seen as responsible for the emotional state that is expressed (for example, the longing of the composer for his homeland, as in Dvoràk's 'New World Symphony'). Thus, emotion might be induced by the identification with a performer seen as living through an emotional experience produced by an underlying idea. We expect that such a process of musical empathy will be more likely in the case of listening to an admired performer (a listener feature, for example, an attitude) who is performing in a highly emotional manner (performance features such as skill, interpretation, and affective state). Finally, one might wonder whether, even in the absence of such performance cues, the 'underlying idea' might induce an emotional state on the basis of the evaluation of the musical structure of the piece alone. While these hypotheses are highly speculative, they do have the merit of bringing the investigation of the emotional effects of music theoretically closer to other kinds of live or mediated performances (theatre, movies, TV) that are generally considered to have the potential for emotion induction in the viewer, thereby providing opportunities for theoretical and empirical cross-fertilization.

16.1.3 Peripheral route production

Proprioceptive feedback

This route, while much less established than those described above, provides an interesting alternative, especially for some types of music. It is based on the idea that the emotion system consists of integrated components and that the system as a whole can be activated by manipulating the patterning of one of its components. For example, in a series of studies, Ekman and Levenson have provided some evidence that it may be possible to induce physiological and experiential emotion reactions by asking an individual to produce the facial patterning that is characteristic of certain emotions (without the person being aware of this purpose; see Ekman *et al.* 1983). While these findings are often contested, explaining the effects by a variety of experimental artefacts (e.g. Boiten *et al.* 1994), Ekman, Levenson, and their collaborators have systematically replied to these criticisms by adding further controls in replication experiments (P. Ekman, personal communication). The general idea is also consistent with proprioceptive feedback theories (e.g. facial feedback; see McIntosh 1996) that claim, in their strong form, that subjective feeling can be produced, or in their weak form, enhanced or intensified, by increased or uninhibited motor expression.

Thus, if music could be assumed to systematically influence one of the emotion components, peripheral mechanisms might be invoked to explain a spread to other emotion components, thus in fact producing emotion states that did not exist before. One potential candidate for such influence is rhythm. We all know the contagious effect strong musical rhythm has, at least on susceptible individuals who find it difficult not to move their heads or their legs in unison with the rhythm (e.g. in the case of dance rhythms, marches, or techno beat). Recent evidence suggests that such coupling of internal rhythms to external drivers, as originally described by Byers (1976), might be present at

a very early age (Rochat & Striano 1999). If there is, indeed, a fundamental tendency for synchronization of internal biophysiological oscillators to external auditory rhythms, such coupling may provide a promising explanatory venue for the emotion-inducing effects of music. For example, given the close relationship of respiration and cardiovascular function, a change of respiration through musical rhythm may have an impact on a variety of neurophysiological systems (Boiten *et al.* 1994), in many ways similar to emotion-induced physiological changes.

Facilitating the expression of pre-existing emotions

So far, we have discussed the production of emotions where there were none before. Another potential effect of listening to emotionally arousing music can be the weakening or the elimination of control or regulation efforts. Due to sociocultural display and feeling rules, or because of strategic considerations, emotional reactions are often highly controlled or regulated, both with respect to motor expression and subjective feeling (Ekman 1984; Goffman 1959, 1971; Hochschild 1983; Scherer 2000*b*). One interesting effect of music, so far reported more often in an anecdotal fashion than empirically established, seems to be a loosening of such control or regulation effects. Movie-goers often report that, while watching a moving film, when the music started they could no longer hold back their tears. This effect may be partly due to similar contagion effects as described in the section above: when a pre-existing tendency toward specific motor expressions and physiological reactions is reinforced by external stimulation, it may be much harder to keep affect under control.

This remark on facilitating mechanisms concludes our overview of some of the mechanisms that may underlie the production of emotion through music. It should be noted, however, that we do not suggest that these mechanisms function in an exclusive manner. Rather, we assume that, generally, all of these mechanisms are operative jointly but having, depending on the circumstances, more or less of an impact on the emotional state produced. Thus, the peripheral route via rhythm entertainment may be particularly powerful for certain types of musical structures (lullabies, waltzes, or marches) and for particular occasions (a ballroom setting or a carnival march). In contrast, the central route, both via appraisal, associative memory, and empathy effects may be dominant in cases where one listens to well-known music in a reflexive mood, as in a concert setting.

16.1.4 Evidence

While there is massive evidence that listeners consistently *attribute* specific emotions to certain types of music, it is much more difficult to find convincing evidence that music can indeed *produce* emotion through one of the mechanisms described above. This task is rendered all the more difficult by the problem of deciding on a valid criterion for the *presence* of a certain emotion. As shown below, most studies have used a verbal report criterion, that is, listeners reporting that they are actually experiencing a certain emotion or affective feeling state as a consequence of listening to a particular piece of music. However, the danger of experimental artefacts, demand characteristics, social desirability, and many other problems besetting verbal report make one wonder whether verbal report can really be considered the gold standard as a criterion for genuine emotional experience (see below).

Ideally, the criterion to be used should be linked to the psychological definition of emotion as a hypothetical construct, that is, the operationalization, accessible to empirical measurement, as to the necessary and sufficient conditions to diagnose the presence, including beginning and end, of an emotional episode. So far, there is no consensus on such an operational definition in the literature. However, there is increasing convergence on the notion that emotions need to be seen as multicomponential phenomena (Scherer 2000*a*), involving at least the components of physiological arousal, motor expressive behaviour, subjective feeling, and possibly also a motivational component in the form of action tendencies and a cognitive component consisting of emotion-constituent appraisal and reappraisal (of external and internal events, including the emotional reaction itself). In addition, there is widespread agreement on the need to conceive of emotions as constantly changing processes, or episodes, rather than steady states. Thus, Scherer (1984, 1993, 2000*c*, 2001), proposing a *component–process model of emotion*, has suggested that researchers should use the criterion of coupling or synchronization of the different emotion components as evidence that an individual *has* a certain emotion at a particular point in time (see Table 16.1). Using this strict criterion, the claim that music induces emotion would have to be instantiated by studies showing that listening to a piece of music reliably leads (at least for a clearly specified group of listeners and under specified context conditions) to a synchronization of cognitive, physiological, motor-expressive, motivational (in the sense of evoked action tendencies), and experiential (subjective feeling) processes.

Although a few musical mood induction studies have incorporated multiple measures of affect (e.g. Albersnagel 1988; Kenealy 1988; Pignatiello *et al.* 1989; see also below), it may take a while until a study that measures at least three of the different components and determines their synchronization, is designed, excecuted, and published. In consequence, we will review the available evidence on the basis of individual components, providing an inventory of empirical findings separately for each of the components.

Cognitive changes

The philosophical literature across the ages has credited music with multiple effects on the mind, especially the power to provoke specific images or ideas that were, in turn, assumed to produce some of the emotional effects (for recent overviews of the philosophical literature, see Budd 1985; Davies 1994). Similarly, music is often supposed to affect judgment and evaluation. Unfortunately, few of these presumed effects have been empirically validated, demonstrating significant, experimentally induced effects for appropriately operationalized variables. The most frequently examined effects of music on cognitive performance have focused on memory.

For example, Martin and Metha (1997) examined the effects of musical mood induction on recall of childhood memories and found that music had an impact on the total number of memories recalled in the happy condition, but that there was no significant effect of sad music on eliciting sad memory recall. Balch *et al.* (1999) demonstrated mood-dependent memory effects following mood induction through music (i.e. the facilitation of remembering events one has memorized under the effect of a certain emotion when a similar emotion is elicited) (Blaney 1986; Forgas 1991). Their results suggest that it seems to be mostly the valence dimension of the emotional state that triggers the effect.

In one of the few experimental studies on the effect of music on judgmental processes, Bouhuys *et al.* (1995) showed that participants who felt depressed after listening to sad music perceived more rejection/sadness in faces with ambiguous emotional expressions and less invitation/happiness in faces with clear, unambiguous expressions. Some pertinent work may also be found in the studies on the effect of music on consumer attitudes and behaviour (Hargreaves & North 1997; see also Brown & Mankowski 1993, which is discussed below under 'subjective experience').

Physiological arousal

The idea that music can influence the ANS (also called the peripheral or vegetative nervous system) both in an arousing and a calming fashion is a very old one, going back at least as far as Greek philosophy (Bartlett 1996). Similarly, in many contemporary, popular treatments of this issue, the power of music to affect our autonomic nervous system and even the immune functions of our body are evoked. Thus, Ornstein and Sobel (1989) suggest that music evokes a calmness that may decrease blood pressure and reduce stress, and that it may help control hormones that suppress the immune system.

As to the empirical study of this idea, the French composer Grétry (1741–1813) is credited with the first reported attempt to measure cardiovascular effects of singing by counting the pulse rate by placing a finger on an artery (Diserens 1923, cited in Bartlett 1996). Serious study of the notion that music affects the ANS started as soon as the first instruments for physiological measurement became available and has continued unabatedly for the last 120 years, the period reviewed by Bartlett (1996). In general, researchers were concerned with the arousing or stimulating versus calming or sedating effects of music. Bartlett concludes that in the majority of studies (estimated at 61 per cent), an effect of music on different ANS parameters, corresponding to the prior hypothesis (e.g. increased heart rate and muscle tension for arousing music vs. decreased heart rate, decreased muscle tension, increased skin temperature, increased skin conductance for calming music) was found. There were, however, important differences between physiological variables: while the cardiovascular predictions were confirmed in only 39 per cent of the studies, skin temperature predictions were confirmed in almost all studies.

The large majority of studies reviewed by Bartlett (1996) focused on the issue of arousal versus relaxation as emotional effects of music. Given the period of time in which most of these studies were conducted, this is congruent with the dominant view of emotion during the heydays of behaviourism in psychology. This view defined the emotions as states of the organism characterized by different degrees of psychophysiological arousal or activation (Duffy 1941).

More recently, following the work of Tomkins (1962, 1963, 1984), and particularly his followers Ekman (1984, 1992) and Izard (1971, 1994), the Darwinian notion of a limited number of 'basic' or 'fundamental' emotions serving adaptational purposes (which has been postulated by philosophers since the dawn of time) reasserted itself (see Sloboda & Juslin, this volume, for further discussion). If the induction of emotion via music is seen from this theoretical angle, the issue becomes to demonstrate which of the basic emotions are elicited by a specific piece of music, as judged from the physiological

response pattern observed. This question is consistent with the idea prevalent in musical circles ever since the baroque *Affectenlehre* (Mattheson 1739), claiming that music can express specific emotions, a position violently attacked by Hanslick (1854). One could presume that if music can express discrete emotions, it might also be able to generate or induce these same emotions (see 'production rules' above). The evidence required to prove such induction is the production, via music, of the specific patterns of physiological reactions that are postulated for the basic emotions by theorists in that tradition (Levenson 1992) and that have been demonstrated, more or less convincingly, in studies using film stimuli, imagination, or other induction techniques (Ekman *et al.* 1983; but see also Cacioppo *et al.* 1993; Stemmler 1996).

In an exploratory study, Krumhansl (1997) attempted to examine this prediction. She presented 38 Berkeley students with six excerpts from pieces of classical music that are generally expected to induce specific emotional states (and which were consensually rated, by another group of judges, to express the emotions of sadness, fear, happiness, or tension). Eleven physiological parameters, the large majority tapping respiration and cardiovascular functioning, were measured while subjects were listening to the music excerpts (average duration 3 minutes). The results supported the general prediction that music does indeed affect the ANS: during the listening periods, many of the physiological parameters had values significantly different from those during the pretrial (resting) period. Furthermore, Krumhansl was able to show statistically significant differences between the music samples (chosen to express the three emotions, sadness, fear, and happiness) in the extent to which they seemed to influence specific parameters (e.g. sadness excerpts producing large changes in heart rate, blood pressure, skin conductance, and temperature; fear excerpts producing large changes in pulse transit time and amplitude; and happy excerpts producing large changes in respiratory patterns). The author found that these changes were rather well correlated with subjectively reported experiences when analysed on the level of dynamic change over time, but not for the averaged physiological parameters and an overall judgment of emotion for a piece.

However, with respect to the central piece of evidence, the matching of the emotion-specific physiological response patterns, the results were far less encouraging. While, in some cases, the changes for a particular parameter went in a similar direction as the theoretically postulated ones, it would be difficult to argue that complete physiological response patterns, prototypical for 'discrete' or 'basic' emotions, were found. In any case, this would be a tall order, given that even psychologically highly sophisticated induction techniques, designed to produce specific emotions, so far have not yielded the kind of specificity in physiological response patterning that is expected by discrete emotion theorists (see Cacioppo *et al.* 1993; Stemmler 1996).

In a well-designed and higly controlled study using very naturalistic inductions of anger (harassment by experimenter) and fear (dangerous equipment failure), Stemmler and his collaborators (2001) were able to find systematic differences between anger and fear that can be directly linked to the differential action tendencies (i.e. fight and flight; see Frijda 1986; Scherer 1984) for these two emotions. The authors conclude that significant differences can only be expected on the basis of functional demands on behaviour and express some doubt as to the existence of highly specific patterns for many different emotions.

In another music induction study, Nyklicek *et al.* (1997) presented 26 undergraduates with 12 classical music excerpts (of 120–220 seconds' duration), with three excerpts each having been found to reliably express emotional states described as happy, serene, sad, or agitated. Physiological measurement again focused on cardiorespiratory variables. Rather than try to match theoretically defined patterns for discrete emotions, the authors employed multidimensional discriminant analysis to examine whether the reactions to the excerpts with different affective tones could be reliably distinguished on the basis of the physiological patterns. The discriminant analysis classified the reactions to the four types of excerpts with an accuracy of 46.5 per cent, the first discrimination function being largely determined by respiration parameters (reflecting an arousal or activation dimension), and the second dimension being determined by dynamic aspects of the cardiovascular processes (interbeat interval and left ventricular ejection time). While the first dimension was directly linked to subjectively perceived arousal, the second is more difficult to describe with respect to subjective meaning of the emotion space (it did not directly represent the valence dimension of subjective experience). The authors interpret their findings as evidence for both a discrete emotion and a dimensional model, arguing that the lower-order discrete emotions may be discriminated in a space formed by higher-order dimensions. This is reminiscent of the claims made by all dimensional models, starting with Wundt (1974). However, it should be noted that emotion theorists proposing dimensional models generally focus on the subjective feeling rather than the physiological or expressive components of emotion (see Scherer 2000*a*).

In a recent series of studies, Witvliet and Vrana (1996; Witvliet *et al.* 1998) looked at the effect of music on autonomic measures of skin conductance and heart rate, as well as on the somatic parameters of electromyographic change scores for the zygomatic, corrugator, and orbicularis oris muscles in the face. The music excerpts had been preselected with respect to their scores on the valence and arousal dimensions. In line with the earlier literature reviewed by Bartlett (1996), their results showed clear arousal effects on the autonomic measures with increased levels of skin conductance and heart rate, as well as increased tension of the orbicularis oculi muscle, during listening to excerpts judged as high on the activity dimension. In addition, they were among the first to show *valence* effects for music, particularly for the somatic measures. As predicted by discrete emotion and appraisal theorists (Ekman 1992; Scherer 1986, 1992), there was increased corrugator activity (used in frowning) while listening to music with negative valence and increased zygomatic activity (used in smiling) for music with positive valence (especially when combined with high arousal). This is consistent with the results of a more recent study (Lundqvist *et al.* 2000), in which facial electromyography, autonomic activity, and emotional experience were measured while subjects listened to happy and sad music. The happy music elicited larger zygomaticus activity, larger skin conductance, lower finger temperature, more (self-reported) happiness and less sadness compared with the sad music.

Limitations of the studies reviewed above include the lack of sensitivity to the dynamic unfolding of the effects of music over time (often with very rapid changes) and the lack of attention to the determining role of musical structure. Indeed, much of this research only examined physiological reactions integrated over a relatively long time interval. Furthermore, often no expert analyses of the structural features (musical

score) were done to examine, or at least derive hypotheses about, what exactly in the music might have been responsible for the reported physiological phenomena.

A pioneering study by Vaitl *et al.* (1993) took both of these aspects into account. In a field study carried out in the festival theatre of Bayreuth in the summers of 1987 and 1988, 27 listeners were psychophysiologically examined while listening to a number of Wagner operas, from *Tannhäuser* to *Parsifal.* However, only data produced by three subjects in response to the leitmotivs during *The Mastersingers of Nuremberg* were analysed in depth. Electrodermal responses, respiratory activity, and ratings of emotional arousal were continuously recorded and analysed during the leitmotivs. It was shown that physiological responses differed markedly with respect to the leitmotivs and their musical features (e.g. melody, rhythm, continuation). An important additional finding was the interindividually variable, but overall weak, correspondence between emotional arousal ratings and physiological responses. Although this case study has obvious limitations, it is a good model to follow for future studies, combining dynamic measurement, on line, of physiological changes and feelings of emotional arousal within a live performance and linking the observed values to particular features of musical structure.

Motor expressive behaviour and action tendencies

From ancient times, there has been an assumption that movement is a key component, if not the underlying mechanism, of emotional reactions to music. This position is, for example, articulated by Aristotle as follows

> Why is sound the only sensation that excites the feelings? Even melody without words has feeling. But this is not the case for color or smell or taste . . . But we feel the motion which follows sound . . . These motions stimulate action, and this action is a sign of feeling (cited in Helmholtz 1954, p. 251).

Among modern philosophers, it is, in particular, Edmund Gurney and Carroll Pratt who gave a central place to movement in their theories of emotional effects of music (Gurney 1880, Pratt 1931).

The fact that much of modern-day music listening occurs under ritualized conditions in the concert hall, under more relaxed conditions in one's living room or car, or via earphones while pursuing all kinds of activities, masks the fact that throughout history much music was composed with very specific action tendencies in mind—getting people to sing and dance, march and fight, or work and play together. Composers of dance music and marches attempt to entice listeners to produce the appropriate rhythmic movements, and many people actually report that they cannot sit still and have trouble suppressing rhythmic body sway and other movements when hearing some bars of a Strauss waltz. On the other hand, lullabies evolved because of their presumed ability to put children to sleep, thus leading to the opposite effect of inhibition of motor arousal (Trehub & Schellenberg 1995).

One would expect, then, to find mechanisms that can produce motor expression and action tendencies via the peripheral production route described above. In one of the few attempts at theoretical foundation, Todd (1992) suggests that expressive sounds may induce a percept of self-motion in the listener via the central vestibular system. The

argument is that expression based on elementary mechanics may sound natural because the vestibular system evolved to deal with similar kinds of motions (i.e. gravity and linear and rotational acceleration). As mentioned above, Byers (1976) reviewed potential mechanisms for rhythm induction. Clynes (1977) also argued for pervasive emotion-specific dynamic motor patterns.

Unfortunately, hard empirical, especially experimental, evidence for the production of motor patterns and action tendencies by music is rare (but for some attempts, see Fraisse *et al.* 1953; Harrer & Harrer 1977). Kneutgen (1964) discussed the biological significance of rhythm synchronization in different species and emphasized the role of music in driving biological rhythms. In an interesting pilot study (Kneutgen 1970), an Argentinian lullaby was played to four listeners in sessions lasting from 30 minutes to 2 hours (almost every day for a period of 3 months). It was found that the lullaby had the effect of markedly decreasing heart rate. In addition, the breathing rhythm became synchronized with the rhythm of the music. Interestingly, no such effects were found in a control group exposed to jazz music.

DeVries (1991) used Clynes' (1977) *sentograph* to measure affective motor responses to music and reported that the pressure patterns shown for 11 brief musical excerpts were similar across subjects and seem correlated with the expressive content of the music. However, so far convergent evidence from methodologically sophisticated studies on the validity of the sentograph are missing, and also the theoretical assumptions underlying its use seem rather elusive (but for studies in this area, see Carmean 1980; Gorman & Crain 1974; Nettlebeck *et al.* 1989; Trussoni *et al.* 1988).

Generally, there have been very few controlled studies using measures other than verbal report, on the induction of dynamic motor behaviour or specific action tendencies by music. The same is true for motor expression in the voice and face. In one of the very few studies looking at the facilitation of vocalization by music, Pujol (1994) varied the instrumentation (flute vs. bells) in two types of melodies (pentatonic vs. major) and studied the effects on physiological (respiration and pulse rate) and behavioural responses (eye movement, facial expression, vocalizations, and motor movement) of 15 profoundly handicapped persons. The music (particularly the major flute melody) stimulated the production of vocalizations, an effect which decreased over time.

Given the assumption that the face is 'the primary theatre' of the emotions (Ekman 1992; Tomkins 1984), one would expect to find much evidence for the facilitation of facial expression via music. Again, appropriate studies are rare. However, as reviewed above, Witvliet and Vrana (1996) reported evidence that different kinds of music differentially stimulate the innervation of the zygomatic muscle or corrugator muscles (see also Lundquist *et al.* 2000).

Studies on the effects of music on the tendency to perform certain actions (e.g. prosocial or aggressive acts) tend to be rare. In an experiment by Fried and Berkowitz (1979), different groups heard 7-minute-long musical selections that were either soothing, stimulating, or aversive in nature, while a fourth group was not exposed to any music. Those who heard the soothing music were most apt to show altruistic behaviour immediately afterwards (volunteering for another study). Mood ratings indicated that the soothing and stimulating music created somewhat different positive moods, while the aversive music tended to arouse negative feelings.

Subjective experience (self-report of feeling)

Among the methods used to study emotion induction through music, the self-report of feeling has been the most widely used approach. However, most studies having examined emotion *production* via self-report were not carried out within the area of music psychology, where the main emphasis has been on the perception of emotion in music. Assessments of emotion production via self-report is typically found in *mood induction* studies. The aim of such studies is often to examine the effects of different affect states, moods, and emotions on cognitive and evaluative processes, memory, behaviour, and physiology. Such 'instrumental' use of music as a means of emotion or mood manipulation has rapidly increased in recent years, placing music among the most widely used techniques for mood induction in psychology (for a review of mood induction studies, see Westermann *et al.* 1996).

There are two ways to examine the success of a given mood induction. One is indirect, relying on significant effects of the mood conditions on the dependent variables of interest. However, in addition, a self-report of mood or emotion is often used as a so-called manipulation check for the success of the mood induction. Typically, after the mood manipulation, the subject is given a self-report measure of mood. The results are then compared across mood conditions and significant differences among the conditions are interpreted as evidence for the success of the mood induction. Some of the most frequently used self-report instruments to assess emotion or mood production via music include: the multiple affect adjective check list (MAACL(-R-)) (Zuckerman & Lybin 1985); the Nowlis mood adjective checklist (Maslach 1979); the visual analogue scales (VAS) (Bond & Lader 1974); and the brief mood introspection scale (BMIS) (Mayer & Gaschke 1988).

The use of self-report measures as evidence for emotion production has both advantages and disadvantages. It remains the only method that allows access to the subjective emotional experience. Therefore, it should not be replaced by any other measure. However, the data collected in this way are sensitive to the following potential biases and artefacts that need to be carefully considered before conclusions are drawn. Firstly, demand characteristics can be responsible for the mood effects found. Secondly, listeners may confuse the emotions expressed in the music with what they actually feel unless they are specifically requested to distinguish between the two emotion modalities, as has been the case in our recent studies (Zentner *et al.* 2000).

To be taken as indicators of mood effects of music, then, self-report measures have to be validated against other criteria, or they have to be experimentally controlled. Following the latter avenue, Kenealy (1988) has compared self-reported mood effects in two conditions; one in which demand characteristics were intentionally created and one in which the effect of demand characteristics was minimized. She found no effects of demand characteristic on self-reported mood effects, concluding that the 'music procedure is relatively free from demand characteristics' (Kenealy 1988, p. 46). However, one could argue that the so-called 'no demand' condition was in reality also affected by demand characteristics. Subjects were left alone in a room by the experimenter who left on the pretext of having something urgent to attend to. Then, happy or sad music (depending on the condition) was played for 8 minutes. The subject, knowing they were in a psychological experiment and suddenly hearing music, might well have guessed the

purpose of the experiment even without explicit demands and even without admitting it after the experiment. Such difficulties in the interpretation of the results notwithstanding, Kenealy's research is important in suggesting possible strategies for controlling demand effects.

The second criticism, confusion of perception and induction, is particularly relevant to studies in which subjects are explicitly instructed to report what they feel in response to the music. Kivy (1989) has argued that listeners make a fundamental attribution error in that they *habitually* take the expressive properties of the music for what they feel. This position is not new. In fact, it has already been summarized by Meyer (1956, p. 8) as follows: 'it may well be that when a listener reports that he felt this or that emotion, he is describing the emotion which he believes the passage is supposed to indicate, not anything which he himself has experienced'.

To our knowledge there is little, if any, empirical evidence to back up this claim. For this reason, we recently conducted a study in which participants were instructed to describe both what they *felt* and what they *perceived* in response to different genres of music. We found that the type of instruction (felt vs. perceived) changed the results quite dramatically (Zentner *et al.* 2000). Overall, the majority of emotions were reported much less frequently when the participants were instructed to focus on the *production* rather than the *perception* of emotion. This does, of course, not suggest that particular emotions are never felt in response to music, as Kivy would have it. (As a matter of fact, for particular emotions the reverse was true—they appeared to be more readily felt than perceived.) However, it indicates that the distinction between perception and production of emotion is empirically valid and that it is essential to take this distinction into account when instructing people to report their emotional responses to music. The studies by Kenealy (1988) and preliminary evidence from our group show that, although verbal reports of moods and emotions have their limitations, there still is much to be done to improve their quality.

In addition to asking listeners directly about their emotional reactions, there is also the possibility of assessing the feeling state without asking subjects directly about their emotional experience. Little use has been made of this possibility in the present area. In a recent review of mood effects on judgments and social cognitions, Forgas (in press) discusses several paradigms that could also be easily applied to the study of music and emotion. In some of these paradigms, subjects are asked to rate something other than affect or mood, for example certain individual dispositions related to attitudes, personality, or self-esteem. In a typical study (Brown & Mankowski 1993), a musical mood induction was used to induce positive, negative, or neutral affect. Afterwards, listeners evaluated *their* specific qualities and characteristics (How smart are you? How kind are you?). It was found that subjects rated themselves more favourably after listening to happy compared with sad music (see also Bouhuys *et al.* (1995), which is discussed above under 'cognitive changes'). Interestingly, this effect was stronger for subjects with low self-esteem, suggesting greater sensitivity to mood manipulation for this particular group.

In sum, because access to the subjective emotional experience of a listener is logically impossible without verbal report, optimization and extension of these methods is indicated. Perhaps, in the future, various brain-imaging techniques can be used as additional

indicators of subjective feeling state (cf. Peretz, this volume). At present, verbal report remains the only means to assess this important component of emotional experience. Therefore, it is surprising that there has not been more effort made to systematically develop a vocabulary suited to describe what listeners feel in response to music. This is even more striking if we consider the doubts, expressed by several theorists, that emotional responses to music may not resemble everyday life or basic emotions, such as anger, fear, joy, sadness, shame, and disgust. Thus, Lippmann (1953, p. 569) suggested: 'Musical feelings have their own character: they are not the feelings we know and roughly name in our experience outside of music . . . Thus music may be an emotional experience, and still not represent emotional contexts belonging to other areas of life, for the emotions it formulates are not identical with those accompanying extra-musical experience, nor does the one kind necessarily remind us of the other'.

As is often the case in this domain, there is little empirical evidence to confirm or invalidate this conjecture. Few efforts have so far been made to examine whether the basic emotion categories derived from emotion psychology are theoretically sensible, empirically valid, or musically plausible for describing the emotional experience induced by music. The few systematic attempts at creating a taxonomy of 'musical emotions' (e.g. Hevner 1936; Rigg 1964; Wedin 1972; see also Gabrielsson & Lindström, this volume) were entirely focused on perceived, not aroused, emotions. As has been pointed out by Sloboda (1992, p. 36), 'The relevance of these studies to emotional experience, however, is not proven. It is possible to make character judgements on the basis of conventional characteristics without experiencing any emotion whatsoever'. Moreover, these attempts lacked rigour, as has been pointed out recently by Gabrielsson (1998, p. 2): 'Procedures followed for this purpose are not always explicitly described and are rarely, if ever, based on some theory, rather on the researcher's own experiences and ideas and material used by earlier researchers'. Clearly, then, adopting a systematic approach for deriving a taxonomy of musical emotions while focusing on the aroused, not the perceived, emotions, is an important task for future research in this area.

Such work requires a theoretical background that does not prejudge the issue, as is the case with emotion theories that either, like discrete emotion theories, start from the assumption of a limited number of basic or fundamental emotions or that, like dimensional theories, focus exclusively on the valence and arousal dimensions of emotional feeling (see Scherer 2000*a*). Unfortunately, neither of these make any provision for emotion processes that may be specific to music. Scherer (1984) has suggested that there may be as many different emotions as there are differentiated outcomes of appraisal processes, rejecting the very limited taxonomy that is imposed by the semantic structure of the 'basic emotion' vocabulary in a specific language. Thus, componential process approaches (Scherer 2001) are perhaps better suited to provide the theoretical underpinnings for research on the specific emotions produced by different types of music. It should be recalled that this does not mean that conscious appraisal implying all criteria is necessarily involved in emotion elicitation via music (see above). It may be necessary to discard the standard, 'fundamental' emotion terms altogether and to focus more strongly on terms for more subtle, music-specific emotions (such as longing, tenderness, awe, activation, solemnity) that seem to describe the effects of music more readily than anger, sadness, or fear (Zentner *et al.* 2000).

16.2 Perspectives for future research

The review of the research evidence presented above has suggested that we are far from being able to provide a clear answer to the question of how music can actually *produce* emotional states. Apart from a general lack of sufficient research evidence, particularly with respect to non-verbal measures of affect, it is difficult to avoid the impression that this research domain suffers from lack of theoretical rigour. This is a bad omen for future research, since it is to be feared that additional, isolated research efforts with little or no theoretical underpinnings are more likely to add to the current confusion than to the insight to which the researchers aspire. We believe that much of the problem is due to the lack of differentiation between the different types of affective processes as described in Table 16.1. Clearly, confusion is hard to avoid when researchers apply different criteria for the evidence they require to infer the presence of the successful induction of an affective process via music. Therefore, it would be advisable for researchers to specify more carefully what kind of affective process they attempt to induce through the presentation of musical stimuli.

We suggest the adoption of the distinctions proposed in Table 16.1 for further work in this area. In what follows, we will attempt to specify in greater detail what criteria, both verbal and non-verbal, might be chosen to infer the presence of the respective process. Since it seems unrealistic to assume that music can produce any of the long-term affect dispositions in rows 4–6 of Table 16.1, only the short-term processes in rows 1–3 are discussed. Because there is no established consensus for either the classification proposed or the criteria suggested, the recommendations made below will have to be judged on the basis of their plausibility.

Preferences, defined as evaluative judgments of stimuli in the sense of liking or disliking, or preferring or not over another stimulus, are the simplest form of affect manifestations and some theoreticians may deny that they have an affective as well as a cognitive basis. However, because they are treated as emotional phenomena by some theorists (Zajonc 1980; Zajonc & Markus 1984) and because they are directly linked to valence which is seen by many theorists (especially the dimensional theorists) as an essential component of emotion (see Scherer 2000*a*), it seems mandatory to include them here. The verbal criterion for the existence and strength of induced preferences is the verbal claim by a person to like or dislike a certain piece of music with a certain intensity or certainty, or, in a comparative context, to like a piece of music more than (or prefer it over) another piece. One can also ask listeners to sort pieces of music in ascending fashion for greater liking or arrange them on a bipolar scale from extreme disliking to extreme liking.

On the non-verbal level, preferences can be assessed rather precisely by observing choice behaviour, that is, the choice of listening to one type of music rather than another, the length of listening behaviour, and other behavioural measures. Another non-verbal measure of liking is facial expression, measured either through observer coding of visible behaviour (Ekman 1992) or facial electromyography measurement (Cacioppo *et al.* 1993). The presence and strength of musculus zygomaticus innervation (smiling) can be taken as an indicator of degree of liking, and of musculus corrugator innervation (frowning) as a sign of degree of dislike. On the level of physiological measurement,

Lang and his collaborators have suggested that the startle probe (e.g. Lang *et al.* 1990) can be used as a measure of valence (positive or negative feeling state). It should be noted that these behavioural changes are expected to be stimulus-driven, that is, they should only be present in the anticipation, presence, and possibly immediate aftermath of the stimulus, in this case, the music presentation. In contrast, the cognitive judgment, and verbal expression, of liking should be permanently accessible once a stimulus is identified and remembered.

Music seems to elicit preferences almost automatically, as the work on low-level automatic appraisal, reviewed in Section 16.1.2, suggests. Even if there is no comprehensive empirical evidence at present, there is little music that people find completely neutral and for which they are impartial as to whether to listen or not, if given a choice. Judging from informal evidence, most individuals seem to have little trouble in rating the degree of preference or liking (or disliking) on standard scales. However, it seems that there are powerful differences with respect to liking and disliking (e.g. Behne 1997). This seems quite natural since music that nobody likes is unlikely to survive (although detractors of modern music often claim that this is listened to for reasons other than liking). Thus, research on the induction of preference or liking may only be of interest in a differential context.

Contrary to preferences, *moods* are generally not elicited by concrete stimulus events at a particular point in time. Rather, they are defined as diffuse affect states, most pronounced as a change in subjective feeling, of low intensity but relatively long duration, often without apparent cause and thus persisting across encounters with multiple stimulus events. Because the labels for moods and emotions are often similar, care has to be taken to clearly distinguish the two in the instructions by specifying the long-term, non-event-related character of mood states (e.g. scales of good or bad mood, touchy vs. serene mood, etc.). Similarly, behavioural indices have to remain present over a lengthier period of time and not be related to an immediately preceding stimulus. This obviously rules out behavioural choice measures because these are automatically stimulus-driven. However, enduring evidence for morose versus serene facial expression, or prosocial versus aggressive acts, might serve as behavioural indicators.

Music may well be able to produce mood effects. At least this is what the music industry suggests, in particular for positive moods, by selling selections of music destined to produce relaxation or to generally improve one's mood (Bruner 1990; for concrete marketed examples see the mood-inducing compilations by Conifer Classics 1997 and Sony 1995). Similarly, claims for the effectiveness of music therapy are based on the assumption that the effect outlasts the presentation of the music (cf. Bunt & Pavlicevic, this volume). In contrast, music designed to incite customers to buy something or to calm aggression at football games, may rely on co-presence for its effect. There are only a few studies that have addressed the issue by carefully selecting valid *mood* criteria as defined above. Future research in this area, using appropriate measures, seems of prime importance, given the important implications for applied settings.

Can music induce *emotions* in the strict sense of Table 16.1, that is, defined as relatively brief episodes of synchronized responses of all or more organismic subsystems in response to the evaluation of an external or internal event as being of major significance? According to the senior author's theory, this implies that the emotion

process is directly produced by an appraisal of the musical event and that the response pattern generated is specific to the event. While it may last beyond the presence of the event, in the case of certain emotions even for relatively long periods (e.g. Frijda *et al.* 1991; Scherer & Wallbott 1994), it is generally expected to be of shorter duration and of higher intensity than moods. Thus, contrary to preferences, valence cues should be accompanied by the presence of arousal indicators in the ANS. While these might also be present for mood, they should be more intense and less stable than in the case of mood. Furthermore, emotion processes should entail motivational changes and preparation of adaptive action in the form of modes of action readiness or action tendencies (Frijda 1986; Scherer 1984).

As mentioned above, Scherer (1984, 1993) suggested that the most salient criterion of the presence of an *emotion* process (in the strict sense defined in Table 16.1) is a high degree of coupling or synchronization of all organismic subsystems, including cognition, during the emotion episode. In order to answer the question of whether music induces emotion in this strict sense, all pertinent indicators in the respective organismic subsystems need to be measured and the degree of their synchronization assessed. So far, none of the studies in this area has attempted to do this, and it is not to be denied that it is a formidable undertaking. Yet, if one agrees to define emotions in this narrow or strict sense, it will be necessary to engage in comprehensive verbal and non-verbal measurement and powerful mathematical modelling of coupling or synchronization.

It is rather probable, of course, that one will not be able to find as intense and highly synchronized response patterns as found in the case of violent rage leading to fighting, for example. Ellsworth (1994) has pointed out that music is quite a special emotion-inducing stimulus in that it is difficult to specify the underlying concerns or goals that tend to be the motor of emotion (cf. Sloboda & Juslin, this volume). One could add, that it is also difficult to see which modes of action readiness or action tendencies that, according to Frijda (1986), define the quality of emotions, can be evoked by music. The exceptions are action tendencies like singing or dancing that are quite regularly provoked by certain types of music. However, it is likely that these action tendencies are provoked by peripheral entrainment, as described above, rather than by centrally controlled motivational changes as is generally the case in the provocation of adaptive action tendencies in 'real' emotions.

We believe that progress in the area will be difficult as long as researchers remain committed to the assumption that real intense emotions must be traditional basic emotions, such as fear or anger, for which one can identify relatively straightforward action tendencies such as fight or flight. Progress is more likely to occur if we are prepared to identify emotion episodes where all of the components shown in Table 16.1 are in fact synchronized *without* there being a concrete action tendency or a traditional, readily accessible verbal label. In order to study these phenomena, we need to free ourselves from the tendency of wanting to assign traditional categorial labels to emotion processes. Take, as an interesting example, the feelings that are rather vaguely described as 'being touched' or 'being moved' for which there is not even a substantive in some languages such as English and French (but there is *Rührung* in German). Examples are the tears shed during sentimental movies in the cinema or the flash of warmth experienced when hearing about a good deed. It would seem that such experiences are what music often produces. One is 'moved' by music (accompanied by symptoms such as moist eyes, chills, thrills, or goose-

flesh) without there being a readily accessible label to describe what one is feeling or why. Of course, this does not mean that the lack of suitable verbal labels (or the inability of normal people to discriminate different states) absolves scientists from making the necessary differentiation, falling back to simple arousal models. On the contrary, the task is to develop both suitable non-verbal and verbal indicators that allow one to identify music-induced states that may not correspond to the traditional categories described in emotion textbooks. Finally, and taking this reflection a step further, we have also to be open to the possibility that, in certain instances, responses to music may not fit the states presented in Table 16.1 and may be of a thoroughly non-affective nature.

16.3 Conclusion

The suggestions for more principled research efforts in this area, studying several components of emotion, require substantial research investments and competencies in several areas of measurement. It may be unrealistic to expect that such research efforts will emerge in the near future. Yet, even if one is unable to launch such a sophisticated research programme, one still needs to define the theoretical suppositions in greater detail if the work in this area is to achieve a status that permits systematic comparison, replication, and eventually accumulation of findings. Following the specification of the theoretical model to be tested, the appropriate measures would need to be obtained, particularly in the non-verbal domain. This chapter provides an entire spectrum of possibilities for multimodal measurement approaches, encouraging research that does not only rely on standard self-report inventories with their well-known limitations (e.g. Nisbett & Wilson 1977; Scherer & Ceschi 2000). Thus, in future research, the criterion for successful induction should be multimodal, for example verbal report complemented by non-verbal measures such as physiological responses and expressive behaviour. Some of these measures are particularly well suited for this purpose since they provide a continuous, variable signal and are in large parts resistant to conscious regulation.

What are the requirements for measurement for proponents of different theoretical approaches, as outlined above? Researchers adopting dimensional theories would need to specify the expected values for valence and activity for the emotions to be studied and include physiological and expressive indicators in addition to verbal report measurement. Proponents of discrete emotion theories would need to clearly specify the expected emotion-specific response patterns for the emotions studied and include all pertinent variables in their measurement operations. In addition, with respect to the statistical analysis it would seem necessary to use pattern-matching procedures (e.g. profile analyses) rather than simple comparisons for differences (e.g. univariate *F*-tests) between various emotions. Finally, appraisal theorists, in addition to sharpening the predictions for the outcomes to be expected for different appraisal results and the measurement of the respective variables (Johnstone *et al.*, 2001; Pecchinenda 2001), need to indicate how appraisals can be determined in the case of music. Obviously, this requires a much greater research effort than obtaining verbal reports, and one might claim that the suggestions made in this chapter are unrealistic. Yet, similar approaches can already be found in several research domains in the affective sciences and we believe that this tendency will continue.

In brief, we have suggested that by linking research on the emotional expressiveness of music more directly to the progress in the affective sciences generally (see Davidson *et al.*, in press), it may be possible to design empirical studies that are likely to yield results that can be interpreted against a background of theoretical predictions as compared with multiplying studies that have been designed on an *ad hoc* basis and that are difficult to integrate into a coherent body of literature.[1]

CHAPTER 17

CONTINUOUS MEASUREMENT OF SELF-REPORT EMOTIONAL RESPONSE TO MUSIC

EMERY SCHUBERT

By definition music requires time to happen. Many styles of music also express or evoke different emotions as time unfolds. Logically, it follows that to understand the relationship between music and emotion, psychologists need to investigate their time-varying relationships. It is therefore surprising to find that the study of *continuous* self-reported emotion in music is less than 20 years old. Continuous response tools measure self-reported emotional responses *during* the listening process and help researchers to better understand the moment-to-moment fluctuations in responses that traditional 'asynchronous' approaches cannot. The approach means that the music does not need to be broken into small portions to enable lucid response, nor does the listener have to compress their response by giving an overall impression at the end of the excerpt. A more realistic listening experience is possible. This 'realism' (Hargreaves 1986, p. 105) contributes to the ecological validity of experimental design at the expense of experimental control.

Given that the methodology is relatively new, there is a need to examine the literature and to provide a framework for future directions. Gregory (1995) and Schmidt (1996) review one kind of continuous response device, and the reviews encompass emotional response as one aspect of a broader scope. The present chapter examines a wider range of continuous measure devices, but restricts the discussion to those studies that investigate self-report emotional response. In this chapter, I will define 'continuous', describe the response formats used for collecting continuous responses, discuss the ways in which researchers have applied continuous response methodology, and then provide an evaluation of the major issues.

17.1 Definition of continuous response

The term 'continuous' is arguably used incorrectly in the literature. Continuous means without break, inferring that responses are measured without interruption. Modern techniques of measuring response require some form of sampling because they are associated with digital computers. At best, the frequency of sampling may be high, but is

still interrupted. Even a rate of tens of thousands of samples per second is still not, strictly speaking, a continuous measure. Instead, the more correct term is *continual*, or perhaps *multiple equispaced*. It is apparent that the 'erroneous' terminology stems from the kymographic devices used in physiological response studies since the late nineteenth century (Dogiel 1880 cited in Radocy & Boyle 1988, p. 205; Weld 1912), which drew line plots of physiological activities as a function of time. These analogue devices were indeed continuous. And, to be sure, high sampling rates associated with modern digital equipment can give the impression of a continuous measure.

However, the patterns and latency of emotional response makes the need for strict continuity or even high sampling rates of measurement superfluous. For example, a lexical response task alone will take in the order of 1 second (Greene & Royer 1994), and the response latency in the tracking of a musical feature, such as loudness, is 1–1.5 seconds (Geringer 1995). By the same token, the term *continuous* has been used consistently in the literature, and consequently its use will be retained to mean continuous *or* continual.

17.2 Response formats

17.2.1 Open-ended format

Three of the traditional self-report formats found in the asynchronous emotion–music literature are also found in continuous response research: open-ended (or free-verbal) format, checklist, and rating scale (Gabrielsson & Juslin, in press; Sloboda 1992; see also Gabrielsson & Lindström, this volume). Open-ended approaches (e.g. one part of the study by Watson 1942) are rarely found in the literature because of the obvious problem of the response task *during* listening interfering with the listening process.

17.2.2 Checklist

Checklist formats have also been used infrequently (Goins 1998; Hair 1995; Hevner 1936; Mull 1949; Namba *et al.* 1991). An innovative and pioneering example is Hevner's (1936) study, which was the first to use what could be called a self-report continuous response approach. Hevner addressed the problem of collecting an overall response for a piece (that may have actually expressed several different emotions) by asking the listener to make judgments at the end of each section of music as the music unfolded. For example, if a piece of music had several sections, the participant would place the number '1' next to the selected term or terms which best described the emotion in the first section of music, and when the next section of the music began (signalled by the experimenter), a '2' would be placed next to the term characterizing that section. This process continued until all sections were heard. The pieces Hevner reported were divided into three sections and, together, these sections usually made up an entire movement.

In one experiment, Hevner collected responses to *Reflections on the Water* by Debussy. She discovered that responses to the piece were widely distributed across the eight clusters (Fig. 17.1a). The experiment was conducted again using the continuous procedure. In the first section of the piece, the responses were made predominantly in clusters 5 and 7 ('humorous' and 'exhilarated'), whereas in the second section, responses shifted

to cluster 4 ('lyrical'). In the final section, clusters 4 and 5 ('lyrical' and 'humorous') were chosen most frequently (Fig. 17.1b). These results demonstrated that different sections of music evoked different, though internally consistent responses.

Despite this and later studies, the categorical approach of the checklist does not easily lend itself to continuous methodology. Categorical responses require the participant to select one or several answers from a range of answers. Unless lengthy training time is administered (e.g. 30 minutes per participant in the Namba *et al.* (1991) study), a large range of choices will require the participant to constantly shift attention between the various response options, in addition to concentrating on the music. In a continuous response task, this may either interfere with the listening experience, or lead to the omission or guessing of some responses so as to minimize interference. This might explain why there are relatively few checklist studies that employ the continuous response approach at high sampling rates. Hevner's approach of gathering responses

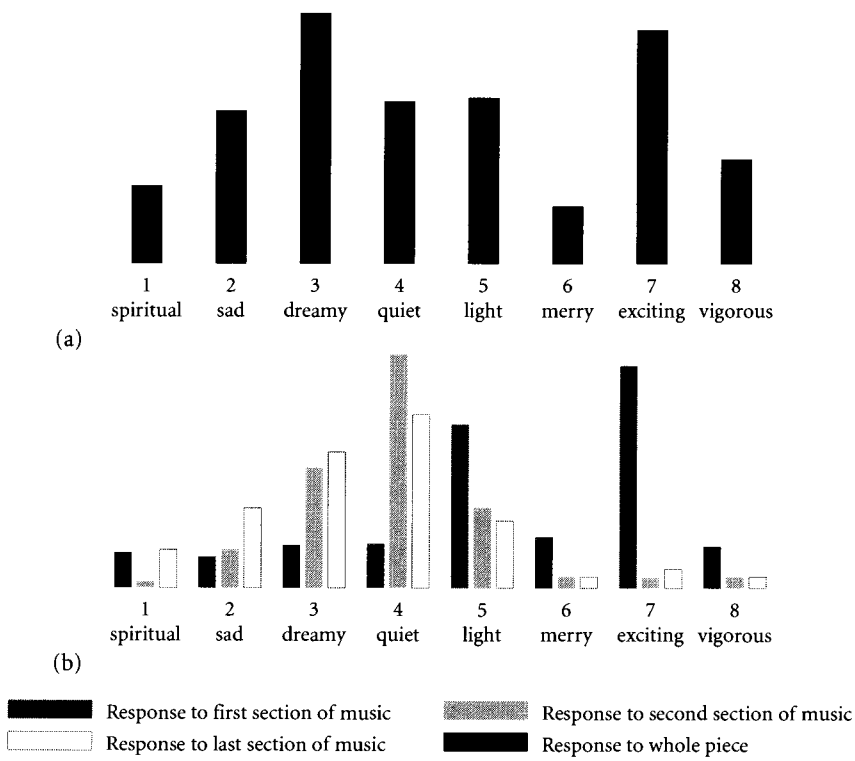

Fig 17.1 Hevner's adjective checklist responses to Debussy's *Reflections on the Water* for the whole piece and in sections (adapted from Hevner 1936, pp. 251 and 254). The numbers correspond to the cluster from the Hevner adjective circle with a representitive word from each cluster number appearing under each number (the complete adjective circle is presented in Gabrielsson & Lindström, this volume). (a) The relative frequencies of each adjective circle cluster, and (b) the responses to the same piece in a different experiment with separate responses recorded for the three sections of the music.

once only per section of music mitigates the problem, but it does not allow for the investigation of changing shades of meaning within a section of the music.

17.2.3 Rating scale

A useful subdivision of continuous response literature employing rating scale measures is according to the number of simultaneous dimensions measured. Most studies use one dimension, and more recently two scales have also been used simultaneously. One-dimensional studies have used a variety of labels representing either one specific aspect or dimension of emotion (such as happiness or tension) to more general labels (such as aesthetic experience or 'when the music causes something to happen to you'). A selection of studies using one-dimensional scales is shown in Table 17.1.

Table 17.1 Labels used in one-dimensional measures of continuous self-report emotional response, with scale labels and scale poles (or task) indicated

Self-report label	Poles/task	Examples
Aesthetic experience	Negative-positive	Capperella-Sheldon (1992)
	Negative-positive	Madsen *et al.* (1993*a*)
Chills	Raise hand if present	Panksepp (1995)
Emotion	Minimum-maximum	Krumhansl (1998)
Emotional reaction	Positive-negative	D. Gregory (1998)
Emotional response	No emotional response-emotional response	Adams (1994)
	Negative-positive	Lychner (1998)
Emotionality ('the capacity of the performance at that moment to suggest, communicate, or evoke musically relevant emotion', p. 631)	High-low	Sloboda *et al.* (1997)
Fear	Amount of fear	Krumhansl (1997))
Felt emotion	Negative-positive	Lychner (1998)
Happiness	Amount of happiness	Krumhansl (1997)
Humour	Raise hand if present	Mull (1949)
Intensity of emotions	Low-high	A. H. Gregory (1998)
Perceived artistic tension	Decrease-increase	Frego (1999)
Sadness	Amount of sadness	Krumhansl (1997)
Tension	Less-more	Byrnes (1996)
	Less-more	Frederickson (1995, 1997, 1999)
	Amount of tension	Krumhansl (1997)
	Less-more	Madsen & Fredrickson (1993)
	Amount of physical pressure on a pair of tension tongs	Nielsen (1983)
	Minimum tension-maximum tension	Krumhansl (1996)
Thrill	Raise fingers for strength and location of thrill	Goldstein (1980)
When the music causes something to happen to you	Frequency of responses	Waterman (1996)

An important criticism cast against one-dimensional rating scales is that they cannot capture the complexities of emotion satisfactorily (Schmidt 1996). One solution to this problem is to track more than one dimension simultaneously. Since 1996 there has been a trend toward the measurement of two dimensions simultaneously. An early example of what could be referred to as a two-dimensional, continuous response instrument, namely the *sentograph*, was developed by Clynes (Clynes 1977, 1980; Clynes & Nettheim 1982; see also de Vries 1991; Gabrielsson & Lindström 1995). However, because it was used to measure 'inner' emotional experience and 'essentic forms' it is, strictly speaking, not a self-report instrument. Three self-report continuous, two-dimensional 'emotion spaces' (2DES) were developed independently and almost simultaneously by Schubert (1996), Tyler (1996), and Madsen (1997). For each of these instruments, the listener makes responses by moving about a two-dimensional space (computer interface), with each axis (or scale) of the space representing a separate dimension of emotion.

There are various problems associated with rating scale measures. The following sections discuss the kinds of questions asked by continuous response researchers, followed by some of the issues and concerns relevant to continuous response methodology.

17.3 When are continuous measures used?

Continuous measures of self-report emotion in music have been used for four broad purposes: validation, comparative investigations, stimulus–response investigations, and system–dynamics investigations.

17.3.1 Validation

Continuous response measures have been used to validate traditional asynchronous response formats and vice versa. Goins (1998) compared grand mean categorical continuous response digital interface (CRDI—a dial whose manipulations are recorded on a computer in real time) responses with conventional asynchronous responses using a modified version of the Hevner adjective checklist. He noted a strong similarity between the two methods. This supports the external validity of the approach. However, with just eight categories identified (with asynchronous $n = 30$, and continuous $n = 40$), it becomes difficult to identify subtle differences between the measures and to provide a quantitative index. In a study of intensity in music, Brittin and Duke (1997) found that overall, asynchronous responses tended to be higher in magnitude than the averaged continuous response. Schubert (1999*b*) used an adjective checklist *and* an asynchronous 2DES to investigate the validity of the continuous 2DES rating scales. Participants were required to respond to a piece of music in three ways: continuously, then with an overall judgment, and finally by selecting a word from a checklist. While the checklist responses provided good agreement with averaged responses on the continuous 2DES, the overall 2DES gave a result consistent with Brittin and Duke's findings. Specifically, overall responses were more exaggerated than the average of continuous responses. Continuous responses may gravitate to the centre of the scales being used, or the relationship between averaged and overall responses are in some way scaled.

17.3.2 Comparative investigations

An example of the use of the continuous response measure for comparative studies can be found in the Madsen *et al.* (1993*b*) study which used the CRDI to compare non-musicians' and musicians' perceived aesthetic experiences. They concluded that aesthetic experiences do not differ between musicians and non-musicians. Similarly, Lychner (1998) found no significant differences between musicians and non-musicians in their continuous ratings of three classical music extracts and a Sousa march according to felt emotion, aesthetic response, and free response. Another example is the study by Sloboda *et al.* (1997) where 'emotionality' in performances of a Chopin prelude perceived by non-pianists, pianists (a subset of the pianists who had provided the performances), and music jurors were investigated. These researchers found that the pianists responded with significantly lower emotionality scores in the first segment of the piece, and significantly higher scores in the last segment of the piece, compared with the other two groups.

17.3.3 Stimulus–response investigations

The use of the continuous response device to investigate the music–emotion system (M→E) is hinted at in several studies. Madsen (1996, p. 106) compared data in studies conducted by himself and John Geringer, producing correlations between musical features (melody, dynamics, timbre, rhythm, and 'everything') that were the focus of listeners' attention with aesthetic response. The highest correlation reported was with melody ($r = 0.67$), and the next highest was dynamics ($r = 0.59$), when listening to an excerpt from Puccini's *La Boheme*, and rhythm ($r = 0.69$) when listening to the first movement of Haydn's Symphony No. 104. A. H. Gregory (1998) observed that higher intensity emotions appeared to occur during vocal passages and periods of higher loudness. In a comparative study (degrees of familiarity with the test piece), Fredrickson (1999, p. 50) described a region of judged high musical tension over bars 32–45 of 'Chaconne' from Holst's *First Suite in E♭*:

> There is a *crescendo* to a dynamic peak at measure 41, where a series of running sixteenths begin in the upper woodwinds. The musicians who are unfamiliar with the music (singers and high school pre-test) indicate a higher tension level here that continues through another statement of the melodic material in the trumpets at measure 49, where the melody moves above a heavy (*pesante*) eighth-note section in the low brass. Graphs for musicians who are familiar with the music (wind ensemble and high school post-test) drop off sharply after the *crescendo* and rise only slightly before falling off along with the other groups at the *diminuendo*, which ends the section.

Since Hevner's (1936) early exploration, a small number of studies have used continuous response methodology to focus *specifically* on the issue of the relationship between musical features and emotional response. Nielsen (1983, 1987) and Krumhansl (1996) asserted that there was a relationship between structural features (based on the theories of Lerdahl & Jackendoff (1983) and Narmour (1990)) and tension response. However, graphical examination of the Nielsen (1987) study, and Krumhansl's own observation (1996; p. 415) suggests that loudness matches reasonably well with tension responses; in the case of Nielsen perhaps better than the higher-level structural analysis. Both studies

also identified specific locations where the melodic contour was related to the tension response: for Nielsen, in the development section of the first movement of Haydn's Symphony No. 104, and for Krumhansl, in the first movement Mozart's Piano Sonata in E♭ Major, K. 282, Krumhansl found that Lerdahl's pitch-space model (which provides a quantitative coding of pitch and harmonic dissonances) accounted for a significant proportion of the tension response. In another study, Krumhansl (1998) correlated high-level musical features, referred to as 'topics' (Ratner 1980; see also Cook & Dibben, this volume), with judged emotionality. While correlations were not very high, the 'gavotte' and 'alla zoppa' musical topics produced relatively strong emotional responses for the allegro from Mozart's String Quintet No. 3 in C Major K. 515 ($r < 0.2$ and $r < |-0.3|$, respectively), and the 'brilliant style' topic for Beethoven's String Quartet No. 15 in A Minor, Op. 132 ($r < 0.3$).

Sloboda (1991) constructed a list of musical structural features that produced particular physical emotional responses. For example, a harmonic descending cycle of fifths to tonic, a melodic appoggiaturas, and a melodic or harmonic sequence tended to produce a 'tears' response, and a new or unprepared harmony tended to produce a 'shivers' response. Schubert (1996, 1999*b*) found that the best predictor of arousal was loudness. He also proposed that perfect cadence harmonic progression increased valence response (Schubert 1999*a*).

Continuous response methodologies have provided an enriching alternative to the study of music as a causal agent of emotional response. While the methodology is inefficient compared with conventional, asynchronous, single-sample-per-stimulus approaches, it has facilitated an understanding of the processes of the M→E system that are difficult to isolate and may require musical context to have an effect. For example, it would be hard to determine empirically the emotional effect of the appoggiatura or the perfect cadence within an ecologically valid framework (musical context) without continuous response methodology.

17.3.4 System–dynamics investigations

The single most important purpose of continuous measures is in better understanding the time-dependent, dynamic nature of the M→E system. The analytical method proposed by Schubert and Dunsmuir (1999) provides an example of how lag structure can be better understood. Before continuous response methodologies were accessible, experimental music psychologists could do little more than speculate about the delay in emotional response after a 'causal' musical event. The findings and issues concerned with the dynamic nature of emotional response to music using continuous response methodology are discussed below under Sections 17.4.5 and 17.4.6.

17.4 Evaluation of continuous measure devices

The growing interest in continuous measure approaches to emotion in music necessitates the consideration of several issues pertaining to the design, reliability, and validity of continuous measure instruments. Important issues to emerge are the defining and coding of the stimulus and of the emotional response, synchronizing response and

stimulus, and determining the optimum and adequate response sampling rates. Pertinent issues in examining the relationship between musical features and emotional response are the response latency (or 'lag structure') and the method used to analyse data. These issues will be discussed with reference to the literature described above and with respect to possible future directions.

17.4.1 Stimulus coding

To determine how emotion varies in response to music, the musical stimulus must be analysed and coded. One approach is a *post hoc* analysis where once a significant or important emotional response is identified, the musical features or structures thought to be responsible are then ascertained. Sloboda (1991) and Krumhansl (1996) operated in this fashion. This approach requires a high degree of musicological skill on the part of the researcher. A more objective approach is to code musical feature variables before collecting emotional responses, and to use a statistical method to determine which combinations of musical features can explain the temporally nearby changes in emotion. This technique treats the musical stimulus as a multidimensional set of interacting musical and psychoacoustic features or structures. These features can be coded at a high level, for example in terms of their aesthetic association or 'topics' (used by Krumhansl 1998, based on Ratner 1980), or according to some coding strategy deduced from a theory of harmony or pitch dissonance (Krumhansl 1996, based on Lerdahl's theory of tonal pitch space), or grouping structure (Nielsen 1983, after Lerdahl and Jackendoff's theory of generative grammar in music). Alternatively, low-level musical features could be coded (Schubert 1999*a*), such as pitch, loudness, duration, timbre, and harmony.

The kinds and levels of variables coded will be a function of the requirements of the researcher, and the feasibility of the coding scheme. Some musical features, such as pitch and loudness, can be coded as perceptually relevant, objective multilevel variables (e.g. Cabrera 1997, 1998; Hall 1987; Moore *et al.* 1997; Rossing 1990; Schubert 1999a). Other musical features, such as harmony and rhythm, require some form of polychotimization to achieve multilevel coding. For example, Schubert (1999a) coded cadential progressions as a continuous, dichotomous variable having the value 'perfect cadence' or 'no perfect cadence'.

17.4.2 Response coding

A theoretical consideration that can help to determine response format and coding strategy is the paradigm of emotion. There are two broad systems of classifying emotions: categories and dimensions. Categorical classification of emotion assumes that emotions carrying different meanings, such as happy and sad, are distinct and independent entities. While Goins (1998), Hevner (1936) and Namba and associates (1991) have used the checklist format to obtain data that are essentially continuous, the categorical approach does not lend itself easily to continuous methodology. Categorical approaches require the participant to select one or several answers from a range of answers. A large range of choices will require the participant to constantly shift attention between the various response options, in addition to the experimental task. In a continuous response task, this may either interfere with the listening experience, or lead

to omission or guessing of some responses so as to minimize interference. Hevner's approach of gathering responses once only per section of music is an improvement to continual checklist evaluation, but it does not allow for the investigation of changing shades of meaning.

The dimensional classification of emotion holds that all emotions are in some way related within an *n*-dimensional *semantic space* (or, more correctly, *emotion space).* For example, the dimensional structure suggests that happy and sad are more or less opposite emotions along the *valence* dimension of emotion (Russell 1989). To distinguish distinct emotions having similar valence, such as sad and angry, a second dimension, *arousal,* may be added: Sad expresses low arousal and angry expresses high arousal (see also Sloboda & Juslin, this volume).

Many researchers have assumed that participants can manage concentrating on one dimension only while listening to music (e.g. Madsen & Fredrickson 1993; Nielsen 1983; Sloboda *et al.* 1997). Because emotion is multidimensional, the dimension to choose has been problematic. My review of the literature supports Schmidt's (1996) criticism that most unidimensional continuous response formats refer to a general, abstract construct such as 'aesthetic experience' or 'emotionality', or, even more vague, 'when the music causes something to happen to you' (see Table 17.1). A reasonably specific term was 'musical tension' (Fredrickson 1999; Krumhansl 1996; Nielson 1983), and even this is problematic—what, exactly, is musical tension? Schmidt is critical of vague instructions and non-specific criteria. However, the complexity of the theoretical concepts in some ways demands that the participant uses some implicit and intuitive judgment criterion.

The validity of choosing a non-specific dimension as a means of tapping into emotion is a major issue. For example, when preparing this chapter I compared the response of the first 37 bars of Rodrigo's *Concierto de Aranjuez* obtained from the Schubert (1999a, p. 510) study with that obtained by Waterman (1996, p. 60). The peak responses in the Waterman study ('when . . . something . . . happen[s] to you') occurred at the same locations as the peaks in arousal response gradient in the Schubert study, namely at bars 23, 31, and 33, but no such similarity was found between the valence response gradient and the Waterman data. This prompts me to propose that the more general instruction may actually be tapping into the arousal dimension as a default response, rather than some general, idealized emotional/aesthetic response. I tentatively extend this proposal to include 'tension' because of the large amount of literature which supports a correlation between tension and arousal (e.g. Berlyne 1973; Krumhansl & Schenck 1997).

Another solution attempted by researchers to the problem of measuring emotion on a rating scale is to add more response dimensions. Here, the problem of cognitive load and attentional resources must be considered carefully (Damos 1992; M. Zentner, personal communication). If enough dimensions are responded to simultaneously, researchers will obtain a more complete picture of emotion expressed but, on the other hand, the participant's capacity to execute the more complex task will lead to poorer quality of data. The general consensus in the research community appears to be that two dimensions provide an optimal balance between a parsimonious definition of emotion and limiting the complexity of the task. While there is a lack of agreement on

the exact nature of these dimensions, they agree in principle with two of the three dimensions of semantic space proposed by Osgood *et al.* (1957). Through their work on semantic differentials, they asserted that meaning space could be largely described in terms of the dimensions *evaluation*, *activity*, and *potency*. Labels implying the first two dimensions (evaluation and activity) are commonly found in the music–emotion literature (e.g. Asmus 1985; Collier 1996; Collins 1989; Wedin 1972). The labels used by Madsen, Mulder, Schubert, and Tyler are listed in Table 17.2, grouped so as to reflect the matching dimensional constructs.

Table 17.2 Two-dimensional response labels

Evaluation	Activity	Examples
Ugly-beautiful	Relaxing-exciting	Madsen (1997, 1998)
Valence	Arousal	Schubert (1996)
Unhappy-happy	Not excited-excited	Mulder (1997); Tyler (1996)

It remains to be seen whether a third dimension will be added by future researchers, what the dimension will be, and how the response format will be interfaced. Based on the literature (Russell 1980; Whissell *et al.* 1986), a possible third dimension is likely to include *potency*, with polar labels of *dominant–submissive*. The participant of two-dimensional continuous studies usually moves the mouse around a two-dimensional surface. Either a three-dimensional mouse could be employed (M. Zentner, personal communication), or the participant's unused hand could be used to provide additional information. A second pass in listening is a problematic solution, because it makes the assumption that the listener is responding on the second pass as he or she would if asked to perform the third dimension task on the first pass. However the 'second-pass' approach (with counterbalancing across listeners) seems to be the most feasible alternative.

The rating scale format is particularly suited to a computer interface. In a study on the reliability and validity of the 2DES, Schubert (1999*b*) found that participants required a resolution of approximately 10 per cent per dimension to distinguish words and pictures of faces expressing different emotions. On a 201-point scale, there was general agreement as to the emotion expressed by a word with a boundary of 20 × 20 points. Therefore, a coding that provides a higher resolution than one unit on a ten-unit scale should adequately capture the resolution of human semantic and emotional response. Given that computer displays are restricted by the number of pixels (in the order of hundreds), the issue of resolution and coding of rating scale formats using computer interfacing poses no problem to continuous response research.

17.4.3 Synchronization

Early studies had considerable problems with synchronization. Mull's (1949) use of a stop watch as a means of synchronizing response and stimulus was apparently unreliable and the dependent data were discarded. Hevner's (1936) ingenious solution of using numbers for different sections of music was adequate provided that the piece had clearly distinguishable moods or sections. However, it mainly served to distinguish gross characteristics of the M→E system, rather than more subtle ones.

While computer technology has mitigated problems of synchronizing the musical signal with the emotional response, there are other techniques that do not depend on computer technology. For example, Sloboda (1991) used the musical score as a response form. This method ensured precise matching of response and stimulus because the participant was responsible for locating the emotion-evoking episode on the musical map of the stimulus (a musical score). A problem with using the musical score as a response sheet is that it restricts respondents to those who are able to read the particular score in question, although in the Sloboda study respondents unable to read music could refer to recordings. Furthermore, data collection so removed from conventional pen and paper formats could be a precarious task, as the coder searches for some mark, perhaps clear, perhaps esoteric, that signifies an emotional, or some other, event. Sloboda's solution was to have the participant make a mark on the score and then provide a written explanation (J. A. Sloboda, personal communication). The techniques employed by Flowers (1983) and Waterman (1996) also used a physical link between the response and the stimulus, the former by recording the stimulus and response onto an audio tape, the latter by using one of the spare audio tracks, parallel to the stimulus storing tracks, for recording responses.

By far the most common method of synchronization availed to the contemporary researcher is the use of a computer-generated clock which the software uses to track the location of the music and is used as a tag for the participant's response. In the case of Schubert (1996, 1999*b*), the musical stimuli were taken from an audio CD that was controlled by the software. One routine in the software (Sudderth 1995) was able to read the elapsed time (in seconds) directly from the CD. This value was then tagged with the response in real time. After data collection, the experimenter converted the time into bar (measure) locations so that the concomitant musical structure could be easily identified. This conversion to bars made the analysis independent of the CD recording of the piece under investigation. Another technique of making the music independent of the performance was to employ the method of Sloboda *et al.* (1997), who recorded response after every sixth note. MIDI (Musical Instrument Digital Interface) coding of the performance lent itself to this kind of synchronization strategy.

17.4.4 Sampling rate

While a variety of sampling rates have been found in the self-report literature, varying from five emotional response samples per second (Madsen *et al.* 1993*a*) to one per second (e.g Brittin 1991), the majority of studies have used two samples per second. The choice of two samples per second appears to be based on intuition rather than a firm theoretical foundation. However, the lag structure of the M→E system provides a clue of the optimum sampling rate—optimum meaning the balance between minimum data and maximum information. By applying Nyquist's sampling theorem (e.g. Pohlmann 1995), that the optimum sampling rate is twice the highest frequency which is likely to be encountered, it is possible to posit a suitable sampling rate for measuring continuous emotional response to music. Although no literature was cited which indicated the fastest *emotional* response to a musical feature, the fastest response to a musical feature alone necessarily sets the upper limit (assuming that the listener is not trying to predict an emotional response). Geringer (1995) reported that the response latency

in detecting loudness information was in the order of 1.5 seconds (see also Robinson 1988, p. 64). On the basis of this information, responses should be sampled at half this interval—once every 0.75 seconds. Therefore, the popular, slightly higher sampling rate of two per second is a good choice (Gregory 1992).

17.4.5 Lag structure

The main benefit to be sought from continuous measures of emotion in music is to determine why responses change as a function of the stimulus. Surprisingly, very few studies have attempted to do this. Unfortunately, the kinds of issues investigated by continuous response studies verge on trivial. Nearly all the studies investigated *describe* the movement of the response time-series, but only a handful have made serious attempts to *explain* these responses in terms of the changing stimulus (e.g. Capperella-Sheldon 1992; Krumhansl 1996, 1998; Nielsen 1983; Schubert 1998, 1999*a*; Sloboda 1991).

Given the primitive state of stimulus-response (M→E) analysis, it comes as no surprise that our understanding of lag structure in emotion in music is minimal. Lag structure refers to the delay in response after an emotion-producing stimulus event. When any stimulus is presented, the response is not instantaneous. Schubert (1998, 1999*a*) proposed that responses are causally related to the stimulus. Consequently, he analysed response according to specific musical features. Using regression analysis (discussed below), he found that a dynamic relationship between emotional arousal and loudness was present. In general, positive changes in stimulus loudness led to positive changes in the arousal dimension of emotion, and these changes occur 2–3 seconds after the change in the stimulus. This is in reasonable agreement with Krumhansl's (1996) identification of a lag of up to 3.25 seconds from the time an event occurs to the time a tension response is made.

Schubert and Dunsmuir (1999) further proposed that the M→E system is non-linear. For example, sudden changes in loudness produce a faster change in arousal response (1–2 seconds instead of 2–3 seconds). In other words, lag structure is dynamic. Indeed, understanding lag structure is perhaps the single most important application of continuous response methodology. However, the work of Schubert and Dunsmuir is introductory and largely exploratory.

Continuous response methodology provides a fruitful foundation for the investigation of the M→E system dynamics. A hint of the value of this methodology has been provided in Schubert and Dunsmuir's (1999) categories of outliers responsible for altering the hypothetically linear lag structure of the M→E system (or more specifically in the case cited, the 'loudness→arousal system'). They proposed that a faster than typical linear response lag is a *startle* response, while a slower than typical linear lag is an *inertia* response. Three kinds of inertia responses were identified:

1. *Orientation*, where the participant needs time to adjust to a new piece or section of music.
2. *Overshoot recovery*, where the participant has overreacted to a change and requires extra time to recover to the linear model-predicted lag.
3. *After-glow*, where the participant still notices an emotion in the music, even though the music has finished.

An example of an overshoot recovery inertial response is shown in Fig. 17.2 (taken from Schubert 1999*a*). The system-predicted arousal response (based on regression analysis) is shown for seconds 137 to 146 (bars 166–180) of Dvorak's Slavonic Dance Op 42 No. 1. When 142 seconds of the piece had elapsed, the actual change in arousal dropped suddenly at the same time as the change in loudness and spectral centroid (which is related to perceived timbral sharpness) increased. The rate at which the model-predicted arousal gradient changed (Δ) was much slower, and the model was not able to predict the actual response satisfactorily.

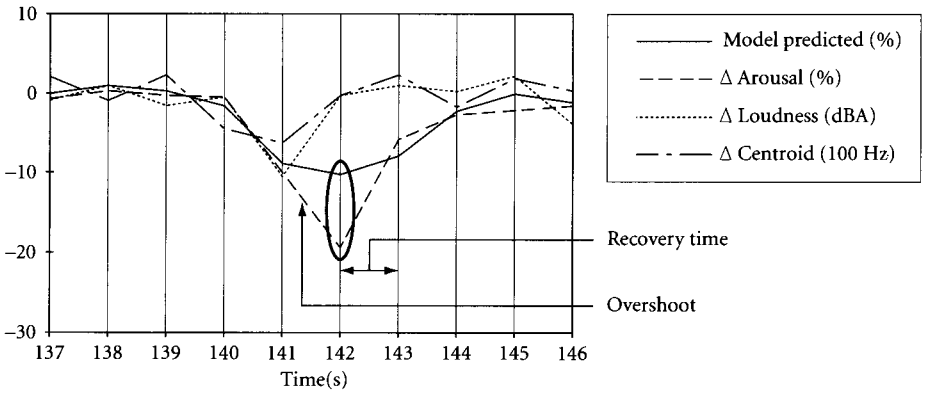

Fig 17.2 Example of an overshoot recovery inertia response.

Another prudent area for investigating lag structure is in how individual differences affect response time. A common example is the comparison of 'musician and non-musician' responses to music. Capperella-Sheldon (1992) defined such groups and examined where aesthetic peaks and drops in responses occurred while listening to the first movement of Holst's First Suite in E♭ for Military Band. She found five peaks and drops for each group, but could not identify any consistency in response lag between the musicians and non-musicians.

17.4.6 Analysis

Perhaps the most grave concern faced by continuous response researchers in music-emotion is the analysis of data. While econometricians and engineers have developed traditions of sophisticated time-series analytical techniques (Box & Jenkins 1976; Hamilton 1994), in the field of self-report emotion research, music psychologists have failed to do much more than provide descriptive, interoccular tests of their continuous response findings. This is somewhat odd because music and emotion are both time series, requiring special analytical techniques. Consequently, an important advantage of continuous response measurement has been neglected, if not resisted. While general empirical psychology publications are subjected to fairly intense statistical rigour and scrutiny, the continuous emotional response to music literature has produced a stream of studies that report simple, weakly substantiated, descriptive claims. This

means that the potential benefits of continuous measure methodology are, to some extent, wasted.

Specifically, continuous response enables measurement in response to an entire piece or movement of music. Instead of listening to a few bars of a piece, the music context can be laid out for the listener, and a response can be made in a more realistic listening situation. Measurement of this kind of approach provides the advantage of ecological validity (Lipscomb 1996). In the statistical world, this realistic approach may be best described as a process involving *serial correlation*—that a response or experience at a given point in time is in some way related to something that happened at another point (or points) in time. It is this process of serial correlation that must be addressed to make continuous measures productive tools for research. The analytical approaches used by researchers can be divided into four broad classes that are, in order of (more or less) increasing validity and sophistication: interoccular analysis, correlation of means, analysis of variance, and adjustment for serial correlation.

Interoccular analysis

The dimensional rating-scale studies provide potential for a closer analysis of the time-variant relationship between emotional response and musical features (Schmidt 1996). However, there are numerous instances in the literature where a complete analysis will consist of general comments about the appearance of a time-series chart of mean responses. For example, Gregory (1995, pp. 206–7) concludes her review of the CRDI by stating that 'visual comparisons of graphic contours provide immediate discrimination of response similarities across total time spans and at selected samples within time spans. This may be the CRDI's singular contribution to music research instrumentation.'

While visual inspection is an important approach for commencing analysis, it would be unfortunate if this remains the 'singular contribution' of the CRDI or any other continuous response measure. Gottman (1981) points out the foibles of the interoccular test (or 'graphic analysis') that is implied by Gregory's comment. It lacks statistical rigour and is prone to biased interpretation. Further, visual analysis of a chart can be misleading, particularly when deviation scores are omitted—a regular feature of continuous response data reports in the literature under investigation.

Correlation of means

A common kind of analysis reported in continuous measure studies is the Pearson product-moment correlation analysis of time-series data averaged across participants. Correlation is used to describe the similarity of two time series, and is the most common statistical approach used for comparative studies (such as comparing non-musicians with musicians). With comparison of categorical data, agreement quotients have been used, where the numerical index is obtained by dividing the number of categories in which there are concomitant agreements across test–retest listenings by the total number of categorical responses (Gregory 1995). None of the studies cited have attempted to provide correlation analyses with serial correlations removed, and only a handful have considered a cross-correlation analysis (Schubert 1999*a*), which provides information about correlations at non-instantaneous lags (i.e. correlations between two time series separated by one sample or more).

Schubert (2000) demonstrated that correlation coefficients were inflated in comparison to correlation analyses made with repeated measures of independent data sets. Indeed, the literature does have a tendency to report boastfully though misleadingly high correlation coefficients, often well above 0.8. For example, Johnson (1996) compared the experimentally obtained correlation coefficient of serially correlated data with the range recommended by Anastasi (1987, p. 106, cited in Johnson 1996) for a reliable measure, without considering this problem. Schmidt (1996) has suggested that, in some cases, a Spearman rank-correlation analysis might be more appropriate because it is more conservative. There are other non-parametric approaches to correlation analyses, and many of the techniques discussed below are applicable (e.g. see Howell 1997). Schubert (2000) proposed that differencing each time series (so as to produce *changes* in response) prior to conventional Pearson product-moment correlation might produce a more valid correlation analysis.

Accounting for deviation

A more sophisticated approach than interoccular tests and correlation analyses are techniques that examine variations in responses. The first study of continuous response to emotion in music cited which used mathematical techniques to analyse time-series data was the de Vries (1991) study. While it used the *sentograph* (see Section 17.2.3), and so strictly speaking is not a self-report instrument, it is worth examining the techniques de Vries used. His approach was based on the method of analysis of electrocardiograms developed by Van Bemmel (1982, cited in de Vries 1991). De Vries produced five parameters from a two-dimensional response time series (force and angle of finger pressure). The parameters were: (1) mean angle of pressure direction; (2) roughness (or fluctuation) of pressure angle; (3) roughness of force; (4) pointedness of force; and (5) skewness of force. This produced five time series. Discriminant analysis resulted in three weighting functions that were produced so as to maximize the distinction in responses across musical selections. In other words, de Vries could map musical selections onto a three-dimensional music space using the transformed response parameter weightings. Together, these three functions accounted for 97 per cent of the variance. However, de Vries did not disclose if and how he accounted for serial correlation. Uncontrolled serial correlation may have inflated the explained variance.

The first published *self-report* study among those reported to use some form of inferential statistical analysis (aside from instantaneous correlations) was by Byrnes (1996), who used paired sample *t*-tests to determine the effect of the music as a 'treatment' on the first and last responses. While this is a statistically valid procedure, it seems difficult to justify the collection of so much data between the first and last samples when only the two end-points are used for the analysis.

Another 'early' attempt at using inferential statistical analysis of time-series data was presented by Sloboda *et al.* (1997), who conducted analysis of variance on the grouped responses to performances of Chopin's Prelude No. 4 in E Minor. After eye-balling the time-series plots, the piece was divided into four sections that also coincided roughly with structurally salient points in the music. The repeated measures ANOVA produced significant results, and it was found that adjacent sections were significantly different. Sloboda and associates then used this information to claim that they had captured

different levels of 'emotionality'. While it is commendable that inferential statistics were applied, the question of why the analysis was performed remains. It is not clear why it was important to have a piece with varied emotional expression within it (as distinct from across different versions of the same piece). More relevant to the research problem of the study would have been 'what produced these changes?' The notion of musical features as the cause of the response was implied: 'The present study aims to discover how score-based structural indicators, observed performance parameters, and listener characteristics influence the emotional response to music' (Sloboda *et al.* 1997, p. 630). To this end, it would have been of greater relevance if the relationship between response variations and musical structure could be identified using the data obtained.

Accounting for serial correlation

Krumhansl (1996) used multiple regression to model tension response as a function of musical feature variables based on an analysis by Lerdahl. While no coefficents were reported, the multiple correlation coefficent was estimated as $R_{7\,177} = 0.79$ ($P < 0.0001$). Krumhansl supported Lerdahl's predictions by leading (or 'shifting backward in time') responses by 0 to 3.25 seconds, and found that the predictions were not as smooth as the actual mean responses. Therefore, Krumhansl smoothed and lagged the predicted response, thus introducing serial correlation and lagging into the model, and hence making it more realistic. A second regression analysis produced an improved fit ($R_{14\,170} = 0.91$, $P < 0.0001$). However, it is not clear that Krumhansl overtly accounted for the serial correlation in the model: No comment was made about the serial correlation in the residual series (the time series which could *not* be explained by the regression model). This is important, because the presence of serial correlation in the residual violates several assumptions of the linear regression model (Ostrom 1990). Krumhansl's study is ground-breaking because it attempts to explain lag structure. In a later study (Krumhansl 1998), she applied a similar approach by modelling one-dimensional emotional response in terms of dichotomized musical topics. The model fit was $R_{14\,767} = 0.52$, but again no consideration of modelling serial correlation was mentioned.

Schubert (1998, 1999*a*; Schubert & Dunsmuir 1999) examined stimulus time-series features including tempo, melodic pitch, and loudness, *and* response time-series dimensions of valence and arousal. His approach was to produce a univariate, linear regression analysis, where each emotional dimension was described in terms of a linear combination of the musical features. The traditional least squares approach was not satisfactory because the assumption of independence was violated. Instead, Schubert used a three-step procedure: (1) differencing all variables; (2) lagging the musical feature variables; and (3) making an autoregressive adjustment (Box & Jenkins 1976; Gottman 1981; Ostrom 1990) to model the remaining serial correlation.

Differencing variables provided a meaningful transformation (it meant 'change in response', denoted by the Greek capital delta symbol, 'Δ') and at the same time removed a large amount of serial correlation (see Gottman 1981). In other words, relative values of variables rather than absolute values were modelled. Lagging the variables (by 1, 2, 3, and 4 seconds) enabled the examination of the dynamic lag structure in the M→E system and satisfied the assertion that emotional response is causally affected by

musical features. The remaining serial correlation component was modelled using the technique of autoregressive adjustment (Ostrom 1990). Autoregressive adjustment could be described as the addition to the mathematical model that acted as a kind of 'memory', adding a proportion of the linear-system-produced error of the previous point in time. The difference-lag-autoregressive adjusted regression model produced a series of satisfactory models, explaining up to 73 per cent of the variation in response for arousal, and up to 62 per cent of the variation in response for valence in terms of a selection of musical features alone.

The approach taken by Schubert provides researchers with a relatively simple and valid analytical technique for modelling time-series data. However, this approach will not work in all cases. Schubert assumed that the time series investigated were only first-order autoregressive (Gottman 1981; Ostrom 1990). More research is required to determine whether time-series processes in the M→E system may contain higher-order autoregressive processes, or indeed other processes altogether, heading, for example, toward the more sophisticated ARIMA (Autoregressive Integrated Moving Average) models proposed by Box and Jenkins (1976). The possibility of analysing the data in the frequency domain (Gottman 1981) or using other techniques such as neural network models (Todd & Loy 1991) and dynamic system models (Abraham *et al.* 1990) also await investigation in modelling self-report continuous emotional response data (see also Beran & Mazzola 1999).

17.5 Concluding remarks and future directions

The literature on self-report continuous response methodology to understand emotion in music has been growing considerably since the pioneering days of Hevner (1936) and, particularly, since Nielsen (1983). The methodology enables researchers to better understand the moment-to-moment fluctuations in emotional response caused by the musical stimulus within an ecologically valid framework (because the listener is usually listening to an uncontrolled, real piece of music rather than an excerpt or contrived auditory stimulus). This methodology has been used to find convergent evidence with traditional asynchronous approaches regarding, for example, the influence of musical features upon emotional response. However, its main advantages are yet to be fully exploited. In particular, continuous response methodology allows researchers to examine the relationship between moment-to-moment fluctuations in music and response as well as the lag structure of response—that is, how quickly people respond after a change in musical structure, or how quickly they respond in comparison to other people listening to the same music.

Important, major issues which remain unresolved are which dimensions of emotional response should be recorded, the dynamic nature of the M→E system, and which analytical techniques to use. Using two dimensions appears to be a reasonable compromise between a meaningful emotional response and cognitive overload. One such combination of emotion dimensions is *valence* (happy–sad) and *arousal* (aroused–sleepy), although the optimal solution is yet to be determined.

A relatively less important issue in continuous response methodology is the genre of musical stimulus to use. Selections have largely been based on the music of romantic

Western art music idioms (I include Holst's band music in these idioms). While it would be interesting to examine different styles, such as contemporary, pre nineteenth century, and popular styles, it is also sensible for the time-being to restrict the number of styles investigated, given that continuous response methodologies are still being established and are already associated with a potentially large number of complex, interacting variables. Restricting stimuli to the romantic music idioms is logical because these are idioms that are defined by the importance of expressing emotion (e.g. Gorbman 1987).

Continuous self-report measures have arisen from a need to provide greater ecological validity in emotion-in-music investigations and through technological developments that have made such an approach to research feasible. However, researchers using this methodology need to remain cognisant as to why they are using the technology. It seems that experimental music psychologists have required a period of exploration and discovery to more fully realize the potential of continuous response measures.

In conclusion, continuous response researchers need to become more aware of the analytical problems created by serial correlation, an inherent part of much time-series data. There are simple, effective solutions available for dealing with the problem, such as differencing, autoregressive adjustment, and other techniques associated with regression-type analysis. It is vital that researchers are willing to apply these methods and other non-parametric techniques to maximize the benefits of continuous research methodology, and in particular to exploit its capacity to provide a basis for understanding the still elusive dynamic nature of emotion in music.

CHAPTER 18

EMOTIONS IN EVERYDAY LISTENING TO MUSIC

JOHN A. SLOBODA AND SUSAN A. O'NEILL

There are several key assumptions underpinning our focus on emotion and 'everyday' music listening. Firstly, music is always heard in a social context, in a particular place and time, with or without other individuals being present, and with other activities taking place which have their own complex sources of meaning and emotion. The emotional response to the music is coloured, and possibly sometimes completely determined, by these contextual factors. Emotions should not be thought of as abstract entities such as 'anger' or 'elation', but rather as actual moments of emotional feelings and displays in particular situations within a particular culture. Emotional responses to music are linked to a sequence of events based on conventions and rules that depend not only on shared understanding and representations, but also a common background of knowledge and beliefs. Music is a cultural material (as is language) that provides a kind of semiotic and affective 'power' which individuals use in the social construction of emotional feeling and displays. As such, the impact of music on emotion is not direct but interdependent on the situations in which it is heard. Any meaningful account of music's role in the emotional response of individuals must involve the recognition of these complex, interdependent social factors. We therefore focus in this chapter on several investigations which attempt to preserve, or take account of, as much of the social context of music listening as possible.

Secondly, music is ubiquitous in contemporary life. The prevailing contexts in which we encounter music are, by definition, mundane. They include those contexts in which the most routine activities of life take place: waking up, washing and dressing, eating, cleaning, shopping, travelling. There are, of course, special and 'out of the ordinary' events which music can form a part of, even a crucial and defining part, but we would argue that in order to understand fully these special events and their emotional significance, we must consider them in relation to everyday experience. It is the everyday and normal which frames and helps define the special. This chapter focuses, therefore, on habitual and routine modes of engagement with music.

Thirdly, despite the growing recognition that our experience of emotion is inextricably linked to the social world and the linguistic practices used to make sense of that world, we tend to think of our emotions as personal, 'private' experiences, especially if they do not involve 'public' emotional displays. For example, when we feel angry, we might experience our anger as a private emotion which may or may not be 'acted out' in the things we do or say. However, this is not the case in all cultures. Lutz (1982) describes

the way in which the Ifaluk (Samoan and Pintupi Aborigines) use emotion words to describe their relationship to events and other people, and not as expressions of private, internal states. The closest translation of anger in the Ifaluk language is the word 'song' which means 'justifiable anger'. It is not considered a privately owned feeling but rather a moral and public account of some transgression of accepted social practices and values (cf. Burr 1995). As such, emotional feelings and displays are not considered to represent internal states of an individual (whether innate or acquired through learning and experience) that result in physiological reactions to environmental stimuli. Rather, they are meaningful displays that are taken as emotional when they are embodied expressions of judgments, and in many cases, ways of accomplishing certain social acts (Harré & Gillett 1994). Our focus in this chapter is on research which attempts to understand, at least in part, the inextricable connection between individual 'personal' emotional experience and the 'social' forms of meaning associated with music listening.

Our perspective makes it necessary to exclude any significant treatment of three types of phenomenon. The first exclusion relates to the extremely intense, sometimes transcendent, experiences to music which people characterize as defining or life-changing (e.g. Gabrielsson & Lindström 1995; see also Gabrielsson, this volume). These events rarely occur in the lives of individuals, and so are difficult to study empirically. One retrospective study by Sloboda (1989*a*), which we will discuss in more detail in a later section, provides suggestive evidence that these 'peak' events can occur in childhood, and, when they do, can have a profound influence on a person's attitudes towards, and commitment to, music. Indeed, people who devote their lives to music often include such experiences in the stories of their developing commitment (e.g. Brodsky 1995). This, then, brings us to the second exclusion of our chapter. We shall not be examining the everyday emotional world of the professional musician or the intending professional musician (i.e. the music student). The emotional experiences of these groups are covered in other chapters in this book (Persson, this volume), and we would wish to claim that the everyday contexts in which musicians experience music are so different from those of non-musicians (who form the vast bulk of the population of industrialized nations) that they require separate treatment. Finally, we do not intend to provide a comprehensive review of the literature associated with emotional response to everyday music listening. Much of this literature is covered elsewhere in this book (DeNora, this volume; Becker, this volume; Gabrielsson, this volume). In many cases, previous research in this area include laboratory studies or semiquasi experimental research, which have quite specific social features that make it unlike many other music-listening situations. Rather, our aim is to highlight a number of key features of research in this area which are based on the assumptions outlined above, using examples from several studies, many of which we have been involved in ourselves. In this way, we hope to address important questions that are left unanswered by laboratory research, stimulate further discussion and debate on the topic, as well as indicate some directions for future research.

18.1 Capturing everyday experience

One of the problems with studying everyday experience is that it happens outside the laboratory in a wide variety of settings. Although an investigator may make observations

(or even attempt to experimentally manipulate) musical engagement in a single setting, it is difficult to observe directly the entire range of settings in which music might be experienced, even in the course of a single day. A second problem is that the everyday is, by definition, unmemorable, and so retrospective studies (such as interviews) may not capture the richness and diversity of musical experience. The more mundane occurrences are simply forgotten or filtered out. Understanding how music interacts with everyday contexts requires a method that not only examines the phenomenon in 'real-world' situations or events, but that does so as the events are unfolding and are experienced by individuals in the course of their daily lives. For these reasons, we (Sloboda *et al.*, 2001) recently conducted a pilot study with eight individuals where we adapted a method developed by Csikszentmihalyi and Lefevre (1989) which enables everyday experiences to be studied in some detail. Our aim in presenting this research is not to make generalizable claims about the frequency of musical occurrences in everyday life. Rather, our aim is to illustrate, through this exploratory research, a method in which we might begin to capture individual subjective experience of emotion concurrent with everyday activities where music is heard, and highlight the heuristic features of the findings in order to inform future theoretical development and research.

The method we employed in our study is known as the experience sampling method (ESM). It involves participants carrying electronic pagers with them at all times during their waking hours. The pagers are connected to a computer that is programmed to call participants at preprogrammed intervals. In our study, participants were paged once in each 2–hour period between 0800 and 2200. The precise timing of a call within each 2–hour block was determined randomly. On each paging, participants were asked to stop what they were doing as soon as practicable and complete one page of a response booklet, which they were also asked to carry with them at all times. The booklet asked questions regarding the most recent experience of music listening since the previous paging. If there had been no music experienced in that period, participants completed the booklet with respect to the activity taking place when the pager sounded.

The eight participants in our study were all adult non-musicians between the ages of 18 and 40 years who were either studying or working at our institution (half of the participants were not involved in psychology). They each carried a pager with them for a 1–week period. Analyses of the data collected provided some quite revealing information about their everyday music use. First, 91 per cent of pagings resulted in a page of the booklet being filled in (we call each event described in the response booklet an 'episode'). This suggested a high level of compliance and involvement in this task over an extended period of time. It also meant that the method provided an almost complete picture of the musical and non-musical experiences of each participant over a normal week (none of the participants reported the week in question being unusual or atypical). The 9 per cent of pagings which did not result in a report sheet being recorded were primarily due to technical problems, participants not having the pager with them at the time (e.g. during swimming or showering), or participants not hearing the pager's signal (e.g. due to travelling or being in a very noisy location).

A second major finding was that 44 per cent of all episodes involved music. In other words, there was a 44 per cent likelihood of music being experienced in any 2–hour

period. It has repeatedly been claimed that music pervades everyday life. Our data confirm this and provide a specific estimate of its frequency.

Participants were asked to respond in their own words to the question: 'what was the *main* thing you were doing?' Reported activities were coded *post hoc* according to three main categories: personal, leisure, and work. Personal activities cover those everyday activities that are a necessary consequence of living, and were further divided into states of being (e.g. sleeping, waking up, being ill, suffering from a hangover), maintenance activities (e.g. washing, getting dressed, cooking, eating at home, housework, shopping), and travel (e.g. leaving home, driving, walking, going home). Leisure activities were divided into three subcategories: music listening (there were no examples of performing music), leisure-passive (e.g. watching TV/film, putting on the radio, relaxing, reading for pleasure), and leisure-active (e.g. games, sports, socializing, eating out, chatting with friends). Work activities were categorized according to whether they were primarily solitary activities (e.g. writing, computing, marking/assessing, reading for study) or primarily group-based activities (e.g. planning for a meeting, in a lecture/seminar, making appointments, in a meeting).

It is particularly significant that listening to music as a main activity accounted for only a small percentage of all episodes (2 per cent). This suggests that the concentrated, attentive, focusing on music that is paradigmatic of the classical concert or the laboratory experiment is a rather untypical activity for most listeners. Instead participants were distributing their attention across a complex situation of which music is only a part. In fact, there were three categories of activity which seemed particularly likely to involve music. These were the personal maintenance, personal travel, and active leisure categories.

Emotional reactions to the music were measured by asking participants to rate their state on eleven bipolar scales (e.g. happy–sad, irritable–generous, bored–interested) with respect to how they felt before the music started and how they felt after it had ended. We found that these scales grouped under three main factors. The first factor related to the degree of positivity or negativity, the second factor to the degree of arousal or alertness, and the third factor to the extent to which participants' attention was focused on the present situation or elsewhere (e.g. reminiscing, daydreaming, nostalgic). These factors have characteristics in common with previous research done on emotional response to music (see Sloboda & Juslin, this volume).

We found that, on average, the experience of music resulted in participants becoming more positive, more alert, and more focused in the present. Insofar as such emotional transitions are desired and beneficial, it could be concluded that in general music made these participants 'feel better'. An examination of the number of episodes resulting in change for each of the factors indicated that where there was change, arousal rarely moved in the direction of lower arousal (7 per cent of changes), and little more so in the direction of less positivity (13 per cent). However, present-mindedness showed 35 per cent of change episodes involving moves away from the 'positive pole'. It seems, in other words, as though emotional states arising from a focus on 'things and people not present', such as nostalgia, are a particularly important subcategory within everyday responses to music.

18.2 Functional niches within daily life

Our working assumption has been that music has different emotional functions in different contexts (cf. Merriam 1964). In our ESM study we were, therefore, interested to see whether there were any cases in which mood change factors were dissociated from one another (i.e. cases where one mood increased simultaneously with another mood decreasing). Inspection of cases showed that 16 per cent of music episodes were in this category. These cases are particularly important in beginning to identify distinct functional niches for music engagement. The largest group of such episodes ($n = 10$) involved increases in positivity along with decreases in present-mindedness.

One example of this comes from a male participant who reported being at home relaxing with a group of friends and acquaintances. The activity was being done out of choice. There was ambient music playing on a CD, although the participant had not chosen it. The participant commented that 'the music was very tranquil and relaxing', that others present were 'discussing work boringly', and that he was 'very, very tired'. This episode was also associated with a decrease in arousal during the music. It would be reasonable to assume that the participant was using the music as a means of relaxing and disengaging from the surrounding conversation.

A second example from the same category is provided by a female participant who reported being at home, tidying a bedroom as part of the normal basic routine. The participant had chosen to listen to a piece of pop/chart music on a tape. The participant commented that the music was chosen to 'enhance the wonderful experience of cleaning' and was 'very lively'. This episode was associated with an increase in arousal during the music. It seems as if the purpose of this music was to allow the participant to focus attention on the music, and away from the uninteresting domestic chore, and this focused attention was used to increase energy levels.

It was less easy to find examples of episodes where positivity decreased, but one clear episode involved a female participant at home, alone, doing the washing up as part of a basic routine. She had chosen to listen to rock music on the radio and commented that the track was 'a favourite song I had not heard for some time . . . It brought back certain memories'. The music increased this participant's nostalgia, sadness, and loneliness, at the same time as making her more alert. It is clear that this episode reminded the participant of a significant past event which brought on nostalgia. At the same time, it appears that she had chosen the music to engage and arouse during an uninteresting routine task.

In a separate study, using a stratified sample of 76 panel members from the Sussex Mass Observation Archive (Sloboda 1999; see also Sheridan, 2000), respondents were asked to write, in open-ended fashion, about the uses they made of music in their everyday lives. Table 18.1 shows the activities and functions spontaneously mentioned by members of the sample. The most frequently mentioned activities were housework and travel. This mirrored quite closely the distribution found in the ESM study. Functions mentioned were varied but had a predominantly affective character, with many participants (particularly women) explicitly mentioning music as a mood changer or enhancer. The most frequently mentioned function was essentially nostalgic. Participants found it natural to link functions to activities, often mentioning both in the same sentence (e.g. on arrival home from work 'music lifts the stress of work: it has an immediate healing effect').

Table 18.1 Percentage of mass observation respondents reporting various functions and activities chosen for music

Activities	
To wake up to	6
While having a bath	4
Whilst exercising	4
To sing along to	6
To work to (desk work)	14
To work to (housework)	22
On arrival home from work	2
Whilst having a meal	12
Background while socializing	4
To accompany sexual/romantic events	4
Whilst reading	6
In bed/to get to sleep	14
While driving/running/cycling	22
While on public transport (Walkman)	4
Functions	
Reminder of valued past event	50
Spiritual experience	6
Evokes visual images	2
Tingles/goose pimples/shivers	10
Source of pleasure/enjoyment	6
To put in a good mood	16
Moves to tears/catharsis/release	14
Excites	2
Motivates	2
Source of comfort/healing	4
Calms/soothes/relaxes/relieves stress	8
Mood enhancement	8
To match current mood	6

In an interview study involving 52 women ranging in age from 18 to 78 years, most of whom were not accomplished musicians, DeNora (1999) also found examples of emotional self-regulation involving a number of musical strategies described by participants as 'revving up' or 'calming down', 'getting in the mood' (e.g. for a particular social event), 'getting out of a mood' (e.g. to improve a 'bad' mood or to 'destress'), or 'venting' strong emotions. For the most part, as in the two previously mentioned studies, these were predominantly described at the 'personal' or intrapersonal level as a means of creating, enhancing, sustaining, and changing subjective, cognitive, bodily, and self-conceptual states. According to DeNora, the women exhibited considerable awareness of the music they 'needed' to hear in different situations and at different times, often working as 'disc jockeys' to themselves:

> They drew upon elaborate repertoires of musical programming practice, and a sharp awareness of how to mobilize music to arrive at, enhance, and alter aspects of themselves and their self-concepts. This practical knowledge should be viewed as part of the (often tacit) practices in and through which respondents produced themselves as coherent social and socially disciplined beings (DeNora 1999, p. 35; see also DeNora, this volume).

In addition to the emotional functions at the intrapersonal level, DeNora found examples in which music played a social function in communicating emotions to others. For example, a university student described repeatedly playing at full volume a song from Radiohead entitled 'We Hope You Choke!' not only as way of diffusing her anger against her boyfriend's parents when she lived with them over the summer holidays, but also as a way of communicating her anger to them. In other words, the display of anger or irritation described by the respondent expressed a judgment of the moral quality of some other person's actions. Such a display was also an act of protest directed towards the boyfriend's parents. Music provided one means by which this display was 'acted out' at an interpersonal level. However, as DeNora points out, music is not simply used to express some internal, private feeling or state, nor does it simply 'act upon' individuals, like a stimulus. 'It is a resource for the identification work of 'knowing how one feels"—a building material of 'subjectivity"' (DeNora 1999, p. 41). In this way, music becomes part of the construction of the emotion itself through the way in which individuals orientate to it, interpret it, and use it to elaborate, 'fill in', or 'fill out', to themselves and others, an emotional feeling or display.

18.3 Autonomy and individuality

One of the questions in Sloboda, O'Neill, and Ivaldi's ESM study asked participants to rate the music in each episode on an 11-point scale according to the degree of personal choice exercised in hearing the music (from 0 = *none at all*, to 10 = *completely own choice*). There was a significant effect of degree of choice on the degree of emotional change experienced while listening to the music. For each emotion factor this showed a similar effect—the greater the choice the greater the change. We found that high choice situations were most likely to occur when the person was alone, travelling, or working, at home or in a vehicle, or undertaking activities for duty. Low choice situations occurred more often when with others, during active leisure or personal maintenance activities, in shops, gyms, and entertainment venues, and when doing activities because one wants to. Most of these findings are not surprising, although the link between choice and activities undertaken for duty is not intuitively obvious. It may be that choosing music to accompany duties is a way of bringing some autonomy and personalization back to them. DeNora (1999) suggests that the music associated with duties is used as a catalyst to shift individuals out of their reluctance to adopt what they perceive as 'necessary' modes of agency, and into modes of agency 'demanded' by particular circumstances.

The issue of choice and individuality also permeated the responses of the mass observation panel (Sloboda 1999). Many of the musical situations described were solitary, and some participants graphically characterized a difference between the private arena, where emotional work of one sort or another could be accomplished with the help of music, and the public arena, where self-presentation or the conflicting demands of others precluded this kind of activity. One respondent wrote: 'When I'm down I listen to this [a specific track] and go down as far as I can, then I cry, I cry deep from inside. I wallow in self-pity and purge all the gloom from my body. Then I dry my eyes, and wash my face, do my hair, put on fresh makeup, and rejoin the world'. Another

reported 'the car is the only place where I can listen to it loud enough without annoying other people'.

Many participants displayed negative, or at best, ambivalent reactions to the music that they experienced in public places, such as shops, restaurants, and bars. These attitudes were sometimes associated with reports of dramatic behavioural consequences with high emotional charge (e.g. abruptly leaving a shop with disliked music, arguing with waiting staff in a restaurant about getting the music turned off). In several responses, the appropriateness of the music was a major theme. Judgments were made both about the situation itself, and about the fit between the music and the person's own identity and preferences. For example, restaurant music could be acceptable so long as it matched the ambience or mood of the venue (e.g. oriental music in an oriental restaurant, 'mellow' music during a romantic encounter), or if its general acoustic characteristics matched the listeners' needs (e.g. not so loud that conversation was difficult, but loud enough to cover potentially embarrassing silences and to prevent people at nearby tables overhearing one's conversation). In other cases, although music in public places might be generally disliked, exceptions were made where the music itself had value for the participant (e.g. 'I have discovered Waterstones Bookshop in Newcastle plays good music: the last time I was there Beethoven's 'Egmont Overture' was playing, and the trouble is that I pay more attention to the music than to finding the book I want'). In this example, because the music was judged to be 'good', the participant was prepared to let his appreciation of the music partially override his main intention of buying a book. The issue of 'fit' between music and its context has been investigated experimentally. For instance, North and Hargreaves (2000) showed that people make consistent discriminatory judgments about the music that is suitable for such activities as aerobic exercise or yoga, and that specific characteristics of the music (e.g. tempo) are implicated in these judgments.

There is evidence that resistance to music in public places increases with age. DeNora (1999) found that most of her respondents over 70 years (and, interestingly, those who were trained musicians) found it antithetical to conceive of music as 'background' to anything. Data from the Sussex Mass Observation Archive also showed that males in the 40–60-year age group reported more negative emotional reactions to music in public places than any other group. It may be hypothesized that the higher average status a group has, the less tolerant it will be of removal of autonomy. However, there are also often more complex subcurrents to do with intergenerational and intergroup stereotypes. The following example reveals much about the attitudes of one middle-aged man to the public self-presentation of some younger men: 'I also dislike the din that some cars make when they pass by, infesting the streets with their thumping noises from within. How they can drive properly with such a din in their cars, God knows. It concerns me too that they wouldn't be able to hear the sound of an ambulance or police car with such a noise going on inside their cars. It seems to me, rather like the fastest drivers, it is usually young men between the age of 17 and 25 who are the main culprits. They usually like to have their driving-seat window open, elbow leaning out of the car and looking macho.' It appears as though young people are more tolerant of, and positive towards, music in public places. Further investigation is needed of these apparent age-related differences.

One phenomenon which deserves greater study and theorizing is the unique position of the busker (street musician) in the affections of even the most hardened opponents of music in public places. Many mass observation respondents spontaneously singled out buskers as evading the opprobrium of other forms of public music. It often was reported as relevant that this music is live rather than prerecorded. Two quotes are provided as representative: 'Both my husband and I have performed on the streets. My husband is still a regular busker. This to me is musical entertainment at its purest form. The joy of busking is its spontaneity. Your audience is free to come and go as it wishes, to pay or not pay, to listen or not listen. There is a beautiful freedom about busking that I love, and I hope we never lose street entertainment.' 'The music in the streets is acceptable. Quite often the musicians are quite good and anyway the noise is dispersed.' Arguably, street musicians do not undermine the sense of agency and autonomy that people like to experience. The musician is potentially amenable to interaction (you can request your favourite song, and audience reactions can be assumed to matter to the busker). There is also a sense of groundedness in a busker. The piped music in shops is produced by unknown people in unknown places, and mediated through hidden production mechanisms (e.g. an under-the-counter sound system), for hidden purposes (e.g. suspected manipulation of buying behaviour). The busker, by contrast, is earning an 'honest' living by aiming to please and entertain through the exercise of visible craft that is the result of personal effort and investment. It may also be significant that modern busking is probably the phenomenon which comes closest to meeting the conditions under which most people in most cultures through history have interacted with music. It is live, public, improvisational, spontaneous, participatory, and social. It creates a small arena of the communal in a pervading culture of individualism and isolation. It may meet an emotional need that is quite fundamental, but which there are few opportunities to indulge in.

18.4 Personal and social identity

In recent years, there has been a growing questioning of traditional approaches to the study of identity, which fail to take into account the multiple dimensions of identity as a continual process of negotiation and change. Discursive psychology, which views identity as constructed out of the discourses that are culturally available to us and that we use when communicating with others, has radically altered the way social psychologists conceptualize and study identity. Music provides numerous ways in which musical materials and practices can be used as a means for self-interpretation, self-presentation, and for the expression of emotional states associated with the self. According to DeNora (1999, p. 50), a sense of self is locatable in music, in that 'musical materials provide terms and templates for elaborating self-identity'. For example, one of the respondents in her study described a preferred type of musical material ('juicy chords') as like 'me in life', associating certain musical structures with her sense of self. DeNora (1999, p. 51) suggests that 'music is a "mirror" that allows one to "see one's self". It is, also, however, a "magic mirror" insofar as its specific material properties also come to configure (e.g. "transfigure", "disfigure", etc.) the image reflected in and through its (perceived) structures.'

Nowhere is this more apparent than during adolescence, where identities are being forged, experimented with, and explored. According to Green (1999), music can offer a powerful cultural symbol, which aids in adolescents' construction and presentation of self. Several studies suggest that musical tastes are predictive of a wide range of non-musical activities and attitudes, such as clothing, media preferences, drug use, and degree of sexual activity (Hanaken & Wells 1990; Lewis 1995).

Insofar as the processes involved with the formation and maintenance of adolescent identity are key to an individual's self-image and well-being (e.g. Shotter & Gergen 1989), then we would expect emotions to be deeply implicated in this process. Because most adolescents do not have jobs or family responsibilities they have more 'discretionary' time than many adults do (estimated as up to 50 per cent of waking hours by Csikszentmihalyi and Larson 1984). Much of this time is taken up with media use, mainly TV and music. Eighty-one per cent of young people say that music is an important part of their life, and has influenced how they think about important issues (Leming 1987). This is in direct contrast to TV watching, which most adolescents do not believe has had any major influence on their lives (McCormack 1984). In an experience-sampling study of adolescent daily lives, Larson *et al.* (1989) found that music listening was associated with greater personal involvement than TV watching (which was associated with feeling less happy, less alert, more passive, and more bored than at other times). Larson and Kleiber (1993, p. 130) summarize their findings as suggesting that:

> . . . the moving lyrics of ballads and the hard-driving beat of rock appear to stimulate a level of personal involvement that is lacking in TV watching. A teenager may be lying face-down on her bed, but her mind is alive and active, thinking about friends, school, or the future'.

In a recent study by North *et al.* (2000), marked gender differences were found in adolescents' reasons for listening to music. Girls were more likely to report that music could be used as a means of mood regulation, whereas boys reported that music could be a means of creating an external impression with others. It is perhaps not surprising that more girls than boys referred to emotionality in relation to music listening, given that 'masculine' identity tends to be associated with an ability to keep one's emotions out of one's reasoning. However, the boys' reason for listening to music was particularly interesting in that the majority of respondents reported that they usually listened to music on their own. Thus, the external impression the boys sought to accomplish did not necessarily involve direct social contact with others at the time they were actually listening to music. Rather, it appears as though adolescent boys, in particular, were actively involved in the construction of their identity through the use of stereotypes and gendered role models associated with the music they listened to (e.g. the 'macho' and 'sexy' image of male pop/rock musicians playing mainly guitars and drums). In other words, the cultural stereotypes, attitudes, and opinions associated with particular styles of music appears to provide adolescent males with a vision of what it means to be 'trendy' or 'cool', which is 'acted out' or reinforced during their music listening experiences. O'Neill (1997) points out that adolescents' musical values are influenced by culturally defined stereotypes that, once learned, are extremely resistant to change and disconfirmation. In this way, musical associations or 'prevailing discourses' in a culture are both established and maintained through their use as a 'thread' out of

which we might fashion or construct aspects of the self and the expression of emotional states associated with the self.

18.5 The balance between context and content

Emotional responses to music are a complex outcome of the contribution of a person's reaction to the content (i.e. the musical materials themselves and their associations) and their reactions to the social context in which the music is embedded. For instance, the context may determine the amount of attention available to place on the musical content (e.g. a parent out shopping with an irritable and loudly complaining small child and being embarrassed by the hostile looks of other shoppers may barely notice the 'soothing' Mozart playing quietly in the background). At the same time, the content may be subtly changing the way the person construes the context (e.g. the Mozart excerpt suggests the subliminal message that this is a 'high-class' store for serious, 'well-behaved' adults, and small noisy children have no place here—thus intensifying the feelings in the parent of embarrassment and shame). These effects have been studied experimentally by, for instance, manipulating music–film pairings or music–picture pairings and observing how construed emotional meaning is affected (Cohen, this volume).

However, everyday life does not provide opportunities for controlled manipulation of variables, and so it is difficult to disentangle the unique contribution of content and context. The work that comes the closest to providing an insight into these issues is a study by Sloboda (1989*a*) in which 70 individuals were asked to recall any incidents from the first 10 years of life that were in any way connected with music. This period was chosen because a major aim of the study was to find connections between early music experience and later attitudes to music. For each incident recalled, participants were asked to say as much as they could about the context (who they were with, what event the music formed part of), and what meaning or significance the event had for them. This allowed each incident to be assigned a value on each of two dimensions—an internal dimension, concerned with the musical content, and an external dimension concerned with the context. On each dimension the significance could be positive, neutral, or negative.

When the 113 incidents elicited were cross-tabulated on these two dimensions, some interesting features emerged. First, there were very few cases where the musical content had a negative significance. One person recalled disliking the sound of a particular set of pipes on a church organ, but there were few other clear cases. This was not, however, the result of a rosy view of childhood where all negative memories had been erased, because there were many cases where the musical context was negative. Many people remembered situations of anxiety, pain, and humiliation, mainly connected with negative appraisal of their musicality by adult authority figures (particularly teachers). The most extreme incident was where a teacher physically beat a child for a performance error. There were, however, positive contexts too. For instance, one respondent recalled rehearsing carols for a school carol concert. What gave the incident its positive significance was the sense of enjoyment among the group, undertaking this festive preparation in place of normal academic classes.

The second important feature was the almost complete absence of incidents where the musical content was appraised positively and the context was appraised negatively.

One might interpret this finding by supposing that where the immediate context is a source of threat or emotional challenge, there is little chance of musical content capturing the emotional system. This study suggests that positive emotions derived from engagement with musical materials is only possible when the context is appraised as, at worst, emotionally neutral. The specific contexts where strong content-related emotions were felt included home, church, and the concert hall, alone or with friends and family. They tended not to include lessons at school, or situations in the direct presence of a teacher. Although hopefully not inevitably so, it seems that formal instructional settings have a tendency to be inimical to emotional engagement with music. This may be because of the emphasis within such settings on achievement, success, and failure, with the concomitant threats to self-esteem and self-worth. It has the paradoxical consequence that people may be driven to express their deepest and most personal relationships with music in private, or in supportive peer reference groups outside, and hidden from, the formal educational process.

18.6 Everyday music use as self-therapy

In the preceding paragraphs, we have seen much evidence of music being used deliberately and consciously to achieve psychological outcomes which are reflected in emotional change. Music clearly is used by people to make them feel better or different, or help them accomplish or attune themselves to some concurrent or anticipated activity. These kinds of activity have sometimes been, perhaps rather glibly, cited as examples of 'self-therapy' (Sloboda 1989*b*, 1992). However, therapy, as understood by therapists, is not simply about manipulation of emotions, it is about helping the individual in therapy to develop more appropriate and functional responses to the problems of living (cf. Bayne & Nicolson 1993; Bunt & Pavlicevic, this volume). There is almost nothing in the literature on everyday uses of music that would count as strong evidence that particular self-chosen music improves problem solving or decision making, as compared to no music, or different music. It would be an interesting study to ask people to deny themselves any self-chosen music for a period of time, and compare their adjustment on a number of psychological measures to that found during normal music use. ESM would seem to be particularly well suited to the measurement of the effects of such manipulations.

However, the strong claims made by users of music in a wide range of studies, supported by subjective and anecdotal evidence, make it likely that such effects do exist, although the mechanisms by which they are mediated are poorly theorized. There is, however, one very plausible class of mechanisms by which music could have a therapeutic effect. Much is made in the literature about 'everyday' psychological disorders, such as depression or the effect of cognitive set or narrowing. A depressed person is often locked in a cycle of negative and self-defeating cognitions, unable to call to mind plausible alternatives to the narrow circle of linked aversive scenarios (Blaney 1986; Pollock & Williams 1998). These cognitions are also often accompanied by anomalous states of arousal, such as high anxiety, insomnia, or lethargy. Well-chosen pieces of music may be able to help individuals break out of such cycles by the specific combination of intrinsic and extrinsic cues that they provide (Sloboda & Juslin, this volume).

Extrinsic cues may remind the person of situations, scenarios, people, and emotions that lie outside the closed loop of the pathological state. Intrinsic cues (the ebb and flow of tension, resolution, expectancy, etc.) may provide means for altering arousal states in positive directions. In addition, the unique capacity of music to engender emotional release (as in crying; see Sloboda & Juslin, this volume) may be in itself therapeutic. For reasons that are not well understood, emotional release appears to assist psychological adjustment (through a process sometimes called *catharsis*; e.g. Davis 1988). A fuller working out of some of these ideas in the context of music's role in spirituality is provided by Sloboda (2000).

18.7 Conclusion

It is a significant feature of many of the emotional feelings and displays that individuals experience in relation to the everyday musical scenarios that we have outlined that although they may occur in solitude, their point of reference is the relationship between the music user and others. Although viewed as essentially 'private' experiences, involving a great deal of autonomy or agency, emotional feelings and displays are deeply embedded in a social context, which exerts a powerful influence (albeit often implicitly) on our music listening. Reliving past relationships, constructing identity, using music to 'siphon off' emotions that are not for public presentation: all of these depend on, and are used to negotiate and develop, the complex web of cognitions and behaviours that constitute social life. As such, music becomes part of the construction of emotional feelings and displays that are both reflective and communicative 'embodied' judgments used to accomplish particular social acts. In other words, musical emotions are a form of social representation, which is negotiated as an interaction between cultural/ideological values of a society, the values and beliefs operating in a social grouping or subculture in that society, and the individual's own social and personal experience.

Our research highlights the importance of studying emotional feelings and displays as part of a sequence of everyday music listening based on conventions and rules of a particular social context and the unfolding episodes in which they occur. Our recent study (Sloboda *et al.*, 2001) involving electronic pagers and self-reports (experience sampling method) provides one approach which may be used to capture individuals' subjective experiences of emotions during 'real', evolving musical episodes. Another possibility is to approach the analysis of episodes involving music and emotion in a similar way to how we might analyse conversations in discursive psychology. This is not to say that we should analyse the actual vocabulary used by individuals to define emotion words in relation to music. Rather, a 'discourse' in this sense can be thought of as a kind of frame of reference, a conceptual framework in which our emotional feelings and displays can be interpreted. One method of discursive analysis which may prove particularly useful in the study of music and emotions is what has been referred to as the 'positioning triad' (cf. Harré & van Langenhove 1999). It consists of three elements: (a) the story (or content) of an evolving episode; (b) the relative positions of individuals in terms of the cultural/social conventions involved in speaking (and listening) during or about the episode, displaying judgments, and/or expressing acts; and (c) the social act the episode performs. The 'positioning triad' provides a framework for investigating the dynamics

of real-life, evolving situations that could be used by researchers seeking to identify and further our understanding of the role of music and the people engaging in emotional displays.

However, a word of caution may be necessary. Most of us are not aware of the fact that our musical activities are completely enmeshed in a social and cultural world. Our engagement with music leads us to 'forget' or become unaware of the grounds on which our feelings and behaviours are based. This 'forgetting' is the product of years of training, socialization, and the institutionalization of music. Not only have our musical practices become routine and invisible, but as musicians and psychologists we are limited in our ability to describe musical materials in a way that is free of the assumptions and biases associated with our own experiences and training. For example, there are many examples of research where specific discourses involving musicological characterizations of emotions (e.g. reference to specific musical works or to structural and symbolic features of these works) are introduced before an attempt is made to characterize the user's emotional responses in relation to them. In doing so, we continue to perpetuate the historical projections and social preoccupations of the various professional elites that have dominated the work of defining what music is and what it is for, not only for themselves but for the wider culture. By turning our attention to the role of emotional 'work' in relation to music, which takes into account individual subjective experience of *both* emotional feelings and displays as they occur in everyday evolving situations, it might be possible to retrieve some of these 'forgotten' or 'hidden' practices. Only by revealing the meanings associated with our evaluative judgments embedded within a particular context or general conceptual framework, can we hope to gain a better understanding of the complexity of emotions and music in everyday life.

CHAPTER 19

EMOTIONS IN STRONG EXPERIENCES WITH MUSIC

ALF GABRIELSSON

In most people's minds there is a strong association between music and emotions. Music can be felt to express emotions as well as to arouse emotions. While musical expression has been given considerable attention in empirical research (cf. Gabrielsson & Lindström, this volume; Juslin, this volume), emotional reactions to music have been less studied. The purpose of this chapter is to describe emotional reactions that occur in particularly strong experiences of music, and further to explore which factors can elicit such reactions.

Strong experiences of music may have many properties in common with other types of strong or exceptional experience, for instance, mystical experience which is described and discussed in many religious contexts. In the following, I first briefly review some earlier research on strong experiences, and then describe a research project on strong experiences of music (Section 19.3) and the associated analysis of emotional reactions (Section 19.4), followed by a discussion (Section 19.5).

19.1 Earlier research on strong experiences

In empirical psychology, the best known analysis of strong experiences was furnished by Abraham Maslow, one of the founders of the so-called humanistic psychology. Maslow coined the term *peak experience,* which he originally associated with self-actualization, the highest level in his well-known hierarchy of needs (Maslow 1954, Chapter 5). To explore such experiences, Maslow asked people to describe 'the most wonderful experience of your life; happiest moments, ecstatic moments, moments of rapture, perhaps from being in love, or from listening to music, or suddenly 'being hit' by a book or a painting, or from some great creative moment' (Maslow 1968, p. 71). Surveying the contents of these descriptions, he found several characteristics of generalized peak experience, for example, total attention on the object in question, complete absorption, disorientation in time and space, transcendence of ego, and identification or even fusion of the perceiver and the perceived. Peak experience is good and desirable, there is a complete loss of fear, anxiety, inhibition, defence, and control. Moreover, 'the emotional reaction in the peak experience has a special flavor of wonder, of awe, of reverence, of humility and surrender before the experience as before something great' (Maslow 1968, pp. 87–8), even a fear of being overwhelmed with more than one can bear. The experience may occasionally be described as sacred. Maslow found music,

especially the great classics, to be one of the easiest ways of getting peak experience (Maslow 1976, pp. 169–70).

As an extension of Maslow's investigations, Panzarella (1980, p. 71) gathered reports on 'intense joyous experience of listening to music or looking at visual art' from a sample of 103 persons, 51 describing musical experiences and 52 visual art experiences. His analysis (content analysis followed by factor analysis) revealed four major factors of the experience: (a) *renewal ecstasy*, an altered perception of the world ('The world is better, more beautiful than had been thought before'; Panzarella 1980, p. 73); (b) *motor-sensory ecstasy*, physical responses (changes in heart rate, breathing, posture or locomotion, presence of shivers, chills, tinglings, etc.) and quasi-physical responses (e.g. feeling 'high', 'floating'); (c) *withdrawal ecstasy*, loss of contact with both the physical and social environment; and (d) *fusion-emotional ecstasy*, merging with the aesthetic object. Motor-sensory ecstasy and fusion-emotional ecstasy were more pronounced in music reports than in visual art reports.

Earlier, Laski (1961) asked 63 individuals whether they had known an experience of 'transcendent ecstasy' and further analysed texts from selected literary sources and from books on religious experiences. Triggers of such experiences included nature, sexual love, childbirth, religion, art, science, creative work, 'beauty', and others. The contents of the descriptions were classified into four broad categories: (a) feelings of loss of something (e.g. loss of time, place, sense, self); (b) feelings of gain of something (e.g. gain of timelessness, release, satisfaction, joy, salvation, perfection, new knowledge); (c) feelings of ineffability (e.g. the experience is indescribable, eludes verbal communication); and (d) quasi-physical feelings (e.g. light and/or heat words, improvement words, pain words, calm and peace words). Classical music was the most frequently mentioned trigger among the arts.

The concept of *flow* developed by Csikszentmihalyi (e.g. Csikszentmihalyi 1990) has several aspects similar to peak experience and self-actualization. It refers to a state of intense yet effortless involvement in an activity, the experience of which is 'so enjoyable that people will do it . . . for the sheer sake of doing it' (Csikszentmihalyi 1990, p. 4). Some major characteristics of the phenomenon are full concentration on the relevant stimuli, total absorption in the activity; altered perception of time, and loss of self-consciousness. Flow may appear in connection with a manifold of activities, for example, rock climbing, sailing, chess, games, dancing, and making music. With regard to music, the flow concept seems most applicable to performance (see Persson, this volume), for instance, in mastering a difficult piece in a fully concentrated but seemingly effortless involvement, a phenomenon often reported by musicians as the most happy moments in their activities (I agree). Flow experience in listening to music is briefly mentioned as well (Csikszentmihalyi 1990, pp. 68 and 108).

Evidence from the above-mentioned studies indicate many different physical, quasi-physical, perceptual, cognitive, emotional, and transcendental phenomena in strong experiences, whether they are called peak experiences, mystic experiences, ecstasy, flow, or something else. Emotions are important ingredients and may manifest themselves, not only as experience, but also in physical responses (e.g. Plutchik 1994, p. 136).

19.2 Physical responses

Physical responses, such as thrills, shivers, and changes in heart rate are often mentioned in descriptions of strong experiences and are commonly associated with strong emotional arousal. From answers to a questionnaire, Goldstein (1980) concluded that thrills—a chill, shudder, tingling, or tickling—are a common response to music, primarily to musical passages with special emotional meaning for a person.

Sloboda (1991) obtained reports from 83 respondents on various physical responses—shivers, tears, lump in the throat, goose pimples, racing heart, and others—that they often experienced to music. In about a third of the cited cases, the response was located to a specific theme, phrase, motif, bar, chord, or moment, all of them belonging to pieces of classical music. Tears or lump in the throat were provoked by melodic appogiaturas, shivers or goose pimples by sudden changes in harmony, and heart race occurred in connection with acceleration and syncopation (see also comments in Sloboda 1999).

Panksepp (1995) investigated chills induced by music. In general, chills were reported more for pieces brought by the participating students themselves than for other pieces, which suggested effects of conditioning. Most examples belonged to popular music. When subjects listened to unfamiliar music, sad pieces produced significantly more chills than happy pieces for females but not for males. Chills tended to peak at the most intense and dramatic crescendos.

19.3 The SEM project

Evidence from the studies reviewed above suggests that music may be a common trigger of extraordinary experiences. In the following, I briefly describe a research project aiming to gather further, more detailed knowledge of this topic.

The strong experiences of music (SEM) project was initiated independently of the works described above. The main impulse was my disappointment that music psychology rarely, if ever, comes to grips with the questions that most people consider the most relevant regarding music—simply, how are we affected by music? I was also approached, typically in private, by people who told me about exceptional experiences of music, affecting them deeply in ways that they could not understand.

I started this project at the very end of the 1980s together with psychologist Siv Lindström Wik. We studied Maslow's writings on peak experiences, but found no concrete examples of what people told about their peak experiences, rather 'an impressionistic, ideal, 'composite photograph' or organization of personal interviews . . . and of written reports' (Maslow 1968, p. 71). Panzarella's (1980) pioneering study was very useful as it provided examples of subjects' reports, and procedures for obtaining and analysing them. However, his musical sample was limited to some 50 persons, and in both Maslow's and Panzarella's studies classical music seemed to be the (almost) sole elicitor of peak experiences. This was also stated by Laski (1961). We were also concerned about definitions such as 'intense joyous experience' (Panzarella 1980, p. 71). All this seemed to imply some limitations in relation to the purpose of the SEM project, that is, to obtain descriptions of any type of strong experiences (including negative

ones) in connection with any kind of music. In order not to prejudice our potential subjects, we avoided any examples or suggestions of what would define a strong experience of music or of what kind of music could be involved.

The purpose of the project was first of all descriptive, to analyse which phenomena are contained in strong experiences of music—in other words, to find out how people are affected. We also wanted to explore how SEM is related to properties of the actual music as well as to characteristics of the respondent and of the situation in which the experience occurred. Moreover, we were interested in possible consequences of SEM for the individual's future.

The very beginning of the project was briefly reported in Gabrielsson (1989). A classification of SEM phenomena was sketched in Gabrielsson and Lindström (1993), and further elaborated in Gabrielsson and Lindström Wik (2000). Examples of the potential therapeutic effects of SEM were given in Gabrielsson and Lindström (1995); and SEM in relation to musicality is discussed in Gabrielsson (in press). Given the present volume's focus on emotion, the following chapter will be centred on the description of emotional aspects of SEM. Some connections to other aspects and to underlying factors will be briefly discussed within the available space.

19.3.1 Data collection

Briefly, subjects were asked to describe 'the strongest, most intense experience of music that you have ever had. Please, describe your experience and reactions in as much detail as you can.' Supplementary questions concerned, for example, if this was the first time the subject had listened to the music in question and if the same strong experience had recurred at later listenings, if any, to the same music; how the respondent felt before and after the experience and what the experience had meant in a longer perspective; how often such strong experiences occurred and if similar strong experiences occurred in other situations than with music; and if the respondent had any idea about what caused the strong experience. The reports were obtained by means of interviews and, mostly, as written reports.

19.3.2 Subjects

All participation was on a voluntary basis, and there was no attempt to achieve strict representative sampling of some defined subject population. However, attempts were made to ensure variation with regard to gender, age, occupation, and musical preferences. The present account is based on about 400 reports obtained from some 300 persons (many subjects provided two or more reports). Gender distribution is about equal. Almost 60 per cent of participants are between 20 and 40 years old, about 30 per cent between 40 and 60 years old. About 50 per cent are amateur musicians, about one-third professional musicians, and about one-sixth non-musicians. Although musicians, professional and amateurs, are thus in the great majority, about 80 per cent of the reports refer to experiences as listeners. Musical preferences are spread over many genres.

19.3.3 Analysis

Subjects' SEM accounts are subjected to content analysis (see, for example, Patton 1990, Chapter 8), gathering all relevant phenomena mentioned and successively exploring

different ways of sorting them into a limited number of fundamental categories. This work was/is conducted independently by the author and his co-worker, also at times by students in connection with writing theses on SEM. After the necessarily tentative analysis of the earliest reports, the agreement between the analysts has usually been very good. However, as human experiences and reactions are hard to fit into truly exhaustive and mutually exclusive categories, there are still some problems regarding proper classification. Some double classifications seem unavoidable, and the classification process may never come to a definite end. A basic problem is, of course, the large interindividual variation in participants' vocabulary and linguistic competence. We stay as close as possible to the descriptive terms used by the subjects themselves, but a certain amount of interpretation from our side is unavoidable. For more complete accounts of methods, see Gabrielsson and Lindström (1993) and Gabrielsson and Lindström Wik (2000).

19.3.4 Some general results

The length and detail of the reports vary widely, from only a few lines up to eight pages. A few respondents even wrote poetry to describe their experience. Each report represents a unique case with regard to contents of the experience and influencing factors.

Briefly, the present classification of SEM aspects comprises the following basic categories: general characteristics; physical and behavioural aspects; perceptual aspects; cognitive aspects; emotional aspects; existential and transcendental aspects; and developmental aspects. Each of them contains a number of subcategories as seen in Table 19.1. For discussion and examples of these subcategories, see Gabrielsson and Lindström (1993) and Gabrielsson and Lindström Wik (2000). As noted earlier, we do not pretend that these categories are completely exhaustive, nor quite mutually exclusive. However, repeated application of this classification to lots of SEM reports shows good results. The number of doubtful cases is relatively small and decreases as the classification is successively refined. The classification has also proved useful in pilot studies on strong experiences of dance and of visual art. The present account will be limited to emotional aspects of SEM and related matters.

19.4 Emotional aspects of SEM

The emotional aspects of SEM have been classified into four subcategories: (a) intense emotions; (b) positive emotions; (c) negative emotions; and (d) mixtures of emotions/conflicting emotions.

19.4.1 Intense emotions

As could be expected, emotional reactions in SEM are typically of unusual intensity, regardless of which specific emotions are experienced. Some illustrative quotations are given here:

I had to close my eyes, it was such an enormous emotional experience.

Table 19.1 Classification of SEM phenomena

General characteristics of SEM
Unique, fantastic, incredible
Hard-to-describe experience, words insufficient
Physical reactions, behaviours
Physiological responses
Behaviours
Quasi-physical responses
Perception
Auditory
Visual
Tactile
Kinaesthetic
Synaesthetic
Intensified perception
Musical perception-cognition
Cognition
Changed attitude
Changed experience of body, time, and space
Changed attitude to music
Thoughts, memories
Imagery
Cognition-emotion
Musical cognition-emotion
Emotion
Intense emotions
Positive emotions
Negative emotions
Mixtures of emotions/conflicting emotions
Existential and transcendental aspects
Meaning of existence, being
Transcendental states
Religious experiences
Personal development
New insights, new possibilities
Confirmation of identity
Feeling of community
Music: new interests, attitudes, motives

. . . overwhelming waves of feelings that were thrown forth as reaction to the music . . . I could absolutely not control the emotional outburst . . . so ABSOLUTELY IMPOSSIBLE to change it.

This song arouses so strong feelings in me that I cannot listen to it more than once a year.

. . . and last an internal peace that words cannot describe.

Although intensity of emotions may seem mainly associated with high arousal, as in the second quotation above, it may as well refer to states of low arousal such as peacefulness (last quotation).

19.4.2 Positive emotions

Positive emotions dominate in SEM reports. The by far most frequently mentioned feelings, singly or in various combinations, are happiness, joy, elation, and bliss. In many cases, the feelings are described in even stronger terms, such as a kind of intoxication, rapture, or euphoria boarding on ecstasy. Below are some illustrative excerpts from SEM reports. They are designated E1, E2, etc. to facilitate finding them again when referred to later in text.

A young lady attended an outdoor concert with the artist known as Prince:

[E1] The music began before the curtain rose, and you just stood there as semi-paralysed and screaming . . . Everybody in the audience is exciting each other to a stage next to a climax, and when the artist at last comes on stage he does not have to say more than 'hi' to trigger that climax. It is very much the atmosphere in the audience that gives this concert feeling. If I was standing there all by myself looking at Prince, it would not be the same thing at all . . . One feels so free somehow. At concerts one can dance, jump, scream and sing as much as one wants. You are like a part of it all, not just a spectator. Throughout the whole concert the audience was in total ecstasy. It was only one thing that mattered: the music! You are filled with the wonderful feeling that everything is all right, that you are living only for what is happening 'right now'. You are in a way 'intoxicated with joy' . . . You don't think about what you are doing. You do what you feel like, without even thinking about it.

A young performer was rehearsing a piece by Bach and then:

[E2] . . . suddenly experienced a tremendously strong feeling that was felt both in my body and in my head. It was as if I was charged with some kind of high tension, like a strong intoxication. It made me ecstatic, inconceivably exhilarated, everything concentrated to a single now. The music flowed as by itself. I felt like I was penetrated by Bach's spirit: the music was suddenly so self-evident. There was no doubt any longer how it should be played, as if I had come to the deepest insight and found the genuine, true and correct expression. The intoxication lasted the whole piece, and I staggered out afterwards . . . What a fantastic happy experience!

A woman attended a performance by a band playing Finnish tango in a pub:

[E3] I was filled by a feeling that the music started to take command of my body. I was charged in some way . . . I was filled by an enormous warmth and heat. I swallowed all tones . . . the music became so distinct. I was captured by each of the instruments and what they had to give me . . . Nothing else existed. I was dancing, whirling, giving myself up to the music and the rhythms, overjoyed, laughing. Tears came into my eyes—however strange it may seem—and it was as a kind of liberation . . . Afterwards I was standing there intoxicated with joy. That was a real kick for me.

There are lots of reports of this kind in which happiness and joy abound. In other cases a 'happy end' is attained although actually nothing indicated such a possibility—as in this report by a depressed mother, alone at home with her little child. She felt:

[E4] . . . so tired, so alone . . . grey sky, cold . . . nobody would know if I was to die . . . For some reason, I put on Mozart's *Requiem* (I am not aware of logically thinking in any way about this act) . . . I read the sleeve notes and sink, sink, sink deeper—no time—only the sounds enveloping me in a world aside of this—sinking deeper beyond words, beyond thoughts, only the waterfall of sound cascading around and through me . . . My head is gone, body too, and yet I am here. The grey 4 square table leg is exquisite in its perfection—beyond meaning in the intensity of its

greyness, displays a perfection that defies description . . . the whole room, the whole universe is present here in perfect harmony. All colors are vivid beyond description . . .I seem to be experiencing directly and have no words to express this state of bliss, harmony, meaningless beauty. I am totally a part of it all . . . The whole world is dancing before my eyes—I am calm, tears run down my cheeks. I have no idea why . . . I am not happy, I am not sad, am not anything in particular, yet feel the potential for anything to pass through me . . . secure and warm and full of love. I want to kiss the postman, ring the whole world and tell it, it's okay, it's all okay . . . the total qualitative shift in my relating to the world, universe, whatever you can now call it, remains. That pure existence and nothing else could be so beautiful! Satisfaction. Ecstasy.

This is a good example of what Panzarella (1980) named 'renewal ecstasy'. Other commonly mentioned feelings are enjoyment, delight, loveliness, and beauty; for instance, 'I felt an enormous delight' or '. . . it was lovely. It was God and heaven and all angels'. Closely related to this type of responses are also feelings of perfection: 'It can't be better than this!'; 'I remember the feeling of "this is not true, I am dreaming, it is not possible to do like this"'; 'When I came out after the concert, I told my company that I could die happy now'. Performers may feel that they surpass their usual achievements, and manage things that they usually do not master: 'This feeling when everything fits together is wonderful'; 'The music one created was far beyond one's usual capacity'.

While the emotional reactions described so far are associated with high or rather high levels of arousal, another common class of responses reflects feelings at rather low arousal, such as feelings of calm, peace, repose, safety, warmth, and love: 'I experienced a stillness that was not like anything else . . . everything else felt irrelevant . . . the important thing was to be able to exist in the present and the stillness that felt as eternal'; 'I listened to the tape 2–3 times a day . . . it became a safety among all chaos and misunderstandings'; 'I was in a state of warmth and kindness'; 'I felt in love with this music'.

Many feelings seem to represent a mixture of cognitive and emotional aspects. They are contained within the cognition-emotion subcategory in Table 19.1. Feelings of expectancy and tension may occur both before and during the music: 'It is always thrilling to sit down and know that the orchestra is going to perform'; '. . . building up an almost insufferable tension concerning what this would lead up to'. Music may make the listener surprised, amazed, shaken, even shocked (examples of the latter appear under negative emotions): 'I was brought away by the music, amazed and surprised by its beauty'. A common phrase, almost a cliché, is to 'be hit' by the music, feel that it goes straight into oneself, bypassing or crossing all cognitive barriers: 'A pianist played Beethoven's *Appassionata*. It hit the poor, musical child who had neither radio or gramophone at home'; 'The monumental work . . . hit me like a storm'; '. . . the piece goes so directly into me. Quite mercilessly it cuts through all barriers straight into the emotions'.

Still other examples within this subcategory may be feelings of longing ('The music brought me away in dreams, longing'), wonder ('The feeling when you experience this totality is just wonder'), smallness and humility ('It was an enormous experience, I felt small and humble'), gratitude ('I felt so infinitely grateful'), honour ('It was . . . almost an honour having had the possibility to experience this'), solemnity ('I remember the solemn feeling of being present at such an evening'), and sacredness ('I felt myself standing in the midst of a sacred moment in life').

19.4.3 Negative emotions

A few extremely negative SEMs were reported. A young man attended an outdoor rock concert:

[E5] After a while, they announced a female's band . . . Malaria was their symptomatic name. They played a hard, heavy, fateful synthetic rock at high volume. We had been sitting quite close but it soon became unbearable. The base was roaring a heavy, deafening monotone sound, that penetrated one's body. The drummer was also beating heavily and tired . . . a saxophone screamed in anguish, completely free from melody . . . accompanied by a singer who completely freely sang the most monotonous and howling song I had ever heard. Their make-up was black and pale, they wore black clothes . . . This naked and gruesome death music that was flowing from the loudspeakers and drowning us made me feel physically ill. I just wanted to get away from the music, and got on my feet to walk away. At the same time whole groups of black-dressed guys and girls came flowing toward the stage and loudspeakers. Everybody looked so pale and listless without life. I tried to remain but felt that it only provoked a destructive feeling of sickness . . . I thought that the Malaria band and the audience, in open anxiety before life and future, allied themselves, horribly and totally, with death and destruction . . . It was a deeply negative experience, strong and gruesome.

One report refers to a special chord in Mahler's Tenth Symphony. A man sat listening to this music shortly after a beloved relative's death:

[E6] But there it was. A chord so heart-rending and ghost-ridden that I had never experienced before. A single tone . . . is added with an endless number of instruments from the orchestra. Not unlike a huge organ where you pull out every organ stop at random. A dissonance that pierced my very marrow. My brother and I reacted the same: we were both filled with such a primitive horror, almost prehistorical, that none of us could utter a single word. We both looked at the big black window and both of us seemed to see the face of Death staring at us from outside.

While the negative emotions in these reports seem to be mainly caused by the music, in other cases the negative experience is associated with various personal and/or situational factors. A female alone at home in a large house a dark evening told:

[E7] I was sitting reading with the radio on. Suddenly Stravinsky's *Rite of Spring* breaks loose without notice. I almost panicked and felt an intense discomfort and had to switch off the radio.

Another negative experience was related to a frightful experience during childhood:

[E8] The Stockholm Philharmonic Orchestra was playing *Finlandia* by Jean Sibelius. The then aged composer was sitting in an armchair a little way from the orchestra. I felt immensely split—not to say that I was in a kind of chaos that would not pass off. The reason was that the work was said to describe the varying nature of Finland, barren landscape, wind and storm—and nothing else. The first time I listened to *Finlandia* was on radio in August 1940 . . . while the war was raging. I was a child living with my grandmother, separated from my parents and did not know when I would meet them again. I was very scared by the piece because I immediately interpreted the trumpet blows as machine guns, bomb explosions and the like. I felt anguish.

Some persons reported strong feelings of sadness associated with a piece of music. Usually the music had originally occurred in connection with negative circumstances, such as unhappy love, illness, attempted suicide, death, or memories of war. Strong frustration was felt by a female in the midst of an SEM when 'the grand mother steps in and

turns off the radio telling 'You need not wear out the batteries for such noise'. It felt like she tried to stifle me, I got quite frustrated.' One subject felt anger at a funeral, because quite inappropriate music was played. There was a single report of shame; a child was so affected by the music that 'I started crying by emotion. But I felt ashamed because of this . . . and I did not want to show that I was crying.'

19.4.4 Mixtures of emotions and conflicting emotions

While the preceding categories have provided examples dominated by positive or negative feelings, there are many reports with mixed appearances of feelings, feelings that change during the course of listening, feelings that are opposites to one another or in conflict with each other. Musicians' nervousness before a public performance may turn into feelings of joy and inspiration:

[E9] The whole day before I was very restless and tense . . . When I sat down to begin playing I felt, beside tension, increasing feelings of joy. The whole first piece became like a joy-intoxication, particularly as the audience looked very happy and helped to beat time through the whole piece . . . Afterwards I felt both elated and glad and totally relaxed.

Listeners may feel nervous concerning musicians' possibly unsatisfactory capacity, a nervousness that may soon disappear:

[E10] During concerts it often happens that I begin to worry about how it is going to turn out . . . Only a few minutes listening was enough to make me feel quite safe, lean back and let the music speak.

Listeners may be shaken, even shocked by the music, but after a while these feelings may turn into positive ones. A mainly perceptually conditioned shock is the overwhelming loudness and volume perceived when a musician is sitting inside an orchestra for the first time:

[E11] Then came the shock. The sound shock. The sounds that filled all of me, pressed me together into a small louse. Where would I go? I must get away . . . But soon this feeling changed into a courage to grow into the sounds, become a part of the music.

Anxiety or depression may be relieved by music:

[E12] I was in a deep depression, everything was black . . . This day began as all the others. I had great difficulties to bring myself to leave the bed's hiding place and get out into the threats that the new day meant . . . I went to a church where XX as usual was going to play the organ at noon. . . Somewhere in the piece by YY the fantastic happened, my mood was totally changed. Darkness became light and my uneasy mind calmed down . . . I left the church full of appetite on life.

Mixtures of positive and negative feelings may cause confusion:

[E13] One moment I felt like an abandoned child, lost and lonely, the next moment I was like a child in its most carefree moment . . . Suddenly a terrible feeling of confusion came upon me. In what I believe to be but a few seconds, a whole series of conflicting emotions: fright, sorrow, hate, love, anger, and last an internal peace that words cannot describe.

A report that provided penetrating introspective evidence of conflicting emotions was given by a young lady, fascinated by Gustav Mahler's music, when she attended a performance of the reconstruction of Mahler's unfinished Tenth Symphony:

[E14] I was waiting in an atmosphere of terror, waiting for what was to come after the intermission . . . I was scared. In fact already long before, at home and in the subway, I was scared. Afraid of being disappointed, afraid that this work of music which I had been wondering so much about would not be that precipice that I had imagined, would not be that step toward the new music that I thought it would be . . . The intermission had come to its end . . . I had never been so full of expectancy before. The conductor arrives. Silence. He raises his baton and starts the lonely violin part. After a few bars with this monotonous, curiously ambiguous song, like a doubt, the sun arrives. The orchestra is breaking out in a warmth that is fascinatingly painful. I remember tears filling my eyes. I felt as if I understood a message, from one time to another, from one human to another. I sat as if turned to stone, with my fingers gripping the armrest. After a while I became quite dizzy. Then I realized that I had forgotten to breathe . . . At the end of the first movement the whole orchestra is joining in a terrible great organ-like sound—a cry of pain and terror. It came as a shock after quite an enduring pianissimo. I was totally overwhelmed by the violence of this dread for death. I perspired and was hardly able to breathe. For once in my life, I had been totally knocked to the ground by something so great and strong that it wiped out all those thoughts that can slip by when one listens without fully concentrating . . . The last movement opens with eleven beats of an enormous wooden club against the largest bassdrum. The effect is horrible. A flute, followed by the strings, starts hesitatingly to develop a melody, but is suddenly crushed by a beat of the wooden club. I was totally taken by surprise. Each time the club beat, I was seized by terror. Each time an instrument began to sound, doubtfully, I anticipated the hit of the wooden club, I mourned. Here, too, I felt like I was a receiver of a message . . . I felt like I had not missed a single note . . . the feeling of being spoken to, strongly and directly, lived inside me. Maybe it was because I knew the music was not composed to completion, had not been ornamented, that it was so naked—an uncensored document about a condition oscillating between the deepest fear of death and an attraction towards darkness. After the orchestra silenced, the audience sat quiet for a long while . . . I think there were many like me who felt that we had been given the opportunity to look into a soul and therefore felt joy. Then the applause broke loose. And it would not stop. The way through the symphony had been hard and frightening, even shocking, but it was a great happiness—almost an honour—having had the possibility to experience this. I was flying home, weightless. I was glad that I attended the concert alone because now all words would have seen superfluous, even my own. My thoughts had nothing to do with words.

19.4.5 Relations to other SEM aspects

Physical responses

Physiological and behavioural responses were often reported (see E14 for some examples). By far the most common response was tears, meaning anything from getting moist eyes to uninhibited crying. In most cases tears were associated with positive feelings, but there were also examples of tears in connection with sadness and grief. Next in frequency came shivers/chills, thereafter gooseflesh, to feel warm/perspire or feel cold, muscular relaxation, changed breathing, heart race, pressure over the chest, hairs standing on end, various stomach responses, muscular tension, trembles/quivers, lump in the throat, dizziness, pain, and single examples of clouded eyes and dry mouth. Among overt behaviours, the dominating response was moving or dancing to the music (e.g. E1), followed by singing, shouting, smiling/laughing and—in a certain contrast to the preceding ones—closing one's eyes, sitting absolutely still hardly breathing (e.g. E14), and being unable to sing, play, or talk because of overwhelming feelings.

Note on other SEM aspects

In the excerpts we note the occurrence of many other phenomena, most of them also mentioned by previous authors (see Section 19.1): *quasi-physical feelings* (E3: 'the music started to take command of my body. I was charged in some way . . . I was filled by an enormous warmth and heat', E14: 'I was flying home, weightless'); *intensified perception* (E3: 'the music became so distinct', E4: 'All colors are vivid beyond description'); *total concentration on the music* (E1: 'It was only one thing that mattered: the music!', E3: 'Nothing else existed'); *disorientation of time* (E4: 'no time'); *loss of self-consciousness* (E4: 'My head is gone, body too'); *no thoughts* (E1: 'You don't think about what you are doing'); *intense feeling of living* (E1: 'you are living only for what is happening 'right now"'); *direct experience* (E4: 'I seem to be experiencing directly. . .feel the potential for anything to pass through me', E14: 'I felt like I was a receiver of a message . . . the feeling of being spoken to, strongly and directly, lived inside me'); *merging with the music* (E2: 'I felt like I was penetrated by Bach's spirit', E3: 'giving myself up to the music and the rhythms', E4: 'only the waterfall of sound cascading around and through me'); *feeling of freedom* (E1: 'One feels so free somehow', E3: 'it was as a kind of liberation'); *gaining new insight* (E2: 'I had come to the deepest insight and found the genuine, true and correct expression'); *altered perception of the world* (E4: 'the whole room, the whole universe is present here in perfect harmony . . . That pure existence and nothing else could be so beautiful!'); *community* (E1: 'You are like a part of it all', E4: 'I am totally a part of it all'); *transcendence* (E4: 'the sounds enveloping me in a world aside of this—sinking deeper beyond words, beyond thoughts'); *experience eludes verbal communication* (E4: '[I] have no words to express this state of bliss, harmony, meaningless beauty', E14: 'My thoughts had nothing to do with words').

SEM includes many other aspects as well (cf. Table 19.1). Further analysis of these and their relationships to each other is outside the scope of this chapter.

19.4.6 Influencing factors

Factors influencing SEM may be classified into musical, personal, and situational factors, briefly examplified in the following.

Musical factors

The music featuring in these 400 reports came from many different genres. Only a crude classification is made here. Art music (anything from old church music up to electronic music) appeared in barely half of the reports. The remaining half included pop/rock, jazz, folk music, and various kinds of popular music. Thus, SEM may occur in connection with 'any' music, and one can hardly find any distinct differences in emotional reactions to music of different genres.

In the excerpts, there are some examples of specific musical factors which caused or contributed to the strong emotional reaction. The negative SEM in E5 was attributed to the high volume, heavy drumming, screaming saxophone, and monotonous and howling song. In E6, a 'heart-rending and ghost-ridden' chord in Mahler's Tenth Symphony led to a horror reaction. It is probably the same chord that also was mentioned in E14: 'the whole orchestra is joining in a terrible great organ-like sound—a cry of pain and

terror' causing a shock in the listener. The notation of this chord (Fig 19.1) reveals a fortissimo chord extending over the whole frequency range of the orchestra with intervals of (mostly) minor thirds between its component tones contributing to very pronounced dissonance (cf. dissonance in relation to critical bandwidth, Dowling & Harwood 1986, pp. 82–5). There is also hardly anything in the immediately preceding music that would make the listener expect such an outburst. The chord thus works as an icon of strong negative emotion and also violates expectations, two ways of representing or arousing emotions (Dowling & Harwood 1986, pp. 205–24). The same chord appears again, further elaborated, in the final movement of the symphony (bars 275–283). To my knowledge, such a complex chord has no earlier equivalent, and it appeared at a time around 1910 when atonal music made its appearance, also in Vienna, with Schoenberg, Webern, and Berg. The listener in E14 also referred to the beginning of the last movement in this symphony, where the beats of 'an enormous wooden club against the largest bassdrum' crushed any attempt by other instruments and caused horror.

Rather than indicating specific moments in the music, many respondents more generally referred to musical factors such as timbre (e.g. an unusual instrument or unusual combination of instruments), loudness/dynamics (e.g. crescendo, diminuendo), tempo (e.g. accelerando), mode (e.g. transition minor to major), rhythm (often in connection with dancing, as in E3), beautiful melodies and harmonies, thick texture, increasing tension followed by relaxation, and still others. It is striking, however, that although many respondents were active musicians, in their reports they did not often use conventional musical terminology but rather terms that can be used by 'anyone': 'brutal chords', 'heavenly beautiful tones', 'majestic sound', 'pure music', 'enormous power and energy', and the like. Metaphors were used now and then: 'every chord goes like waves through yourself', 'in the last bars it is like a light over my closed eyes which more and more goes out in the following diminuendo'. Respondents also often attributed their reaction to the qualities of the performance—the skill, concentration, and involvement displayed by the musician(s), including conductors as well. This was very much due to visual impressions of the musicians, the instruments, and the physical and social environment.

Personal factors

Besides common demographic variables such as gender, age, educational level, and profession, our classification of person-related factors influencing SEM includes a variety of factors, for example:

1. *Physical state*, for instance, feeling well, rested, tired, ill.
2. *Cognitive factors*: expectations (positive, negative, not specific, see, for example, E14); feel a need for listening to or performing music; be attentive, receptive, sensitive, open-minded, or not; having heard or performed this music earlier, or not; be familiar or not with musical style, composer, performers, etc.; use or abandon analytical attitude; have pleasant or unpleasant memories of the music (e.g. in E8 trumpet blows were associated with war).
3. *Emotional state*: be in high or low spirits, calm, relaxed, nervous (e.g. E9, E10), stressed, depressed (e.g. E12), in crisis, in love, unhappy love, etc.

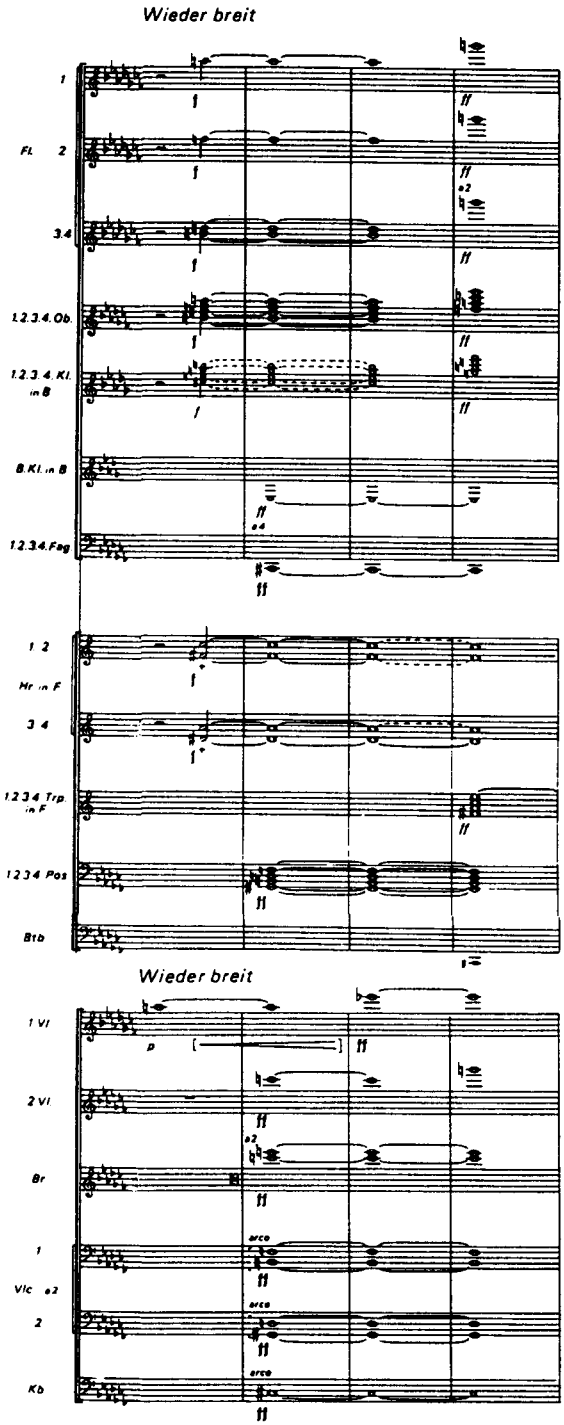

Figure 19.1 The chord in bars 203–206 of the first movement of Gustav Mahler's Tenth Symphony arranged by Deryck Cooke (1976). The chord is repeated in bar 208. Copyright ©1966 (Renewed) by Associated Music Publishers, Inc. (BMI). International Copyright Secured. All Rights Reserved. Reprinted by permission.

4. *Personality-related variables* (as suggested by respondents themselves) such as temperament, maturity, and dispositions.

Situational factors

Factors related to the listening or performing situation included, among others, the following:

1. *Physical factors*: acoustical conditions; listening to live or recorded music; listening or performing at home, in a concert hall, church, restaurant, outdoors, or on a Walkman, etc.; position, close or far away, in relation to performers or among co-performers (e.g. E9); visual conditions (e.g. good sight) and impressions, time of day, season, weather, etc.
2. *Social factors*: listening or performing alone or together with others; size, appearance, and behaviour of audience (see, for example, E1 and E9), of performers, or co-performers (see, for example, E5).
3. *Special occasions/circumstances*: experience during vacations, in another country, in unusual environment, etc.
4. *Performance conditions*: for instance, music well rehearsed or unrehearsed.

Interactions among factors

A reasonably full treatment of these factors and their effects on SEM goes far beyond the scope of this chapter. It is obvious, however, that emotional reactions in SEM, as in any music situation, depend on interactions between musical, personal, and situational factors (the latter two are sometimes indistinguishable). The relative importance of each factor varies, but none of them can ever be excluded. Even in reports where musical factors appear to be very strong determinants, there are influences of personal and/or situational factors, for instance, in E6 (grief after relative died), E7 (alone at home in a large house on a dark evening), E8 (memories of war during childhood), and E14 (expectancy and fear of disappointment before listening to Mahler symphony).

In many cases, it is obvious that personal and/or situational factors are in fact more important than the music in question, as when, for instance, a piece of music is associated with war (e.g. E8), happy or unhappy love, an exotic environment, beautiful nature, pleasant holidays, certain ceremonies, etc. (for examples, see Gabrielsson & Lindström 1993, 1995). Such cases illustrate what Dowling and Harwood (1986, Chapter 8) call indexical representation, that is, a piece of music is associated with some extramusical object or situation.

In consideration of the ever present interactions between musical, personal, and situational factors it may be appropriate to speak of strong experiences *of and with* music (Gabrielsson & Lindström Wik, 2000) or strong experiences *in connection with* music.

19.5 Discussion

In accordance with the title of this chapter and this volume, the focus here has been on emotional aspects of SEM, supplemented by some brief outlooks to other aspects and influencing factors. A look at Table 19.1 shows that this represents but a limited part of the

available material on SEM. Cutting out a part of a whole inevitably leads to gaps and imperfections, and the loss of relevant connections and of broader context. For further content and analysis, I refer to our earlier reports as well as to reports in press and in preparation.

19.5.1 Comments on emotion

A general difficulty with the concept of emotion is how to make a reasonable demarcation of emotions or emotional feelings versus other feelings. Both psychologists and people in general use terms such as feelings, emotions, and mood in very variable, sometimes idiosyncratic, ways (e.g. Plutchik 1994, Chapter 3; see also Sloboda & Juslin, this volume). This is certainly also true for the corresponding terms in Swedish (for instance, the Swedish word 'känsla' is used in a variety of contexts and meanings). We have therefore simply stayed as close as possible to the terms used by the respondents themselves, provided that they have a reasonable emotional meaning, or at least an emotional connotation. Most of these terms appear in alphabetical order in Table 19.2, divided into positive and negative emotions. No further division is made presently (however, a distinction between different levels of arousal was hinted at in Section 19.4.2). Of course, some reservations must be made regarding the proper translation of Swedish terms into corresponding English ones.

Table 19.2 Emotions mentioned in SEM reports

Positive emotions
Amazement, beauty, bliss, calm, contentment, delight, ecstasy, elation, enjoyment, euphoria, excitement, exhilaration, expectancy, fascination, freedom, gladness, gratitude, happiness, harmony, honour, hope, humility, intoxication, joy, longing, love, loveliness, overjoy, overwhelmed, peace, perfection, pleasure, rapture, relaxation, repose, sacredness, safety, satisfaction, smallness, solemnity, surprise (positive), tension (positive), thrill, warmth, wonder
Negative emotions
Afraid, anger, anguish, anxiety, chaos, conflict, confusion, depression, disappointment, discomfort, fear, fright, frustration, gloom, gruesome, hate, horror, mourning, nervousness, pain, panic, sadness, scare, shaken, shame, shock, sorrow, split, surprise (negative), tension (negative), terror, uneasiness, worry

In the reports, we find numerous examples of so-called 'basic' emotions. However, opinions differ concerning which and how many basic emotions there are. The survey by Plutchik (1994, p. 58) indicates the best agreement regarding emotions like happiness, sadness, anger, and fear, but proposals by various authors also include (in alphabetical order) amazement, anxiety, elation, enjoyment, expectancy, grief, interest, love, pain, panic, pleasure, satisfaction, shame, shock, surprise, and tension, all of which are represented, to varying extents, in our material. Also proposed, but not represented in the present material, are boredom, contempt, disgust, and guilt—negative emotions which seem less plausible in connection with SEM. However, other negative emotions such as panic, shame, and shock may seem equally implausible, yet they have appeared; so too hasty exclusions should be avoided.

In previous studies on peak experience and flow (Csikszentmihalyi 1990; Laski 1961; Panzarella 1980), rather little was written about emotions. However, Maslow (1968, pp. 87–8) in his survey of 'generalized peak experience' mentioned happiness, ecstasy,

rapture, love, wonder, awe, reverence, humility, surrender before the experience as before something great, fear of being overwhelmed, and occasionally a description of the experience as sacred. These feelings are also represented in the present reports (although not all of them in the selected excerpts). None of them, except happiness, love, and fear, appears in lists of basic emotions but rather represent complex mixtures with considerable ingredients of cognitive character. Generally, the borderline between cognition and emotion is blurred, and from the standpoint of investigating strong experiences with music, this distinction may not be very important.

Whether some form of cognitive appraisal precedes emotion or not can be discussed at considerable length. In several SEM reports, respondents described their reaction as a kind of 'direct experience', something that bypasses cognitive barriers and goes 'straight into the emotions'. This suggests that there was no cognitive appraisal, at least not at a conscious level. However, there are also many reports in which the respondent first told about, say, the beautiful timbre of a singing voice, fantastic acoustics, irresistible rhythm, etc., which may be interpreted as rather deliberate cognitive appraisal mediating the emotional reaction. Of special interest are wordings referring to the beauty of the music (which we subsume under enjoyment). In some cases, there is obvious cognitive appraisal behind the beauty response—an insight into, and admiration of, say, the composer's ingenious construction of the music, its formal properties, delicate instrumentation, combination of text and music, etc.—that is, a kind of 'intellectual' enjoyment. In other cases, the response comes as a direct and spontaneous exclamation—'Oh, my God, how beautiful!'—devoid of any analysis or reflection.

The distinction between emotions *expressed* in music and emotions *aroused* by music is not always easy to make in the reports. For instance, 'the music became more and more gruesome' can be interpreted as the respondent's 'neutral' description of perceived expression, or as indicating that the respondent felt anxious, or as a combination of both possibilities.

19.5.2 Comments on methodological issues

Verbal reports are associated with several well-known problems (Ericsson & Simon 1993), not least with regard to retrospective reports as here. Many reports refer to experiences which happened many decades ago and are obviously sensitive to memory distortions. Furthermore, subjects differ much in linguistic competence, vocabulary, and willingness to use language to describe their experiences. Many respondents frankly stated that their SEM was impossible to describe by words. Others wrote long and penetrating accounts but still complained about the validity of words to describe what they actually felt—the experience seemed ineffable. However, presently we have no better tools available than language in attempts to approach phenomena like SEM, and I am convinced that language will remain the main instrument for a considerable time still. For some further comments, see Gabrielsson (1989, 1991) and Gabrielsson and Lindström (1993).

19.5.3 Continued research

Recently, Lowis (1998) tried to investigate peak experiences under experimental conditions. Subjects listened to prerecorded classical music: five pieces of 'gentle' music (e.g.

'Nimrod' from *Enigma Variations* by Elgar) and nine pieces of 'up-beat' music (e.g. the ending of *The Firebird* by Stravinsky), and used a button device to indicate 'a moment of particularly deep and profound pleasure or joy . . . the sort that produces a tingle in the spine' (Lowis 1998, p. 212). Further definitions of peak experience alluded to phenomena described by Maslow (see Section 19.1). Roughly two-thirds of the subjects pressed the button at least once. The up-beat music generated significantly more responses than the gentle music. Significant correlations were found between frequency of button pressings and ratings for the following feelings evoked by the music: joy, love/tenderness, longing, sadness, reverence/spirituality, action, and memory/thoughtfulness. Waterman (1996) and Sloboda (1999), although not directly referring to peak experiences, used other, partly similar methods for obtaining listeners' continuous and immediate indication of emotionally loaded moments in the music, thereby also increasing the possibilities of relating them to properties of the music in question.

The advantages of experimental procedures are the control of musical stimuli and the immediate, continuous response by the subjects. On the other hand, the situation is by necessity more or less artificial, and a 'button response' does not not tell much about the contents of the experience unless it is supplemented by other information, as is somewhat examplified in these reports. For continued research of strong experiences of music, whatever they are called, a flexible interplay between naturalistic and experimental approaches seems appropriate in order to combine their respective advantages and compensate for their respective drawbacks.

That music is one of the most effective triggers of strong emotional experiences is amply confirmed by several studies referred to in this chapter. 'The power of music' is a cliché that has considerable validity. It remains a fascinating challenge, although frustrating at times, to investigate how, why, and in what contexts we can be so strongly affected by music.[1]

POSTLUDE

CHAPTER 20

MUSIC AND EMOTION: COMMENTARY

JOHN A. SLOBODA AND PATRIK N. JUSLIN

The chapters collected here have highlighted a range of dichotomies (or bi-polar dimensions) which 'open windows' to a wider view than that with which most of us will have started our consideration of emotion in music. For many of us who would be naturally drawn to this book, and the enterprise it represents, the assumptions we make about emotion are probably a result of our by now effortless (and hence often unreflexive) accommodations to the specific musical culture which we inhabit. These assumptions often embody one pole of a particular dichotomy. Progress in understanding musical emotions may require the distancing from our own perspective that an articulation of such dichotomies can provide. This postlude highlights five core 'dichotomies' (from a considerably larger potential set), calls for attempts to reach beyond these dichotomies, and concludes with some general evaluative comments about the field as a whole, based on the evidence provided in this book.

20.1 Emotion as reception versus emotion as construction

A theme running through many of the chapters concerns the role of the person experiencing the emotion in the causal process. At one extreme is the case where the emotion is 'induced' in someone by the 'force' of the music, in much the same way as the appearance of a snake might induce fear in someone, pretty much independently of whether or not the person concerned had it in mind to feel fear. This case motivates the concern of many contributors to this volume with fundamental emotional processes (see, especially, the chapters by Peretz, Juslin, and Scherer & Zentner). At the other extreme is the case where the person appropriates the music in order to generate an emotional experience, using the music as a resource in a more active process of emotional construction. In such a case, there would be no emotion had the person not decided that there should be. Such a case is driving the arguments of contributors such as DeNora, Cook and Dibben, and Sloboda and O'Neill.

Some of the historical confusions and perplexities engendered by the phenomenon of music's emotionality may have been contributed to by an overemphasis on the 'receptive' rather than 'constructive' pole of the dichotomy within explanatory discourses. The receptive approach has sat comfortably with the apparent role of the listener in both the concert hall and the psychological laboratory. In these settings, the superficial appearance is one of passivity. We sit still and silent, and music is 'presented'

to us by powerful others whose purpose is to influence our thoughts and feelings (and, in the case of the laboratory, record them).

Several chapters in this book suggest that the 'active' view of emotional engagement is revolutionizing many of the intellectual approaches to the music. From the 'new musicology' through 'social constructionism' in psychology to the 'interpretive' approach in sociology, a new appreciation is being elaborated. This places the person experiencing music as the crucial agent at the junction of a network of forces and influences—an agent who *makes* emotion happen by his or her 'musicking', to use Small's (1998) deeply appropriate neologism. In one sense, the still silent member of a classical audience is no less active than the performer on the stage. It is simply that the form, vectors, and boundaries of that activity are different.

20.2 Emotion as biology versus emotion as culture

A second dichotomy, which is strongly related to the first (in practice if not by necessity), is that between a biological and a cultural approach to musical emotion. On the one side of this dimension, we find the biological perspective on musical emotion, evident in the chapters by Peretz and, to a lesser extent, Juslin, and Scherer and Zentner. This approach recognizes that emotions have a biological basis and reflect the workings of neurological and neurochemical mechanisms developed by natural selection. Emotions have a long evolutionary history, and their neural substrates show 'homologies' with those of non-human primates. The biological perspective takes advantage of the fact that natural selection is the only force in nature that can build functional organization into organisms. Indeed, natural selection is a casual process in which a structure spreads precisely because of its functional consequences, that is, function determines structure (Cosmides & Tooby 2000). The flagship of this perspective on emotion is the 'affect program' approach represented by Paul Ekman, among others. According to this view, each emotion should be defined functionally in terms of how it is adaptive in managing a particular problem scenario that has occurred frequently during evolution.

A biological perspective on music and emotion recognizes that neuropsychological and evolutionary considerations are crucial also for the case of music. Expression, perception, and induction of emotion via acoustic signals did not begin when human beings invented the first musical instrument. Humans have always communicated emotions via the voice, and many animals communicate emotions via acoustic signals as well. Thus, as Juslin notes, it seems plausible that some aspects, at least, of how music intersects with emotion are constrained by psychological mechanisms for acoustic communication that have been 'shaped' by evolution. A biological approach assumes that music recruits essentially the same emotional circuits as other emotion-inducing events, and that we, therefore, can learn a lot about musical emotions by understanding the functional design of emotions in general. Moreover, as Peretz observes, neuropsychological studies may help to resolve some controversies and conceptual problems with regard to the nature of musical emotions.

On the other side of the biology–culture dichotomy, we find a sociocultural approach to musical emotions, represented in this book by the chapters by Becker and DeNora, and also to some degree by Sloboda and O'Neill. Although a greater understanding of

emotions in wider non-musical settings is clearly important to the progress of the musical enterprise, we have to remember that music is first and foremost a cultural artefact, and so unlike many of the other things and events to which we may experience emotions. Fearful responses to evolutionarily 'time-honoured' threatening situations (such as snakes) are, in some sense, non-optional. Our genes have designed it so that we have 'quick and dirty' responses to certain situations that impinge directly on our survival (LeDoux 1996). The behaviour of other human beings, and the things they say within practical discourse, can often point directly to these 'basic' event types, and so take on their power and immediacy.

However, cultural artefacts often require a great deal more 'mental scaffolding' to hold them in place. Although this scaffolding quickly becomes second nature within a particular 'habitus' (in the sense outlined by Becker in this book), it can take on different forms, even in superficially similar situations. If even one unnoticed element in the scaffolding is absent in a particular musical event, then the emotion achieved can be quite different, for reasons which may be obscure to the participants. Thus, for instance, the well-known phenomenon among classical performers of the unpredictability of the performance that 'really comes alive', or the perplexity of the adult listener returning to a favourite piece of music and finding that it does not exert the usual emotional power. In both of these cases, it may be a mistake to look for the difference inside the auditory musical object itself, but rather in the way that the participant is construing or appropriating the musical event.

It is important to note that mainstream psychological research on musical emotion has occupied a middle position in regard to this biology–culture dimension. In other words, most psychological studies have taken neither the biological foundation of emotions, nor the wider social context of emotions, into consideration. Thus it seems important that psychologists are willing to broaden their perspectives on musical emotion, keeping themselves informed about the latest developments in neighbouring fields like neuropsychology and sociology. This very book may represent one small step in that direction.

20.3 Emotion perception versus emotion induction

One further dichotomy involves the notion (known from ancient Greece) that music may both 'represent' emotions (that are perceived by the listener) and 'induce' emotions (that are felt by the listener). Such a distinction between emotion perception and emotion induction is made in many, if not all, of the chapters in this book. Some (for example, those by Gabrielsson & Lindström and Juslin) focus mainly on perception of emotion. Others (for example, those by Simonton, Meyer, Scherer & Zentner, Sloboda & O'Neill, and Gabrielsson) focus mainly on emotion induction.

It is pointed out by some authors that it is difficult sometimes to separate these different processes in empirical studies. Moreover, the interaction between perception and induction is still little investigated. Research summarized by Scherer and Zentner, however, indicates that it is important to take the distinction into consideration when designing research (this has not always been done in earlier research). Becker reviews some evidence which suggests that the perception–induction distinction may not be

unique to the Western world, but also appears in other cultures. There is also some evidence that the distinction has neurophysiological reality, because both expression and perception of emotion seem to be associated with processing in the right hemisphere of the brain, whereas induced emotion seems to be lateralized according to emotional valence—positive emotions processed in the left hemisphere, and negative emotions in the right hemisphere (Blonder 1999). It is possible that brain-imaging techniques, such as PET, fMRI, and ERPs (reviewed by Peretz, this volume), in combination with other measures, might help us to empirically separate felt emotions from perceived emotions in future research. It seems likely that different theories may be required to explain these different processes.

20.4 Emotion as private experience versus emotion as public expression

At the heart of some of our dilemmas in understanding how emotion in music 'works' is the common Western view that emotion is primarily a private experience. This view has made it deeply problematical for researchers to confidently identify when an emotion is taking place (cf. previous section). We seem to be required to 'infer' emotion from a variety of unreliable and incomplete cues, such as verbal and physiological data. We are not even sure to what the supposed emotion is a reaction. Within a complex and rapidly changing musical structure, our emotional response may be slightly delayed from the crucial precipitating event, or may be an integrative response to a cumulative series of transitions across time (as discussed in different contexts by Meyer, Scherer & Zentner, and Schubert, among others).

Such problems are unravelled, at least in part, when one considers traditions in which the emotional outcome can be rather more directly read from the emotional behaviour of the participants, or from agreed conventional signals of such outcomes within the musical act. Becker, perhaps, provides the most radical challenge to our common conceptions of emotion by showing how these link to conceptions of the self, which are by no means universal. In some cultures, emotional displays associated with music are the means by which social relations are codified, expressed, and given 'power'. They express an accepted social reality, and the issue of whether a particular individual really feels the emotion expressed becomes secondary. Cook and Dibben remind us that the 'individualistic' approach to emotions in music has had a fairly short history, even within the Western tonal tradition.

Having articulated an important dimension, much work is now needed to locate various types of musical 'habitus' along it. Becker's example of the Pentecostal service is particularly interesting, since the surface discourse suggests a private perspective (the goal of achieving a state of individual ecstasy), yet there would be no 'point' to the occasion if individuals who achieved this state did not display their state through relatively ritualized behaviours which tell other participants 'I've made it'. And, of course, the willingness to indulge in such affect displays creates a kind of self-fulfilling prophecy, through the mechanism that Scherer and Zentner describe as 'peripheral route production'. The mere actions involved in building up to and displaying ecstasy will, along with the 'emotional contagion' of other people providing the same affect display, in themselves help to bring about the desired inner state. Becker also emphasizes the impor-

tance of being in a properly receptive frame of mind. Critical responses will 'block' the emotional path to ecstasy. Thus the music will not 'work' for someone unless they have already decided to allow it. Those of us who find it goes against the grain to enter into such activities are only too painfully aware of the complex web of socially engendered beliefs, interpersonal obligations, and dispositions that underpin the Pentecostal 'habitus' (because they are so alien to us). Similar belief systems are, however, there in every 'habitus'. The Pentecostal example highlights the often intricate relationship between private experience and public expression of emotion in relation to musical events.

20.5 Emotion as separate from the musical experience versus emotion as constitutive of the musical experience

Many of the chapters in this book express a general perplexity that it has taken so long for emotion to gain even a modest foothold in the arena of academic discourse about music (from whatever disciplinary perspective). Although methodological difficulties have slowed the progress in some disciplines, notably psychology, this cannot be the whole story. The psychology of emotion in general is far more advanced than the psychology of emotion as applied to music. It is more plausible to attribute the delay in progress to two factors.

First, there is the problem of tying down musical emotion to some 'formal object'. The formal object of an emotion, according to Solomon (2000, p. 11), can be described as 'the minimum essential set of 'beliefs' defining an emotion and an emotional experience'. Emotions have intentionality: they are always 'about' something (e.g. an event, person, or state of affairs). This notion is problematic in the case of music. It is difficult to say what musical emotions are 'about'. (Besides the obvious: that they are, in some way, about the music.) As recognized by philosophers, an emotion can also be about some non-existing, merely imagined object (e.g. a 'virtual persona' in the music). An important task for the study of musical emotion (as noted by Davies) is thus to understand how music can come to express and induce emotions despite an apparent lack of 'beliefs' that usually underlie such a response. Many chapters in this book propose possible theoretical solutions to this crucial problem, for instance in terms of 'musical expectancy' (Meyer), 'emotional contagion via independent brain modules' (Juslin), 'melodic originality' (Simonton), 'emotional memories', 'proprioceptive feedback', and 'conditioning' (Scherer & Zentner).

Second, delayed progress in understanding musical emotions partly reflects the cultural assumptions about music that have been shared by those people most well-equipped to move the field decisively forward. At the centre of these assumptions for the last 150 years or more has been the belief that music is epitomized by the canon of masterworks produced by a small circle of 'great' composers. Such works are expressions of things that the composer has grasped (which may include emotions), and the job of the listener is thus to 'learn'. What the listener 'feels' is largely irrelevant to this serious task. This task is traditionally accomplished through a grasp of formal structural descriptions of the work; that is, analysis. This activity can be undertaken at elementary level through the digestion of programme notes and other forms of commentary

designed for a wider public, in what has sometimes been called the 'music appreciation movement', or at an advanced level through participation in formal analytical activities.

Since dominant conceptions of music are almost entirely determined by what dominant groups *do* with music, it is inevitable that the belief should have developed that emotion is not core to music. Such a stance has contributed enormously to the disengagement of the general population from entire genres of music. Even among intellectuals in other spheres, the claim that 'I like classical music but don't understand it' is tragically common. Such people engage deeply and thoughtfully with music, are often excellently provocative concert companions, but since they lack a set of vocabularies and techniques which would allow them to coherently address structure independently of emotion they feel 'excluded' from the musical world. In effect, many people feel they are being told 'the thing that strikes you most immediately and powerfully about the music you hear, the thing which keeps you engaged with it and wanting to hear more of it, is really totally irrelevant to a proper appreciation and understanding of it'.

Fortunately, the winds of change are blowing at great speed through the musicological communities. In 20 years, many of the core assumptions of the field have been turned on their head, in favour of emotion (and much else that has traditionally been excluded). Some of the historical and social parameters of this are outlined in this book by Cook and Dibben. However, seeds of change were planted much earlier than 20 years ago, and, in the present context, there can be few more fertile seed-planters than Leonard Meyer. Meyer's (1956) persuasive arguments that structural engagement *requires* emotional engagement have provided music psychologists, philosophers, and musicologists with a firm launch pad to escape the gravitational inertia of traditional historical musicology. (His theory provides one fruitful solution to the problem of the formal object of musical emotions.) Yet, paradoxically, Meyer's theory initially had the opposite effect. Meyer, and later Lerdahl and Jackendoff (1983), implied that understanding musical emotion is best achieved through an understanding of musical structure. As noted by Cook and Dibben, this position could be taken to justify the almost indefinite postponement of consideration of expressive qualities in musicological practice, and a resultant separation between structural analysis and expressive interpretation.

This separation is, in many ways, still with us. The contributions of Persson, Bunt and Pavlicevic, Juslin, and Steptoe show, in their different ways, that a fully articulated discourse (and associated practice) of 'emotional development and management' within the musical profession is a long way off. The core aspects of the training of musicians have remained unchanged for 50 years, largely because those who are most important to the delivery of that training (that is, senior professional performing musicians) received their own training long before any of the ideas summarized in this book were in circulation. These ideas are slow to reach them, and those they teach, because there are few contexts in which the necessary dialogues can take place. However, there are huge changes that economic and cultural factors are forcing on training institutes for performing musicians. These changes provide a unique opportunity for rethinking both what is taught and who gets taught it. In this process, it surely must be inevitable that the world of 'academic and classical' music has to effect a far more thoroughgoing *rapprochement* with popular music, its audiences, and the industries it supports, than anything hitherto achieved.

20.6 Sources and components of emotion and different levels of analysis

In the foregoing, we have outlined five dichotomies that characterize this book. In doing so, we do not wish to imply that these dichotomies are valuable as such. Rather we feel that it is important to move beyond these dichotomies, and try to reconcile the different perspectives. Admittedly, this is far easier said than done. None the less, we believe it is important that we attempt to find a common ground upon which different approaches can meet. A case in point is provided by the biology–culture dichotomy discussed earlier. Biology and culture are both crucial aspects of phenotypic development, and it is therefore time to start exploring ways in which neurobiological factors *interact* with environmental inputs to produce phenomena like musical emotions. (How do sociocultural factors, such as learning and language, impact upon the neuronal patterning associated with musical emotions? Do neurological aspects constrain what is learned?) But how can different approaches to music and emotion be integrated? We believe that one key to understanding how the different approaches fit together is to be found in some of the theoretical distinctions introduced in various chapters of this book.

Sloboda and Juslin discuss two primary sources of emotion in music: *intrinsic* and *extrinsic* sources. Intrinsic sources are those that are non-arbitrarily embedded in structural characteristics of the music and that contribute to the creation, maintenance, confirmation, or disruption of schematic expectations (along the lines sketched by Meyer). Extrinsic sources include both *iconic* sources, which come about through some formal resemblance between a musical structure and some event carrying emotional tone, and *associative* sources which are premised on arbitrary and contingent relationships between the music being experienced and a range of non-musical factors, which also carry emotional messages of their own. We believe that failure to specify which source(s) of emotion one is investigating can lead to unwarranted controversies with those who investigate another source; what counts for one particular source may not count for another.

Second, it has been suggested in psychology that emotions can be broken down into various subcomponents, such as eliciting events, appraisal, subjective feeling, physiology, expressive behaviour, action tendencies, and emotion regulation (Mesquita & Fridja 1992). Such a componential approach drives Scherer and Zentner's review concerning emotional reactions to music. Different authors in this book tend to focus on different components. For instance, Gabrielsson focuses on subjective feeling, Peretz on physiological measures, Cohen on appraisal, Juslin on expressive behaviour, and Sloboda and O'Neill on emotion regulation. Again, what counts for one particular component does not necessarily hold for another component. One final distinction (already mentioned here) is that between emotion perception and emotion induction. It is likely that theoretical accounts of musical emotions will differ depending on which of these two processes a researcher is focusing on.

In addition to these different sources of emotion and subcomponents of emotion, it is clear that different authors operate at different levels of analysis, ranging from the biological and the psychological to the social and the cultural. Several commentators have pointed out that, unlike the natural sciences, the social and behavioural sciences

lack vertical integration; that is, they are not mutually consistent. However, an increasing awareness of research carried out at different levels of analysis should help to yield such consistency. An important goal for researchers of music could be that the theoretical accounts that they propose at one particular level of analysis should not be inconsistent with the accounts obtained at another level.

Given these distinctions, any research endeavour may focus on a specific combination of features. By being as clear as possible about the particular source(s) of emotion involved, the emotion components studied, the level(s) of analysis applied, and whether perception or induction (or both) is being studied, researchers may be able to integrate their approach with the work carried out by others. While it seems perfectly legitimate to conduct research on one particular level of analysis (or one component of emotion), and to bracket another domain of analysis, researchers should recognize that they are doing so, and acknowledge the legitimacy of other analytical levels.

In some cases, the apparent contradictions of different disciplinary approaches may be reconciled by observing that they focus on different sources of emotion, different components of emotion, or different processes (perception vs. induction). It is further possible that certain approaches may be more relevant for particular combinations of sources, components, and processes than others. A few examples may suffice to illustrate this point: An understanding of *intrinsic* sources of *induced* emotion requires structural analysis of the music and a model of the *appraisal* component involved. For this particular focus, a musicological–psychological level of analysis may be especially suitable. On the other hand, if we want to understand how *iconic* sources of *perceived* emotion are produced via reference to some non-verbal *expressive behaviour* component, a biological–evolutionary level of analysis may be highly fruitful. And, finally, if we want to understand how people talk about musical emotions, and interpret them within the social web of everyday life; how they use music to regulate their own emotions and influence their own self-identities, the *emotion regulation* component, a social constructionist approach, may be most suitable. (Of course, this does not preclude that other levels of analysis may have important contributions in each example.)

20.7 Is the field of music and emotion in good shape?

On the basis of the chapters collected here, and the work they refer to, there are grounds for considerable optimism. This is not a collection that largely rehashes old work, nor it is a collection of pious platitudes and promissory notes on work not yet undertaken. The vast majority of chapters refer to substantial research programmes yielding new data and new conceptualizations, the great majority of which have been undertaken and published in the last 10 years. A second source of optimism is the high level of theoretical and methodological incisiveness displayed within the research reported.

Emotion work is attracting the attention of some of the best-trained and most rigorous senior exponents of the various disciplines. Younger researchers are, as a result, gaining the confidence to develop focused programmes that branch outwards from PhD projects and find their ways into the most prestigious publication outlets. At least in some parts of the world, and in some disciplines, we have the conditions for what Kuhn (1962) described as 'normal science'. A third source of optimism is to be found in

the willingness of researchers from different disciplines to contribute to a book such as this (we do not know of many such resolutely multidisciplinary enterprises).

As psychologists we are particularly pleased that psychology appears to be playing such a central role in the resurgence of emotion studies in music. Psychology may be particularly well suited to such a role at the current time, because of the breadth of its scope (from the neurophysiological to the social), its methodologies (which are rigorous but at the same time also sufficiently 'neutral' to create a meeting place for researchers from different intellectual and ideological traditions), and its well-established record in advancing the understanding of a range of musical phenomena.

On the other hand, optimism should not lead to complacency. Several authors point to deficiencies, some rather major, in what has been achieved, and point out quite significant barriers to further achievement. Deficiencies include a lack of common understandings and definitions of key terms, a piecemeal approach to data gathering, and a narrowness in the domains studied. This narrowness applies to musical traditions (most work is on Western classical music), ages (there is very little work with children and older people), and contexts (a limited range of cross-cultural and subcultural contexts have been addressed). Barriers to further progress include the enormous difficulty of measuring emotions, particularly using multiple measures over extended events, such as pieces of music whose emotional expression may be constantly changing. The recent developments of increasingly non-intrusive methods of measuring brain activity may offer one important way forward.

Another barrier to progress is the relatively independent way in which research in the various disciplines develops. This may be an inevitable consequence of the structuring of the academic world. Researchers can only make substantial contributions if there is relatively secure employment. Employment is only available to those who have important things to contribute to their own discipline, as judged by opinion formers within that discipline. It matters far more to a young musicologist what other musicologists think of his or her research than what a psychologist might think. We have noticed several points within the collection of chapters here where links could have been made to work going on in another discipline but were not. More fundamentally, each discipline has its own trajectory, and issues which seem of great importance to psychologists might seem irrelevant to musicians. Therefore, what constitutes progress in this area may be a matter on which the representatives of the different disciplines will be unable to agree. Several authors end their chapters with a set of suggestions for further research. From outside the specific discipline one can certainly see that the research programmes suggested are possible, rational, and defensible. But are they necessary, or even important? Who would decide? Could the different disciplines ever agree, and would the practising musician or the untrained listener agree with them?

This is an issue that is not specific to music and emotion studies. It is a constant preoccupation of many people involved in the musical sciences. To put the question at its most blunt—does what we do help better music to be made, or for people to obtain more benefits from engagement with music? The answer is not clear. Music scientists sometimes look with envy on medical researchers. Everyone agrees that finding cures for major diseases such as cancer is worthwhile. As a result, governments and industry employ hundreds of thousands of people to research possible solutions.

Interdisciplinary teams are created. Researchers know what the goal is and can assess their success against the goal. What is the goal of music emotion research? There are probably as many answers as there are researchers. However, this book shows that researchers have common and overlapping concerns. Could these concerns ever coalesce into common agreed research agendas, which would direct the shape of the field for the next 10 years? Should they so coalesce? Would any major external body be concerned enough about these questions to provide major long-term funding? We feel that the answers to these questions are not obvious from the contents of the book. However, we hope that the book's existence may stimulate the debates that will lead to clearer answers to these questions, and that a future book on this topic might report progress in a rather more self-conscious and self-confident manner.

SUBJECT INDEX

abstract form, of classical music 205–6
abstraction, of emotional experience 343
accuracy, of emotion communication in performance 313–14, 326
achievement motivation, of performer 277
action tendencies
  effect of music 377–8
  invoked by emotion 87–9
active music therapy 182–3, 186–7
activity dimension 226, 228, 257, 315–16, 402
  and circumplex model 77–8
  physiological effects and 376
adaptive function
  of emotional reactions 82, 88
  of maternal singing 114
  of music 115
adolescents, music and 424
advertisements, classical music in 257
aesthetic emotion 81–2
aesthetic motivation, of performer 278
'aesthetic reflexivity' 168
aesthetics
  automatic evaluation of 368
  and belief 352–3
  of film 258
  formulation of 47, 48
  and melodic originality 211–15
affect, *see* feeling
age effects 422
agency, emotional, and music 174–6

That music has an incredible power to move us emotionally is without question. Whether performing music, listening to music, or creating music, this bond with our emotions is always there. The nature of this relationship is clearly complex however, and emotional aspects of music have received surprisingly little attention in the 45 years since the publication of Leonard Meyer's classic work 'Emotion and meaning in music.' During that time, both 'music psychology' and 'emotion' have developed as vibrant areas of research, and the time is fitting therefore to try and bring together this multidisciplinary interest and take stock of what we now know about this powerful relationship.

A new volume in the *Series in Affective Science*, *Music and emotion: theory and research* brings together leading researchers interested in both these topics to present the first integrative review of this subject. The first section reflects the various interdisciplinary perspectives, taking on board views from philosophy, psychology, musicology, biology, anthropology, and sociology. The second section addresses the role of our emotions in the composition of music, the ways that emotions can be communicated via musical structures, the use of music to express emotions within the cinema. The third section looks at the emotions of the performer - how do they communicate emotion, how does their emotional state affect their own performance. The final section looks at the ways in which our emotions are guided and influenced while listening to music, whether actively or passively.

A state of the art account of the subject, *Music and emotion* is a book long overdue, one that will fascinate psychologists, musicologists, music educators, and philosophers.

Preface

JOHN SLOBODA

This book was conceived to remedy an imbalance in the Psychology of Music literature. The vast majority of serious psychological research has been devoted to an analysis and understanding of the processes involved in listening to music. This is reflected in the existence of a major journal with the title *Music Perception*. There could not be a journal entitled *Music Performance*, because there just would not be enough research to fill it.

The reasons for the relative neglect of generative processes (including performance, improvisation, and composition) are various. I wish to comment briefly on three of these: cultural bias, measurement problems, and problems of control. I shall then turn to some general comments about the contributions to this volume.

Through a long social and historical process contemporary Western art culture has become characterized by functional specialism. In the case of music, as with most other art forms, a gulf has emerged between producer and consumer. Adult producers are typically few in number, often institutionally trained. Adult consumers are typically large in number, usually untrained, and often unskilled in most forms of music production. With the advent of sound recording and other forms of mechanical transmission it has become possible for the various functions to be completely separated in both time and space. Consider, for instance, a Beethoven symphony. A group of performers construct their interpretation in necessary isolation from the composer, and also from the audience for whom the performance is intended (for example in a recording studio). A member of the audience may then 'receive' the interpretation in social isolation from both composer and performer as a disembodied aural experience. This is particularly true of the domestic listener who may, through use of headphones and darkened room, create the impression of being totally and exclusively enfolded by sound. Even at the concert there are usually strong social and geographical factors which separate listeners from performers. Performers and listeners go in and out by separate doors; they do not interact with one another. Any form of audience interruption is usually violently resisted. Such constraints tend to reinforce an 'illusion' which projects the sound of the music away from the realities of its origins

in human work, both physical and mental. As in the puppet theatre, the modes of production become veiled in mystery, and we may have no particular wish to venture behind the proscenium arch.

In such a culture it is, perhaps, inevitable that the listener's response to music should become the primary focus of the psychology of music. This focus would, however, be less than fully comprehensible in cultures (maybe the majority of the world's musical cultures so far) where functional specialism had not gone so far. In many cultures it would be strange to hear music without joining in in one way or another. The separation between performer and composer is also necessarily less clear. Especially when the music is without notation, the originator of the music must necessarily perform it to communicate it. Also, composition/improvisation is often a social process, with several individuals in a group contributing substantially to the form of the music.

One of the recurrent themes of the contributions to this book is inextricable connection of generative and receptive processes. Their separation can only ever be partial. The reality is that all music must reflect the psychological propensities and capacities of humans as composers, performers, and listeners. To an extent, each type of involvement with music includes the others. Composers temper their compositional processes against their own aural judgements (see Lerdahl, Chapter 10) and their understanding of the performance characteristics of various instruments. Performers refine their performances against both their own aural awareness and their ability to image alternatives (see Pressing, Chapter 7). Listeners grasp a work of music by attempting to sing or hum parts of it, or by engaging in some form of rhythmic movement. They may also 'compose' variants or elaborations of the music in informal (but not necessarily overt) behaviour. Sagi and Vitanyi (Chapter 8) go so far as to propose that the ability to receive music is constrained by the extent to which people are capable of generating variants within a particular genre. In a similar vein, Dowling (Chapter 6) shows that young children's ability to discriminate tonal from atonal melodies is dependent on the level of singing ability that they have achieved.

We may suppose, in fact, that the impulse to generate and perform music is as inherent a part of the human constitution as is the impulse to generate language. The research reviewed by Dowling (Chapter 6) shows that very young children produce spontaneous songs which incorporate but by no means mimic elements of adult productions. Just as in language development, song development seems to go through a set of ordered, rule-governed stages. It may be that the failure of early generativity to flower into full-scale compositional ability is a result of both the ubiquitous concern of the 8–11 year old with 'correctness' and also traditional educational styles which undervalue experimentation and self-discovery. Where opportunities are given for self-directed musical productivity (for

example Swanwick and Tillman 1986), children demonstrate an impressively varied yet ordered progression of compositional strategies right through the school ages. Davidson and Scripp (Chapter 9) support this picture by an intriguing study of children's spontaneous notations for music.

A second reason for the neglect of generative processes relates to problems of measurement in psychological science. It is always easier to collect one's data in the form of responses from a limited and pre-ordained set (for example yes–no decision, same–different decisions) than it is from relatively unconstrained and multidimensional behaviour. This concern for precision and simplicity in measurement has led to a concentration within the psychological community on rather simple laboratory tasks. Claxton (1980, p. 13) paints a humorous but not altogether inapposite picture of the typical study in cognitive psychology:

> cognitive psychology does not, after all, deal with whole people, but with a very special and bizarre—almost Frankenstinian—preparation, with consists of a brain attached to two eyes, two ears, and two index fingers. The preparation is only to be found inside small, gloomy cubicles, outside which red lights burn to warn ordinary people away. It stares fixedly at a small screen, and its fingers rest lightly and expectantly on two small squares of black plastic—microswitches. It does not feel hungry or tired or inquisitive; it does not think extraneous thoughts or try to understand what is going on. It simply processes information.

In terms of music psychology, this 'Frankenstinian' orientation has led to many studies in which subjects hear short computer-generated fragments through headphones and then are required to make some (usually binary) judgement about them, whose accuracy and reaction time may be measured relatively simply. The advantages and limitations of this approach are well known and discussed (for example Sloboda 1985; Longuet-Higgins 1987) and need not be rehearsed again here. Suffice to say that every single empirical contribution to this volume has, at one stage or another, adopted a different approach to measurement. In general, subjects have been allowed to produce responses of some complexity and length, free from excessive experimental constraints. This approach is essential is one is to make any meaningful contribution to the psychology of performance or composition.

The problems of recording and analysing these responses have been approached in a number of ways. Some researchers rely on auditory transcription into conventional (or amended) notation, and then perform formal or informal anayses on the transcripts (for example Gruson, Chapter 5; Dowling, Chapter 6; Sagi and Vitanyi, Chapter 8; Davidson and Welsh, Chapter 10). The advantages and disadvantages of the transcription method have been discussed at length by Sloboda and Parker (1985). Whilst transcription produces a record which is easily understandable by literate musicians, it runs the risk of making the performance seem more coherent than it actually was (by the transcriber's 'intelligent'

cleaning up of inherently messy data). It is also necessarily selective, and cannot reliably record information about expressive parameters of the performance. There also remains the problem of how to turn such transcriptions into quantitative form, for the application of statistical techniques. The contributors to this volume solve this problem in a number of ways, ranging from highly elaborate coding schemes (Gruson, Chapter 5) to informal stylistic analyses (Sagi and Vitanyi, Chapter 8).

Other researchers have used mechanical and electronic means of recording performance parameters in a precise quantitative fashion (for example Clarke, Chapter 1; Gabrielsson, Chapter 2; Sundberg, Chapter 3; Rasch, Chapter 4). This allows for more sophisticated statistical analysis, the testing of precise models with quantiative predictions, and the capturing of highly important expressive dimensions of performance. The disadvantages of this method arise largely from the data overload that is generated, and from the fact that it is much more difficult (although not impossible) to apply informed musical intelligence to the interpretation of data. The ubiquity of the computer has made the first problem more manageable and has, one suspects, been largely responsible for the modest upturn in the quantity of this work in the last ten years.

A third set of researchers have used tasks which require subjects to write down the end-products of their cognition in notation, traditional (Davidson and Welsh, Chapter 10) or otherwise (Davidson and Scripp, Chapter 8). This is a particularly useful method of studying composition, especially when coupled with verbal protocols. The disadvantage of the method is that schemes of quantitative measurement are hard to devise, and are usually descriptive in nature. They are, however, particularly rich sources of ideas and insights.

The third reason for the neglect of generative processes is linked to the second, and relates to the difficulties of devising suitable experimental controls over generative behaviour. Without some form of control over the conditions under which subjects exercise their generativity it becomes very difficult (but not entirely impossible) to extract any generalities about the processes involved; and without generality there is no science. The range of controls deployed in this volume varies from the very broad (in the case of improvisation and composition) to the very tight (in the case of some performance studies, where note, speed, and fingerings are specified). For instance, Sagi and Vitanyi (Chapter 8) offer the minimum constraint of a text. Subjects of varying abilities and backgrounds are required to improvise any tune they like to that text. Davidson and Welsh (Chapter 10) adopt a similar but rather more constrained tactic. They offer their subjects a rhythm, and ask them to assign pitches to the rhythms so as to produce a melody which must modulate in a certain way. Again, subjects of varying levels of ability are tested. Gruson (Chapter 5), in her study of piano

practising, simply specifies the piece to be practised, and leaves everything else up to the subjects.

Clarke (Chapter 1) is at the other extreme in his studies of expressive performance. He studies piano performance so as to control (by exclusion) the possibility of subjects using pitch and timbral variations, and then devises melodies with special qualities to test very specific hypotheses (such as that sliding the bar line along a single melodic fragment will affect expressive performance of it in systematic ways). Subjects are required to produce accurate performances of these melodies. Control is also obtained in another way by several authors. Instead of gathering data by looking at many different subjects, they obtain relatively large amounts of data from one or few subjects, looking for generalities *within* the behaviour of individual subjects (for example Clarke, Chapter 1; Gabrielsson, Chapter 2; Rasch, Chapter 4). It may be more important to show that the behaviour of an individual is systematic and rule governed, than to show that many individuals are systematic in precisely the same way. Indeed, in the study of artistic behaviour one may argue that one would neither expect, nor wish for, high degrees of uniformity between subjects.

The final part of this preface is concerned to make some general points about the contributions to the volume, and to highlight some specific aspects of individual contributions.

The first thing to say is that most of these contributions report pioneering work. There is no long tradition of research into most aspects of music generation. Thus, to my knowledge, Gruson (Chapter 5) is the first person ever to have subjected rehearsal behaviour to systematic quantitative analysis. Davidson and Welsh (Chapter 10) are the first to apply systematic analysis to a compositional task undertaken by groups chosen to represent differing ability levels. Sagi and Vitanyi (Chapter 8) have created the first large-scale corpus of improvisations by untrained people. With the pioneering comes an element of risk. It is not clear which of these approaches and ideas have a future. Some of the work is necessarily exploratory, and without the substantial backing of related research. It is not clear that all the theorizing contained here will actually be confirmed by data. Lerdahl makes a provocative and highly original claim about what constitutes a viable relationship between methods by which composers compose and how listeners listen. Will composers be able to use Lerdahl's constraints to guide them towards composing structurally rich yet comprehensible pieces? We do not yet know. Can Pressing's impressive theory of improvisation be tested against actual improvisations? The ideas are rich and plausible, but do they have predictive value? Such issues are raised but not resolved here.

The second point about the contributions is that they are truly interdisciplinary in nature. The contributors are roughly equally divided

into those working in psychology departments or other scientific setings, and those working in music or socio-cultural studies. The individaul contributions draw on ideas from linguistics, sociology, neurophysiology, acoustics, artificial intelligence and computer science, as well as psychology and music. This diversity of approach is welcome, particularly when similar ideas recur in contributions from quite different sources. It does mean, however, that several languages and perspectives rub shoulders with one another, and this sometimes makes for tensions. Psychologists may well find the contributions of the musicians unsatisfactory because of their apparent disconnection from the task of data gathering. Experimentalists may well find the rather informal analyses in some of the papers disappointing. On the other hand, musicians may well find the interpretative caution of some psychologists irritating and pedantic. Others may find the cultural narrowness of the types of music discussed less than satisfactory. Neither I nor the contributors should have to apologize for this. As a reflection of the 'state of the art' this volume represents the growth pains of a young discipline, full of ideas and enthusiasm, but not wholly co-ordinated in approach or methodological priorities.

Chapters 1 to 3 form a relatively coherent group of contributions, all focusing in slightly different ways on the question of what makes a musical performance. It is abundantly clear that a mechanical performance reproducing exactly what is contained in the notation rarely makes a satisfactory performance. Clarke (Chapter 1) emphasizes the role of performance in exemplifying structural aspects of the music through expressive gradients, discontinuities, and contrasts. He embeds several ingenious experimental studies within a theoretical framework that emphasizes the importance of hierarchical mental representations as a means of controlling performances. Gabrielsson (Chapter 2) supplements Clarke's study with some naturalistic data on rhythmic performance. This data confirms that performers make systematic and significant deviations from strict metricality, but also that it is hard to make generalizations about the nature of the deviations. The same figure may be played differently in different contexts, or by the same performer on different occasions. Sundberg (Chapter 3) describes some ingenious studies where a computer 'learns' to play expressively by being supplied with a set of rules for modulating timing and loudness in certain musical contexts. These rules are modified by playing the results to a panel of human judges and asking for judgements of appropriateness. Sundberg amplifies the interesting point that 'apt' expressive devices are very often not explicitly identified as such by judges, but simply contribute to a sense of 'rightness' about a performance.

Rasch (Chapter 4) summarizes his painstaking and elegant work on synchronization in ensemble performance. He is one of a tiny number of researchers who have examined any aspect of ensemble playing. He

reports many intriguing results, including the finding that musicians achieve better synchrony at faster speeds than at slower speeds. It also seems that a degree of asynchrony increases the perceptual clarity of individual lines, even though listeners are not consciously aware of quite large degrees of asynchronization in musical performance. Finally, Rasch provides an elegant mathematical justification for the fact that ensemble of more than 10 players tend to need a conductor while smaller groups do not.

Gruson (Chapter 5) reports a pioneering study on rehearsal strategies of musicians at different levels. She finds that people at any given level do not change their strategy much over the course of learning a given piece, but that significant strategy differences do exist between different levels of expertise. For instance, experienced players are more likely to repeat musically coherent sections of the piece. Beginners are much more likely to repeat individual notes. The general drift of her evidence is that experienced rehearsers are more aware of the structure of what they are rehearsing, and that this makes rehearsal more efficient.

Dowling (Chapter 6) explores the strong links between perception and production in the development of musical competence in young children. He reviews the literature on developmental aspects of song production and reports two new empirical studies. The first shows that children as young as three years old can reliably discriminate tonal from atonal melodies so long as their song performance is relatively advanced. The second study explores the structure of nursery songs as opposed to folk-songs and art songs. The analysis shows that nursery rhymes very rarely depart from strict diatonicity, and Dowling argues that such songs are optimal for children extracting and internalizing rules of tonality. This chapter is, in a sense, the pivot of the book, since it reminds us that children's song has elements of reproduction and improvisation inextricably intertwined. The preceding chapters deal exclusively with reproductive performance. Those to follow deal exclusively with the creation of new music through improvisation or composition.

Pressing (Chapter 7) provides a monumental survey of concepts from a number of disciplines that are relevant to an understanding of improvisation, and outlines a theory of improvisation that concentrates on the psychological bases for moment-to-moment choices within an improvisational structure. The theory is associationistic in nature, and proposes that improvisation proceeds by means of choices of elements which either *continue* or *interrupt* some aspect of the immediately preceding context. In its concern with the note-by-note structure of an improvisation it contrasts with the contribution of Sagi and Vitanyi (Chapter 8). Here, the emphasis is on global features of structure and style in the spontaneous improvisations of ordinary Hungarians. A principal finding of the study was that the majority of untrained subjects were able to use *some* coherent strategy to provide a

melody, often based on forms available in their culture, but to some extent affected by the nature of the words they were required to set.

Davidson and Scripp (Chapter 9) present intriguing data from children aged five to seven who were asked to notate various musical fragments without explicit instruction. What is particularly impressive about these data is the coherence of the schemes devised by children. Even at age five, many children devise abstract symbols to represent particularly the rhythmic structure of the music. By age seven, pitch becomes an increasing focus for notational attention. Interestingly, at age five performance skill and notational skill seem largely uncorrelated; but by age seven the two seem to have become 'yoked' together into a unified domain of musical intelligence.

The final two chapters in the book turn to the skill of composition. Lerdahl (Chapter 10) draws some logical yet provocative consequences from his influential work with Jackendoff (Lerdahl and Jackendoff 1983). If a listener understands music by constructing a hierarchical mental representation of it, then effective compositions will abide by constraints which allow listeners to do just that. Lerdahl identifies a number of specific constraints, and shows that serial music falls foul of several of them. This, he argues, is the reason why such music is so impenetrable.

Davidson and Welsh (Chapter 11) adopt a data-driven approach, in contrast to Lerdahl's theory-driven one. They look at the processes by which music students of differing expertise construct a melody given certain conditions that the melody must fulfil. Their analysis yields some tempting pointers as to the nature of compositional expertise. The more expert group worked with larger units (as shown by the size of section they would play over). They also engaged in more reflection, while the less experienced group worked in an enactive fashion (for example trying out possibilities at random until hitting on one that 'worked'). The study also highlights the dissociation of skills at this level. Even very gifted performers can be 'poor' composers without specific practice.

It is customary for the editors of multi-author volumes to draw some general overarching conclusion from the set of studies he or she has gathered together. I am reluctant to do this. My reluctance stems from the fact that the unity of a set of papers is often to be found, not in their outcomes, but in the shared assumptions that motivated them. In the case of this volume, many of the contributors attended an international conference on Psychology and the Arts held in Cardiff in 1983 (Crozier and Chapman 1984). It was primarily as a result of conversations there, and a sense of shared purpose, that the idea for this book was born. To find, therefore, that the contributions point in the same general direction is as little of a surprise as it would be to discover that the occupants of a given aeroplane are all headed for the same destination.

In the case of this volume, I would identify five core assumptions which run explicitly or implicitly through the majority of contributions:

(1) Music generative capacity is inherent in all human beings, although it may be developed to a greater or lesser extent.
(2) The capacity to generate any but the most primitive musical sequences is based on the ability to derive sound sequences from higher-order structures or rule systems.
(3) These rule systems have some universal constraints on them (arising from general facts about human cognitive capacity) but incorporate specific constraints picked up from the prevailing musical culture.
(4) Specific instruction is not necessary for skill acquisition, but practice is. Through practice, and possibly through general developmental changes, similar stages in skill acquisition can be observed in the several generative domains.
(5) Many aspects of skill become partly automated, and not open to conscious introspection. Their nature must therefore be elucidated by observation and analysis of generative behaviour rather than (or in addition to) verbal self-report.

The papers in this volume all attempt to put flesh on the bare bones of one or more of these assumptions through theorizing and/or empirical observation. Their success may be judged by the degree to which the reader is more inclined to assent to these assumptions after reading the book than he or she was before. If the reader wishes for elucidation on different but equally important issues, such as the role of motivation and emotion in sustaining and shaping generative behaviour, or the nature of effective training in these skills, then he or she must search elsewhere. If the search is successful then I would certainly like to know about it.

Generative principles in music performance

ERIC F. CLARKE

Introduction

The aim of this chapter is to give an account of generative principles involved in music performance at two levels. One level concerns the representation of musical structure in a form that gives a coherent and intelligent input into a motor system. The word generative is understood here in the same descriptive and analytic sense as in Chomsky (1957), and in the more recent music theory of Lerdahl and Jackendoff (1983). The second level at which generative principles are identifiable is in the production and control of the expressive aspects of performance, which function so as to convey a particular interpretation of a musical structure. This sense of the word generative is much closer to the idea that something is actually generated, rather than simply being describable in terms of generative principles. These two usages of the term correspond to rather different psychological orientations, and while there are certain circumstances in which the two become closely associated, one purpose of this chapter is to illustrate the distinction between them.

The generative structure of musical knowledge

Playing music is an activity that is comparable in cognitive complexity to speaking a language, and comparable in its demands on motor control to playing a sport like tennis. It has thus been a focus of attention for psychologists interested in issues of motor control (for example Gates and Bradshaw 1974; Shaffer 1981), and for those interested primarily in musical cognition (for example Bengtsson and Gabrielsson 1983; Sloboda 1983). The motor programming perspective adopted in most recent work on motor control has, however, diminished the separation between these two lines of enquiry by emphasizing the importance of cognitive structures in the control of movement. Continuous reference to a large body of musical knowledge is required in music performance if the result is to be

fluent and intelligent, making it difficult to maintain a definite distinction between the cognitive structures of abstract musical understanding and those embodied in a motor programme for musical performance. This discussion of the knowledge structures that form the basis for musical performances therefore starts at a comparatively high level of abstraction by considering first some aspects of music theory.

Although the relationship between music theory and psychology is rather loosely defined, most music theory not only incorporates psychological principles of one sort or another (for example gestalt principles in Meyer 1973), but also takes the explanation of musical experience as one of its primary aims. It is, in other words, a theory of how people hear music, as well as a theory of how music is formally structured.* The structures described by music theory can therefore be taken as reasonable indicators of the nature of cognitive structures for music, particularly since recent work (for example Shepard 1982) has tended to confirm the perceptual significance of these structures.

The most widespread characteristic of musical structure embodied in music theory is its hierarchical nature (see Narmour 1983 for a recent review). In the parameters of both pitch and rhythm, structures are represented almost without exception as being organized in a series of levels, between which relationships of reduction or elaboration operate. Although hierarchical structures should not simply be equated with generative structures, they are nevertheless closely related, and as a number of authors have shown (for example Longuet-Higgins 1976; Sundberg and Lindblom 1976; Lerdahl and Jackendoff 1983) truly generative theories can be shown to have considerable explanatory power.

All of these studies make use of tree diagrams as representations for a generative structure, although it is not a requirement that a generative structure be represented in this way. Since a tree diagram is a useful shorthand that conveys generative relationships, I will make use of it for illustrative purposes in the following discussion. In considering the generative structures of musical knowledge, my aim is to examine their more global characteristics, rather than the precise nature of the generative principles themselves. It is the topology of generative relationships that is of interest, or put another way, the pattern of hierarchical structures that constitutes musical knowledge.

The issue can be tackled only in relation to specific performance conditions. It is inevitable that the knowledge structures that underlie a performance of a piece from memory will be different, at the highest levels at least, from those associated with a free improvisation, or a sight-read performance from notation. Starting at one extreme, performances of

* Note that this is not the case with all music theory. For example many of the structures discussed in Forte (1973) are of a level and type of abstraction that makes it extremely unlikely that they could be perceived in any direct fashion.

classical music from memory appear to offer the most deeply embedded generative structures. Though something of an idealization, we can imagine a performer who, at the start of a performance, has a complete knowledge of the generative structure of the piece, from the very highest level, where the whole piece is represented as a unity, down to the lowest level, where each individual note is represented. Figure 1.1 is a schematic representation of such a knowledge structure. Evidence for the highest level in this structure is rather sparse, and is confined to statements by a number of composers (Mozart, Beethoven, Hindemith) which indicate that they were able to hear (or imagine) their own compositions in a single 'glance'. Since these composers were also performers, the unified conceptions of which they claimed to be capable can be regarded as the basis of performances as well as compositions.

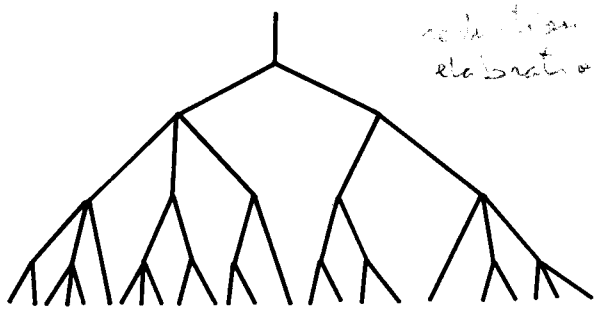

Fig. 1.1. Schematic representation of an idealized knowledge structure for a memorized musical performance.

The evidence for totally unified structural knowledge is a little tenuous, but does not affect the essential point that high-level musical structures acquire unified cognitive representations. It is easier to accept that a performer may have a unified conception of each of three large sections, for instance, that together make up a movement. These units connect with all the individual events of the piece through the multi-levelled branching structure that a tree diagram illustrates. It is difficult to know quite how one might experimentally test the existence of these very high levels of generative structure, but tonal structures of a fairly abstract nature (and hence at a fairly high hierarchical level) such as the concept of key, or tonal area, have been demonstrated to have psychological reality as well as theoretical value (see Krumhansl 1983).

The idea that a performer who has memorized a piece of music has a complete generative representation is an idealization not only because the structural depth of the representation is uncertain, but also because it seems implausible that a complete structural representation of the

complexity required for a piece of even moderate length could be activated. It is more likely that only a part of the entire structure is active at any time, the remainder being in a latent state, or active only in broad outline. At any particular moment the generative structure is incomplete or only partially activated, the active region shifting as the performer progresses through the music, revealing different areas and levels of the structure. For instance, in the middle of a deeply embedded musical phrase, only a region of low-level generative connections might be active, since there is little need for a performer to have access to high-level structural information; his or her main concern is the detailed structure of connections within the phrase itself. At a phrase boundary, however, it may be important for the performer to know how the previous and subsequent phrases are related to one another and to the overall structure of the piece. At these moments a small area of low-level structural connections may be active, sufficient to specify the immediate succession of events to be played, together with a section of the higher levels of generative structure specifying larger-scale relationships. Figures 1.2(a) and 1.2(b) illustrate schematically these two conditions. This suggests that in the course of a performance, a player's structural awareness constantly

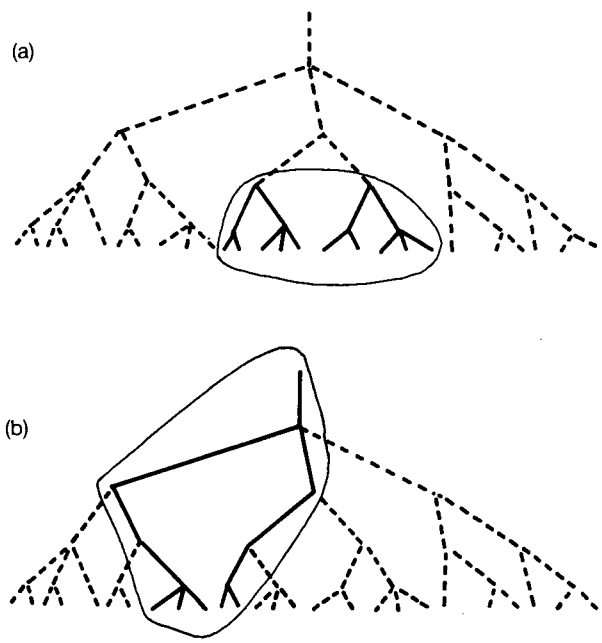

Fig. 1.2. Schematic representations for partially activated knowledge structures in a memorized performance: (a) illustrates active parts of the generative structure (ringed) in mid-phrase; (b) illustrates active parts approaching a phrase boundary.

shifts between regions of activated structure that vary in durational extent and generative depth. As a general rule, the depth to which the generative structure is activated is directly related to the structural significance of phrase boundaries lying close to, or at, the player's current musical location.

The second type of performance whose representational structure I wish to consider is music played from a notated source. Unless the performer already knows the music extremely well, and is simply looking at the notation for reassurance, a variable amount of uncertainty surrounds his or her anticipation of how the music may develop, and the relationship between current and future events. The future course of musical events is not, of course, completely unknown, since listeners and performers continually make projections on the basis of acquired stylistic knowledge (see Meyer 1956; Narmour 1977); but it seldom turns out that the music exactly matches these projections for a number of reasons: (1) performers and listeners may envisage a number of different possible continuations; (2) stylistic knowledge, on which projection is based, is never perfect and complete; (3) it is in the nature of music to depart from stylistic norms in the interest of creativity. Figure 1.3, which represents the knowledge structure of a piece performed from notation midway through the music, indicates these uncertainties with dashed connections and question marks.

The significance of the mismatch between projection and outcome lies in its effect upon the continuous construction of a generative representation during a performance. With memorized performance, the generative structure is known entirely (or at least to a high level) in advance, and is simply unpacked during a performance. Thus misrepresentation of the generative structure on the part of the performer is essentially restricted to memory lapses at various levels. By contrast, in an unmemorized performance it is likely that incorrect projections will result in inappropriate attributions of structual significance, failure to grasp long-term connections,

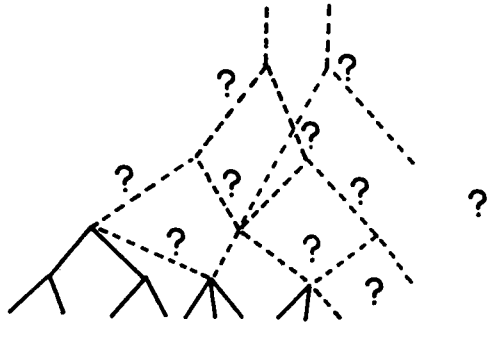

Fig. 1.3. Schematic representation for the knowledge structure of a musical performance from a notated score.

and so on. It is a feature of generative structures that they can be perfectly represented only when all the information has become available. In the course of assembling a representation from the raw data of notation, mistaken assumptions and oversights will inevitably result in a flawed structure that must be continually reassessed and retrospectively modified in the light of new evidence. Such re-evaluations are jeopardized by memory limitations, and may also lead to constructive rationalizations which distort the true structure of the music. In short, a performer playing unfamiliar music from notation is viewed as working from a generative representation that is incomplete in certain respects, almost certainly limited in the depth to which it extends, and subject to continuous modification in response to unfolding musical developments.

As a final example, let us consider the knowledge structures of improvised performance. Improvisation itself varies from the comparatively constrained conditions found in traditional jazz, where a harmonic sequence and metrical structure must be closely adhered to, to the almost entirely undetermined format of free improvisation. Taking the freer end of this spectrum, an improvising performer is necessarily working from a structural representation that is radically incomplete, since s/he does not yet know how the structure will turn out. A performer may start out with a more or less clear idea of the overall shape of the piece, but will typically have only the vaguest idea of how that shape will be realized. Alternatively, s/he may have no preconceived ideas whatsoever concerning the overall outline and may simply start off from a comparatively low-level structure —a motivic germ for a piece.

The questions are therefore how some sort of structure is developed (if it is), and whether that structure is generative in nature. Sudnow (1978, 1979) has provided an account of some of the processes involved in playing improvised jazz on the piano, based on an introspective analysis of his own playing. He takes the view that improvised piano playing should be viewed as the creation of 'an improvisatory hand' (Sudnow 1979, p. 14) and the logic and necessity of its movements, rather than as the outcome of abstract musical thought, with the hands acting simply as executive agents.

In accounting for the way in which these movements are structured, Sudnow questions the extent to which a hierarchical, generative process is involved, particularly at high levels of skill. Three stages of skill acquisition can be identified in Sudnow's account, differing in the extent to which they involve generative structure. At an early stage, his improvisations consist of relatively rigid routines that are executed in an invariant fashion, and which are structured together either according to the dictates of a predetermined framework, or simply by virtue of what comes most easily to the fingers. Such improvisations are therefore hierarchical up to a certain level (the level of the individual routine), and then either

predetermined (and usually hierarchical in the case of jazz 'standards') or regulated by manual dexterity at higher levels. However, the rigidity of the individual units, and the problems of accommodating them to a variety of overall frameworks, cause Sudnow considerable problems in performance, and result in a rather frantic and discontinuous style.

The second stage is to break down the preformed gestures of the first stage into their individual elements so as to recover the flexibility that his performance lacks. This is relatively easy to achieve, but presents a problem which the final stage must overcome: a method of structuring the elements together that achieves coherence without rigidity. Sudnow implies that the strategy he adopts is principally associative, or if hierarchical then only to a very limited extent. His aim is to start an improvisation with few preconceptions as to how it will develop, and to allow the hand to explore new consequences and ramifications of its current activity in an unfolding exploration of the keyboard. The impetus to continue comes not from an overall scheme into which the material must fit, but from a continual monitoring of the events just completed that generates ideas for events just ahead. The style is thus characterized by a precarious, unpredictable, associative structure.

> a single voice at the tips of the fingers, going for each next note in sayings just now and then, just this soft and just this hard, just here and just there, with definitions of aim throughout, taking my fingers to places, so to speak, and being guided, so to speak. (Sudnow 1978, p. 152)

A note of caution, however, must accompany Sudnow's account. It has been demonstrated by many authors that complex motor skills cannot achieve fluency and accuracy if they do not develop the hierarchical structures of motor programmes. Shaffer (1981) cites the example of moving a stylus to a number of targets with and without advance information, the former condition leading to hesitant, slow, and inaccurate performance when compared with the latter. Similarly, in his own work (Shaffer 1976), Shaffer showed that a copy-typist given no text preview (and thus unable to construct a motor programme) was reduced to a low level of speed and fluency when compared with her performance when she was given an eight-character preview. As far as motor control is concerned, typing is very similar to playing music, and it demonstrates that a literal interpretation of Sudnow's claims is untenable. An improviser must construct a representation for at least a short sequence of events in advance, and cannot operate at speed or with any fluency on an event-to-event level. Sudnow may have become unaware of these hierarchical structures, and the structures themselves may be no more elaborate than the eight-character preview of Shaffer's typist, but they undoubtedly exist.

The associative structure that Sudnow describes corresponds to a particular style of jazz improvisation, and in a different stylistic context a

more considered approach is often required. This can either take the form of carefully constructed and rehearsed schemes, involving complex extended melodic and harmonic strucutres—in others words hierarchical/generative structures—or can be characterized by a process of selecting patterns from a fixed repertoire. With this latter genre in mind, Sudnow comments that:

> Some musicians do no more improvising than the stand-up comic who decides only in which order to tell the same jokes the same way at each performance. (Sudnow 1979, p. 43)

The various representations underlying an improvised performance can be brought together by considering the abstract representation of an improvised performance in its very earliest stages, as shown in Fig. 1.4. All

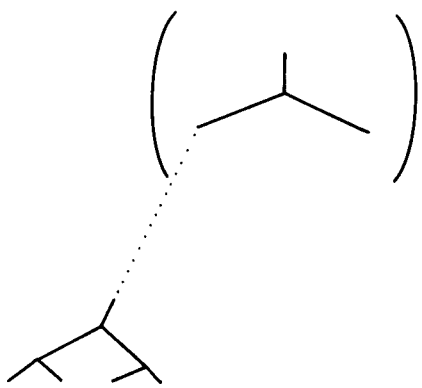

Fig. 1.4. Representation of the musical knowledge structure at the start of an improvised performance.

that exists is a low-level musical unit, characterized here as a small-scale, hierarchically organized event. A complete performance will consist of a large collection of such events, organized in different ways, and related to this first event according to three possible principles:

(1) The first event may be part of a hierarchical structure, to some extent worked out in advance, and to some extent constructed in the course of the improvisation. Figure 1.5 (a) is a schematic illustration of a complete piece formed according to this principle.

(2) The first event may be part of an associative chain of events, each new event derived from the previous sequence by the forward transfer of information. Figure 1.5(b) illustrates a complete piece formed on the basis of this principle.

(3) The first event may be selected from a number of events contained within the performer's repertoire, the rest of the improvisation consisting

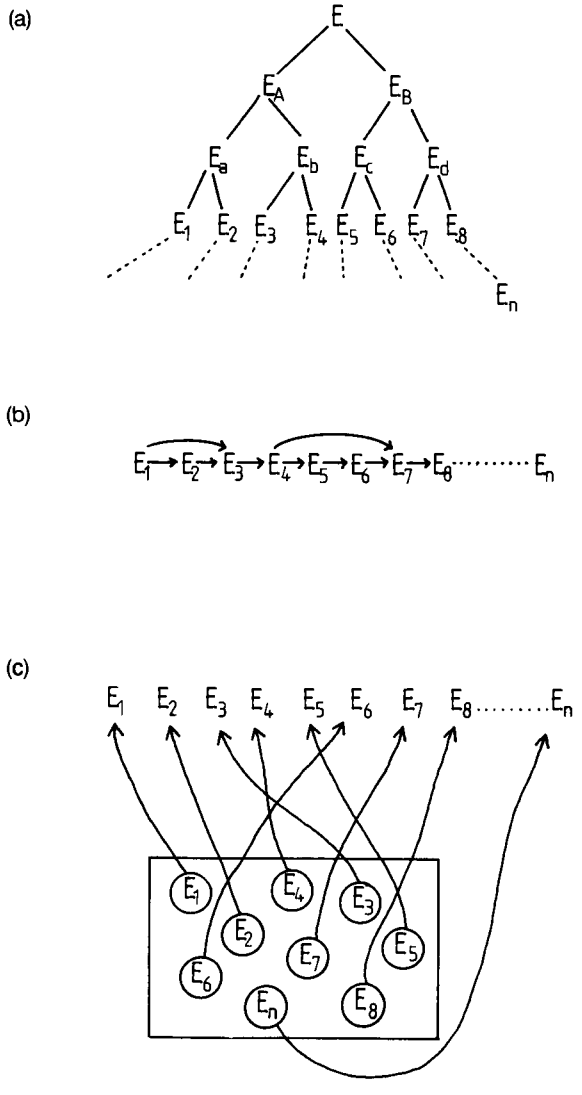

Fig. 1.5. The idealized knowledge structures for improvisations structured in three different ways: (a) hierarchically; (b) associatively; (c) by repertoire selection.

of further selections from this same repertoire, with a varying degree of relatedness between selections. Figure 1.5(c) illustrates this principle.

In any real performance all three principles will contribute to the improvisation. As we have seen, performance structures are never entirely associative, or perfectly hierarchical, and the selection of patterns from a

repertoire of possibilities will necessarily take place within an overall framework (associative or hierarchical) of some sort, however vague. It may be, however, that different improvising idioms can be characterized by the balance of the three principles, and the interactions between them. The improvising style known as free jazz is principally characterized by associative structure, since it eschews the constraints of a pre-planned structure, and attempts to avoid the use of recognizable 'riffs'. More traditional jazz improvisation tends towards the hierarchical principle, in its adherence to a fairly strict harmonic outline. And be-bop improvisation illustrates the selective principle in the way in which a performer may try to construct an improvisation so as to include as many 'quotes' from other sources as possible (ranging from other jazz pieces to national anthems).

To summarize the main points of this section, the representational structure of musical knowledge can be shown to have a generative component in all performance contexts. However, the strength of that generative component differs considerably when the variety of performance contexts (memorized performance, performance from notation, improvisation) is considered. Memorized performance illustrates the most pervasively generative representational structure, though it seems likely that at any moment during a performance only a part of that structure is active. Performance from notation demonstrates a less complete generative structure which, in the case of music that is poorly known or sight-read, is constructed from the projections of a player's stylistic knowledge coupled with the continuously unfolding input of detailed information derived from the score. The result is a hierarchical structure that is incomplete in certain respects at high levels, and perhaps at odds with the music's formal structure. These are the errors and omissions which are rectified through extended practising and general musical training. Finally, improvisation illustrates a performance context in which musical representations of a variably generative character are constructed on the spot, or with an element of pre-planning, according to the principles of hierarchical, associative, and selective elaboration. The balance of these three may offer a succinct way in which to characterize improvising idioms.

As stated at the outset, no radical discontinuity need be imagined between the abstract, and essentially static, representational structures discussed here and the representations for action contained within a motor program. Indeed, Shaffer (1976, 1981) has shown that in both typing and musical performance abstract properties play a vital role in the control of performance. None the less, motor programs result in the generation of real activity in a way that abstract knowledge structures do not. At a certain point declarative knowledge becomes procedural, and the term generative comes to mean not description, but production. One area of particular interest in which such a process is crucially implicated is the control and shaping of the expressive properties of a performance.

Generative processes in performance expression

Whenever a skilled performer plays music, whether at sight or after years of practice, alone or in an ensemble, s/he plays with expression. Continuously variable modifications of the timing, dynamic, articulation, vibrato, and timbre of notes and note groups are identifiable and can be preserved with astonishing precision from one performance to another, sometimes separated by years. On the other hand dramatic changes in these expressive parameters can be observed between successive performances of the same piece of music separated by only a few minutes. These observations prompt the following questions: how is it possible for a performer to introduce expression into a performance when the music is unknown, to preserve an interpretation over long periods of time, and to alter an interpretation at a moment's notice?

The options available that account for these facts are limited. Either one must assume that a performer has simply learned a fixed expressive pattern that is applied to each piece of music, and exists in a number of fixed variants; or one must assume that the expressive profile is generated at the time of performance from information specified in the musical structure. The first option is not really a serious possibility since expressive profiles have been shown by a number of authors (Shaffer 1981, 1984; Sloboda 1983; Clarke 1984) to be closely related to musical structure. Given the structural differences between pieces of music even within the same style, it is inevitable that a mismatch between structure and expression would result from the application of a fixed expressive profile to different pieces. There is no plausible alternative, therefore, to the idea that expression is derived from structure.

Structure and expression

Some aspects of the relationship between structure and expression can be illustrated with two different studies of piano performance. The first (Clarke 1982) is primarily concerned with the interaction between rhythm and performance tempo, and demonstrates that the changes in expressive timing structure that accompany changes in tempo relate to structural properties of the music. The performances (of a highly repetitive piece by Erik Satie called 'Vexations') show consistent deviations from strictly metrical timing that produce a profile of partially periodic timing curves. Maxima in these curves indicate boundaries which segment each performance into a number of groups. Significantly, these group boundaries correspond to positions in the musical structure at which formal breaks can be identified, using analytical principles similar to those of Lerdahl and Jackendoff (1983). At faster tempi there are relatively fewer groups in

the timing profile, and at slower tempi relatively more, the additional boundaries being formed at positions where the music indicates a structural discontinuity of some sort. Thus the expressive changes that accompany changes in performance tempo are based on structural properties of the music, and can be characterized as the transformation of latent expressive possibilities into manifest expressive features in accordance with the dictates of tempo and musical structure.

A second study investigated the expressive changes that result from modifying the relationship between a constant rhythmic structure and its metrical context. The metre of a piece of music is a regular framework of accented and weak beats, existing at a number of levels of structure, around which individual notes and groups of notes are organized. A partial representation of metrical structure is contained in the time signature, bar lines, and beams connecting notes that are used in conventional music notation. In the study a single-line melody was constructed, which was written so as to start in a variety of positions within the bar while keeping all the note values and pitches constant. The result was a complete cycle of orientations between the metrical framework and the note sequence, such that the sequence started on each of the available beats in the bar. Experienced pianists were asked to play each of these variants a number of times, in random order. Figure 1.6 shows two of the variants as examples.

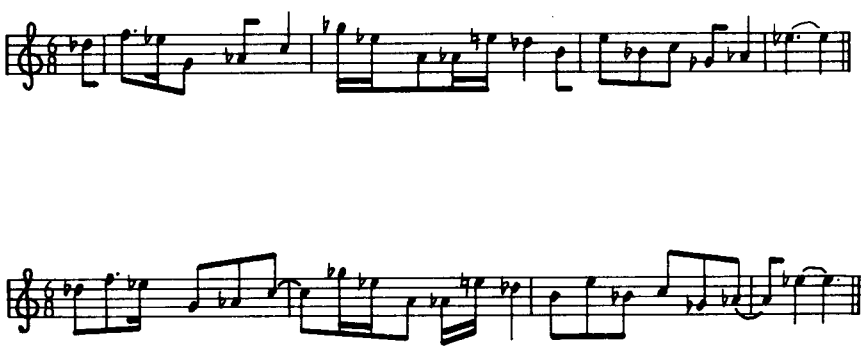

Fig. 1.6. Two of the metrical variants of a constant pitch/duration sequence used in the study of interactions between rhythm and metre.

The study showed that significant changes in the expressive profile of the sequence accompanied the cycle of metrical reorientations, and could be identified in all three of the expressive parameters available (timing, dynamic, and articulation). The expressive changes are, however, related to the metrical changes in a manner that is rather more complex than might be expected, for the following reasons.

(1) Changes in the notated metre of the sequence precipitate other

structural changes. These include changes in the position of group boundaries and changes in the melodic/harmonic function of notes brought about by an altered relationship to the main metrical accents. Figure 1.7 shows two of the tunes used in the study which illustrate this point. The metrical change is simply specified and is directly observable in the notation, while changes in group structure and melodic/harmonic function (see Fig. 1.7) are more concealed since they are not directly represented in the notation. Expression is related to a whole range of structural features, and will reflect these second-order structural changes no less than the metrical changes. Added to this are further structural effects brought about by what may be termed the functional resistance of notes: a short note, for instance, resists functioning as a group ending simply by virtue of its brevity, and similar resistances can be identified for long notes.

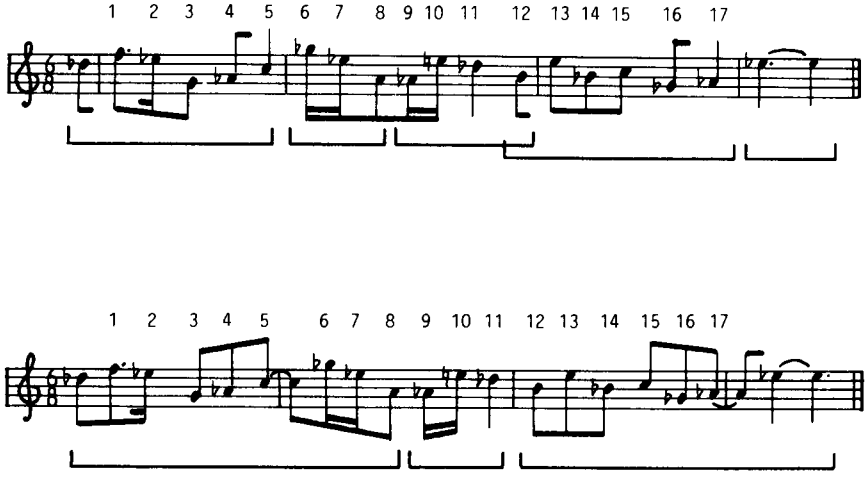

Fig. 1.7. Two tunes from the rhythm/metre study showing changes in group structure (indicated by brackets) and melodic/harmonic function that are triggered by metrical changes. Note 3 functions as an appoggiatura to note 4 in tune 2, but not in tune 1; and note 16 functions as an appoggiatura to note 17 in tune 1, but not in tune 2.

(2) Within each of the three expressive parameters (timing, dynamic, articulation) expressive gestures can perform a number of different functions: these include altering the relative proportions of events within a rhythmic group, indicating the position of a group boundary, marking a metrical accent, and creating an expressive gradient towards a focal point (that is, a pattern of directed motion). As a result expressive gestures are functionally ambiguous, in the sense that they specify a number of alternative interpretations. It is only through interactions with the underlying musical structure that these ambiguities are resolved.

(3) The three expressive parameters interact with one another in at least two ways: first, they may substitute for one another, so that, for instance, an accent may be conveyed by making a note longer, or louder, or more legato, or delaying its entry; and second, they may combine to form expressive complexes that possess a compound function that is not simply the sum of the individual expressive components. For example, in the appropriate context a note that is played loud and staccato will receive a particularly emphatic accent, despite the fact that staccato articulation is usually associated with metrical weakness. The combination of dynamic intensity and staccato articulation appears to convey an expressive meaning that is not explicable in terms of a summation of the individual components.

In the study described here, most expressive changes could be explained on the basis of changes in the position of metrical accents (those points being played louder, or longer, or more legato) and group boundaries (indicated by points of discontinuity in the timing, dynamic, and articulation curves), a more minor role being the emphasis of peaks in the melodic contour. With more complex musical material, the subtlety and complexity of the relationship between expressive features and the associated structure would undoubtedly increase.

What this study demonstrates, however, is that a performer generates an expressive strategy for a musical extract on the spot. This is evident from the brevity of the preparation time that the players needed for the study; from the way in which the players were able to activate an appropriate expressive strategy almost immediately when going from one variant of the sequence to another randomly selected sequence; and finally from the evidence that in many cases a player used a number of different expressive strategies for the same sequence on different repetitions, each strategy nonetheless conveying the main structural characteristics of the material. This suggests strongly that a performer is aware of a number of interpretative options in his or her approach to the music, which might emphasize different structural aspects, but which are in some sense equally adequate. In order to understand how this range of options is structured and controlled, the nature of an interpretation and the general function of expression must first be considered.

Interpretation and the function of expression

Shaffer (1984) has described an interpretation as a compact coding of expressive forms, from which an expressive performance can be generated when required. Two qualifications, or additions, can be made to this. First, the expressive forms which constitute the interpretation are rather abstract. This is evident in the way in which performers use a variety of different expressive strategies to project essentially the same interpretation,

as mentioned in connection with rhythm and metre. This suggests that an interpretation consists of a set of abstract expressive markers that can take a material expressive form within any of the parameters available. Second, an interpretation is not only an expressive coding, but also a structural coding. A performer must form an understanding of the musical structure, or decide between structural alternatives offered by the music, and encode that in some stable and compact manner. The structural component then acts as a framework around which the expressive markers are organized.

Pieces of music are invariably open to a number of different structural interpretations, and the primary role of expression is to limit the extent of this ambiguity by emphasizing certain structural interpretations at the expense of others. This does not mean that expression necessarily operates in the service of clarity, since a performer may choose to emphasize either those structural characteristics that are most obvious, or to extract more hidden and disruptive features of the music. Similarly, although a performance must aim to be expressively coherent, that aim does not entail the resolution of all structural ambiguity, since a performance may intentionally attempt to manipulate conflicting aspects of the music.

At a detailed level, however, each expressive act operates so as to project a particular functional meaning for a given musical structure. This is achieved in a variety of ways, the most general underlying principle being the intensification of gestalt properties of the musical structure that are already evident, or the establishment of gestalt features when the music is structurally neutral. Examples of this are the establishment of boundaries in the grouping structure of the music by means of changes in dynamic, articulation, or timing; the imposition or emphasis of a sense of direction towards a structural focal point by means of dynamic, articulation, or timing gradients; or the modification of the accentual status of events (that is, changes in figure/ground relations) by means of dynamic or agogic emphasis. (Agogic emphasis is the accentuation of a note by prolonging its inter-onset duration.)

In a majority of these examples the relationship between the expressive aim and the expressive means is very direct: boundaries are indicated by relatively large parametric changes, directed motion is indicated by graduated parametric increase, and accentual strength is indicated by relative parametric intensity. Within at least two of these parameters (timing and articulation), however, the directness of this expressive function is threatened by ambiguity. The lengthening of a note can indicate that it is accented, that it finishes a structural unit at some level, or that the following (delayed) note is of structural importance. Similarly, although an underlying correlation between structural significance and increased legato articulation appears to hold, structural significance can also be indicated by means of emphatically staccato articulation.

This uncertainty concerning the meaning of an individual expressive

gesture is usually clarified by two considerations. First, the expressive sequence in which a particular gesture is incorporated will frequently resolve any ambiguity, and second, the structural context in which the gesture occurs may clarify its meaning. Figure 1.8 shows a short musical extract with a hypothetical expressive profile in three parameters.The penultimate note receives an expressive treatment (long, legato, loud) which in isolation might indicate that it was a strong beat. In reality the correct interpretation of the note as an emphasized upbeat (weak beat) is virtually guaranteed by the previous expressive profile, which helps to establish the metre, and by the structural context, which makes the note weak and unstable. Under conditions of structural clarity, and for listeners well-versed in the musical idiom, expressive characteristics function as responses to, or refinements of, the immanent properties of the music.

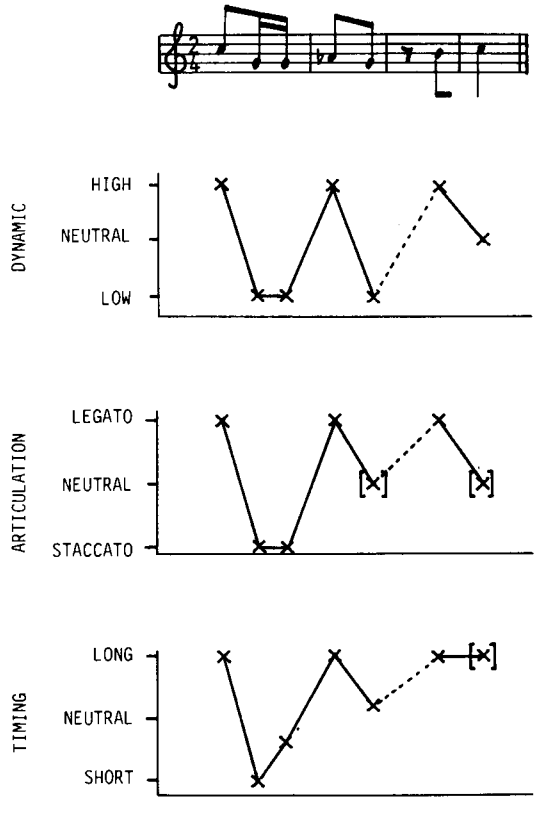

Fig. 1.8. A short melodic sequence with associated hypothetical expressive features, illustrating the way in which the expressive and structural context affect the meaning of an individual expressive gesture (on the penultimate note). See text for details.

When the musical structure is weak or indeterminate, however, expressive effects may function primarily to impose a particular structural interpretation onto a neutral structural base.

The distinction betweens strong and weak musical structures may also affect the way in which listeners distinguish betwen expressive deviations and mistakes. A strong structure may be sufficiently stable that if a feature of the performance conflicts radically with the structural implications of the piece, it is perceived as a mistake, or, if less prominent, simply ignored. In an ambiguous piece, on the other hand, a listener is likely to be more strongly influenced by expression and is more or less forced to take at face value anything that a performer does. Strong structures therefore act selectively to filter out inappropriate expressive features, which are then labelled as mistakes by a listener, or not noticed. Weak or unfamiliar musical structures, on the other hand, provide a listener with no clear reference against which to judge performance features, which must therefore be accepted as structural indicators, with all the ambiguities that have been discussed. In these circumstances the performer is under particular pressure to pay the most acute attention to details of expression, since an unintended deviation may jeopardize a listener's understanding of the music. It may be for this reason that the performance of contemporary music puts such great expressive demands on performers, since both listeners and performers are on the whole unfamiliar with its structural principles.

The generative source of expression

The close relationship between structure and expression embodied in an interpretation forms the basis for an account of the source and systematic construction of expression. Using the structural component of an interpretation as its input, a set of generative rules derives an expresive strategy as output. A range of studies (for example, Shaffer 1981, 1984; Clarke 1982, 1984; Sloboda 1983) indicate that the generative rules for expression in piano performance can be summarized as follows. Within the domain of timing three principles operate:

(1) Graduated timing changes can be used to indicate the group structure of the music, group boundaries being marked by maxima in the timing profile. This principle can be described by a quadratic function, with the position of the minimum point in the curve specified by a variable parameter, allowing a range of related curves to be generated that differ in the balance of upbeats and afterbeats. When the minimum point is displaced to the left in a group, upbeats predominate, and the internal dynamic or directed motion of the group is towards its ending. When displaced to the right, afterbeats predominate and the internal dynamic or directed motion of the group is a dissipation away from its beginning.

Figure 1.9 illustrates this principle with three schematic curves which differ in the balance of upbeats and afterbeats. Todd (1985) has formalized this function using a parabolic curve, and has shown that with only a single function at one level of structure a reasonable approximation to some of the piano data can be obtained which also reflects structural properties of the music being performed. More recent attempts at elaborating this formalization, using hierarchically nested levels of the function (Shaffer 1985), indicate that even better approximations can be achieved with only a minimal increase in formal complexity. It appears that the amount of timing modification is directly related to the structural significance of a musical segment. By displacing the minimum point of the parabola relative

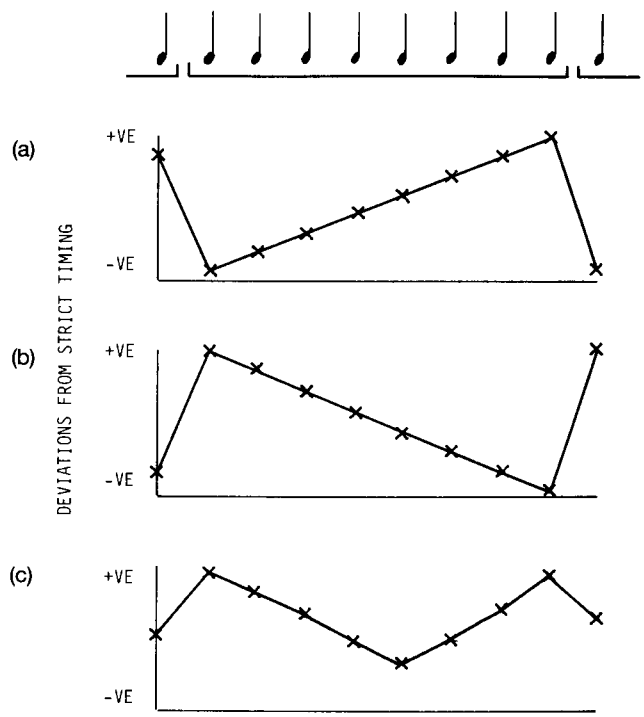

Fig. 1.9. Schematic diagram of three related timing curves differing in their pattern of upbeats and afterbeats, and produced by displacement of the minimum point in the curve to left or right. The top of the figure shows a succession of notes with group structure indicated by brackets. In (a) the minimum is displaced to the left, resulting in a predominance of upbeats and a sense of end-oriented direction. In (b) the minimum is displaced to the right, resulting in a predominance of afterbeats and a sense of dissipation away from the beginning of the group. In (c) the minimum is positioned roughly in the middle of the group, giving a balance of upbeats and afterbeats, and a centred focus of direction.

to the segmental boundaries according to criteria of structural significance, a timing curve of appropriate slope and degree of rubato is generated.
(2) A note may be lengthened so as to delay a following note, the function of the delay being to heighten the impact of the significant delayed note. This function is frequently associated with the first principle, since the delayed note is often the start of a new group, the previous note being lengthened both for reasons of delay and because it falls at a group boundary. Delay is therefore only observably distinct when it occurs mid-group, or when applied to isolated notes that are not part of a graduated timing curve.
(3) A note that is structurally significant may be emphasized by increasing its inter-onset interval (agogic accent). Since significant events usually occur towards the beginning of musical groups (see Lerdahl and Jackendoff 1983), the principle balances the predominantly end-effects of the first principle.

Within the domain of dynamics, three principles can be identified:
(1) Graduated changes in dynamic may be used to indicate a pattern of upbeats and afterbeats, and directed motion, within the group structure of the music. This is essentially a translation of the first timing principle into the dynamic domain and should be formalizable in the same way, namely by a quadratic function fitted to the group structure of the music, with the position of the dynamic minimum specified by a variable parameter that alters the balance of upbeats and afterbeats. Figure 1.10 illustrates the principle with performance data from the rhythm and metre study discussed earlier. The figure shows two performances of the same tune, in which the positions of the dynamic maxima remain the same (positions 1, 4, 6, 11, 13 and 16), but the positions of three minima change. This has the effect of transforming notes 3, 9, and 10 from upbeats in the first performance into afterbeats in the second, and notes 14 and 15 from afterbeats in the first performance to upbeats in the second.
(2) Dynamic contrast may be used to articulate group boundaries, employing an association between dynamic discontinuities and underlying structural discontinuity. As an illustration, Fig. 1.11 shows dynamic data from performances of another tune in the rhythm and metric study. The sharp change in dynamic level between positions 8 and 9 coincides with the first clear opportunity in this tune of establishing a group boundary.
(3) Significant structural events (for example metrical accents, melodic peaks, harmonic changes) may be dynamically intensified, a principle equivalent to the third timing principle.

Within the parameter of articulation, three principles can once again be identified, equivalent to those of dynamic usage:
(1) Graduated changes in articulation may be used to indicate a pattern of upbeats and afterbeats, and directed motion, within the group structure of the music. This appears to be rather less distinct as a principle than its

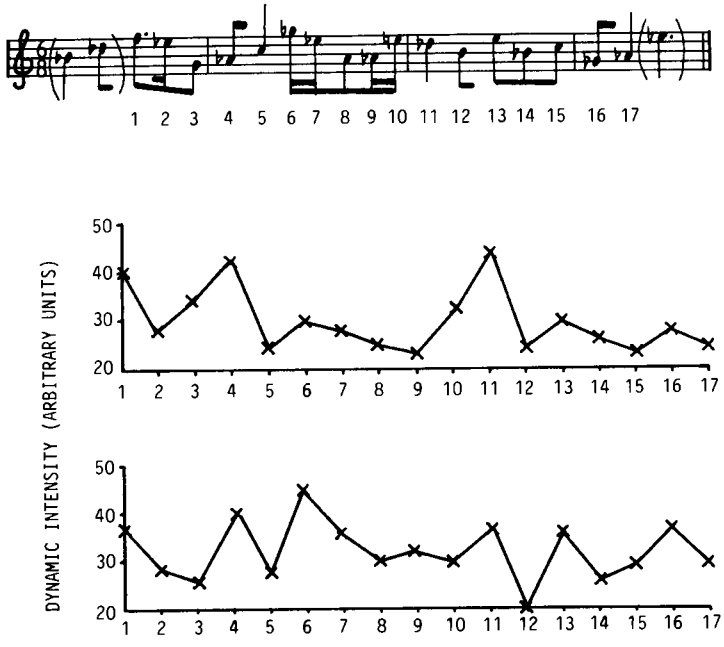

Fig. 1.10. Dynamic data from two performances of the same tune showing changes in the pattern of upbeats and afterbeats reflected in displacements of three dynamic minima.

dynamic equivalent, and cannot be formalized with the same quadratic function. It is more often associated with upbeats, a pattern of increasing staccato indicating the approach to a downbeat, though it can also be used to indicate afterbeats.

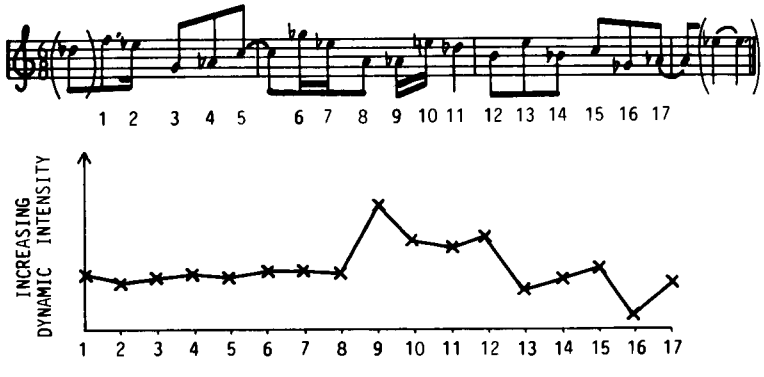

Fig. 1.11. Dynamic data illustrating the use of dynamic contrast to mark a group boundary between notes 8 and 9.

(2) Group boundaries may be indicted using discountinuities of articulation. This can either take the form of sustained articulatory contrasts that define different groups, or the use of an isolated staccato (or detached note) at a boundary as a separating device. This is illustrated in Fig. 1.12, where the isolated staccato articulation at note 8 serves to establish a group boundary. Conversely, an exaggerated legato articulation can be used as a device to hold together the components of a group.

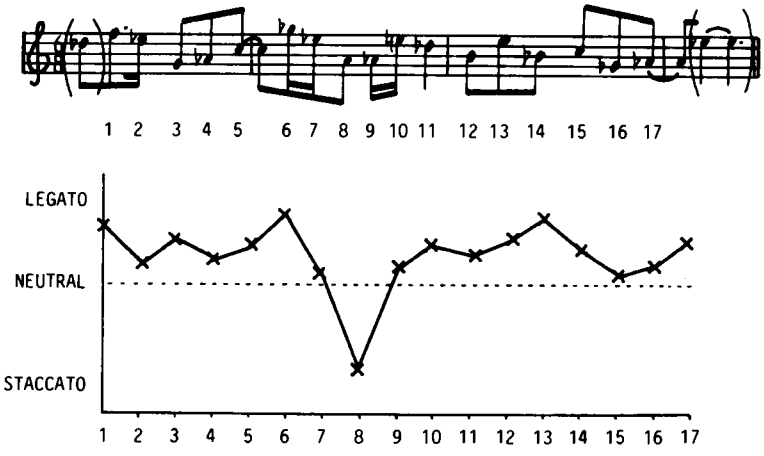

Fig. 1.12. Articulation data illustrating the use of an isolated staccato note (data point 8) to mark a group boundary.

(3) Individual events may be accentuated by articulation. There appears to be an underlying association between structural significance and legato articulation, although this association is rather weak, and in the correct structural context staccato articulation may serve to accentuate a note (Clarke 1984).

These, the essential principles of expression in piano performance, demonstrate three underlying expressive functions:
(1) The indication of structural direction by means of parametric gradients.
(2) The indication of group structures by means of parametric continuities and discontinuities.
(3) The accentuation of individual events by means of local parametric intensification or contrast.

A number of factors influence choices within this system of expressive options. To begin with there are the resources of the chosen instrument, which vary considerably in restrictivenesss. At one end of the spectrum only timing and articulation can be varied on a harpsichord, whereas the voice, for instance, offers expressive opportunities that include timing, dynamic, articulation, timbre, verbal content, vibrato, and the continuum

between speech and song. The piano falls towards the restricted end of this range, offering systematic control over only timing, dynamic, articulation, and pedalling. Since the same piece of music may be played on different instruments, a performer who switches from one instrument to another may have to make a considerable readjustment to the resources that the instrument offers. Quite apart from the different tone qualities of the two instruments, the differences in the use of timing in harpsichord and piano performances of Bach's keyboard music illustrate this adjustment. Performers who play both instruments confirm that they must make a conscious stylistic modification to suit the instrument. On a more refined level, changes in instrument design and construction affect performance expression: the range of dynamic contrast offered by a modern grand piano was not possible on the pianos available to Mozart or Haydn, and expressive effects are consequently obtained in different ways on the instruments of that period.

The second factor affecting expressive options is the influence of performance style. Just as instruments show historical development in their design and construction, so also do conventions of performance expression show significant historical (and geographical) variation. These may be linked to instrument technology, but are by no means simply the consequence of such changes. Writings on performance practice have a long history (see Donington 1977), but it is only in the last 30 years or so that the study of historical changes in performance practice, and the attempt to reconstruct stylistically authentic performances, have become established.

Writings on performance practice vary from prescriptive statements to rather more considered and closely argued discussions of particular problems. Whether well-informed or not, performers certainly have opinions about the manner in which different styles of music should be played, and adapt their expressive usage accordingly. The debate over the use of rubato and vibrato in performances of baroque music exemplifies the differences of opinion among performers over the need for, and nature of, historical authenticity.

We can regard a stylistic convention as a particular configuration of the expressive principles set out above, that brings about a certain type of expressive characterization. In Baroque performance practice, for example, group-final lengthening (the first of the three timing principles) is used very little, while the second and particularly the third principles (delay and agogic accent) are used more extensively. This results in an overall absence of ritardandi and a more widespread use of agogic accents, coupled with delay, particularly of the final tonic at cadences. By contrast, the nineteenth-century Romantic style placed enormous emphasis on the first timing principle, and the first dynamic principle (by contrast with Baroque and Classical layered dynamics, which correspond to the second dynamic

principle). It should be possible to charactize the performance practice of any period in this manner, as well as the personal style of a performer whose performance practice is sufficiently consistent.

Matters of stylistic convention may be broadly considered part of the performance context—in this case historical context. The details of expression are, however, also sensitive to contextual features of a far more local and immediate kind. It is this detailed context that constitutes the third factor operating on the range of expressive options. Sloboda (1983) has pointed out that it is implausible to assume that the expressive features of a performance are triggered by individual notational symbols. This means that structural information must be integrated from a collection of notational symbols before it can form the basis for an expressive strategy. It must also be supplemented by information about the current expressive context, and any logistical constraints that might apply: it is, for example, impossible to play notes legato that do not lie within the hand's span (without using the sustaining pedal).

Although performers make use of a variety of expressive strategies in the same structural context, this does not mean that expressive features can therefore be freely substituted. Each parameter has certain intrinsic qualities that make it more or less suitable for use in any given context. While articulatory differences may be good indicators of grouping properties, they are less effective than dynamics for outlining the shape and direction of large-scale melodic processes by virtue of their disruptive and divisive characteristics. On the other hand, when playing in an ensemble it may be more effective for a soloist to project an individual line by means of articulation than with dynamics, which might result in an unacceptable overall dynamic level or a muddy texture. Similarly, rubato is effective in solo performance, but in ensemble performances must be more constrained if overall synchrony is to be preserved, although Shaffer (1984) has shown that considerable rubato can be used in piano duet performances. Furthermore, even in solo performances, rubato must be used with discretion when the music involves a high level of rhythmic complexity, so as to avoid obscuring the structure.

The final factor influencing the choice of expressive options is the manner in which a player choses to perform. Seashore (1938/1967) demonstrated that a performer could play the same piece of music with an expressive profile that differed according to whether he was instructed to play artistically or metronomically. The differences were principally in the degree of rubato, rather than the pattern of rubato, but there is every indication that a performer can choose to alter the pattern as well. Sloboda (1983) showed that a professional performer who was experienced in playing exam dictations conveyed the metre of a short tune to listeners more effectively than a performer of similar calibre who did not undertake such duties, apparently by adopting a more didactic approach to the

relationship between metre and expression. This suggests that performers can choose to play in a manner that emphasizes the metre of the piece, or some other basic structural feature, or may subtly contradict those structural features for artistic effect.

Clearly a performer must not contradict the structure to such an extent that the music becomes incomprehensible to a listener, but a performer must also avoid playing music in a trite and obvious way. The choice of a 'mode' of performance is therefore influenced by the audience and occasion, as well as the performer's artistic intentions. The style of performance in a concert recital is likely to be rather different from the same performer's style at a children's concert, or during a melodic dictation exercise.

At a more subtle level, an individual interpretation can be regarded as a personally selected patterning of the expressive principles that may persist over a long period of time, or may be quite ephemeral. The expressive principles will be set in a particular configuration according to considerations such as the desire for contrast or continuity, and novelty or consistency. In a rondo movement, for instance, a pianist may choose either to retain the same expressive configuration at each return of the rondo theme, if the aim is to achieve continuity and consistency, or to make use of as wide a variety of expressive characteristics as possible, if the aim is to convey the potential novelty of the theme on each of its appearances. In a sonata form movement, on the other hand, it is usual to play the recapitulation with essentially the same expressive characteristics as the exposition, in order to make clear the significance of the return to material that has already been heard. As a third example, in a highly contrapuntal piece of music with a number of distinct motivic elements, it would be appropriate to give each an identifiable expressive profile if motivic clarity and identity are to be achieved. The structural 'archetypal schemata' that Meyer (1973) proposes may therefore have their expressive parallels.

Finally, the broad aims of a performance must be considered. Sloboda (1983) has pointed out that a performance can be considered to have primarily artistic or primarily communicative aims. If communication is the primary aim, then it is not too difficult to prescribe a successful configuration of the expressive principles outlined above. If, on the other hand, artistry is the primary aim, then prescription is both impossible and inappropriate. The essential characteristic of artistic activity (and aesthetic objects) is a radical form of ambiguity and creativity, and while the expressive resources may be outlined, their precise disposition on any occasion can be accounted for only in retrospect, not predicted. Were this not the case, and our curiosity in these ambiguities and possibilities not boundless, we might all have given up going to concerts long ago.

Timing in music performance and its relations to music experience

ALF GABRIELSSON

Performance and notation of music

Our experience of music and our ideas about music mainly derive from listening to performed music. The characteristics of musical performances are therefore of fundamental importance. The performance of a piece of music represents the overt, auditory manifestation of the composer's and/or the performer's intentions, ideas, feelings, and whatever is being communicated in music. It is the direct stimulus to the listener and will profoundly affect his way of perceiving and understanding this piece of music. His impression from the performance may remain for years to come, perhaps for his whole lifetime. However, another performance of the same piece may make him revise his ideas about it in different directions. Music critics excel in discussing the merits of different performances, for example, how conductors such as Toscanini or Furtwängler shape a Beethoven symphony, how pianists such as Backhaus or Kempff play a Mozart sonata, or how Glenn Gould performs music by Bach. The relations between the composer's idea, the actually performed music, and the listener's impression are complex, indeed.

In Western art music as well as in much popular music there is also a visual manifestation of the music, the score. However, the 'translation' from the score into sounding music is obviously made very differently by different performers. The notation has to be supplemented by various implicit rules, which relate to the type of music and associated performance practice (for example, church music, dance music, Baroque music, music from the Romantic era), with which different performers are more or less familiar. Of course, they are also influenced by teachers, other performers, their own earlier performances, and their ideas about the meaning of the music they are going to play. The musical score is only a starting point for the performer. It provides him with a skeleton, which he should bring to life with sound. It is one of the fascinating aspects of music that the result of this creative process may become so varied for different musicians and in different situations.

Music may thus be said to exist at different levels and in different forms: as an idea (in a wide sense) in the composer's and performer's mind, in the written score, in sounds, and in the listener's experience. The communication between the composer/ performer and the listener is meant to be realized by the *sounding* music, not by reading of a score. In fact much music (such as folk music over the whole world, and certain jazz music) never appears in notation but relies totally on performance and aural tradition to spread and survive. Nevertheless most thinkers and writers about music take musical notation as the starting point for their discussion. They even provide notations of music which has never appeared in that form (for example, transcriptions of folk music).

There are several reasons for this emphasis on notated, rather than performed, music. The musical notation is in many respects very convenient and efficient. It is also easily reproduced in print, while the handling of phonograph records or magnetic tapes to provide sound illustrations is more clumsy and requires special equipment. Certainly many writers also point out the limitations of musical notation and make due reservations as to its appropriateness. Still, I think that it is very easy to be led astray, even unconsciously, by the properties of notation; they may affect our experience and conceptualizing of music in a similar way that words may do in other areas, encouraging us to 'force' pitches into a limited number of pitch categories, to write down a rhythm using the most common note values, etc. The results from many studies of performances provide further support for this opinion.

Analysis of performances

The characteristics of different performances may of course be studied by simply listening to them. It is often easy to hear differences and changes in tempo, in dynamics, in intonation, articulation, and phrasing. For closer study of certain points you can use simple tricks; for instance, you can play tape-recorded music at half-speed, or even slower, to have more time for listening. However, many characteristic features of a performance elude our perceptual analysis and require accurate physical registrations. Here we meet one important explanation of the relative scarcity of performance studies: to make detailed registrations of sounding music is very difficult, even with the technology available today. I have elsewhere (Gabrielsson 1985) reviewed earlier attempts in this direction, including registrations of organ playing (Sears 1902), of piano performance stored on 'player rolls' for mechanical pianos (Hartmann 1932; Vernon 1937) or studied by filming the action of the hammers (Hendersson 1937; Skinner and C. E. Seashore 1937), of singing (H. Seashore 1937), and of violin playing (Small 1937). The last-mentioned researchers belonged to a very active group gathered

around C. E. Seashore at the Iowa University. Their techniques and results, summarized by C. E. Seashore (1938), are still very impressive. Later advances in registrations of piano performances were presented by Wagner (1971, 1974) and Shaffer (1980, 1981). The methods used in the Uppsala studies of performances are described below.

From a physical point of view the variables manipulated by the performer are durations, intensities (amplitudes), frequencies ('pitch'), and the spectral composition of the sounds. On some instruments (for example, the whole violin family) and in singing one may vary all of them over a considerable range, and continuously. In other instruments, such as the piano and the organ, pitch can be varied only in discrete steps, and once the tone is struck one has no, or very limited, possibilities of affecting its properties any longer. Each instrument presents its own possibilites and limitations. In the above-mentioned investigations on singing and violin playing there were numerous examples of more or less continuous variations in pitch and intensity, for example, pitch and intensity vibrato, sharp or flat intonation before reaching the 'proper' pitch, dynamic swelling and shrinking within tones or phrases, glidings between successive tones, etc. In the piano studies the interest was focused on durations and intensities. Striking variations of tempo and different types of deviations from expected durations of various tones appeared, and it was noted that there was no consistent relation between intensity and (perceived) accent. Of course, none of these phenomena in the actual performances were indicated in the corresponding musical scores; they were truly outside the notation.

Timing in performance

The only variable over which the performer has practically complete control, regardless of which instrument he uses, is the duration of the sound events, as well as of 'non-sound' events (rests or silences). This circumstance is one of the explanations for why the manipulation of various durations, here generally called *timing*, is often considered to be the most important tool available to the performer. If there is a score, this prescribes, of course, the timing in many respects, but there is still a great freedom within these constraints. In the case of non-notated or improvised music this freedom is even greater.

In writings and research on music, timing is usually related to rhythm. This connection is self-evident, but other factors should also be mentioned. Since there is no melody without rhythm, timing is important for melody as well; and since a melody is often harmonized, timing influences the harmonic progression. It may also affect the single chord, since tones within a chord are often played asynchronously (Hartmann 1932; Vernon

1937) or even *arpeggio*. It is known that the time course of different partials in a tone is critical for the perceived timbre (Risset and Wessel 1982). Rasch (1978, 1979, 1981; see also Chapter 4 in this volume) showed that the tone onsets from different instruments performing polyphonic music are usually asynchronized, and that this may facilitate the perception of the different parts.

These hints are enough to show that timing, in one way or another, influences practically every aspect of the music. Instead of using the traditional musical terminology, we may also refer to such categories as the *structural*, the *motional*, and the *emotional* aspects of music experience (Gabrielsson 1973*a*, *b*, *c*; 1982*a*, *b*; 1985; 1986). It is clear that timing affects the way we experience the structure of a piece of music, as a whole and at different levels (Sloboda 1983; Gabrielsson 1986; Clarke in Chapter 1 of this volume). However, little is said about the effects of timing upon the experienced motion character of the music and the related emotional qualities. These two aspects will be briefly discussed before proceeding to different examples of timing.

Motion and emotion in music

Music is often said to be 'the language of emotions', which 'bypasses the intellect' and takes over, when words do not suffice any longer. Sweeping statements like these require much critical analysis, but this will be left for another occasion. On the other hand music is also often considered to reflect various kinds of motions or gestures. That music often elicits overt movements is obvious and sometimes explicitly intentional, as with dance music. However, one can also experience motion in music without moving oneself. A simple example of that is again dance music: there are striking differences in the experienced motion character of, say, waltz, foxtrot, rock 'n' roll, samba, and tango. The concept of 'swing', often referred to in jazz, is an example of a specific motion character. A march should certainly have a special motion character, and so should a properly performed Viennese waltz. The motion character of Baroque music is different from that of music in the Viennese Classical style. Becking (1928) took the difference in motion character between Mozart's and Beethoven's music as the starting point for his speculative but interesting attempts at using 'accompanying movements' (*Begleitbewegungen*) to catch such differences between different composers; see also Truslit (1938). Clynes (1977, 1980) and Clynes and Walker (1982) proposed to use the sentograph (a device for registering the strength and direction of finger pressure in studies of emotion and motion) as a means of finding out the 'inner pulse' in the music of different composers.

Music as expression of emotions and music as expression of motions are

not competing, but rather complementary ideas. The close psychological connection between emotion and (overt or inner) motion is already suggested by the common origin of those two words (from Latin *movere*) and amply supported by commonplace observation: to jump for joy, fight in anger, sink down in despair, etc. To find a suitable method for studying the motional-emotional aspects of music experience is difficult, however. In my earlier research (Gabrielsson 1973*b*) I mainly used conventional verbal methods and identified motion characters such as 'rapidity', 'forward motion', 'dancing', 'walking', 'rocking', 'swinging', and many others, as well as emotional qualities including 'vital vs. dull', 'excited vs. calm', 'rigid vs. flexible', etc. It is obvious, however, that words are clumsy tools for describing these phenomena in all their continuously varying shades and shapes. The increased interest in non-verbal methods (cf. Scherer and Ekman 1982) suggests other possibilities. Clynes's (1977, 1980; Clynes and Nettheim 1982) theory of emotion and its expression primarily relies on a non-verbal method, registration of finger pressure on a 'sentograph'; it has also been used for studying experienced motion in music. Nielsen (1983) used a similar device, pressing a pair of tongs to reflect experienced tension in two pieces of symphonic music. We can expect further developments of these and other methods to facilitate the study of the ongoing processes in music listening and not remain confined to retrospective verbal reports.

This excursion has been motivated by my belief that many types of timing in music performance aim at eliciting various motional-emotional reactions in the listener. Because of the lack of proper methods to study these questions in enough detail there is, of course, little empirical evidence to rely upon. Nevertheless it seems possible to make some reasonable suggestions. They will be discussed in relation to four categories of timing; tempo, different classes of duration, articulation, and deviations from mechanical regularity.

Tempo

Tempo is a common and seemingly simple concept in connection with music. The tempo of a piece is usually indicated either by designations such as allegro, moderato, adagio, etc., or more precisely by stating a metronomic value, for example, MM ♩ = 120, that is, 120 crochets per minute. Musicians differ much in their ability to judge the absolute tempo and changes in tempo: while Madsen's (1979) and Wapnick's (1980) subjects were not especially good in this respect, Wagner (1974) found extreme accuracy in a study with the conductor Herbert von Karajan.

However, how fast the music seems to go depends not only on the metronomic tempo but on other factors as well. A piece with many 'short'

tones (say, semiquavers) seems faster than another piece with the same metronomic tempo but containing only 'long' tones (say, crotchets). The number of tones per unit of time is thus important. Sometimes the situation may be ambiguous. For instance, in certain parts of a Nocturne by Chopin the left hand may have a slow pace, while the right hand performs extremely rapid passages (see Fig. 2.1). In this case the motion may be felt as rapid, or slow, or rapid and slow at the same time (a rapid motion within a slow motion), depending on how you direct your attention.

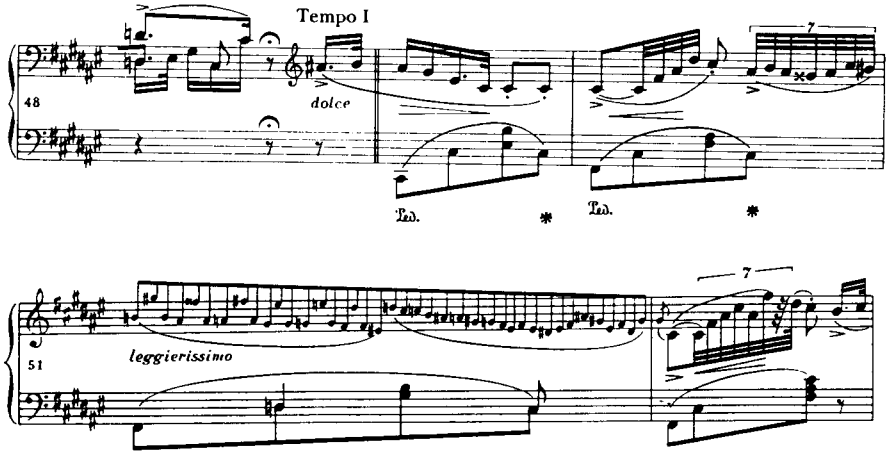

Fig. 2.1. Excerpt from 'Nocturne' Op. 15 No. 2 by Frédéric Chopin. Tempo designation: Larghetto. (Reproduced with permission from *Frédéric Chopin, Nocturnes and Polonaises*, Dover Publications, Inc., New York, 1983.)

With perceived tempo we usually mean the *rapidity of the beat* or pulse. This often coincides with the indicated metronomic tempo but not necessarily. Moreover, since the beat often can be alternatively felt at different rates (say, at the crotchet level *or* at the quaver level in a certain piece), the perceived tempo depends on which beat rate is meant. In either case, however, the perceived tempo is only one aspect, although a very important one, of the listener's impression of the speed of the piece. The experienced 'overall rapidity', as well as the rapidity of different parts, also depends on such factors as the number of tones per unit of time (already mentioned) and various melodic and harmonic factors. For instance, a melody with many large leaps may seem faster than a melody which proceeds stepwise (see data on coherence and fission in tone sequences, van Noorden 1975), and a piece with frequent harmonic shifts may appear more rapid than a piece with fewer shifts. There are thus many problems of definition and of influencing factors. No single work covers all these

aspects, but data and instructive discussions on various related points appear in Behne (1972), Motte-Haber (1968), Bengtsson (1974), Longuet-Higgins (1979), Longuet-Higgins and Lee (1982), and Steedman (1977).

Even if an exact metronomic tempo is given, the performer often deviates from that, consciously or unconsciously, depending on his idea of the piece, his present psychic state, acoustical conditions, etc. During the piece there is usually much more variation in tempo than is realized or consciously perceived. The tolerance for such variation is, of course, different in different music, for example, small tolerance in a march but large in a Chopin Nocturne. One common type of variation is where a phrase begins somewhat slowly, accelerates towards the middle, and then retards towards the end. This contributes, together with other means (for example, dynamic increase and decrease), to the phrasing. Numerous examples appear in the early performance studies mentioned above and in Bengtsson and Gabrielsson (1980, 1983) (see also in Fig. 2.8 below). The exact shaping and the extent of the variation differs, of course, with each single piece and each performer. If you measure the performance of a phrase and calculate its average tempo, you may find that this average tempo in fact never appears at any position in the phrase—it is an average of a continuous variation. But as a listener you find it quite natural and adequate. You would, rather, react (negatively) if the tempo *was* perfectly constant.

A detailed study of the tempo variations in a Viennese waltz (from *Die Fledermaus* by Johann Strauss, Jr.) was presented in Bengtsson and Gabrielsson (1983). Although usually not indicated in the score, a genuine performance of a Viennese waltz includes sizeable, sometimes extreme, variations of tempo, the details of which vary with the structure of different pieces. The calculated mean tempo for the 32 bars in this case was about 170 crotchets per minute, but the actual tempo varied between 148 and 196; in the initial bar of the second period it was in fact only 90.

In such a case the mean tempo is of very limited interest. (How boring the waltz sounds when the tempo is kept constant was illustrated by a synthesized example appended to the paper.) From this, and other, examples it was concluded that

> four different meanings of tempo should be distinguished: (a) the abstract *mean tempo*, calculated as the total duration of a music section divided by the number of beats in the same section, (b) the *main tempo*, being the prevailing (and intended) tempo when initial and final retardations as well as more amorphous caesurae are deleted, (c) *local tempi*, maintained only for short periods but perceptibly differing, and (d) *beat rate* . . . for describing minor fluctuations, which may not be perceptible as such.
>
> (Bengtsson and Gabrielsson 1983, p. 50)

How does the tempo affect the listener's impression of the music? If

there is a relatively stable tempo (regular beat), this provides a fundamental temporal framework for the whole piece, a structural basis for whatever else is happening. By appropriate variations of the tempo the performer can contribute to make the structural subdivisions clear to the listener: where a new motive, a new phrase, a new period, etc., begins, and where each ends. The extent of these variations often corresponds to the size or hierarchical level of the respective structural entities, for example, a certain retardation at the end of a phrase, a more pronounced retardation at the end of a period, and most pronounced of all at the very end of the piece.

However, tempo first of all relates to *experienced motion*. Although the original Latin word *tempus* means time, in music tempo designates the experienced rapidity of motion or flow. When there is a stable tempo, the listener feels a regular motion forwards. And when the tempo is varied, one feels how the motion is accelerated or retarded, how it might be brought almost to a stop now and then—but is resumed and carries on until the definite stop at the end. The performer's way of indicating the structure of the piece by variations of tempo is thus made by affecting the speed of the ongoing motion.

When one compares different performances of a piece, the first thing one notices is in fact often differences in tempo, as well as in the ways of varying the tempo. In this are also included other components of perceived rapidity, such as those discussed above in connection with Fig. 2.1 The 'total' impression of rapidity is thus a more or less complex function of various motions. In a completely homophonic texture the situation is rather unproblematic (Fig. 2.2(a)), while it is more intricate in polyphonic music (Fig. 2.2(b)), and in a piece without a regular beat at all (Fig. 2.2(c)). Whatever the case may be, there are usually considerable possibilities for the performer to manipulate various factors influencing the listener's impression of speed and motion, for the whole as well as for different parts.

With regard to the emotional effects several studies (Hevner 1937; Rigg 1940; Motte-Haber 1968; Behne 1972; Wedin 1972; Gabrielsson 1973*b*) indicated that higher tempo/rapidity was associated with judgements like 'vital', 'happy', 'exciting', 'light', 'restless', and others, while slower tempos got roughly opposite descriptions. However, the authors also point out that because of the complex structure of music, it is very difficult to ascribe such effects to differences in tempo alone—they may result from constellations of various factors, such as dynamics, pitch level, articulation, mode, etc. Although the above results certainly seem plausible and can be easily associated with various types of rapid motion, much work remains to make the picture more complete and accurate.

Different classes of duration

In the score the duration of the tones is indicated by the prescribed tempo and the note value of the respective tone. Note values (semibreve, crotchet, quaver, etc.) are defined in simple ratios to each other, such as 2:1 (for example, semibreve to crotchet) or 3:1 (dotted semibreve to crotchet). Of course, it is realized that there is a certain tolerance around

these ratios in actual performance. However, it is rarely understood how extreme and varying the deviations really are, as found in empirical investigations of performance (see p.41 onwards).

Disregarding this for the moment, it is self-evident that the specific sequence of note values given in the score provides a primary structural characteristic of the piece in question. But in the same sense that the tempo reflects experienced motion, the various tone sequences also have *motional-emotional properties*. Due to the practically infinite number of possible sequences, these qualities are almost innumerable. They provide an endless variety of means for the composer and performer to shape the ongoing flow in the music (also including the use of 'non-tones', rests). As a few, extremely simple, examples consider the short patterns in Fig. 2.3. The motional characters of these certainly vary and may here be loosely described by expressions such as 'even flow', 'rocking', more or less 'jerky', 'galloping', and the like. The last, 'galloping' pattern has a very pronounced 'moving forwards' quality, as used, for instance, in the overture to *Guillaume Tell* by Rossini.

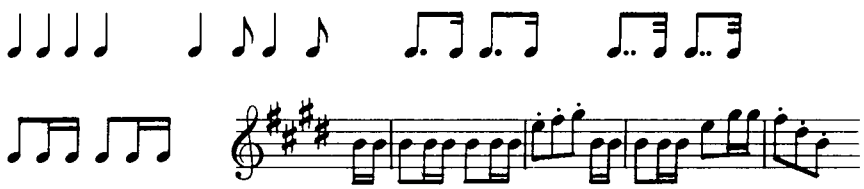

Fig. 2.3. Five short patterns illustrating different motion characters. The music example is taken from the overture to *Guillaume Tell* by Rossini, tempo designation Allegro vivace.

However, there have been few empirical attempts at elucidating these fundamental questions. Suggestions may be found in Motte-Haber (1968) and Gabrielsson (1973*a*, *b*). Clynes and Walker (1982) used a sentograph to study the responses to two-tone patterns, which were varied in the duration and amplitude of the tones. The multitude of different responses obtained even for these simple cases indicates something of the enormous possibilities available in composing and performing music to elicit various motional and emotional reactions in the listener—even richer when including variations of pitch, intensity, timbre, etc. as are found in most music.

In a certain contrast to the statements above, Fraisse (1956, 1982) claims that in a piece of music there are essentially only two classes of durations: 'long times' and 'short times' (*temps longs*, *temps courts*). In his excellent monograph *Les structures rythmiques* (1956), Fraisse described the results of many experiments on motor production or reproduction of rhythm patterns. His subjects' tappings of these patterns indicated the existence of

two separate duration regions, the 'long times' and the 'short times', in an approximate ratio of 2:1 or higher. The absolute duration of these classes varied in different contexts, but generally 'short times' were associated with perception of 'grouping' and 'long times' with perception of 'duration'. Rhythm perception was seen as a play between those two qualities, collection and duration.

Fraisse also finds the two classes of time in the 'long' and 'short' syllables in prosody and in the dashes and dots of the Morse alphabet. With regard to music he studied excerpts from 15 pieces of piano music and found that in each piece two note values, in a ratio of 2:1 or 3:1, were dominant. Of course, there were other note values as well, but they were seen as somehow 'occasional'. The shorter note value corresponded to a duration of 135–410 ms in different pieces, which agrees well with the 'short times' in the above-mentioned experiments; the longer note value corresponded to 270–860 ms ('long times'). Fraisse (1981) further argued that the limitation to two durations relates to our inability to 'discriminate in an absolute way more than two durations in the range of perceived durations (from 10 to 200 centiseconds) (1981, p. 220).

However interesting this may sound, the theory seems simplistic from a musical point of view. There are certainly many pieces dominated by only two note values, but to make a generalization from only 15 pieces is unwarranted. To provide only one counter-example, consider another piano piece, the beginning of Beethoven's Piano Sonata Op. 14 No. 1 (Fig. 2.4). In the exposition of the first movement at least four note values (semibreve, crotchet, quaver, and semiquaver) play an important role in the themes and in the elaborations and transitions between them. A listener should have no difficulties in recognizing them as four different categories.

To reduce timing in music to be a matter of essentially only two classes of duration is not very convincing. And no empirical evidence is given to support the statement that we are unable to discriminate in an absolute way more than two durations within 10-200 cs.

Articulation

Legato and staccato are contrasting forms of articulation. In legato (or even legatissimo) the sounding tone goes on all the way until the beginning of the next tone with no perceptible break between the tones. In staccato (and even more in staccatissimo) the sounding part of the tone is very short and is followed by silence until the onset of the following tone. The silent part is often considerably longer than the sounding part. Between legato and staccato there are various intermediate levels such as non legato,

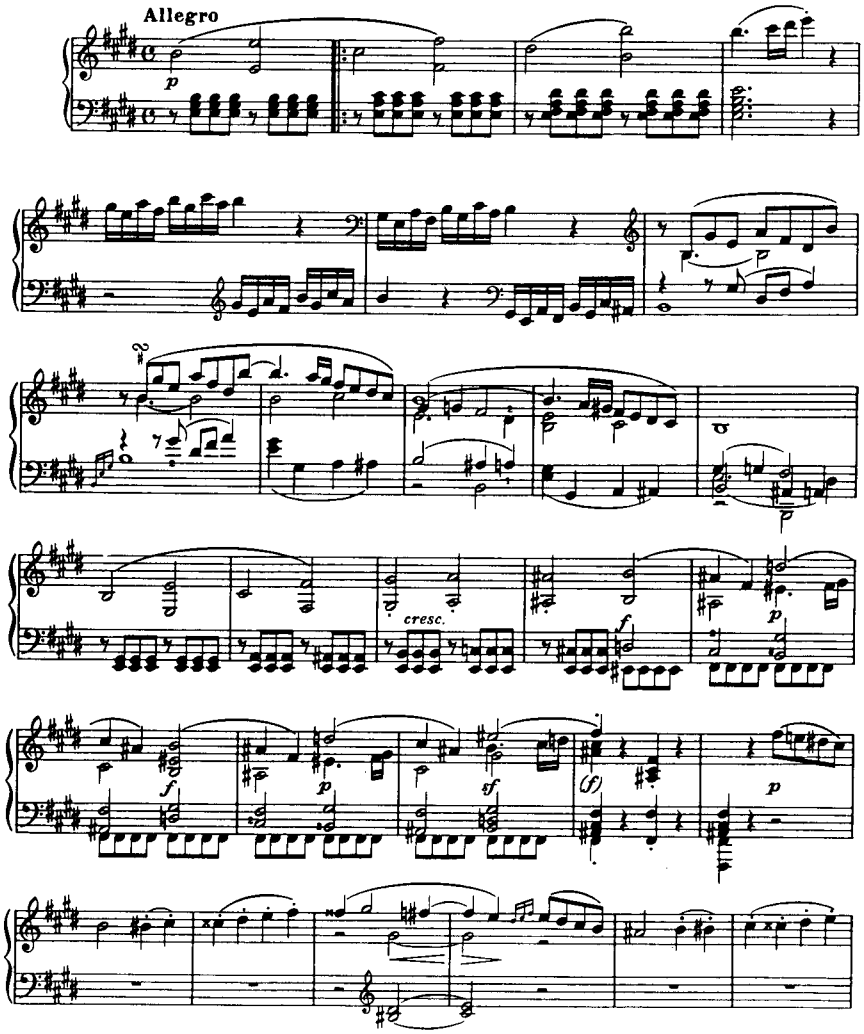

Fig. 2.4. The beginning of Beethoven's Piano Sonata Op. 14 No. 1. (From *Beethoven, Klaviersonaten, Band I*, G. Henle-Verlag, München-Duisburg, 1952. Reproduced by permission from G. Henle Verlag.)

portato, and marcato; for string instruments there are also other terms such as *detaché* and martellato.

In the score the type of articulation is indicated by the above labels and/or by various graphic signs at the notes, such as points (staccato), dashes, wedges, bows, and various combinations of these. The silent part of the tone may be written as a rest, for example, ♩ (staccato) might instead be written as 𝅘𝅥𝅯 𝄾 𝄾 .However, a frequent use of rests makes the

score hard to read and is usually avoided. When there is no indication at all of the articulation, this may be interpreted as legato, or that the articulation should be as is usual for this kind of music, for this type of musical ensemble etc. Sometimes the title of the piece or other designations suggest the proper articulation. Composers differ very much with regard to how accurately they prescribe various articulations.

Whatever the case may be, the articulation is achieved by timing in performance—timing to get the intended or proper proportion between the sounding and non-sounding parts of the tone(s). From an acoustical point of view the situation is very complex, since the performer's control of this timing is affected by the properties of different instruments and by the acoustics of the room. For instance, articulation on the violin is different from articulation on the organ, and playing in a small room is different from playing in a cathedral. Moreover, a perceptual distinction between the sounding and non-sounding part may not reflect acoustic reality: the tone may be sounding all the time, first loud and then soft (for example, in reverberation)— however, so soft that it is masked or otherwise perceptually silent.

The importance of the articulation is well known by performers and is given much attention in musical training. However, there have been few empirical investigations of the performance of articulations in various situations. Even if careful physical registrations are made of the performance, they have to be supplemented by judgements from listening in order to clarify the relations to the perceived articulation. One way of approaching these problems is by means of synthesized sound sequences, which are judged by listeners. An example is given in Fig. 2.5, which contains four bars of a usual form of waltz accompaniment (see the notation at the top). Eight versions were synthesized to represent (almost) legato performance in all three beats of the bar (version 1), staccato performance in all three beats (version 8), and various combinations of legato and staccato in versions 2–7 (for example, legato in the first and second beats but staccato in the third as in version 2). The example is taken from Bengtsson and Gabrielsson (1983), and the sound example appears on an appended phonograph record. Lacking this, you may perform or try to imagine the eight versions yourself.

The perceptual effects of these manipulations are striking. The basic tripartite structure of the bar is felt the same way in all cases, but there is a tremendous difference in the motional-emotional character of the eight versions. Some of them are completely 'impossible' and sound ridiculous (nos. 1 and 5), while the others represent more or less plausible alternatives, each of them with a specific character.

This example was in fact not primarily made to discuss waltz accompaniment, but to demonstrate the effects of different articulations in a systematic way. Considering the possibilities available in real music

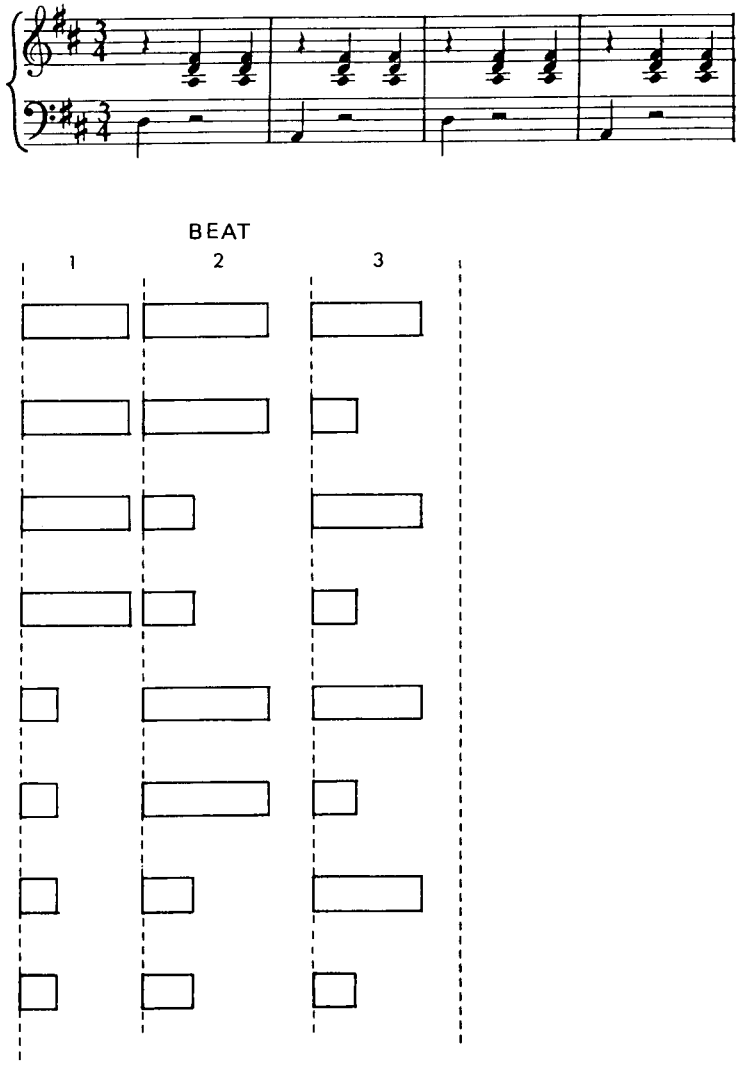

Fig. 2.5. Different articulations of a common accompaniment to waltzes, see further in text. (From Bengtsson and Gabrielsson 1983, p. 45. Reproduced by permission from the The Royal Swedish Academy of Music, Stockholm.)

performance—using even more legato or staccato, or intermediate levels such as non legato or portato (and still finer gradations for which we lack words), and combining them with dynamic means, etc.—we begin to realize the scope of the articulation repertoire available to the performer, and how he may use it to generate so many different and subtly varied

experiences, which we feel so well but which elude our attempts at verbalization.

Deviations from mechanical performance

A spontaneous response to music boxes, rhythm machines, and the like is that they sound mechanical, dead, and boring. The main reason for that is the mechanical regularity in their 'performance': absolutely constant tempo, and perfect ratios (1:1, 2:1, 3:1, etc.) between successive sound events. It is generally known that human performance is not like that, and various types of deviations from mechanical regularity were described in the early investigations by Sears (1902), Hartmann (1932), and the research group around C. E. Seashore (1938); these are summarized in Gabrielsson (1985).

Extensive studies of music performance have been made in Uppsala, Sweden, in collaboration between musicologists and psychologists (Bengtsson 1974; Gabrielsson 1974, 1982*a*, 1982*b*, 1985, 1986; Bengtsson and Gabrielsson 1977, 1980, 1983; Gabrielsson *et al.* 1983; Gabrielsson and Johnson 1985). The general purpose has been to investigate timing in performance, especially with regard to deviations from mechanical regularity in different types of music and with different performers. In most cases the performances were especially for this research project, but performances stored on phonograph records or magnetic tapes are used as well. They are analysed by means of special electronic equipment (Tove *et al.* 1966), which simultaneously displays the variations of fundamental frequency ('pitch') and total amplitude (intensity). By adequate filtering and calibrations it is possible to get very accurate representations of monophonic performances and in many cases also of polyphonic music. The durations may be measured with an accuracy of ± 5 ms. An example of a registration is given in Fig. 2.6.

More recently the equipment has been supplemented by a computerized synthesizer and a sampling system. This allows digital recording and storing of performances, live or recorded earlier. They can be studied in extreme detail with a time resolution of 20 μs and can be manipulated in various ways; for example, any parts(s) of the performance can be extracted for detailed listening and analysis of transitions between tones, for spectral analysis, etc. (see Fig. 2.7 for some illustrations).

Despite the high accuracy there are still problems in certain cases, especially regarding physical and perceptual tone onsets as well as decays. While Wagner (1974) and Shaffer (1980, 1981) make registrations of piano performance directly at the sound source, our techniques mainly rely on registrations by microphone, for any instrument, placed at a distance in the room. The acoustical events thus registered are often complex. Tones

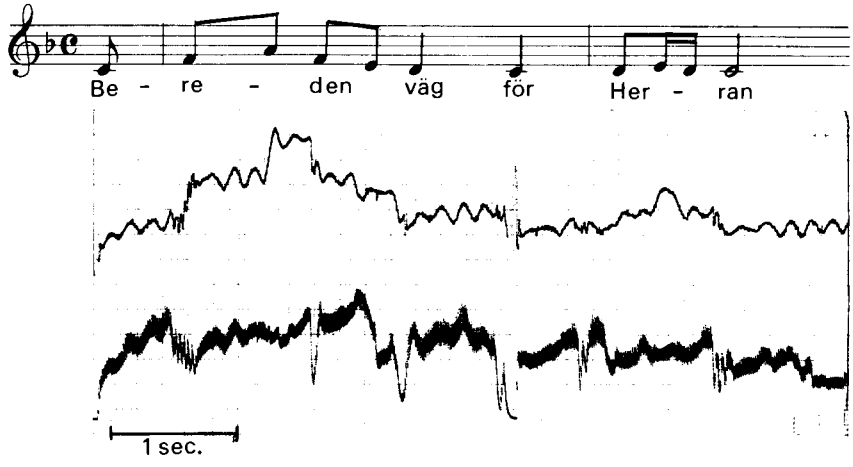

Fig. 2.6. Registration of a professional singer performing in the first phrase of a Swedish folk chorale. The upper curve shows the fundamental frequency, the lower curve the intensity (calibration values not given here). Note the continuous variation in both curves, including vibrato and various glidings. The notes in the notation have been put to positions approximately corresponding to the onsets of the respective tones as seen in the registrations below. For further description, see Gabrielsson and Johnson (1985).

appearing after another in the score overlap each other in the acoustical reality and make us wonder exactly when, and because of which specific feature in the ongoing stimulus, the listener detects the onset of the next tone. This is one reason why performance studies have to be supplemented by studies of the listener's experience. Other, more general, reasons for that are discussed later.

On the other hand the deviations from strict regularity in performance are usually so obvious that they are detected by any reasonable technique in spite of the above-mentioned difficulties. The results described below come from monophonic performances on the flute, the clarinet, and the piano, and from orchestral performances. The music is Western art music, popular music, and folk music; many of the pieces are of Swedish origin. The statistical analysis of the data obtained for each performance generally proceeds as follows:

(1) Calculate the total duration of the performed piece (however, often omitting the very last tone, since its duration may be difficult to measure accurately).

(2) Transform the duration of each tone (from its onset to the onset of the next tone) to per mille of the total duration.

(3) Take the difference between this per mille value and the per mille value the tone would have had in a completely mechanical performance.

The last step thus gives the difference (deviation) for each tone, between the real performance and a mechanical performance. The deviation values are tabulated and/or displayed graphically as in Fig. 2.8 below. Then follows:

(4) Perform adequate statistical operations to get measures of central

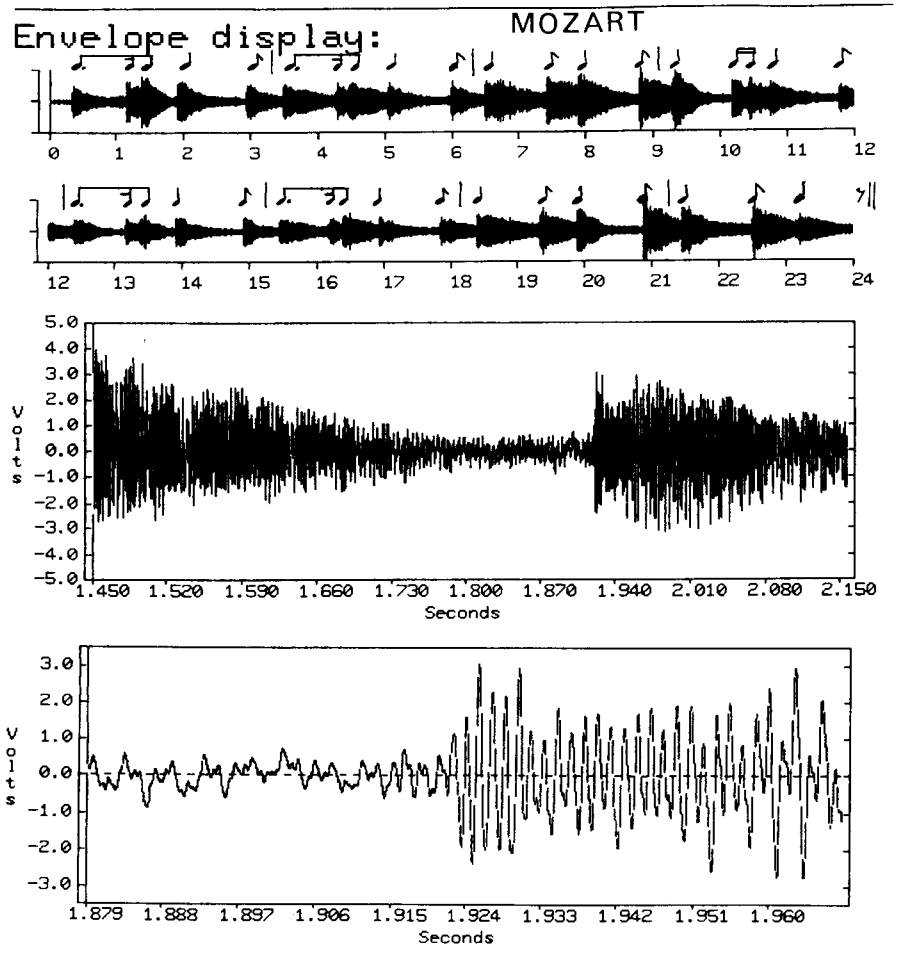

Fig. 2.7. Examples of registrations obtained from a sampling system (Synclavier II) for the pianist Ingrid Haebler's performance of the initial eight bars of Mozart's Piano Sonata in A major (K. 331; see the notation in Fig. 2.8 below). The *upper* figure shows the amplitude envelope; the onsets of the chords are clearly seen (the rhythmic notation is added here to facilitate the understanding of the figure). The numbers represent time in seconds. The *middle* figure shows the decay of the third chord and the onset of the fourth. The *lower* figure displays this in more detail: the very end of the third chord and the beginning of the fourth.

tendency and dispersion for various entities, calculate proportion values for neighbouring tones, etc., within the single performer and over several performers.

(5) Perform factor analysis on the deviation values from different performers or versions to see if there are some characteristically different ways of performing the piece.

This is only a very condensed description, and many other calculations are made, depending on the specific results for each piece or performer (see Bengtsson and Gabrielsson 1980 for details). However, the principle is to find out the deviations from mechanical performance, and to see whether they are the same for all performers, or if there are different types of deviations.

As expected, frequent deviations appear in all investigated cases. However, they are different in different pieces of music and also often between performers. A detailed description can thus only be made in connection with a certain piece and performer, for which the reader is referred to the original papers. Here we will only briefly describe some fairly common tendencies, proceeding from smaller to larger entities.

Sequences of equally long tones (according to the notation in the score), for example ♩ ♩ or ♫ , often show a long-short (LS) or short-long (SL) relation between the two tones; that is, the first tone is longer than the second (LS), or the converse is true (SL). Which alternative appears depends on the context as well as, sometimes, on the performer. In a sequence like ♬ the pattern is often LSSL, that is, the first and the last quavers are lengthened, the two middle ones shortened; but LSLS or SLSL patterns may also occur. In a pattern such as ♩ ♫ the quavers are often performed SL, while the relation at the crotchet level may be LS (the crotchet is longer than the two quavers together) or SL. The corresponding phenomena appear in the analogous ♬ sequence. In patterns such as 𝅗𝅥 ♩ in 3/4 metre and ♩ ♪ in 6/8 metre there is usually a much lower proportion than the mechanical 2:1 ratio between the two tones; it is often between 1.7:1 and 1.9:1 (cf. the example in Fig. 2.8) and may approach 1.5:1 in certain cases. But there are exceptions: for instance, in a march notated in 6/8 metre the ♩ ♪ sequence was performed close to the 2:1 ratio. This suggests that the general motion character of a piece is a decisive factor for the performance of various sequences within it.

The performance of dotted note values such as in ♩. ♪ or ♩. 𝅘𝅥𝅯 varies very much depending on context and performer. The mechanical ratio is 3:1, but the real ratio may be higher than ('sharp dotting'), lower than ('soft dotting'), or close to 3:1. It seems obvious that a ratio higher than 3:1 gives a more marked and 'jerky' character, while a ratio lower than 3:1 tends to sound 'softer'. If there are several sequences with the same type of dotting , it may happen that the dotting is made progressively 'softer' during the course of the phrase. A double dotting like ♩.. 𝅘𝅥𝅯 has a

mechanical ratio of 7:1 but may deviate very much from that in actual performance, sometimes down to about 4:1 or even lower.

At the beat level a well-known example of deviations is the accompaniment in Viennese waltzes. The first beat is considerably shortened, and the second beat thus comes 'too early', which (together with other factors) gives an unmistakable motion character to these waltzes. A synthesized sound example, which demonstrates the perceptual effects of the second beat coming earlier and earlier, is given in Bengtsson and Gabrielsson (1983). There are numerous other examples of deviations at the beat level, more or less specific for each piece; we found, for instance, that in the popular tune 'Oh my darling Clementine' the third beat was generally lengthened.

At levels corresponding to half-measures, measures, and to still larger entities there are deviations of various types, which have to be described in connection with the performed piece. Some results were mentioned under 'Tempo' above. In order to have at least one concrete example of several phenomena mentioned above, we may look at Fig. 2.8. It shows the performance of the first eight bars of Mozart's Piano Sonata in A Major

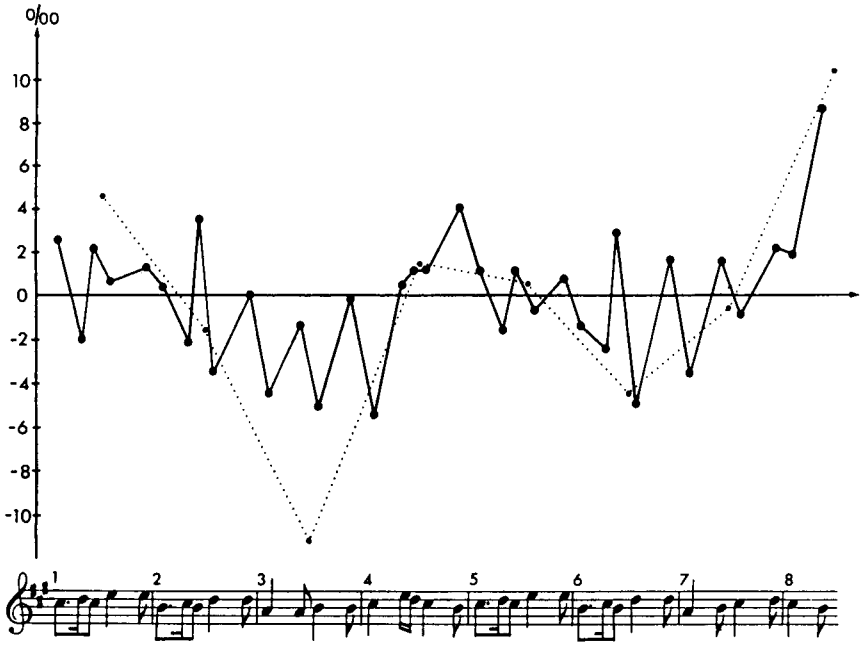

Fig. 2.8. Deviations from mechanical performance in the pianist Ingrid Haebler's performance of the beginning of Mozart's Piano Sonata in A Major (K. 331). The deviations are expressed in per mille of the total duration (until the last tone); one per mille corresponds to approximately 23 ms. See text for further explanations.

(K. 331) by the pianist Ingrid Haebler, renowned interpreter of Mozart. The horizontal line marked 0 represents a mechanical performance. The deviation for each tone is given by the black circles joined by the whole-drawn profile. A position above the zero line means that the corresponding tone is lengthened, a position below this line says that the tone is shortened, in relation to mechanical performance. The profile for the ♩. ♪ ♩ in the beginning of bars nos. 1, 2, 5, and 6 is V-shaped, that is, the dotted quaver and the last quaver are (relatively) lengthened, the semiquaver shortened. The sequences of ♩ ♪ are performed with the crotchet shortened or slightly lengthened; the quaver is mostly lengthened or less shortened than the crotchet. The ratio between the crotchet and the quaver is thus lower than 2:1. In average over all cases it is 1.76:1, but it varies from 1.92:1 down to 1.50:1. The dotted profile shows the deviations at the measure level. It is seen that the relation between the four bars in each half-period is LSSL, that is, the first and the fourth bars are longer, the second and third shorter. In other words, the tempo varies: somewhat slow start, accelerating in the second bar to reach the fastest tempo (= largest deviation downwards) in the third bar, then retarding towards the end of the half-period in the fourth bar. A similar profile is seen in the second half-period (the marking for the eighth bar refers to the first half of this measure). Many further observations can be made, but this may suffice to illustrate the general idea. Of course, the amount of data and interpretation grows considerably for analysis of longer examples.

Relations to the listener's experience

Results from performance studies must be interpreted with caution for several reasons. They may be more or less specific for the individual performer. The aforementioned factor analyses usually indicated two or three different ways of playing even very short pieces, and the variation among different performers' interpretations of a musical work is well known from general musical experience. There may be intra-individual variations as well. The musician changes his performance from time to time, sometimes deliberately in order to present a 'new' interpretation, sometimes unconsciously and for obscure reasons, still other times for adapting to the acoustical conditions (for example, changing the tempo).

To find truly general results in performance data is therefore difficult. The generalities should rather be sought in the *relations between performance and* (the listener's) *experience*. The performance is the overt manifestation of the composer's and/or the performer's idea, and it is the stimulus for the listener's experience of the music. However, the performer is also a listener—he continuously checks that there is a correspondence between his intentions and the music he produces. He strives to convey his

experience of the music as truly as possible to his listeners—so that they should experience the music as he does. The performance is a link joining the performer's experience and the listener's experience.

Of course, various individual characteristics (life history, attitudes towards music, personality traits etc.) affect the experience and make it more or less different for the performer and any individual listener. But there is usually also much in common, and we may assume that this communality is based on 'natural' relations between performance and experience—in other words, that *certain properties of the performance elicit certain qualities in the experience.* Long ago H. Seashore (1937, p. 118) expressed this opinion in the following words:

> The psychophysical relations between the performer and the listener must be worked out; the data presented will contribute to such studies and also will depend for their final interpretation upon such investigations.

However, practically nothing has been done in the direction suggested by H. Seashore. We still discuss the relation between performance and experience in very general terms, as when C. E. Seashore stated that deviation from the regular is a general principle of art, or that 'deviation from the exact is . . . the medium for the creation of the beautiful—for the conveying of emotion' (quoted from H. Seashore 1937, p. 155). My repeated suggestions that various performance characteristics may affect structural and motional-emotional aspects of the experience is another example of such general propositions.

A basic difficulty is that we have no clear identification of the numerous dimensions which constitute our experience of music, nor do we have adequate methods to study them in a reliable way. It is my guess that non-verbal methods will play a greater role in future work on these questions. To study the relations between performance and experience we furthermore need a kind of iterative interplay between analyses of performed music and systematically varied syntheses of 'music'. A beginning of such a programme, with special reference to performance and experience of musical rhythm, is sketched in Gabrielsson (1985).

Meanwhile I again suggest that the frequent deviations from mechanical performance have structural as well as motional-emotional consequences. The experienced structure is certainly affected by variations of tempo, various other deviations, articulation, etc. (see Sloboda 1983). At the same time, however, these phenomena have obvious motional and emotional qualities: to accelerate or retard the experienced flow of the music, to provide a march or a Viennese waltz their proper motion characters, to make a dotting feel 'jerky' or 'soft', etc. For instance, the 'early second beat' in the Viennese waltz does not essentially change the basic tripartite structure of the bar—but it does change the experienced motion character.

Listening to synthesized, systematically varied sound sequences reveals that the ratio between the durations of adjacent tones may vary a lot without obscuring their structural relations (experiments to be reported). This indicates, among other things, that rhythm perception is categorical, and that considerable variation is available within the categories to affect various motional-emotional qualities. Similar results are obtained for synthesized melodies. Some of the variation in performance data may be accounted for in terms of such effects.

Concluding remarks

In this chapter timing has been treated in isolation from other means used by the performer, such as dynamics (in a wide sense), intonation, and spectral variations. Moreover, different aspects of timing (tempo, classes of duration, articulation, deviations from mechanical regularity) have been discussed separately from each other. In reality, however, all these means occur together in a complex, ever-changing interaction, depending on the instrument, the performer, and the situation. It is for the purpose of understanding the ingredients of this interaction that the present analytic approach may be justified. I hope it has also made clear the importance of studying the *sounding* music and its relations to the listener's experience rather than staying content with the simplistic picture given in musical notation. Studying the relations between performance and experience means coming very close to the musical reality, and is a fascinating challenge to all of us.

Acknowledgements

The author wants to express his gratitude to Ingmar Bengtsson, Barbro Gabrielsson, Dan Malmström, Peter Reinholdsson, and Bo von Schéele for invaluable collaboration in discussions and experiments. The investigations were supported by The Swedish Council for Research in the Humanities and Social Sciences, The Bank of Sweden Tercentenary Foundation, Knut and Alice Wallenberg's Foundation, and Uppsala University.

Computer synthesis of music performance

JOHAN SUNDBERG

Introduction

Background of the project

This chapter presents a research project which was started some years ago. Its goal has been to analyse music performance by synthesizing it using a digital computer.

The origin of this project was apparently chance, as is the case with so many other research projects. Three crucial circumstances appeared in combination at the same time and in the same place.

One circumstance was the construction of the singing synthesizer MUSSE (see Larsson 1977), which offered synthesis of sung vowels. These synthetic vowels sounded very natural, as the interested reader can hear from sound illustrations published in Sundberg (1978). When this synthesizer could be controlled from a computer, it could be programmed with melodies, which were subsequently performed by the synthesizer. Musically experienced listeners typically noted that these performances sounded like a singer who was gifted with a good voice but who unfortunately lacked the desire to communicate anything in particular with his singing. This raised the question as to exactly what it is that the performer adds to the music score.

A second circumstance was the author's contact with Lars Frydén, a musician with an extensive background as a violin soloist and quartet player, as well as an accomplished teacher of violin playing at higher levels. His long-term musical experience had resulted in a number of hypotheses regarding some basic principles for the conversion of note signs into sounding music and also in a desire to test these hypotheses.

A third circumstance was the fact that at the laboratory, two of the author's colleagues, Rolf Carlson and Björn Granström, had devoted much work and ingenuity to the conversion of text to sounding speech (Carlson and Granström 1974). This had resulted in computer facilities offering means to synthesize by rules. These rules could concern not only

pronunciation but also pitch contour and timing. It appeared that the task of converting text signs to speech sequences was in important respects similar to the task of converting note signs to tone sequences.

These three circumstances, in no way related to each other, turned out to form a good platform for attempts to improve the musical quality of computer-generated performances of music. Several reports have been published on this project over the years (Sundberg *et al* 1983*a*, *b*; Sundberg and Frydén 1985). This chapter aims both at presenting the strategy, including its advantages and limitations, and at mediating some experiences that have been gained in working with the project.

Topic

It is a well-known fact that traditional music sounds musically unacceptable when performed by a digital computer in an exact agreement with what is nominally given in the music score. This implies that the discrepancies between the sound sequences shown in the music score and those really generated in music performance constitute an essential part of music communication.

Evidently, these discrepancies cannot be random; for instance, it takes considerable training to learn playing, and, also, there is mostly a general agreement among competent listeners as to what is an unacceptable performance of a piece of music.

The above suggests that the discrepancies between notation and sound must be in some sense meaningful, that is, they carry information which the listener needs in order to enjoy listening to the performance. From the point of view of scientific research this is an interesting fact. What is this information? How is the acoustic code chosen which is used by the musician for conveying it? Is this code used in music only or is part of it borrowed from extramusical communication? These question touch on basic aspects of music communication. It seems that important contributions to the answers could be found by analysing music performance.

Nevertheless, music performance has attracted comparatively few researchers in the past (see Sloboda 1982). After Seashore's pioneering work in the thirties (see Seashore 1938), the work of Ingmar Bengtsson and co-workers, started more than two decades ago, remained more or less singular for a long time. (A recent account of their work is given in Bengtsson and Gabrielsson 1983). Researchers in the music acoustic area have been no exception in this respect, even though music performance must be regarded as an essential topic in the science of musical instruments; for instance, it would be hard to define 'instrument quality' were there no scientific understanding of exactly what the sound characteristics are which the musicians make use of when they play their instruments. However, during the last few years, the scientific interest in

music performance has increased considerably (see for instance Clynes 1983). Perhaps the reason for this is the significance of such research to music which is performed without musicians, such as electro-acoustic music, particularly computer music.

The key questions in scientific research are *how?* and *why?* Applied to music performance they concern *how* the note signs are related to their corresponding acoustic signals in acceptable music performances; and *why* such a performance deviates from the nominal values specified in the music score. The present project attempts to contribute to the answers to these questions by formulating and interpreting rules for the conversion of note signs into sounding music.

Method

Set-up

Music performance can be studied by means of two different strategies, namely (1) measurements (see Bengtsson and Gabrielsson 1980) and (2) analysis-by-synthesis. *Measurements* have revealed a complex reality, to say the least. Seashore (1938) found that tones having the same nominal value in the music score occasionally may differ widely in duration. For instance, in the same piece a crotchet sometimes may be played shorter than a dotted quaver and sometimes longer than a dotted crotchet. Similar observations have been made in subsequent studies of timing in music performance (Bengtsson and Gabrielsson 1977; Sloboda 1983). It seems that the rules relating notation to sounding music are numerous and form a complex system. However, when combined with systematic experiments, measurement of music performance is a useful method.

Analysis-by-synthesis is a well-established method in natural sciences, including speech research, of testing hypotheses. When applied to music performance, hypotheses can be tested regarding rules for the conversion of note signs to tones. Thereby, even aspects of performance for which there is no generally accepted term may be investigated, so that a great variety of effects can be investigated.

The block diagram in Fig. 3.1 describes the procedure used in the present project. The overall aim is to convert a melody into tones according to a set of ordered rules. Using a program written by J. Liljencrants the one-part input melody can be written in ordinary music notation on the computer's graphic terminal. In addition to the information normally included in a music score, special signs were introduced to mark (1) chord changes and (2) boundaries between phrases and subphrases.

The rule system then converts the entire string of signs into a string of tone symbols. The rules are expressed in a special programming language,

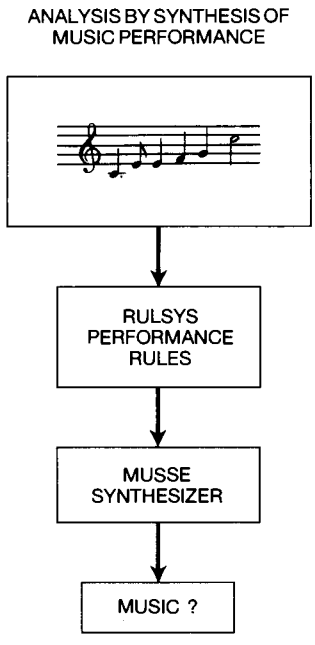

Fig. 3.1. Block diagram of the procedure used in the present project.

'RULSYS', written by Rolf Carlson and Björn Granström (1975) and originally devised for expressing rules regarding pronunciation, etc. in a text-to-speech conversion, as mentioned. The entire melody is processed by each rule in the order given by the rules in the system. The end result is that the tones are represented by vowel symbols which possess a number of different characteristics, such as duration, fundamental frequency, amplitude, vibrato amplitude, and other parameters, which can be manipulated by the rules. Finally, these characteristics are converted into control voltages for the MUSSE synthesizer.

In the present experiment the sound characteristics of the synthesizer were adjusted so as to be similar to the timbre of a double-reed wind instrument with a small vibrato. The fundamental frequencies were in accordance with the equally tempered scale, and could be modified in steps of 7 cents, which is close to the difference limen for frequency in normal subjects (Rakowski 1971). The amplitude was controlled in steps of 1/4 dB. The duration of the tones was computed in ms and then converted into cs. According to measurements by van Noorden (1975) a change in the perceived rhythm of a sequence of tones appeared when the durations were changed by more than 10 ms.

Procedure

As mentioned, the basic idea of the analysis-by-synthesis strategy is that of testing hypotheses. The long-term musical experience of my co-worker Lars Frydén has resulted in a number of hypotheses regarding basic principles for converting note signs into tone sequences.

The hypotheses suggested by Frydén have been expressed in terms of rules which have been implemented in the rule system. Each hypothesis has then been tested informally by listening to several examples which clearly expose the sounding consequences of the rule. Depending on the result, the rule has then been modified. Eventually, formal listening tests were realized in which musically highly competent listeners compared two slightly different versions of the same melody; in one version, all rules were applied in generating the performance, and in the other version all rules except the one tested by that example were applied. In this way each rule can be validated to the extent that it can be decided whether or not it significantly contributes to raising the musical quality of a performance of the melody tested.

Rules

Our present rule system includes about 20 rules. Some of these rules have been presented in detail together with sound examples in some previous reports (Sundberg *et al.* 1983*a*, *b*; Sundberg and Frydén 1985). Even though some rules have been more or less modified since then, only a few examples of the rules will be presented in this section; all of these have been approved of by a listening panel, unless otherwise stated.

The formulation of the rules is quite simple. The basic form of a rule is 'Every note possessing the characteristics A, B, . . . should be assigned the characteristics of D, E, . . . provided that is preceded by F, G, . . . and followed by H, I, . . .'. The context is optional. Also, there are means to fetch values from tones far back and far ahead in the sequence of note symbols.

There are several rules which work within a narrow time window including two or three notes only. In other words, the context is short. Some examples of such rules are the following.

(1) *The higher, the louder.* The amplitude is increased by about 3 dB per octave rise in fundamental frequency.

(2) *Heightening of durational contrasts.* This rule simply states that short note values are shortened. The shortening is very small indeed and, in terms of percentage, it is higher for quavers than for crotchets. No compensaion, such as a pause, is made for the resulting perturbation of the strict regularity of the beats.

(3) *Softening of durational contrasts.* In apparent contradiction to the previous rule this rule states that the durational contrast should be *reduced.* However, there is an important contextual condition for applying the rule, namely that the note is preceded by a note of twice its duration and followed by a tone with longer duration. This rule has not yet been tested in listening experiments.

(4) *Shortening of start tone in rising intervals.* The duration of a note initiating a rising interval is slightly decreased. In sequences of rising intervals the rule has the effect of increasing the tempo somewhat. As before, no compensation is made for the resulting perturbations of the meter.

There are also some rules which work with a wider time window. For these rules the signs representing chords and phrase and subphrase boundaries are decisive. In the input notation the chords are indicated by numbers representing the distance in semitone steps from the root of the chord to the root of the tonic. This number may be complemented by a sign for minor chords. As regards the phrasing we assume that melodies are built up by phrases, which consist of two or more subphrases. The boundaries between such phrases and subphrases are marked in the input notation.

(5) *Marking of harmonic charge.* This rule generates crescendos/decrescendos and ritardandos/accelerandos reflecting the chord progressions.The technicalities are as follows.

The rule assigns to each chord a value reflecting its *harmonic charge.* This harmonic charge is a weighted sum of the chord notes' *tonic charges**. As illustrated in Fig. 3.2, the tonic charge reflects the note's distance from the root of the tonic along the circle of fifths. The harmonic charge value is converted into an amplitude increment, which equals 6 dB for the highest harmonic charge. This amplitude increment is added to the first tone appearing over each chord. Then, the amplitudes of the intermediate tones are linearly interpolated on a dB-scale. Too-slow crescendos are avoided by letting the amplitude remain constant until about 2 s before the new chord appears. The result is crescendos and decrescendos towards harmonic changes which introduce chords having a higher or a lower harmonic charge than the preceding chord, respectively. Figure 3.3 demonstrates how the rule operates. This rule has not yet been verified by a formal listening test.

In addition to this, the tempo is also decreased and increased in synchrony with the crescendos and the diminuendos, respectively. These

* In previous reports on this project the terms 'harmonic distance' and 'tonic distance' have been used. However, as pointed out by Drs D. Butler and H. Brown, Music Department, Ohio State University, Columbus (personal communication), the word 'distance' may be misleading. The term 'charge' seems preferable, although a similar term, '*Quintspannung*', was defined slightly differently by Kurth (1917).

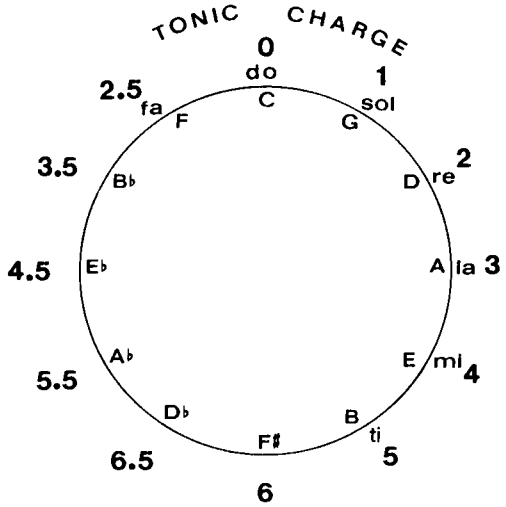

Fig. 3.2. Values of tonic charge for the various tones in the diatonic system. The tonic charge of a tone depends on the tone's distance from the root of the tonic along the circle of fifths. The *harmonic* charge value can be computed for any chord as a weighted sum of the chord notes' *tonic* charge values.

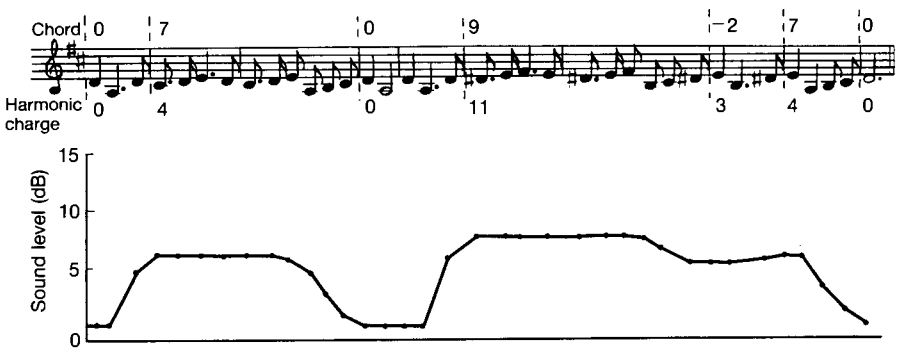

Fig. 3.3. Illustration of the amplitude effects of the rule reflecting changes in the chords' harmonic charge as applied to the second theme from the first movement of Schubert's Symphony No. 8 in B minor, 'Unfinished'. The chords are symbolized by numbers corresponding to the interval (in semitone steps) between the root of the chord and the root of the tonic (top line); the minus sign represents a minor triad. The numbers below the staff represent the chord's harmonic charge value. Crescendos and decrescendos accompany increases and decreases of harmonic charge, respectively.

tempo changes mostly involve note lengthenings of 0 to about 15 per cent. (6) *Phrase and subphrase marking.* The rule first adds 4 cs to the note terminating a phrase and 4 additional cs to the final note of the melody. In addition the final note in each phrase is terminated by a short pause, as the amplitude falls to zero during the last 20 per cent of the note's duration. Similarly, in notes terminating subphrases, the amplitude decays to zero during the last 80 ms of the note.

Discussion

All these rules share an *ad hoc* character, and in some cases they may even seem mysterious. Therefore, a primary concern is to verify the rules. This can be realized in various ways. Before this, it is necessary to consider a more general question, namely the apparent contradiction between two obvious facts: on the one hand, a melody can be played in many different ways, all of which are fully acceptable from a musical point of view; on the other hand, a rule system will predict only one single performance of a given melody.

First it should be pointed out that identity with respect to the sequence of notes does not imply that the melodies are the same. This relates to an experiment recently carried out by Sloboda (1983), who had pianists play a set of melodies several times. Two melodies in this set were identical except for the location of the bar lines. The performances of these two different but 'homonymous' melodies were then analysed. The performances of the most experienced players differed consistently with respect to both timing and amplitude in certain places in the melody. The question then is whether or not different performances will be generated by our rule system in such a case. The answer is yes; the input notation may differ even in cases where the note sequence is identical, because in the input, signs are added for chord changes and phrase and subphrase boundaries, and these would differ in a case such as the one used in Sloboda's experiment. Thus, two slightly differing performances will result, if the rule system processes such 'homonymous' melodies. In many cases it is not even necessary to move the bar lines or the chord changes for obtaining different interpretations in terms of phrase and subphrase boundaries. Music is often ambiguous in this respect, and these ambiguities will cause our rule system to predict differing performances.

Apart from these cases, where the same sequences of tones represent different melodies, there is another possibility for our rule system to predict a variety of performances for the same melody. Even though this possibility has not yet been explored, it will be mentioned here. In our present rule system there are about 20 rules, and several of these affect one parameter, such as the duration of the note. This means that the duration

of one single note in a melody may be lengthened by some rules and shortened by some other rules. Still it is obvious that our system is not yet complete; there must be more rules, which would add to the musical quality of the performance. Introducing them into the rule system may cause problems, though. It seems likely that there is an upper limit on the number of rules which can be used simulaneously to affect one specific sound parameter. Perhaps there are many rules which are alternative, so that the musician may make a new selection of the alternative rules he wants to apply each time he plays the piece. This possibility should be tested in future research. In any event, it would lead to a rule system that could generate different performances of the same piece.

As suggested before, the above has important implications for the possibilities of verifying the different rules in music practice. Obviously, it is not correct to assume that eventually there will be a perfect match between the performance predicted by a complete rule system and an actual perfect performance, as there are many perfect performances. Still, similarities may occasionally occur in some actual performances, so it is still meaningful to compare generated and observed performances.

In Fig. 3.4 a performance predicted by the rule system is compared with

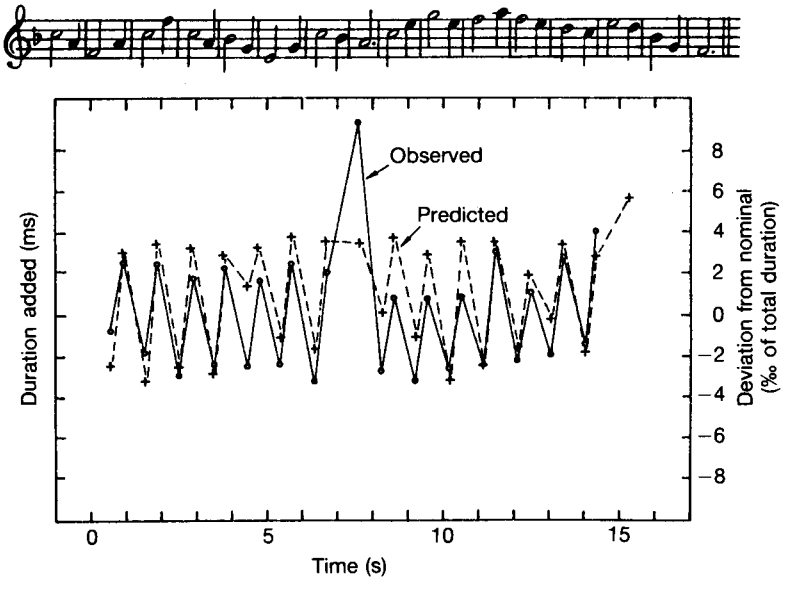

Fig. 3.4. Comparison of observed and predicted durations in a performance of the melody shown. The predicted values are given in cs, and the observed values, quoted from Gabrielsson and Bengtsson (1983), are given in thousandths of the summed duration of the melody.

an actual performance as measured by Gabrielsson and Bengtsson (1983). The figure compares observed average deviations from nominal note values in actual performances with the deviations predicted by the rule system. It appears that rule (3), which reduces durational contrasts in halving of duration, has had a major effect on the end result. Actually, this rule, which was not yet verified in a formal listening test, seems to be efficiently validated by the good agreement between observed and predicted data. Such a high degree of agreement between predicted and observed performances is rare. Particularly in more complex melodic structures, such as the one illustrated in Fig. 3.5, the relationship between observation and prediction is much less clear.

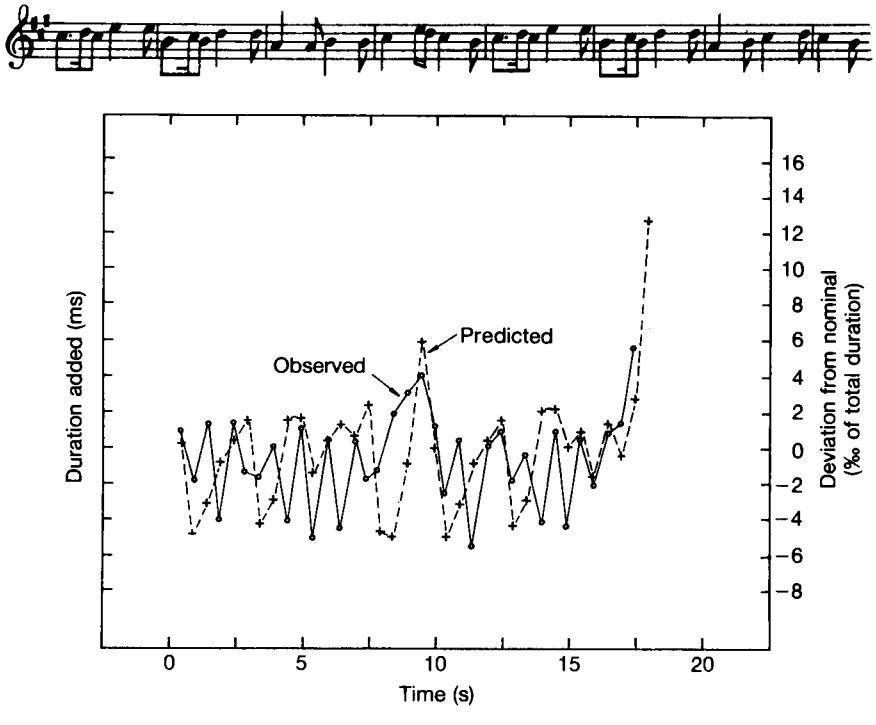

Fig. 3.5. Same type of comparison as in Fig. 3.4 regarding the theme of the first movement in Mozart's Piano Sonata in A (K. 331).

What do such similarities and dissimilarities between predicted and observed performances tell us? Our rule system can be regarded as a predictive model of the reality manifested in music performance. When there is an agreement between observation and prediction, it is safe to conclude that the predicting model represents a fair description of reality.

However, the reverse does not seem to be necessarily true. In other words, a disagreement cannot be used for rejecting the model. The reason for this is the fact that there are many ways of performing the same melody which, although differnt, are all musically perfectly acceptable. Rather, the criterion for an acceptable system of rules is that experienced listeners agree that the performance generated by the rule system sounds musically acceptable. This has been tested in the listening experiments mentioned previously. An evaluation of the complete rule system will be carried out in the future (see Thompson *et al.* 1986).

Let us know turn to a different aspect of the results, namely the quantity of the rules; that is, *how much* amplitude or duration, etc., is added by the various rules. The first question to consider is then to what extent random variation of duration can be tolerated in musically acceptable performances (Gabrielsson and Bengtsson 1983). Our experience is that, mostly, duration changes as small as 10 ms can be noted in motor music (where there is a rapid sequence of beats). This is in accordance with van Noorden's results (1975). It implies that random variations of duration must be smaller than 10 ms, as, obviously, noticeable random variation cannot be accepted in a perfect performance.

As was mentioned, the quantities by which these rules affect the amplitude and duration of the individual note are sometimes exceedingly small. Yet, the effects thus generated as essential to the impression we get of the performance. This is evident when listening to examples where in the input notation the phrase markers have been replaced by subphrase markers and vice versa (the interested reader may experience this by listening to the corresponding sound illustration in Sundberg and Frydén 1985). The typical reaction of music listeners is that this simple substitution results in an unacceptable performance of the melody (Friberg *et al.* 1987). This shows that our sensitivity to these minute perturbations of amplitude and duration is very high indeed. As soon as the microperturbations appear in wrong places, they are easy to hear, but when they appear in correct places, they are hard to notice.

Interference between rules has often forced us to reduce the quantity of one rule when another rule was introduced. For instance, our first crescendo simply implied an increase of the output amplitude. This is an unrealistic crescendo, however, as higher overtones typically gain more than lower overtones when amplitude is increased on traditional musical instruments. When this feature was introduced accompanying the changes in amplitude, it became necessary to reduce the amplitude changes. Similarly, the quantity of other rules has been reduced to a quantity smaller than that which was used when the rule was tested in a listening experiment with experienced musicians. As yet, we have simply added the latest rule to the previous rules which have been adjusted accordingly, if required. This means that the quantity for a rule which is just right with the

present combination of rules may turn out to be too large if more rules are added in the future.

A typical observation should be mentioned which we have made several times when trying to adjust the quantity by which a rule affects a note or a series of notes. When the quantity is too small, the effect cannot be heard at all, of course. More interestingly, when the quantity is too great, two phenomena can be noted. One is that it is easy to hear exactly what the rule is doing in a physical sense. The other is that the effect appears musically unacceptable, simply because it sounds exaggerated. The 'correct' or musically useful quantity is in between these two extremes. It is typically characterized by the situation that a listener notices the effect but is unable to analyse it correctly in physical terms; as soon as this is possible, the quantity is too great and the effect sounds exaggerated. Thus, there seems to be a difference between the quantity needed in order to make a correct aural analysis of the physical means used; what is acceptable from a musical point of view seems to be just beyond the border of what is noticeable.

The analysis-by-synthesis method has previously been applied extensively in speech research and there it has been found useful. Still, the method has certain limitations. The most important one is that, being a basically comparative method, it can merely show what is better or worse than something else. For instance, we can find out if a rule improves the musical quality of a performance, but no conclusions can be drawn as to what is the best possible performance. On the other hand, this limitation is no great concern; even with respect to 'real' music it would be wrong to pretend that this or that performance is *the* best possible performance; there are always several ideal performances of a piece.

The analysis-by-synthesis technique as applied to music performance presupposes that musical experts are capable of agreeing on what is more acceptable and what is less acceptable from a musical point of view in a musical performance. We have regarded this ability as a psychological fact, and there seem to be no serious reasons for doubting its existence among music experts. For instance, if it did not exist, it would be hard to explain why music conservatories can exist.

The analysis-by-synthesis procedure shows striking similarities with the procedure used in teaching music playing; in both cases the principle is to give instructions that strive to eliminate some obvious deficiency in the performance. A major difference is that computers always apply all rules, while this would probably be regarded as a sign of little musical talent in a human musician! However, this difference between the computer and the music student is essential for the evaluation of the 'instructions' which we give to the computer.

Summarizing this slightly rhapsodic discussion so far, our examples and listening tests prove that our rules improve the musical acceptability of a

performance at least in the piece of music that has been tested. This is an interesting fact that asks for an explanation, regardless of the generality of the rule, and regardless of whether the rule could be formulated in a better or alternative way. Thus, as soon as we have formulated a rule and found that it improves music performance, we have reasons to question why it improves the performance. The answer to this question would be interesting, because the rules must be assumed to represent some sort of reality in music communication. Next we will attempt to analyse this reality.

Purpose of the rules

It seems that each of the rules that we have formulated as yet serves a specific purpose or, rather, it seems to have a function in music communication. There are a number of such purposes, and the rules can be divided into different groups according to their apparent purposes.

One group of rules seems to serve the purpose of emphasizing the contrasts along a commonly used dimension. An example of this in the rules described above is rule (2), which exaggerates durational contrasts.

A second type of rule seems to serve the purpose of eliminating sound characteristics which sound queer because no traditional musical instrument possesses them. An example is rule (1), which increases the loudness as function of pitch; most traditional instruments adhere to this principle. If the synthesis does not adhere to this rule, it sounds unnatural or 'electronic'. This is logical: the listener has never heard this sound characteristic before except from electronic instruments.

A third group of rules seems to take into account the fact that a listener might make associations with previous experiences when listening to music. For instance, (a) a rapid, regular pulse would often lead the listener's thoughts to rapid locomotion such as swift walking or running, and (b) an 'upward motion' on the scale would cause many listeners to imagine something climbing upward in space. Perhaps a combination of these associations constitutes the background of rule (4), increasing the tempo with the upward motion of a melody: the slight increase in tempo can be interpreted as an indication that it is not heavy to walk, even though the road leads upward.

A fourth group of rules seems to serve the purpose of emphasizing more or less unexpected tones. It is as if the musician wanted to say that even though this note sounds a bit peculiar, it is just this note that he intends to play. The occurrence of chords having a high harmonic charge is prepared by loudness increases, while the amplitude is decreased towards chords which have a smaller harmonic charge.

A fifth group of rules apparently serves the function of marking the structure of the melody. One example is the rule lengthening the final

element of a phrase. Rule (5), which emphasizes harmonically remote chords by loudness increases, probably serves this purpose too. The background is that in traditional harmony the chord progressions are often used to mark the structure, so that a phrase ending is often marked by a cadenza, that is, a chord preceded by its own dominant—or, in other words, a decrease of the harmonic charge (see Sundberg and Lindblom 1976). For instance, one of the phrases in a melody written in C major might be terminated by the chord progression E major—A minor. Under these circumstances our rules would predict a crescendo towards the E major chord and then a decrescendo towards the A minor chord. This loudness change would then serve a double purpose. One purpose is to inform the listener that the E major is actually intended even though it is rather far from the tonic (no-mistake case), and the other purpose is to inform the listener that this is a termination of a structural unit in the melody (marking-of-structure case).

Apart from the groups of rules exemplified above there is at least one more group. The purpose of the rules in this group is to embed the performance in a sort of emotional atmosphere. Particularly in the synthesis of singing, the need for such rules is experienced as evident; in a melody with a tragic character, it is most disturbing if the performance does not sound tragic. Interesting attempts to investigate how such emotional atmospheres are signalled in music performance are being made by Clynes (see for example Clynes 1983).

If we now survey the groups of rules described above, we find that the rules apparently serve purposes which are not specific to music. The heightening of contrasts in a frequently used dimension seems to be a common psychological phenomenon in communication. Examples of the preference for phenomena that the listener/spectator is already familiar with can probably be found in most fields of human communication. Emphasis is a phenomenon that would appear in all systems of formalized communication. To embed a message in an emotional atmosphere is typical in human behaviour, including speech. Musical communication thus seems to contain several elements that are not specific to music, and many elements seem to be directly imported from speech. This is not surprising: speech and music are the two main forms of systematized interhuman communication by means of sound signals. In future research it would be interesting to see whether great differences in the speech of two cultures correspond to great differences regarding the rules used in music performances.

Code

Above we have considered the question of what *purposes* the various rules in our performance rule system seem to serve. We can now pose another

question, namely, what the *means* are that are used to fulfil these different purposes. Thus, we will consider questions such as 'How is emphasis signalled?' and 'How is the structure of the melody marked?' It is by no means obvious how the code is chosen. It is possible that the code is imported from extramusical communication, such as speech, but it is also possible that the code is unique for music.

Before going into these questions it is improtant to point out that the acoustic parameters that we have dealt with in this work are only pitch, amplitude, timing, and vibrato. There is no doubt that these are sufficient for making music; this is evident from the fact that the organ is useful as a musical instrument, because in this instrument it is only timing that can be continuously controlled by the player. Nevertheless, it is important to remember that we can make inferences about the coding in terms of amplitude and timing only.

Much of the code seems to be taken from speech. One example is the phenomenon that a note appears emphasized when it is lengthened; in speech, emphasis can be signalled by means of an increased syllable duration as has been demonstrated by Carlson *et al.* (1974). Another example is the marking of phrase endings by means of lengthening, because many languages use 'final lengthening' for signalling the end of a phrase (Lindblom 1978). By listening to speech, music listeners have been 'programmed' to interpret lengthening as a possible sign of a termination. If so, lengthening would be impossible to use as a sign of continuation. The previously mentioned queer effect obtained when phrase and subphrase markers were switched in a melody supports this hypothesis.

However, it seems doubtful that speech is the ultimate source of the code. For instance, in some languages, such as Danish, lengthening of syllable duration is not the code used in order to flag the end of a phrase. Still, Danish and Swedish musicians can of course make music together. This lends support to the previously mentioned hypothesis that there may be several codes available for expressing the same thing in music performance; the flagging of termination by means of lengthening is perhaps only *one of many* possibilities.

When a player uses lengthening for marking termination, he exploits the fact that the listener is 'programmed' to couple the phenomenon of lengthening with the notion of termination. In the mind of a music listener there would be many other examples of such couplings between sound patterns and various phenomena which allow the listener to interpret the sound sequences. Such couplings are likely to result partly from the listener's extramusical experience, such as his acquaintance with speech, and partly from his previous musical experiences. The typical final retard is a convincing example of a coupling of the first-mentioned type. It is typically used in motor music, where there is a regular, rapid pulse. It is likely that most listeners tend to associate this pattern of pulses with

locomotion. One way of stopping locomotion abruptly is by collision, which most listeners would agree is an unpleasant experience. It may be for that reason that the final retard is often used in performance of motor music. (Kronman and Sundberg 1987).

The main point, we believe, is that the player always applies rules in his playing, because it is only by means of following rules that the player enables the listener to interpret the performance. Thus, we would speculate that all details in a music performance are interpretable as long as these details were derived from performance rules which exploit the listener's previous intra- as well as extramusical experience. We also believe that the basic requirements for musical communication can be studied efficiently by means of formulating these performance rules.

Concluding remarks

Music performance seems to be a scientifically rewarding topic, where analysis-by-synthesis is a useful method. A number of unexpected findings and observations have emerged, and, no doubt, much work remains to be done, such as a thorough testing of all hypotheses generated by the results. Still, even before this has been done some conclusions can be drawn.

By demonstrating how the sound sequences must be modelled in order to increase the musical acceptability of a performance, explicit information is gained on what is demanded from a musically acceptable performance. The analysis-by-synthesis method offers information in terms of a precise description of sound patterns. In many case these patterns can be recognized as allusions to patterns, which must be well known to the listener because of his or her experience of speech and also of motion as manifested by, for example, footsteps. By means of such allusions, emphasis, structure, and emotional atmosphere can be expressed in a way that the listener can understand. In this way music seems to gain meaning.

In summary, it seems that analysis of music performance is beginning to reveal what exactly it is that musicans add to written music, what the code they use is and from where this code is taken. Therefore it appears fair to propose that analysis of music performance can shed light on basic aspects of music communication.

Timing and synchronization in ensemble performance

RUDOLF A. RASCH

Introduction

For the last six centuries Western music has been largely polyphonic. This means that a piece of music consists of two or more simultaneous parts or 'voices' (either vocal or instrumental). In order to make performance possible, the temporal relations between the various voices as well as those within a single voice have to be defined exactly and unambiguously. These relations must be clearly stated in the score of the music and appropriately realized in a performance. In its initial stage polyphonic music was often called 'measured music' (*musica mensurata*) as opposed to 'plain music' (*musica plana*), that is, plainchant in which there was no requirement of strict time structure.

Observations from such widely different fields as timbre experiments, instrumental sounds, and notation lead to the conclusion that the beginning or onset of a tone is the decisive point in time for that tone. Timbre experiments have shown that recognition of musical instrument tones is severely impaired by taking away the starting transient portion (Clark *et al.* 163; Berger 1964; Saldanha and Corso 1964). Widely used instruments such as piano, harpsichord, and guitar (in general, all plucked or struck instruments) produce tones without steady-state parts, which begin to decay immediately after the onset. Traditional music notation puts notes at the onset moment of the horizontal time scale, and places those with simultaneous onsets together irrespective of their lengths. Investigation of the temporal structure of music is therefore predominantly a study of onset moments.

In this chapter we deal with the problem of synchronization in musical performance, that is, how musicians manage to co-ordinate their own temporal (onset) structures with those of the other performers in such a way that the temporal structures actually match each other and fuse into

one common temporal structure. This means that the tones which are prescribed in the score as simultaneous must be played at the same moment of time, especially with regard to their onsets. In reality, perfect synchronization is never realized and there will always be some asynchronization. Onsets meant to be simultaneous but in performance not exactly simultaneous will be called quasi-simultaneous onsets.

In the first and second sections of this chapter, we will present a model for the description of synchronization of ensemble performances (Rasch 1979, 1981). It is based on the standard deviations of relative onset times and onset time differences. The third section is devoted to the question of how to define the onset times of musical tones in a synchronization situation (Vos and Rasch 1981). Finally, we will speculate a little about the role of the conductor in the synchronization of musical performances.

The description of synchronization

When musicians play together in an ensemble, they will try to synchronize as much as possible the tones meant to be simultaneous. For a number of reasons, such as the restricted accuracy of human motor performance and time perception, the relative ease of tone production within or between instruments, and the time lag between the production of a player's own tones and the perception of the tones produced by others, a perfect synchronization is not possible in a live performance. There will always be some degree of asynchronization.

Onsets of tones meant to be simultaneous will, in reality, scatter a little in time. Assume an ensemble of n players. Figure 4.1, illustrates some of

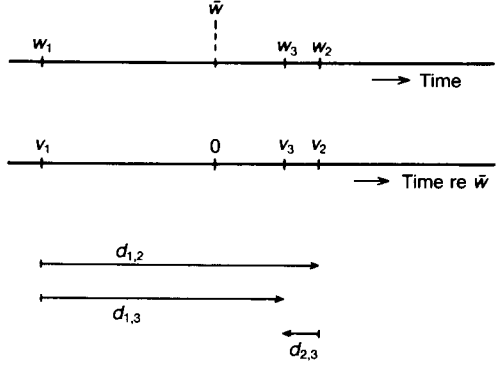

Fig. 4.1. Illustration of the concepts used for synchronization analysis. w_1, w_2 and w_3 are three onsets meant to be simultaneous. $\bar{w}$ is the mean onset time. v_1, v_2, and v_3 are the onset times expressed relative to $\bar{w}$. The onset time differences are denoted by d_{12}, d_{23}, d_{31}.

the concepts used for an ensemble of three performers. The *absolute onset times* of the tones meant to be simultaneous will be denoted by $w_1, w_2, \ldots, w_n$. For each group of such onsets there will be a mean onset time:

$$\bar{w} = \frac{w_1 + w_2 \ldots + w_n}{n}.$$

Now, the absolute onset times can be converted into *relative onset times*:

$$\begin{aligned} v_1 &= w_1 - \bar{w}, \\ v_2 &= w_2 - \bar{w}, \\ &\ldots, \text{ and} \\ v_n &= w_n - \bar{w}. \end{aligned}$$

The relative onset times are relative to the mean onset time, not to other onset times. Below, we will as a rule use the relative onset times. The absolute onset times of the tones in a piece of performed music can be measured and transformed into relative onset times. This will result in a set of n distributions of relative onset times, one per voice. These distributions can be characterized by their means, which will be indicated by $\bar{v}_1, \bar{v}_2, \ldots, \bar{v}_n$, and their variances, which will be denoted by $s_1^2, s_2^2, \ldots, s_n^2$. The means indicate which instruments lead or lag in their onsets relative to the other instruments in a performance.

Time differences between onsets are particularly significant for perception. The *onset time differences* will be denoted by the letter d:

$$\begin{aligned} d_{12} &= v_2 - v_1, \\ d_{13} &= v_3 - v_1, \\ &\ldots, \text{ and} \\ d_{n-1,n} &= v_n - v_{n-1}. \end{aligned}$$

The subscripts refer to the respective voices. Onset time difference has been termed *onset asynchrony* in other contexts. For a piece of music with n voices or performers, there will be $n(n-1)/2$ distributions of onset time differences. These distributions can be characterized by their respective means, to be indicated by $\bar{d}_{12}, \bar{d}_{13}, \ldots, \bar{d}_{n-1,n}$, and variances, to be indicated by $s_{12}^2, s_{13}^2, \ldots, s_{n-1,n}^2$.

The distributions of onset time differences are related to those of the relative onset times. The means of the onset time differences can be calculated directly from the means of the relative onset times. The relation between the variances of relative onset times and onset time differences is more complex. It was found empirically that the variances of the several distributions of relative onset times for one specific piece of music do not differ very much from each other. For simplicity we will assume that they are equal, and denote their value by s_v^2. In addition we will assume that the covariances between distributions are equal. Their value will be denoted

by c_v. With these assumptions it is possible to derive a simple formula that relates the variances of the relative onset times and the onset time differences.

Each relative onset time can be written as a linear sum of all other relative onset times, for example:

$$v_1 = -(v_2 + v_2 + v_3 + \ldots + v_n).$$

The variances of such a sum equals the sum of the variances of the terms of the sum plus twice the sum of all covariances among the terms:

$$s_v^2 = \sum_{i=2}^{i=N} s_{v_i}^2 + 2 \sum_{i=2}^{i=n} \sum_{j=i+1}^{i=n} c_{v_{ij}} \; (j \neq i)$$

in which $c_{v_{ij}}$ is the covariance of v_i and v_j.

Since, by assumption, $s_{v_1}^2 = s_{v_i}^2 = s_v^2$ and $s_{v_{ij}}^2 = c_v$, the variance of the relative onset times in general can be expressed in the following equation:

$$s_v^2 = (n-1)s_v^2 + (n-1)\,(n-2)c_v.$$

This leads to:

$$c_v = \frac{s_v^2}{1-n}.$$

Since an onset time difference can be considered to be a linear combination of the form $d_{12} = v_2 - v_1$, its variance is given by:

$$s_d^2 = 2s_v^2 - 2c_v.$$

Substituting the value of c_v in the last equation leads to:

$$s_d^2 = \frac{2n}{n-1} s_v^2.$$

So the relation between the relative onset times and the onset time differences depends on the number of performers in the ensemble. For a duo ($n=2$) the relation is simply $s_d^2 = 4s_v^2$. For a large ensemble, the relation converges to the limit $s_d^2 = 2s_v^2$.

In actual practice, onset time difference is a variable with a mean not very different from zero (mostly within the range of -5 to $+5$ ms) and a standard deviation that is much greater (mostly within the range of 30 to 50 ms). For this reason the standard deviation of the onset time differences is a better measure for the amount of asynchronization in performed music than the mean onset time differences. We will define the *asynchronization of a pair of voices* as the standard deviation of the onset time differences of simultaneous tones of those voice parts. In formula, the asynchronization will be denoted by the capital A: $A_{ij} = s_{ij}$.

The standard deviations of the various distributions of onset time

differences in one piece of music do not differ very much from each other. We do not lose very much information if the asychronizations of the various voice pairs are averaged, by taking the root-mean-square. This averaging has the advantage that the asynchronization of a piece of music can be expressed as a single value. We will define the *asynchronization of a piece of performed music* as the root-mean-square of the standard deviations of the onset time differences for all pairs of voice parts. The asynchronization of a piece of music will be denoted by the capital A without subscripts.

It should be noted that the asynchronization defined quantitatively in this way indicates ranges in which onset time differences will fall with certain probabilities. The range from $-A$ to $+A$ includes 68 per cent of onset time differences, the range from $-2A$ to $+2A$ 95 per cent. If we discard the sign of the onset time differences, it can be stated that the median unsigned onset time difference is $0.68A$, the lower quartile $0.32A$, and the higher quartile $1.15A$.

The synchronization of simultaneous tones is only one of the temporal tasks of performing musicians. Within one voice, the succession of tones also has to be strictly timed. We will call the timing of tones of equal duration in one voice the *isochronization* of the tones. The isochronization of a voice will be defined as the standard deviation of tone durations meant to be equal. In actual practice, there will be a number of sources that contribute to the variance of equal tone durations, like tempo trends and fluctuations. Also, the asynchronization of simultaneous tones will be mirrored in isochronization. If we exclude all other sources of the variance of 'equal' tone durations, there is a certain relation between asynchronization and isochronization (actually, a-isochronization). We consider two consecutive tones with absolute onset times w_i and w_{i+1} (see Fig. 4.2). The duration of the first tone is

$$h_i = w_{i+1} - w_i.$$

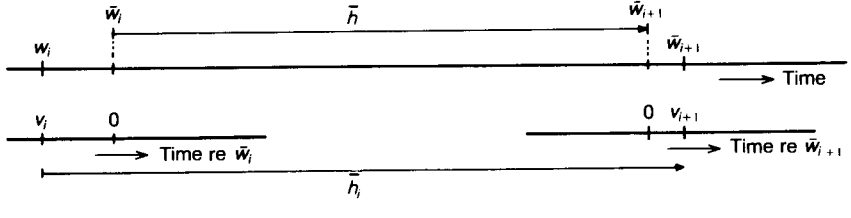

Fig. 4.2. Illustration of the concepts used in determining the relation between asynchronization and the standard deviation of tone durations. $\bar{w}_i$ and $\bar{w}_{i+1}$ are the mean onset times of two successive triplets of tones. w_i and w_{i+1} are the onsets of two successive tones in one voice part; v_i and v_{i+1} are the same onsets but expressed relative to the mean onset times. $\bar{h}$ and h_i are the time intervals between the mean onsets and the onsets in a single voice, respectively.

The absolute onset time is the sum of the mean onset time and the relative onset time. We denote the mean onset time of tones simultaneous to w_i as $\bar{w}_i$, that of tones simultaneous to $\bar{w}_{i+1}$. We assume that the successive mean onset times (. . ., $\bar{w}_i$, $\bar{w}_{i+1}$, . . .) are perfectly isochronous. Therefore, mean tone duration $\bar{h}$ is

$$\bar{h} = \bar{w}_{i+1} - \bar{w}_i.$$

The relative onset times of the two tones in succession will be denoted by v_i and v_{i+1}. Now we can rewrite the actual tone duration as follows:

$$h_i = \bar{h} + (v_{i+1} - v_i).$$

The variance of this last expression is

$$s_h^2 = 2(1-r)s_x^2.$$

in which r is the correlation between v_i and v_{i+1}, or, the autocorrelation of relative onset times. The above equation can also be written as

$$s_h^2 = \frac{n-1}{n}(1-r)s_d^2.$$

The relation between isochronization and synchronization can be used in the comparison of the results of our measurements with the results of experiments on sequential timing behaviour which exist in the literature.

The measurement of synchronization

The descriptive model given will now be illustrated with a set of measurements of live musical performances specifically recorded for this purpose (Rasch 1979, 1981).

In order to study synchronization in musical performances it is necessary to know the exact temporal structure of each individual part of the composition performed. Attempts have been made to analyse the compound sound of a piece into its individual parts, for instance by Tove *et al.* (1967) at the Royal Institute of Technology in Stockholm, and by Moorer (1975) at the Center for Computer Research in Music and Acoustics of Stanford University. Up to now, these attempts have been only partially successful. Several serious problems prevent application of the methods employed to larger, not specially selected samples of music. The main problem areas in this field are the storage and processing of the prohibitively large amounts of data, and the separation of fused harmonics in the cases of musical intervals with simple frequency ratios.

A more feasible approach is the one in which the acoustics signals from each instrument are picked up and recorded before they are mixed into the ensemble sound. This can be done by using either contact microphones

under normal acoustic conditions or directional microphones in an anechoic chamber. The latter method was chosen for our recordings because the recorded sound most resembled the sound in normal listening conditions. The recorded signals passed a logarithmic envelope detector with an output voltage proportional to the sound-pressure level of the temporal envelope of the signals. The sampling rate was 200 Hz, the time interval between two successive samples being 5 ms. The envelopes could be displayed on the graphic terminal of the computer. Peaks in the enveloped were matched with the notes of the score played by the musicians. The onset time of a peak was defined as the moment that the envelope reached or surpassed a certain, previously defined threshold level. This level was taken about 15 or 20 dB below the maximum levels of the signals. Figure 4.3 shows the envelopes of a fragment of 9 s of music, with the peaks numbered according to the computer output and the score of the music inserted for comparison and identification purposes.

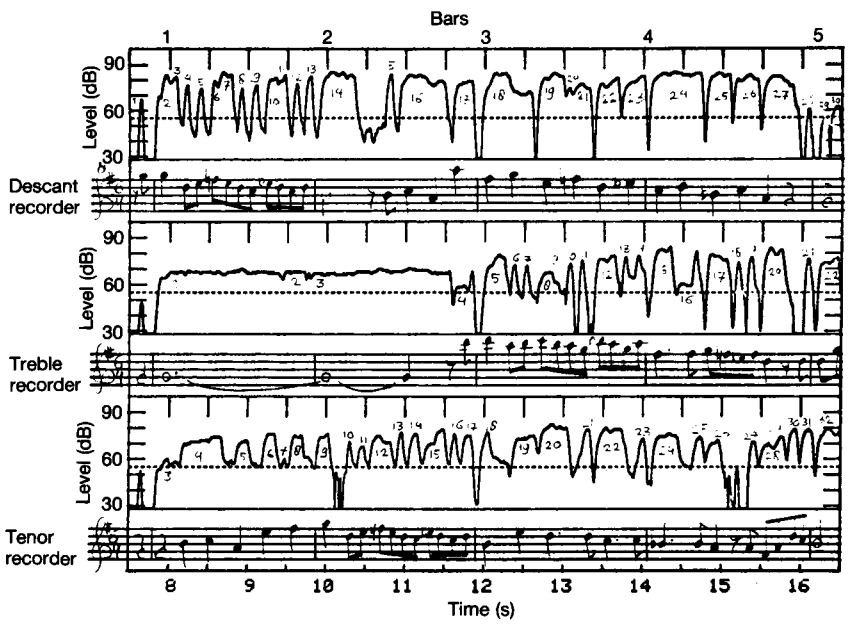

Fig. 4.3. The envelopes of three simultaneous voices of a fragment of 9 s. The peaks have been numbered, and the notes of the score have been inserted.

The following step was to determine which peaks in the three envelopes corresponded to a triplet of simultaneous notes in the musical score. Table 4.1 shows the simultaneous onsets from Fig. 4.3, the relative onset times, and the onset time differences. Note that the temporal resolution of the

Table 4.1 *Peaks corresponding to simultaneous notes from the music fragment of Fig. 4.3, with absolute onset times, relative onset times, and onset time differences.*

27	20	18	15500	15510	15470	7	17	−23	10	−40	30

processing system was 5 ms. As a matter of fact, not all the triplets of simultaneous notes found in the score had a corresponding triplet of peaks in the envelopes. If the initial part of a tone did not correspond to a peak in the envelope, no corresponding onset time was available for the calculations.

The statistical computations were mostly done per composition, sometimes per movement of a composition. First, means, standard deviations, and root-mean-squares of standard deviations of relative onset times and onset time differences were calculated. These figures make up the basic data set of our analysis. Further computations included the autocorrelations of relative onset times, correlations with tempo measures, and conversion of synchronization into isochronization values.

Recordings were made of music played by three professional trio ensembles: a recorder trio, a reed trio (oboe, clarinet, bassoon), and a string trio. Each ensemble played two compositions that were typical for the repertoire.

Means and standard deviations of relative onset times were calculated for each recorded composition. The mean relative onset times are graphically presented in Fig. 4(a). They indicate to what extent certain instruments tend to lead or lag in simultaneous onsets relative to the other instruments. Certain tendencies can be discerned. In the string and wind trios the main melody instruments (violin, oboe) tend to lead relative to the others, with the bass instruments (cello, bassoon) in the second place, and the middle voice (viola, clarinet) in the third place. This corresponds to our intuitive notion that in most of the music for these ensembles the melody part is the leading, 'first' voice. Recorder ensemble music is more polyphonic as a rule, and the bass is the most fundamental voice. This is confirmed by the observation that the tenor recorder—the lowest voice—is the leading voice, on the average.

There are three distributions of onset time differences for each

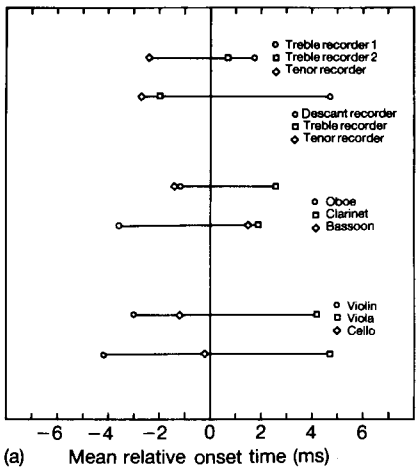

Fig. 4.4(a). Mean relative onset times of the instruments per composition.

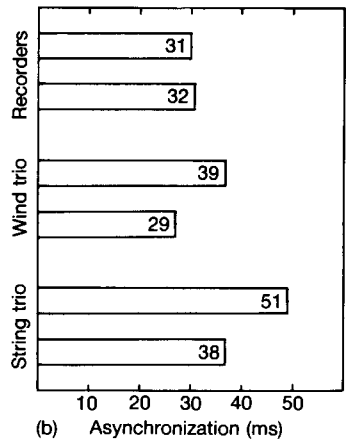

Fig. 4.4(b). Mean asynchronization per composition, averaged over the instruments.

composition. The root-mean-squares of the standard deviations are used as measures for asynchronization. Asynchronization per composition is graphically illustrated in Fig. 4(b). Asycnchronization values fall largely within the range of 30 to 50 ms. Mean asynchronization of this set of data is 36 ms. There are some systematic differences between the ensembles. The recorder ensemble shows a relatively small asynchronization of about 30 ms. The two examples of the wind trio have different amounts of asynchronization: 27 and 37 ms respectively. The largest asynchronizations are found in the string trio examples: 37 and 49 ms. These differences may be related to the rise times of the tones of the instruments in question. Recorders have short rise times, so that the beginnings of the tones are clearly marked. These short rise times make good synchronization both possible and necessary. The conventional woodwinds of the wind trio also have relatively short rise times. The onset of string tones is a more gradual process resulting in long rise times (30 to 100 ms). These longer rise times permit a greater leniency as to synchronization.

The relation between asynchronizatoin and tempo was also investigated (see Fig. 4.5). All data in this table concern single movements of the compositions. As tempo measure we used the time between two successive counting beats, the 'inter-beat time', determined as 60 divided by the metronome value (the number of counting beats per minute). This measure includes a subjective element in the choice of the counting unit. The correlation between the asynchronization of the movements and the tempo measure of 0.80. Evidently, the conclusion is justified that faster

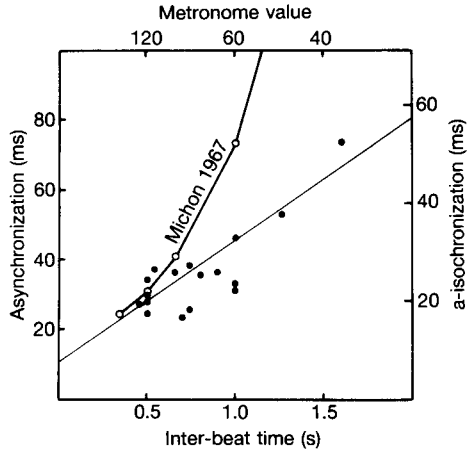

Fig. 4.5. Relation between tempo and asynchronization. Inter-beat time is used as a measure of tempo. The vertical scales indicate asynchronization, defined on the left as the standard deviation of onset time differences, averaged over instruments. On the right, a-isochronization is indicated. The dots are data points for movements. The regression line of tempo on asychronization is based on the correlation between inter-beat time and asynchronization. The results of Michon's experiments (1967, p. 31) are inserted for comparison.

tempo goes with more synchronization, and slower tempo goes with less synchronization.

As already noted, asynchronization of simultaneous onsets can be the cause of a-isochronization, that is, the existence of deviations from equal durations of successive tones within single voices. It is possible to make an estimate of this a-isochronization from asynchronization. For this estimate the correlation between subsequent relative onset times must be known. This correlation is the autocorrelation of a series of relative onset times. The autocorrelations were first calculated per composition and then algebraically averaged over voices and compositions. The resulting value proved to be 0.21. This indicates that there is a slight tendency of relative onset times to be preserved in the subsequent onsets. With $r = 0.21$, we find a ratio of 0.73 between a-isochronization and asynchronization. Apart from the autocorrelation, the asynchronization patterns seem to be more or less random.

Now we can compare our results with those of experiments conducted by Michon (1967). His subjects had to tap synchronously with a pulse train presented through headphones. His results (p. 31, Table 2B) are standard deviations of time intervals meant to be equal, and as such indicate a-isochronization. Tapping rates were 60, 90, 120, and 180 beats per minute. Figure 4.5 includes both the results of Michon's experiments and the

regression line for asynchronization to tempo. For high tempos the correspondence between Michon's data and ours is quite good. For lower tempos the synchronization found in our recordings is better than would be expected from Michon's data. A likely explanation of this discrepancy is that subdivisions of the beat also can contribute to synchronization.

Perceptual effects of synchronization

In a study by Rasch (1977) the effect of onset difference times on the perception of quasi-simultaneous tones was investigated. Each trial included two stimuli in those experiments. Each stimulus contained two simultaneous tones. The lower tones of the stimuli in a trial had the same fundamental frequency, the upper ones differed in fundamental frequency by an (upward or downward) fifth (or other interval). The threshold for perceiving the upper tone of the stimulus was defined as the level resulting in a 75 per cent correct score in a 2AFC paradigm of the judgement of the direction of the pitch jump. For synchronous notes (onset difference time 0 ms) the threshold was between 0 and −20 dB depending on the frequency ratio and phase relation of the simultaneous tones. The threshold could be decreased drastically, down to about −60 dB, by introducing an onset difference time of, say, 30 ms. In the latter case, the threshold was largely independent of factors other than temporal ones. This condition can be compared directly with asynchronization in performed music. In the experiments there was no sensation of order. In supra-threshold conditions asynchronization contributes to the apparent transparency of the compound sound multi-tone stimuli.

When listening to music, onset differences mostly go unnoticed. Actually, the performances of professional ensembles give the impression of perfect synchronization. In the now classic investigation by Hirsh (1959) it was found that, roughly speaking, a time interval of 20 ms between two sounds (tones, noises, clicks) was sufficient for judging which one came first. Several reasons can be mentioned why onset difference times that are considerably longer are not perceived in a musical listening situation. Firstly, the qualities of the simultaneous tones differ, especially as to pitch and timbre (instrument); this impairs an exact judgement of the temporal structures. Secondly, rise times of musical tones are much longer (for example 20–80 ms) than the stimuli used in psychophysical experiments (often 5 or 10 ms). The smoother rise curves also impair exact judgements. Thirdly, the distribution of onset differences is practically random. Fourthly, attention of the listener is not directed to onset differences between voices ('vertical') but rather to melody lines within one voice ('horizontal'). The musicians themselves are, in general, also unaware of the amount of asynchronization, except when unwanted asynchronization

cannot be avoided in very difficult passages or in cases of 'temporal mistakes'.

Among the onset difference times there appeared to be a small number of relatively large ones, that is, from 100 to 200 ms. They were clearly audible during repeated replay. They can be a consequence of mistakes by the performer, but they are also induced by some musical characteristics, such as: the first onsets of a movement, a section with long notes in one voice and short notes in other voices; ritenuto or accelerando sections; onsets of individual part after rests; final notes following a ritardando or separated from the preceding notes by a rest; sections that are complicated with regard to rhythm and/or metre. Underlying factors for these harder-to-synchronize fragments are the absence of directly preceding tones or uncertainty concerning the temporal structure. The threshold for order of auditory stimuli sets a lower limit for synchronization. As yet, there are no experimental data for thresholds of temporal order in musical situations.

As a final remark, mention must be made of Seashore's theory that 'beauty in music largely lies in the artistic deviation from the exact or rigid' (1938, p. 249). This postulate leaves open the question of how to define artistic deviation. However, its negative formulation ('there is no beauty in music if the performers adhere exactly and rigidly to the instructions of the score') is certainly true. In every artistic musical performance there is constant deviation from what is prescribed exactly in the score, as to time, frequency, duration, level, etc. These deviations have strong statistical components without being purely random. They are of primary importance for the 'live' character of music performed by human beings. The asynchronization of simultaneous tones should be regarded as one of the vital deviations in the performance of music.

The moment of synchronization

In the preceding section, the decisive time moment of the tone, used as a basis for the calculation of synchronization, was taken where the temporal envelope of the tones passed a threshold, quasi-arbitrarily defined as the level 15 or 20 dB below the average maximum level of the respective voice part. Since this choice is fairly central in the description of synchronization behaviour, the threshold model concerning the perceptual onset of musical tones will be considered here in some detail. The model assumes that music listeners (including music performers) base their timing on the passing of the temporal envelope through a certain threshold level, which is defined in relation to the average maximum level of the stream of musical tones (Vos and Rasch 1981). The physical temporal envelope of a musical tone can be roughly divided into three successive portions: the rise, the steady-state, and the decay portions (see Fig. 4.6).

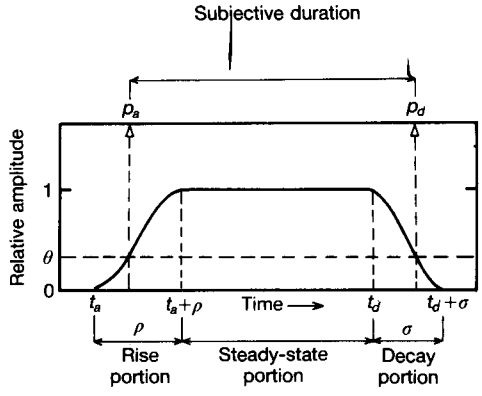

Fig. 4.6. Temporal envelope of a musical tone, divided into three successive portions. The perceptual onset (p_a) and offset (p_d) of the tone are defined as the moment at which the temporal envelope passes the relative threshold amplitude, θ.

If the rise function, which describes the envelope during the rise, is monotonously increasing, then the inverse function is unambiguous. Throughout this chapter, we will regard rise functions as monotonously increasing functions. In our model, the perceptual onset of a tone is the moment at which the temporal envelope during the rise portion passes a certain relative threshold level. If the moment of the perceptual onset is known, the threshold level can be calculated. If the threshold level is known, the perceptual onset can be calculated. The subjective duration of a tone is defined as the time interval between the perceptual onset and offset of a tone. The following paragraphs, describing an extension of our model, will deal only with the perceptual onset.

The model can be extended to groups of tones, either simultaneous or successive ones. Two tones are called *perceptually synchronous* when their perceptual onsets coincide in time (see Fig. 4.7).

Tone sequences are defined as *perceptually isochronous* if the time intervals between successive perceptual onsets are all equal to each other. Figure 4.8(c) shows the temporal envelopes of the tones A, B, and A', which are perceptually isochronous. An experimental paradigm with successive perceptually isochronous tones with different rise functions and/or rise times can be used to determine the threshold amplitude for the perceptual onset (Vos and Rasch 1981). If tones are physically isochronous, that is, when the time intervals between successive physical onsets are all equal to each other but have different rise times and/or functions, the perceptual onsets will not, as a rule, be isochronous.

In the experiments exploring the applicability of the model a paradigm was used in which a sequence of tones had to be isochronized, that is, the tones had to be adjusted in such a way that the onsets were perceived isochronously. Each trial started with a tone sequence that was decidedly nonisochronous. The starting sequence consisted of successive pairs of

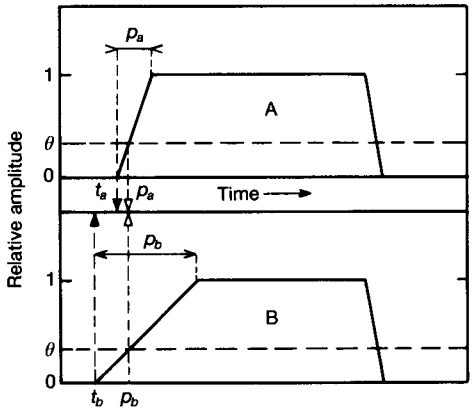

Fig. 4.7. Temporal structure of a perceptually synchronous stimulus, containing tones A and B with physical onsets t_a and t_b, rise times p_a and p_b, and maximum amplitude 1. The perceptual onsets, p_a and p_b, coincide in time and are by definition located at the moment at which the temporal envelopes pass threshold amplitude, θ.

tones, A and B, with a different interval between the physical onsets of A and the following B and between B and the following A (see Fig. 4.8(a)). The onset times of tones B, relative to those of A, could be adjusted by the subjects, by turning a knob. The experimental task was to adjust the onset times of tones B in such a way that the sequence ABABAB . . . was perceptually isochronous, that is, that the perceived onsets of the tones followed each other after strictly the same time interval. This is illustrated in Fig. 4.8(b). Because the tones A were repeated every 800 ms, the subjective repetition time t of the tones in the entirely isochronized sequence is 400 ms. Rise times were varied independently. The time between the successive physical onsets was derived from the position of the turning knob at which the subject judged the tone sequence to be isochronous. Now all variables that are necessary for computing the threshold amplitude for the perceptual onset were known.

Relative threshold amplitudes were computed for a number of combinations of unequal rise times. Mean threshold level was -15.4 dB, and the standard deviation equalled 1.6 dB. Considering this consistent result—that is, that about the *same* relative threshold level was found in ten physically different conditions—it is justified, for the time being, to define the perceptual onset moment of a tone as the time at which its envelope passes a certain threshold level. Moreover, from these experimental data, this threshold level can be estimated as -15 dB, relative to the maximum level of the tones.

The perceptual onset threshold has up to now been given relative to the

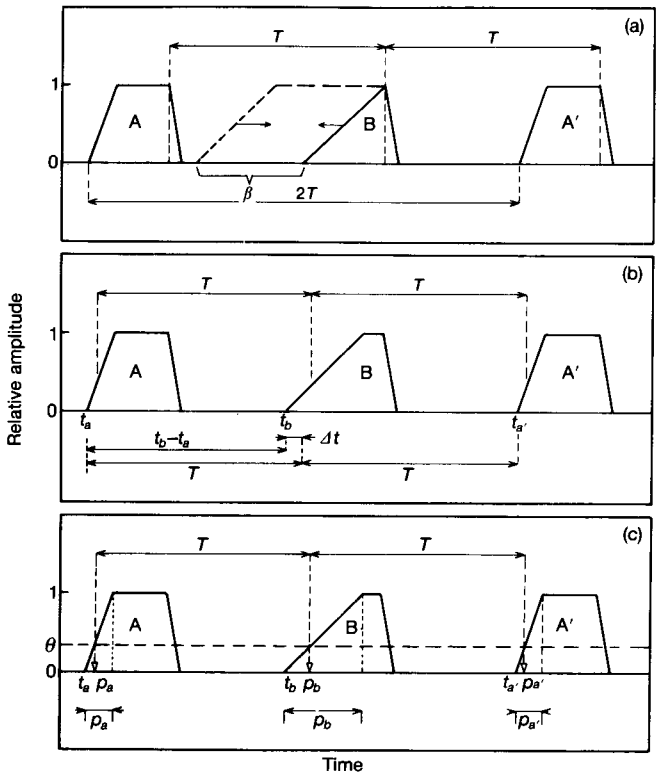

Fig 4.8. (a) Illustration of a perceptually nonisochronous starting sequence. The physical onsets of tones B could be adjusted by the subject within time interval β. At the start of a trial, the physical onset of tone B was either at the beginning or at the end of β. The physical offset of tones A and B, were fixed. (b) Temporal structure of a perceptually isochronous tone sequence in which the time intervals between successive perceptual onsets are all equal to each other. The physical onsets of tones A and B are t_a and t_b, respectively. The repetition time of tone A equals $2T$, so that T is the perceptual repetition time. The dependent variable is denoted by the time interval $\Delta t = T-(t_b-t_a)$. (c) Temporal structure of tones A, B, and A', which are perceptually isochronous. The time interval between successive perceptual onsets is denoted by T. The perceptual onsets p_a, p_b, and p_a' are defined as the moment at which the temporal envelopes pass relative threshold amplitude, θ.

maximum level of the tones. But it is evident that the threshold can also be defined as a level above background noise or hearing threshold. In short, the following question can be asked: Is the threshold fixed, with respect to maximum level, to background, or to some other criterion? Our first experiments were designed to test the threshold hypothesis in general, not

to discriminate between these alternatives. Further experiments were carried out to determine the reference relative to which the threshold had to be defined. This was done by varying the maximum levels of the tones. The stimuli were the same as those in the earlier experiments. The sound-pressure level of the tones, however, was 77 dB(A) in the highest level condition; in the other conditions it was 57 and 37 dB(A). Again, relative threshold amplitudes were computed. In the 37-dB condition, the mean relative threshold was −8.0 dB and the standard deviation equalled 0.9 dB. In the 57- and 77-dB conditions, the mean thresholds were −11.7 and −13.0 dB, and the standard deviations were 0.7 and 1.6 dB, respectively.

The results of these experiments show that the time difference between physical and perceptual onsets increases with decreasing tone intensity, that this increase can be described as an upward shift in the relative threshold by which the perceptual onset is determined, and that the shift in threshold is small relative to the shift in stimulus level. Therefore, the threshold can be most conveniently described relative to the maximum level of the stimulus.

From the experiments, it may be concluded that the perceptual onsets of musical tones can be defined as the times at which the envelopes pass a *relative* threshold of about 6 to 15 dB below the maximum level of the tones. In a number of experiments, we have shown that the level of the relative threshold depends on the tone level above masked or absolute threshold. The data from the present experiments seem to suggest adaptation to a certain constant stimulus level. At the time the adaptation threshold is passed by the stimulus level presented, the onset of the stimulus is perceived.

In studies on the temporal structure of performed music, our threshold model can be applied to determine the perceptual onsets of musical tones. When music is performed on instruments with very short rise times, like the piano, harpsichord, and drums (Gabrielsson 1974; Povel 1977; Sundberg and Verrillo 1980), the difference between the physical onset and the perceptual onset is very small. In these cases, level above threshold, too, does not have a great impact on this difference. However, when ensemble music is performed on instruments producing tones with relatively long rise times, such as bowed string instruments, the perceptual onset heavily depends on the relative threshold.

In such musical practice in which dynamic differences are not very large, perceptual onset is clearly affected only by the rise times and rise functions of the different instruments. This, however, is a variable with which the respective musicians can cope by adjusting their physical onset times in order to establish the appropriate timing of the perceptual onsets of their tones.

Future research should be focused on the perceptual onset of musical tones in synchronously perceived tone pairs. The sensation levels of

simultaneously presented tones, especially, are dependent on the amount of auditory masking (Zwislocki 1978). To apply our model to simultaneously produced tones, experimental results of binaural masking experiments with complex tones are needed. In addition, it would be interesting to see if our model also works in cases of complex tones consisting of partials with unequal rise times and unequal physical onsets (Freedman 1967; Grey and Moorer 1977) and of tones with substantially differing amplitude envelopes (Strong and Clark 1967).

Synchronization and the conductor

Small ensembles usually perform without a conductor, while larger ensembles and orchestras are guided by the gestures of a conductor. Since one of the tasks of the conductor is to keep the performing musicians synchronized, it is interesting to comment upon the present or absence of a conductor in terms of our descriptive model of synchronization.

When there is no conductor, the musicians will have to synchronize upon each others' sound outputs. For this condition, we consider the standard deviation of the onset time differences as being of some fixed, constant magnitude. In that case, the standard deviation of the relative onset times varies as a function of the number of performers in such a way that it becomes larger when that number is increasing (since $s_v^2 = (\frac{1}{2}(n-1)/n)s_d^2$). If we use our mean value of the standard deviation of onset time differences (36 ms), then the standard deviation of relative onset times is 18 ms for an ensemble of two players, 20.8 ms for three players, 22 for four, 22.8 for five, 23.2 for six, 24 for nine. For ensembles with more than nine players it converges to its maximum value of $36/2\frac{1}{2}$ or 25.5 ms. Evidently, synchronization quality is less in larger ensembles.

When a conductor is leading an ensemble or an orchestra, it may be supposed that the performers will try to synchronize not with each other, but with the movements of the conductor. For that condition, it may be supposed that the standard deviation of the relative onset times will be of some fixed, constant magnitude, since all musicians have the same task in this respect. We cannot extract an estimate for this quantity from our experiments, but via a detour a guess can be made. When the standard deviation of relative onset times is a constant quantity, the standard deviation of onset time differences is diminishing when a number of performers is increasing (since $s_d^2 = (2n/(n-1))s_v^2$), or, put the other way around, the standard deviation of onset time differences is increasing when the number of performers is increasing. With this relationship in mind, it is easy to understand that a large orchestra will always need a conductor, or, at least, will do better with a conductor. If the ensemble shrinks, however,

synchronization quality is diminishing when the conductor stays in charge of the synchronization.

A survey of recorded chamber music with five to 15 performances showed that ensembles with up to and including nine performers did, more often than not, without a conductor, while ensembles with 10 or more players almost always had a conductor (see Fig. 4.9). This must mean that the standard deviation of relative onset times of an imaginary ensemble of 9.5 players marks, on the average, the maximum allowable value of that standard deviation (in our average case 24.1 ms). It may be assumed that in this imaginary situation synchronization is as good with conductor as without, which gives us at the same time the assumed constant value of the standard devation of relative onset times in a situation with conductor. When there are those 9.5 performers, the standard deviation of onset time differences (or the asynchronization) is just 36 ms. But when there were only two performers, asynchronization would have been 48 ms; with three, 42 ms; with four, 39 ms; etc. When the number of performers gets substantially larger than 10, asynchronization converges to its limit of 34.1 ms.

Our line of reasoning concerning the usefulness of a conductor when it comes to synchronization is summarized in Fig. 4.10. It amounts to the

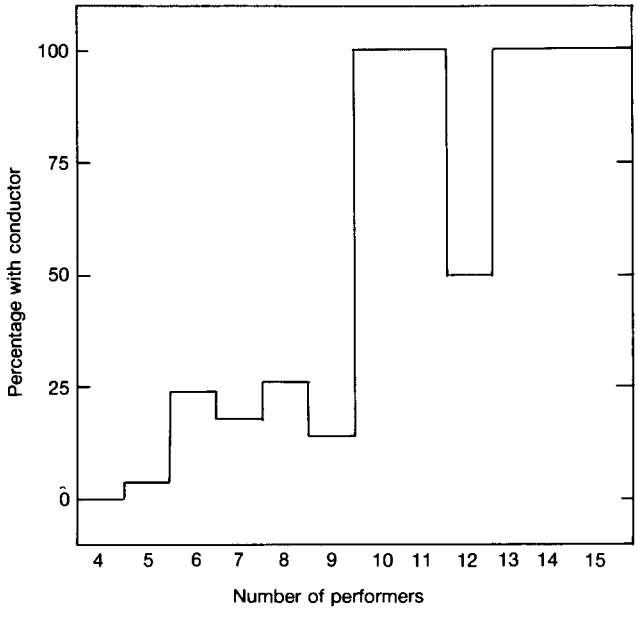

Fig. 4.9. Percentage of performances with a conductor, taken from a representative set of recorded quartets, quintets, sextets, etc. Only two compositions for 12 players could be located, of which one was with, one without conductor.

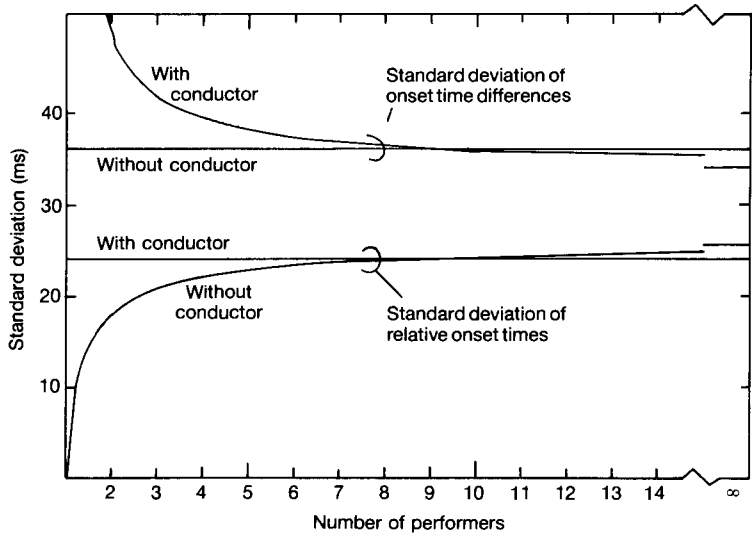

Fig. 4.10. Idealized standard deviations of relative onset times and onset times differences of performances with and without conductor, as a function of the number of performers. Numerical values are anchored to a mean asynchronization of 36 ms.

conclusion that below a certain cut-off value of the number of performers synchronization among performers is better without a conductor, while above that value it is better with a conductor. A caveat must be added, however. The lines marked 'with' and 'without' (conductor) cross at rather small angles, so that the crossing points are relatively strongly influenced by small up or down movements of the lines, which makes the choice of the crossing open to serious discussion. We found differences in synchronization related to the instruments of the ensemble and related to the tempo of the movement performed. The kind of music performed may also be expected to affect the value of a conductor. All these effects may cause upward or downward shifts of the lines inserted in Fig. 4.10. Indeed, the cut-off between the numbers of performers that need and that do not need a conductor is not sharply defined. Our cut-off value of 9.5 performers represents only an average value, although it is much sharper than was to be expected from the shallow curve of the standard deviation of the relative onset times as a function of the number of performers.

Conclusion

In this chapter, we have presented some thoughts and data about timing and synchronization in ensemble performance. The position taken in this

chapter has to do with model making and acoustical measurement rather than with processes of the psychology of music. However, before any such psychological interpretation comes into play, a sound and reliable way of measuring the relevant characteristics of musical behaviour should exist, and that is what this chapter aims to provide.

Measures of musical behaviour, including musical performance, are essentially statistical measures. For this reason we developed our statistical model of synchronization, based on relations between variances of relative time moments. We showed that with this framework it is possible to describe in a sensible way synchronization in ensemble performance. The research we have done was not initiated by the wish to uncover the psychological processes that are behind synchronization behaviour. Eventually, however, the descriptive part should be supplemented by a psychological, interpretative part.

Rehearsal skill and musical competence: does practice make perfect?*

LINDA M. GRUSON

In recent years, research on the acquisition of skills has focused upon the study of a variety of complex skills including, for example, competence in games such as chess (de Groot 1965; Chase and Simon 1973; Simon and Chase 1973), bridge (Charness 1979) and the board game, Go (Reitman 1976); in the academic domain, acquisition of skills in such subjects as mathematics (Krutetskii 1976), physics (Simon and Simon 1978; 1980; Chi *et al.* 1980; Larkin *et al.* in press), compositional writing (Flower and Hayes 1979), and engineering thermodynamics (Bhaskar and Simon 1977); and a number of cognitive-motor skills such as typewriting (Thomas and Jones 1970; Shaffer 1975, 1978) and, most pertinent to the present study, musical skills (Bean 1938; Weaver 1943; Wolf 1976; Shaffer 1980, 1981; Sloboda 1974, 1977; MacKenzie *et al.* 1983).

While the research paradigms and target behaviours studied have been quite diverse, one of the most consistent findings that emerges from the research on skills is that as an individual learns a skill, he or she acquires the ability to process increasingly larger and more complex units of meaningful, skill-related information. Chase and Simon's (1973) work with chess players illustrates this process of 'chunking'. They have demonstrated that with increasing mastery, chess players are able to reconstruct significantly more pieces of meaningful chess positions exposed briefly to them. The reconstruction of randomly placed pieces did not improve with increased mastery. Chase and Simon hypothesized that chess masters' superiority over less expert players was due to their ability to encode

* This study was carried out in partial fulfilment of the Ph.D. degree. An earlier version of this paper was presented at the eighty-ninth Annual Convention of the American Psychological Association, Los Angeles, California, August 1981

meaningful chess information more efficiently into 'chunks' in short-term memory.

The research on musical sight-reading lends support to the 'chunking' notion. Bean (1938) found that professional musicians could play almost five notes of a musical segment presented to them tachistoscopically while non-professional musicians could recall between two and three notes, and beginners, only one to two notes. He discovered that differences in perceptual span could be accounted for by differences in perceptual style; the majority of his professional pianists approached the task by reading musical patterns while most of the non-professinals read the music analytically, note-by-note. Weaver's (1943) finding that professional musicians could perceive between three and five notes at a single glance provided further evidence that proficient sight-readers can, in fact, process groups of notes as a single perceptual unit. Lannert and Ullman (1945) found that sight-reading skill was positively correlated with span of reproduction and ability to read ahead in the score, and Sloboda (1974) reported a correlation of 0.86 between sight-reading ability and the eye-hand span (the number of notes correctly played after the unexpected removal of the stimulus). In an interview study, Wolf (1976) discovered that good sight-readers report that they rely upon their recognition of familiar patterns and on their ability to organize the music into a few familiar patterns and dependable pattern cues. He also found that sight-reading appeared to be a very specific skill depending upon such a pattern-recognition style of information processing. The professional musicians who reported using an analytic strategy (note-by-note) as opposed to a pattern-recognition strategy were poor sight-readers although their ability to memorize was superior to that of expert sight-readers.

Chase and Simon (1973) attribute the skilled experts' superiority to their extensive information bank in long-term memory, developed through experience with the skill domain, which enables them to rapidly perceive and recognize familiar patterns. Thus, long-term memory is hypothesized to contain an internal representation of such familiar patterns together with information concerning appropriate associated actions. Furthermore, Chase and Chi (1980) propose that the information is organized hierarchically. A number of patterns may, therefore, be represented in a single familiar configuration in long-term memory. Experience is proposed as the process through which one's knowledge base and cognitive structure are built up. The importance of skill-related experience or practice in the acquisition of a skill was illustrated in a study by Chi (1978) who compared experienced and inexperienced chess players. In her study, there was an interesting twist; the expert players were children (mean age, 10.5 years) and the novice players were adults. As in the Chase and Simon study, players were required to reconstruct meaningful chess positions presented briefly to

them. They were also tested on a digit span task. Although adults were found to have superior recall for digits, the child experts' memory for chess positions was significantly superior. These results indicate that it is specifically skill-related practice that underlies expert performance rather than maturational factors or general, non-specific experience. It would not come as a surprise to music teachers to assert that 'practice is the major independent variable in the acquisition of skill' (Chase and Simon 1973). However, although practice is undoubtedly a crucial aspect of musical skills acquisition, the behaviour of music students as they practise remains an unexplored area.

In the domain of music, research has focused on sight-reading to investigate the acquisition of skills. While Shaffer (1981) has examined motor programming by investigating musical performance of professional pianists, little work has been directed to the acquisition process itself. The present study was designed to investigate the process of musical acquisition through an examination of the rehearsal behaviour of piano students varying in musical competence. The specific focus of the study was on practising strategies and how they change with increasing musical knowledge and expertise. In the first part of the study, the behaviour of 43 subjects from all music levels from Grade I to the Artist (Diploma) level, including three concert pianists, was compared as they practised three musical selections during a single practice session. In addition, the effect of increased familiarity with particular musical scores on practising behaviour was investigated in an attempt to discern the relative contributions to changes in rehearsal behaviour of musical competence acquired through long-term study and through short-term practice of specific materials. In the second part of the study, a subset of the players representing novice (Grade II students), intermediate (Grade VI students), and advanced (Artist; ARCT) levels of skill continued to practise their pieces for nine additional sessions (10 sessions in all). The pattern of practising behaviour across sessions was investigated in this part of the study. The study therefore used a cross-sectional approach, investigating performance across multiple trials. The behavioural domain under investigation was the subjects' natural practising of musical segments selected for their level of skill. Assessment consisted of two components, behavioural observations coded according to an observational rating scale, the Observational Scale for Piano Practising (OSPP), and self-report, tapped by means of a structured interview format. Of interest in the study were changes in the form and content of both behaviour and cognitive strategy as practising behaviour changed with increasing experience in music. Attention was specifically focused on how students chunked the music and how their chunking changed with musical experience, together with other changes that occurred concomitantly.

Method

Subjects

Subjects were 40 piano students taking individual instruction in piano, and three professional concert pianists. The students were graded according to the requirements of the University of Toronto's Royal Conservatory of Music, which provides grading standards for the region of South-Western Ontario. Subjects were defined as belonging to a particular level if they passed the Conservatory examinations for the previous level and were working on pieces for the designated grade. The subjects were selected so that three or four students from each musical level from Grade I to Grade X, and from the artist (ARCT) and professional levels, were included in the study. There were 33 females and 10 males ranging in age from six to 46 years and in experience from six months to 34 years, receiving instruction from one of 17 piano teachers. Details of the subjects' characteristics are presented in Table 5.1.

Table 5.1 *Subject characteristics*

Grade Level	*n*	*Sex* M	F	*Age* ($\bar{m}$ years)	*Experience* ($\bar{m}$ years)

Materials

In order to present the subjects with music representing a variety of styles and challenges, music pieces were selected for each music level from three musical forms: a Baroque piece, a contemporary piece, and a sonatina. The selections were limited to approximately one page in length in order to maintain the practising demand for the students at a reasonable level.

Accurate grading of the music was important to ensure comparable levels of difficulty for the pieces across grade levels. In order to control for

famliarity, pieces were selected that would have been unlikely to have been played previously. The Conservatory syllabus and the ratings of experienced music teachers were used to select pieces appropriate to the players' grade level that were unlikely to have been practised before.

All subjects were queried concerning whether they had actually played the pieces before; this revealed that the pieces were unknown to all but three subjects. When students had played a piece before, it was excluded from the study for those subjects.

Procedure

Part I

All 43 players were instructed to practise the three experimental scores as they would usually practise new pieces, and the practice sessions were recorded on cassette audio tape and later recorded according to the Observational Scale for Piano Practising described below. The very high reliability (Pearson $r = 0.97$) between *in vivo* observations and observations taken from audio tapes obtained in a previous study (Gruson 1978) confirmed the validity of the audio-taping procedure.

Part II

A subgroup of the players, four students in each of Grade II, Grade VI, and the Artist (ARCT) levels, were selected to represent novice, intermediate, and advanced levels of music proficiency. This subgroup of students was instructed to tape-record nine additional practice sessions (10 sessions in all). To represent a number of points in the acquisition process, the first, fourth, seventh, and tenth practice sessions were coded and analysed.

Observational Scale for Piano Practising (OSPP)

The Observational Scale for Piano Practising (OSPP) consists of the 20 categories defined in Table 5.2. The scale tapped length of uninterrupted playing, errors, repetitions of various unit lengths (notes, measures, larger sections), tempo changes, self-guiding speech, breaking down the piece into separate hands, giving up, playing music other than the designated piece, intervention of another person (for instance, parent), and a number of measures of practice time.

The format for recording required the rater to note, in its natural sequence, each incidence of a behavioural category as it occurred. To aid in this task, a recording sheet was constructed which divided the practice sessions into 5-s intervals. A stopwatch was used to mark the beginning of each 5-s interval. Frequency measures were employed for the majority of behaviours recorded since they tended to be discrete, momentary events. For measures that were more continuous (for example count aloud, hands

separately, and uninterrupted playing), the behaviour was scored for each 5-s interval in which it occurred.

To assess inter-rater reliability, a randomly selected sample from 17 practice sessions recorded from 15 subjects was chosen. The 15 subjects represented in the sample were randomly selected with respect to experience level, age, and sex. In addition, a random selection was made from all practice sessions using the experimental stimulus pieces, from the first to the tenth session. A sample of 3174 behavioural codes recorded over a period of 185.8 min was rated by two experienced observers from audio-tapes using the OSPP. The Kappa coefficients (K) for each behavioural category ranged from 0.96 to 1.00, all of which were highly significant and confirm that the OSPP may be considered to have a high level of inter-observer reliability.

Table 5.2 *Observational Scale for Piano Practising (OSPP)*

Symbol	*Name*	*Definition*
Unint	Playing without interruption	S plays the piece for 5-s interval during which no other behavioural categories occur. Score for each 5-s interval S plays uninterrupted.
Error	Error	S plays incorrect note.
Repetition		
RNote	Repeat Note	S repeats a note on which an error may or may not have occurred with or without correction.
RMeasure	Repeat Measure	S repeats a measure, or a part of a measure, in which an error may or may not have occurred with or without correction.
RSection	Repeat Section	S repeats a section of the piece longer than a measure in which an error may or may not have occurred with or without correction.
RPiece	Repeat Piece	S repeats whole piece from the beginning after completing previous practice of entire piece. If S goes to the beginning of piece after playing only part of the piece, score as RSection.
Tempo changes		
Slow	Slow down	S slows the musical tempo beyond the range permitted by the music.

Pause	Pause	S stops playing for at least 2 s in a 5-s interval. Score for each 5-s interval.
Fast	Speed up	S increases the musical tempo from the normal tempo for a part of the piece. Score for each 5-s interval.
Verbalizations		
Guide Sp	Self-guiding statements	S directs his/her playing verbally, e.g. 'Slow down', 'I made a mistake, I'd better try again'.
Read	Read Aloud	S reads notes aloud before playing them.
Count	Count Aloud	S counts aloud to aid timing. Scored for each 5-s interval.
Frust	Frustration	S verbalizes or emits signs of frustration, e.g. sighs, grimaces, groans, frowns, complaints, negative self-statements.
Hands Sep	Hands Separately	S plays a piece or a section of a piece with one hand only. The onset only is scored by H. The offset is marked by TOG (indicating coordinated hands) or by the end of the piece (/).
Give Up	Gives up	S fails to complete the piece. This behaviour is followed by a new piece or the end of the session. This category would also be scored if S attempts only a part of the piece and does not play piece through to completion.
Play other	Playing other than the designated piece.	S plays something other than the music in the score.
Person	Intervention by another	Other (usually a parent) intervenes in the practice, offering assistance or direction.
TTime	Total time	The duration of time spent in practising, calculated as the sum of time spent practising each piece.
Time	Mean time/piece	$\frac{\text{Total time}}{\text{No. of pieces practised}}$
Tempo	Tempo	No. of notes/s of first practice in each session, averaged over pieces. This value was calculated from the first stretch of *unint* of at least 10-s duration.

Interview

An additional concern of the present study was the subjects' knowledge and understanding of their own practising behaviour. In order to assess the subjects' cognitions concerning their piano practising, all subjects in Part II and the three concert pianists were given an interview concerning their rehearsal behaviour following the tenth or last practice session. The interview included the following six questions:

(1) How did you go about practising the pieces?
(2) What did you pay attention to?
(3) How did your practising change as you learned the pieces?
(4) What did you do when you made an error?
(5) What advice would you have for another student at your level learning these pieces?
(6) Is there anything that you should have done when you practised that you know that you did not do?

Results

Part I

The rate of OSPP behaviours for the Part I data is presented in Fig. 5.1. Across all subjects, the most frequently occurring event was uninterrupted

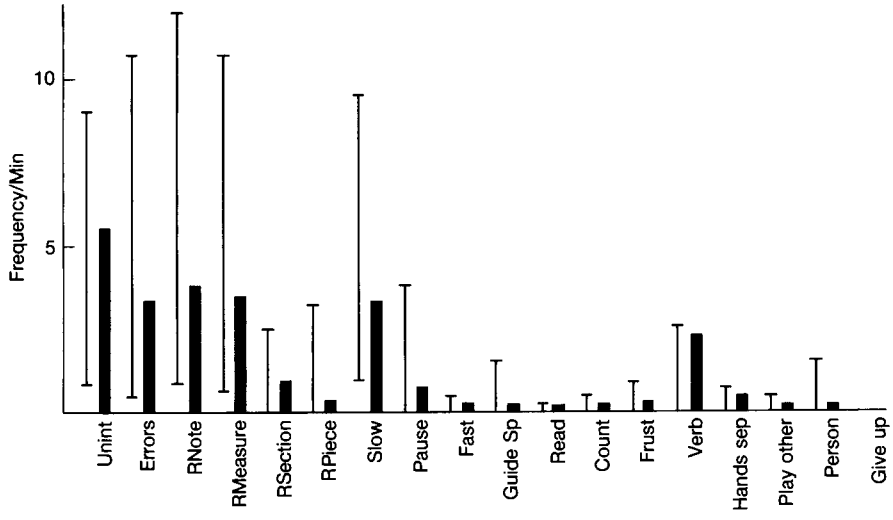

Fig. 5.1. Mean rate and range of practising behaviours per min: Session 1 (n = 43).

playing. The repetition of shorter units was the next most frequent type of event, repeating a single note accounting for 16.9 per cent of behaviours, and repeating measures, 16.7 per cent, while repeating sections accounted for only 2.6 per cent and repeating pieces, only 1.3 per cent. Slowing down was a frequently occurring event (16.0 per cent) while other tempo changes occurred less frequently. Errors also occurred frequently (14.3 per cent). The remaining behaviours occurred rarely, each accounting for less than 1 per cent of the total number of behaviours, although the sum of all self-verbalizations totalled 1.6 per cent of the total behaviours. In sum, students generally spend a quarter of their initial practice sessions in uninterrupted playing. When the flow of playing is broken, it is usually interrupted by errors, repetition (usually of short units), tempo reductions, pauses, and self-verbalizations.

But do all students practise alike? In order to investigate differences that may occur with increasing musical experience, the correlations between practising behaviours and skill level may be examined in Table 5.4. While it is a relatively infrequent event, repeating sections was the variable most significantly correlated with music level. Indeed, music level accounted for over 50 per cent of the variance in repeating sections. Music level

accounted for 24 per cent of the variance in playing hands separately and between 10 and 16 per cent for each of errors, repeating notes, pauses, verbalizations, and, specifically, self-guiding speech, playing hands separately, and time. Higher music levels were also associated with reduced frequency of errors, repeating notes, and pauses.

Another way of looking at the relationship between competence and practising behaviour is to use the practising behaviour itself to discriminate between students of varying levels of competence. A discriminant functions analysis was carried out in order to determine which combination of practising behaviours could most parsimoniously and accurately discriminate students of differing skill levels. An examination of the 43 subjects suggested three groups in terms of the way music educators conceptualize music study. The three groups were divided by points that reflect certain watersheds in the career of a music student. Basic music training takes place in the first eight grades and students successfully completing Grade VIII receive a high-school credit for music. Senior music study begins in Grade IX, and the more difficult study of harmony is included in the programme at this level. Thus, the first cutpoint for the discriminant analysis was set between Grades VIII and IX. The second cutpoint was placed between the ARCT level and the concert pianist level, therefore distinguishing senior students from professional musicians. The three groups were, therefore, Grades I to VIII, Grade IX to ARCT, and professional concert pianists.

In order to arrive at the most parsimonious combination of variables that would successfully discriminate the three groups, a series of discriminant analyses was carried out, successively reducing the number of variables until the shortest, most discriminating series of variables was derived.

The analysis yielded 16 variables which in combination accurately classified all the 43 students into the three groups. A jack-knifed classification (which indicates the classification of a particular case into a group according to a function computed from all the data excluding that particular case) yielded an 88.4 per cent accuracy rate. The discriminant analysis indicated that the number of variables that emerged from the correlational analysis as relating to music level, such as repeating sections, pauses, playing hands separately, and time, were in fact important in discriminating the practising behaviour of students varying in level of skill. Repeating sections, particularly, emerged as an important discriminating variable and in order investigate the proportion of subjects that could be classified using only this single variable as discriminator, a discriminant function was computed including only repeating sections. The function yielded a 79.1 per cent success rate indicating that almost four-fifths of the subjects could be classified according to their use of this single behaviour.

In *summary*, the analysis of the data from the initial session revealed that

a number of changes in practising behaviour occurred as students gained musical skill. Errors, repeated notes, and pauses tended to decrease with competence while self-guiding speech, total verbalizations, playing hands separately, time spent on each piece, and, particularly, repeating sections (0.18 per min for Grades I to VIII, 0.75 per min for Grades IX to ARCT, and 2.40 per min for professionals) increased as music level increased.

Part II

Let us now take a closer look at the subset of Grade II, Grade VI, and ARCT students, how their practising differed and how it changed across practice sessions. Sessions 1, 4, 7, and 10 were selected as samples of the practising process. The descriptive data are presented in Fig. 5.2.

A correlational analysis was first carried out between practising behaviour and music level for each of the four sessions sampled. The results are presented in Table 5.6. In the initial session of Study 2, grade level accounted for the most significant proportion of variance in repeating sections (77 per cent). Repeating sections continued to increase with skill level across all sessions (0.39 per min in Session 1 to 0.62 per min in Session 4). While playing hands separately and time also increased significantly as music level increased in the first session, these variables were not significantly correlated with skill in the later sessions. A number of other behaviours were related to experience at various points in the practising process. Specifically, uninterrupted play in Sessions 4 and 10 increased as music level increased; slowing down and repeating notes in Session 4, and tempo in Session 10, decreased as skill increased.

Another way of assessing changes in the relationship between practising behaviour and music level across practice sessions is by means of discriminant analyses repeated for the data from each of the four sessions examined. The discriminant analyses were used to investigate the stability of the variables discriminating between the three levels (Grade II, Grade VI, and ARCT) across sessions.

The three groups of subjects were successfully discriminated by three variables. For sessions 1, 4, and 7, the discriminating variables were identical: repeating sections, playing hands separately and pausing. In the final (tenth) session, playing hands separately was no longer found to be discriminating and uninterrupted play entered the function as the third discriminator. In all sessions, repeating sections was the most discriminating variable. Indeed, as the sole variable in the discriminant function, repeating sections was able to correctly classify 81.8 per cent of subjects in Session 1 and 72.7 per cent in each of Sessions 4, 7, and 10.

In order to investigate more directly the relationship between practising behaviour and sessions, a correlational analysis was carried out on all

† $p<0.05$
†† $p<0.001$

variables for each group and a one-way repeated measures analysis of variance was performed.

A number of significant correlations emerged although they were not found consistently for all three groups. Across sessions, repeating measures increased for Grade II (1.62 per min in Session 1 to 2.50 in Session 10) and Grade VI (3.55 per min in Session 1 to 4.69 in Session 10) students, repeating pieces increased for ARCT students (0.20 to 0.38), and speeding up increased only for the Grade II group (0.03 to 0.45). Repeating sections increased across sessions for all groups but not to a significant degree.

Analyses of variance were carried out involving a one-way repeated measures design for each behavioural category with music level as the independent variable and session number as the repeated variable. Significant main effects of music level were found for repeating sections, pausing, and verbalizations. These results support the findings of the correlational analyses that as music level increased, repeating sections increased. The correlational analysis for pauses and verbalizations produced no significant correlations although the discriminant functions analysis indicated that pauses could be helpful in discriminating between groups.

The descriptive data indicated a decrease in pauses with increasing skill. Looking at the data for repeated sessions, only tempo yielded a significant main effect across sessions and this variable also produced a significant interaction between music level and session number. The ANOVA and descriptive data indicate that while there were no large, consistent differences in tempo across the three subject groups, the Grade II students increased their tempo considerably more rapidly over sessions than did the more experienced groups. In addition, while the tempo maintained by the Grade II and Grade VI students increased steadily as session number increased, the tempo of the ARCT students had reached an asymptotic level before the seventh session. Thus, the less experienced students spent all 10 sessions increasing their tempo while the most experienced students mastered the pieces' tempo early in practising and were free to focus on other aspects. Self-reports indicated that the ARCT students knew the pieces fairly well after a few sessions and spent the later sessions experimenting with the pieces or memorizing them.

The impact of increased competence and practise experience may also be investigated on a more microscopic level by analysing the sequences of behaviours within practice sessions. In addition to the above analyses, a sequence analysis was carried out in which the behaviours following errors were examined. The analysis indicated that a repeated note was the most common event following an error, although for the more senior artist (ARCT) group, repeated measures increased in frequency across sessions. The category Repeating sections occurred rarely. The subjects' self-reports indicated that repeating sections was an event that would occur later in the response chain, following the repetition of shorter units.

In *summary* then, the results of Part II did not support the hypothesis that consistent changes in practising behaviours occurred with increasing practise of particular music pieces. The most salient finding was the impressive consistency across sessions of the importance of a number of variables, particularly repeating sections, as discriminators of students of different musical levels. Thus it appears to be many hours of practising a wide variety of music pieces that influences practising behaviours.

Interview

The interview was carried out as a means of tapping students' knowledge concerning their practising and investigating differences between subjects differing in musical experience. The Grade II, Grade VI, ARCT students and concert pianists (professionals) were included in this part of the study. Their responses to the six questions were given a quantitative and qualitative score, the quantitative score being the number of strategies described in the response and the qualitative score representing the degree

of cognitive complexity and abstraction reflected in the response. The latter measure involved the rating of each response according to a four-point scale, each point representing the following types of practising strategy:

(1) *Simple undifferentiated.* This category refers to responses that do not specify behavioural strategies nor differentiate between types of music pieces played. The response is excessively general and gives no indication of any particular knowledge of specific strategies, for example, 'I try to do my best'; 'I try to work hard on the piece'.

(2) *Concrete behavioural.* This category includes responses that articulate specific behavioural responses that remain the same regardless of the piece played. The strategies are mechanically employed for all pieces and do not take into consideration the kind of material being practised nor the individual's experience with that kind of piece, for example, 'I go over the piece three times'; 'I play each piece hands separately first', 'I go over each error five times'.

(3) *General strategies.* This category includes responses that indicate the use of generalized strategies for dealing with the practising task. The strategy allows for specific behavioural elaborations that can be flexibly modified for the demands of the particular musical piece, for example, 'I divide the piece into chunks'; 'I correct the error and fit it into its phrase context'; 'I work on the fingering' (or timing, or phrasing' etc.).

(4) *Higher-order strategies.* This category refers to responses that involve higher-order chunking of the task. The strategies specify the general strategies that are carried out. They are abstract and general rather than behaviourally oriented, for example, 'I try to get a feel for the piece'; 'I work on technical problems'; 'I work on interpretation'.

The mean qualitative and quantitative scores for each music level are presented in Fig. 5.3. The graphs indicate that both the qualitative and quantitative scores increased with increasing musical skill. Analyses of variance revealed highly significant main effects for musical level for both qualitative scores (F=8.72; df=3,11; p<0.005) and quantitative scores (F=32.19; df=3.11; p<0.001). Thus, more experienced musicians report using more complex practising strategies and these strategies are more complex and abstract than those of less experienced students. One difficulty with the present results is the possible confounding of linguistic and cognitive complexity associated with age. In the present sample, age was highly correlated with music level (r=0.75) and the number of words produced in the subjects' interview protocols was highly correlated both with the number of strategies enumerated (r=0.78) and with their cognitive complexity (r=0.73). The effects of age on music students' self-reports merits further investigation in future research. For example, with a study following the methodology of Chi (1978) comparing the interview data of older, inexperienced players and younger, experienced musicians,

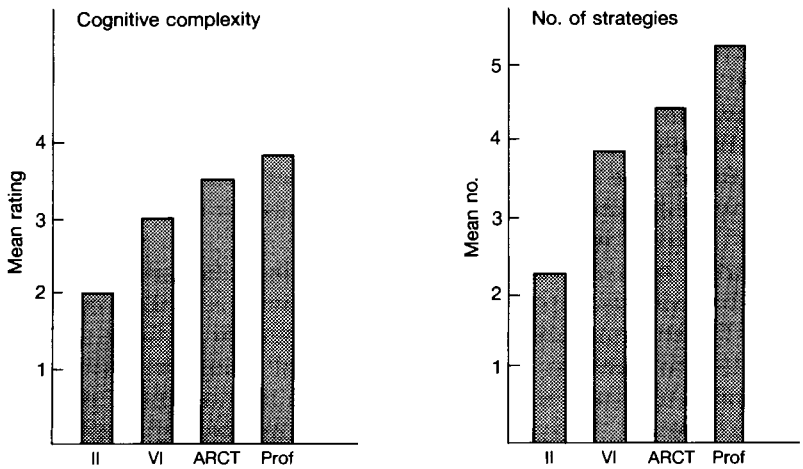

Fig. 5.3. Interview: descriptive statistics and ANOVA.

the confounding of age and cognitive and linguistic complexity could be evaluated.

The behavioural analyses pointed to the importance of repetition in the practising of music students. A specific analysis of Question (4) of the interview (What did you do when you made an error?) was carried out in order to investigate subjects' knowledge concerning the units of music they repeated. Fig. 5.4 presents the percentage of responses represented by each of the units of repetition examined for each group, confirmed by the performers as following errors in the interview protocols. Examination of the figure reveals that repeating notes occurred less frequently and repeating sections more frequently as music level increased. Thus the interview data corroborates the findings from the behavioural data.

Discussion

The results of the study indicate that significant changes in practising behaviour take place as individuals acquire competence as musicians. As music level increased, there was an increase in repeating sections, verbalizing, playing hands separately, and practice time, while errors, repeating notes, and pauses decreased. There were fewer behavioural changes across sessions. Tempo increased across practising sessions for all music levels but reached an asymptote in the early sessions for the more advanced pianists. The most consistent and significant finding was the

change in the units of music repeated during practising as musical experience increased. The behavioural analyses indicated that as musical skill increased, students repeated sections of music more frequently and there was a tendency to reduce the number of notes repeated. Subjects' self-reports also indicated that the size of the unit of repetition increased with music level, corroborating the behavioural data. The interview data also revealed that more experienced students were able to conceptualize their practising behaviour in a more differentiated and abstract manner. They described more practising strategies and these strategies were found to be more cognitively complex. The changes in practising behaviour were far more significant between music levels than between practice sessions of individual pieces. Thus it appears to be the many, many hours of practising involved in mastering a new music level rather than the relatively few sessions it takes to learn an individual piece that bring about consistent and enduring changes in information processing.

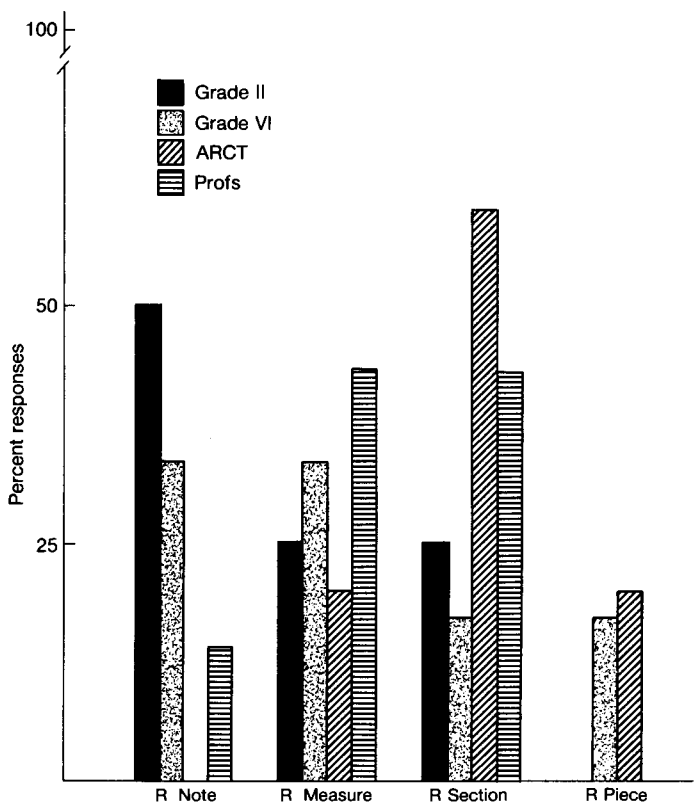

Fig. 5.4 Interview: size of units repeated following error.

In order to understand how changes are brought about through rehearsal, that is, how chunking takes place, two models may be helpful, that of automatization (Shiffrin and Schneider 1977) and that of motor programming (Shaffer 1980).The notion of automatization as articulated by Shiffrin and Schneider proposed that learning a skill requires a shift between information processing modes from controlled to automatic processing. Controlled processing was described as a slow and effortful mode under attentional control which is subject to the limitations of short-term memory and is serial in nature. Controlled processes tend to be accurate and can be flexibly applied to unfamiliar or changing situational demands. Extended and consistent repetition, such as occurs in practising, permits the establishment of associations in the long-term memory store which, with continued practice, may be triggered by familiar stimulus configurations appearing in short-term memory. Thus, an overlearned, routinized stimulus pattern comes to trigger the performance of a highly stereotyped inflexible behavioural sequence which runs to completion automatically, without the involvement of conscious control. Automatically learned sequences may be combined to form more complex units through a process labelled 'composition' by Neves and Anderson (1981). The composition process enables the more rapid execution of the combined routine.

Musical practising may be viewed as a sequence of transitions from controlled to automatic processing in which larger and larger chunks of musical information are built up from more basic subcomponents. The novice student might be expected to focus upon associating individual notes in the printed score with the corresponding positions on the musical instrument by means of controlled processing. With practice, the associations between printed notes and manual positions become automatized and attention may be focused upon more complex musical patterns such as chords, measures, and ultimately phrases and larger units which may, in turn, come to be executed automatically from a single glance at the score. With repeated practising, the unique sequence and integration of musical patterns in the piece may be executed automatically and the practiser finds himself or herself able to play the piece from memory.

Students' repetition patterns following errors can provide us with clues regarding how they process musical information. With musical expertise, a process of structural differentiation takes place. The beginning student tends to perceive a piece as an amorphous whole consisting of a series of independent notes which, with practising, he or she is able to execute in a more automated fashion. Thus, when a mistake is made, the novice will be likely to repeat the erroneous note or measure. The acquisition process for the beginner involves construction with musical building blocks to erect an integrated whole. The expert musician, however, tends to approach a piece from the top down. He or she is more likely to break the piece down into

hierarchically organized patterns, differentiating it, for example, into a number of independent but linked sections. To correct an error, the skilled player is more likely to repeat the entire structural unit, the section, rather than a component note.

The results of the present research indicated that with increasing skill, on a cognitive level, pianists are able to describe a wider variety of practising strategies and these strategies are more complex, more abstract, and more flexible. Together with the notion of structural differentiation, the notion of motor programming may be added to the formulation to explain these changes. A motor programme, according to Shaffer (1980), may be viewed as a hierarchically organized series of plans. The acquisition of skill involves the development of higher-order plans that are more abstract and incorporate a number of simple components of the skill into more complex, superordinate units. Shaffer defines a plan as:

> an abstract homomorphism of the performance, representing its essential structure. It does not represent all the details of the performance but allows these to be generated or accessed as they are needed in the execution.

In the performance of a skill, the motor programme calls into action an intention that provides a goal and the overall structure for the performance. This intention then calls into play increasingly more specific plans that may be executed automatically and in parallel. Thus this model incorporates the notion of the hierarchical organization of cognitive structures proposed by Chase and Chi (1980). In music, such hierarchical processing is found to take place both at a behavioural and a cognitive level. The inclusion of plans in the formulation takes into account not only the execution of automatized sequences of behaviour, but also the flexibility required in the performance of a complex skill.

In the study discussed here, the articulation of higher-order, more flexible plans was found in the self-reports of the more advanced musicians. On a behavioural level, the increase in the size of the units of repetition associated with increasing expertise reflects the hierarchical nature of motor programming in music performance.

Directions for future research

The research decribed in this paper was exploratory. There are a number of limitations and opportunities for future research efforts.

One of the major difficulties in the study was the small number of students investigated at each musical level. The reliability and generalizability of the findings need to be assessed by means of a replication incorporating a larger sample. In addition, a problem in the sample selection was the high correlation between age and music level, which made it difficult to ascertain whether differences in practising behaviour were related to

increasing musical experience, increasing age, or a combination of both. While research in other areas, such as chess (for example Chi 1978), indicates that skill depends upon domain-specific experience rather than age, a similar finding needs to be demonstrated in the musical domain by comparing older beginners to more advanced younger students and including such individuals in the general sample. In addition to age, a number of other variables such as differences in teachers' style, students' motivation, and musical aptitude could also be investigated.

While the present study focused on differences in behaviour among music levels, it would be interesting to examine whether differences in practising behaviours exist between subjects of the same level. A larger subject sample would make such an analysis feasible and would provide important information concerning whether some subjects are able to use comparable musical experience to develop more mature patterns of practising than other students. Such data could be used to predict which students might become virtuosi in the future. In addressing the issue of prediction, a longitudinal investigation would be valuable in examining more directly the development of practising technique with experience. One could compare the earlier practising behaviour of students who are later musically successful to that of those who are less successful (for example, those who fail examinations) and those who drop out of music study. It would be particularly interesting to identify those behaviours which best predict future musical involvement and expertise; aspects of the performance, knowledge assessed by the interview, or both. If it is indeed possible to isolate more mature or effective practising strategies, it would be interesting to investigate by means of a specific training programme whether practising is modifiable or whether it is purely a function of experience.

In terms of the analyses, further modification of the OSPP would be useful. While the results underscored the importance of repetition of sections in the development of musical competence, this category could vary widely in size from a few notes to several lines of music. For future work, it would be important to examine sections of varying length separately. The research of Sloboda (1974, 1977) and the self-reports of students in the present study suggest that the phrase is a fundamental musical unit and it could be investigated singly, in addition to larger units such as a thematic line, a physical line, a page, a movement, and so forth. Hence, a more discriminating investigation of the units of information processing could be carried out.

Also of interest is what happens when information processing breaks down and errors occur. Subjects' interview data indicated that they differentiate between different types of errors and respond differently depending upon the kind of error made. In order to obtain a taxonomy of errors for use in future research, a microscopic analysis of errors derived from videotaped practice sessions could be performed.

A number of problems emerged in the interview study. First, there existed a possibility of confounding linguistic fluency and complexity, since verbal productivity was found to be highly correlated with both the qualitative and quantitative scores. To control for this variable, one could compose one's sample of subjects whose age and music level are not as highly correlated, and include age-matched control subjects with no musical experience. Another direction for future research would be a more formal analysis of the content of the protocols of subjects of varying levels.

In the present study, the interview was carried out following the tenth and last practice session. In order to gain an understanding of changes in students' knowledge and affective experience regarding their practising as it progresses, their self-reports may be obtained at a number of points in the practising process. Such a procedure would also permit an assessment of the impact of subjects' cognitions and affects on their practising behaviour. In addition, one could investigate alternate ways of assessing cognitions and affects by changing the format of the interview. For example, one might investigate differences in the data derived from a structured interview such as the one used in the present study, an endorsement (forced choice) procedure, and a coaching procedure (in which a student is required to teach another student at his or her level to play the same piece).

Finally, the generalizability of the findings may be assessed through the application of the methodology to a variety of complex skill domains. Indeed, the methodology employed in this research may be seen as a model which may be applied more generally to the investigation of the development of any skill.

Acknowledgement

The author wishes to thank Dr Donald Meichenbaum for his advice in designing the study and his helpful comments on an earlier version of this paper.

Tonal structure and children's early learning of music

W. JAY DOWLING

When we listen to speech in our own language we hear words and sentences, and not mere sounds. Just so, when we listen to the music of our culture we hear melodies composed of meaningful pitches, and not uninterpreted sound. As Pick (1979) has pointed out, to hear a melody is to perceive a meaningful event extended in time—an event with structure, with constraints on its pattern organization, and in which still briefer events are embedded. Even the simplest of melodies presents a complex rhythmic organization of pitches in time. This structure is expressed in pitch and time relationships that link the notes of a melody and that remain largely invariant over the course of the event; melodies tend to move at a regular tempo and draw their pitches from a limited set of the infinite range of possibilities. Furthermore, some event patterns found within a given melody remain invariant across other melodies within the style and culture. For example, in Western music melodies usually end and often begin on the tonic (the focal pitch of a key or tonality) and share patterns of phrase repetition (such as the AABA pattern common to many popular songs and hymns). As Pick and Gibson (1969; Gibson and Levin 1975) have suggested, the perceptual learning that provides the listener with the means of understanding meaningful events such as melodies involves learning to extract relevant pattern invariants from the complex of information available.

Invariants of tonal structure

Some invariants of melodic structure are explicitly accessible in conscious experience to the typical adult. For example, most adults know explicitly that 'Three Blind Mice' closes with a copy of its opening phrase, and notice when a child does not end it that way. Other invariants are not explicitly

accessible to adults without training, but with training can become so. For example, adults without music lessons are rarely able to describe the pattern of 1- and 2-semitone intervals in the major diatonic scale, while that pattern is one of the fundamentals learned early in formal musical training. Still other invariants remain implicit in the knowledge of even highly trained adults. For example, certain broad aspects of pattern organization described by Lerdahl and Jackendoff (1983) are unlikely to occur to musicians before reading their book (otherwise the book would not be so interesting). And the regularities of melodic structure pointed out by Rosner and Meyer (1982) had probably not occurred to the reader beforehand. Yet presumably such pattern invariants formed an implicit part of musicians' knowledge of the style described.

Even invariants that can on occasion be explicitly accessible usually remain implicit in their usual functioning in the cognition of music. In fact, effective, enjoyable listening normally relies on their remaining so, since, as Meyer (1956) has noted, focusing attention on formal properties while listening can easily interfere with meaningful experience of the music. That our knowledge of pattern invariants shapes our cognition of music can be illustrated by numerous examples. Shepard and Jordan (1984) showed that listeners' judgements of a scale formed of actually equal logarithmic intervals were distorted in ways predicted by their reliance on knowledge of the irregular diatonic pattern. As Francès (1958) noted, our implicit knowledge of the diatonic scale allows us to hear a performer's minor intonation errors as instances of scale categories. Greater departures from the pattern invariant such as out-of-key notes are glaringly noticeable, as Cuddy *et al.* (1979) showed. Furthermore, listeners often confuse exact transpositions of a melody with imitations in which the same diatonic interval pattern has been shifted along the scale they have just been hearing (Dowling 1978), and this confusion diminishes with increasing alterations in the scale; that is, with shifts in the underlying pattern invariants (Bartlett and Dowling 1980).

Expectancy and encoding

The listener's largely implicit knowledge of invariants of musical patterns serves both to guide expectancies (or 'set') for new events and to provide ready encoding schemes for the events that actually occur. These two processes typically work hand in hand in the cognition of pieces of music. The expectancies created by initial events in a piece probably facilitate efficient encoding of ensuing events, as Haber (1966) suggests. And the ways in which those events are encoded in turn determines the expectancies that are generated for subsequent events. The readying of knowledge-based encoding schemes is very useful in the processing of the rapid and

complex stimulus sequences found in speech and music. As Haber (1966) noted,

> Stimuli for which [a person] has no code for translation into memory are notoriously difficult to remember, even though [an observer] may perform perfectly on . . . discriminations with such stimuli. . . . Most people experience this difficulty in describing colors, tastes, odors, and feelings from recollection. . . . These examples represent instances of excellent matching between the stimulus and prior experience, but very poor encoding of the stimulus into memory.

Fortunately, mere exposure to the music of one's culture induces sufficient perceptual learning to provide a fundamental encoding scheme for pitch. With further training the listener's encoding schemes become more elaborated, leading to changes in performance on memory tasks, and presumably in what is heard when listening to music. This is a process in which listeners become attuned to the perceptual invariants of the music of their culture, and consequently become more efficient perceivers of that music.

This encoding scheme for pitch develops during the first eight years of life, and the pattern of its development is quite regular. New evidence, however, suggests that children's progress in this development may be more rapid than had previously been supposed.

Invariants and development

Infancy

Relatively recent reviews have depicted the development of sensitivity to melodic invariants in broad outline (Dowling 1982*a*, Dowling and Harwood 1986, Chap. 5). The evidence indicates that melodic contour—the pitch pattern of ups and downs—is an important feature in melody perception from early infancy on. In a noteworthy study Trehub *et al.* (1984) used conditioning of head turning to show that infants of 8 to 11 months are sensitive to a variety of changes in immediate repetitions of six-note melodies—changes in pitches height of the whole melody (transposition and changes in pitch within a melody (either substitutions at the same general pitch height, or octave alterations of some pitches), as well as changes in melodic contour. However, when Trehub *et al.* increased the difficulty of the task by adding a 'distractor sequence' interpolated between repetitions of the melodies, the infants responded principally to changes in contour. The infants treated repetitions with altered diatonic pitches and transpositions involving small alterations of pitch height as equivalent to exact repetitions, while noticing gross changes in the pitch height of single notes (octave alterations) and contour changes. Melodic contour is a

critically important feature of melodies for infants, and remains so into adulthood (Dowling and Fujitani 1971). Contour is one of the most obvious features of a melody to remain invariant across its instances.

Contour is important to early song production as well as to perception. Around the age of one year children begin to sing spontaneous songs that are clearly differentiated from speech patterns by their rhythmic regularity and their tendency to elongate vowels on discrete pitch levels.* While the child during the first two years uses discrete pitch levels, those pitch patterns do not correspond to adult pitch categories established by the culture. That is, though single notes typically rest on well-defined pitches (as opposed to a siren effect), those pitches do not recur in invariant patterns from song to song, or even within songs. Children when they begin singing do not have pitch scales, though they have a prerequisite component of scales, namely, discrete pitches.

Singing during the early years consists largely of the control of melodic-rhythmic contour patterns.** In an analysis of 579 spontaneous songs produced by two children between the ages of one and six years, Dowling (1984*b*) found that even at the earliest ages songs consisted of patterns of repetition and alternation of brief melodic-rhythmic kernels. Around the age of two years a typical song consisted of the repetition at different pitch levels of a brief melodic phrase. These phrases remained constant in rhythmic and melodic outline throughout the song, and typically involved the repetition of a verbal phrase (such as 'Come a duck on my house', or 'Hoppy-hoppy run 'round the road'). Time within phrases was organized in a metrical beat structure on which the speech rhythms of the words of the phrase were overlaid, but that structure was often interrupted between phrases by breathing and other discontinuities.

The complexity of spontaneous songs increased over the first four years of life, both in terms of the number of phrases used and the pattern of their use. While songs with more than four distinguishable phrase contours were rare throughout that age range, there was a shift in the frequency of songs with just one repeated phrase. Songs with one phrase contour were fairly common between the ages of one and two years. By the age of three years

* Though I had noted indications in the literature that this spontaneous singing behaviour sometimes began as early as six months (for example, Ostwald 1973), I had been doubtful concerning the clarity of discrete pitch levels and rhythmic organization at such early ages. However, Ann Tubbs, a graduate student at UT/Dallas, has recently collected examples from a six-month-old boy that clearly exhibit rhythmic regularity and discrete pitches. I believe the onset of spontaneous singing can vary widely in the range of six to 18 months.

** We should not allow the emphasis in the adult experimental psychology literature on purely melodic contour (with rhythmic patterns typically held constant) to obscure the fact that in the perception and production of real melodies in the world the critically important component is an abstract contour pattern that captures both rhythmic and pitch-pattern invariants (Monahan 1984). As Dowling and Harwood (1986) pointed out, changing the rhythmic pattern of a tune while retaining the melodic contour will make the tune all but unrecognizable.

those had become rare, and songs in which three phrases occurred in varied patterns of repetition and alternation predominated. For songs where two or three phrases were involved the phrase-structure pattern changed between the ages of one and three years. A pattern that became more and more common with increasing age was one in which two, three, or four phrases would recur in some pattern of repetition, and which ended with yet another 'coda' phrase that had not yet occurred in the song. This last structure occurs in a number of nursery songs such as 'Mary Had a Little Lamb', 'Here We Go 'Round the Mulberry Bush', 'London Bridge', and 'On Top of Old Smokey' (all ABAC); 'D'ye Ken John Peel' (AABC); and 'Good King Wenceslaus' (ABABCBDE). But interestingly, this regular phrase structure pattern was more common in the children's songs that in their nursery song models. The children had latched on to a simple pattern that they used to control their songs, thereby constraining them in this respect more tightly than the song models provided them.

Childhood

Singing during the ages of one to five years is thus largely a matter of controlling the pattern of repetition of rhythmic-melodic phrase contours. On the basis of earlier evidence I had come to believe that until the age of five years or so children remain insensitive to subtler aspects of pitch; that is, they mostly sing 'out of tune' by adult standards. However, during that period they do learn more and more nursery songs that model the adult pitch classes of the *do-re-mi* scale, and they do sing them more and more in tune. And now there is new evidence that such experience leads at least some children by the age of four years to be sensitive to invariants in the details of the pitch pattern of melodies, both in noticing contour-preserving changes in the pitch intervals of familiar melodies, and in distingushing novel tonal melodies (that conform to the scale invariants) from atonal ones (that do not).

Trehub *et al.* (1985) asked four-to-six-year-olds to identify variants of 'Happy Birthday' and 'Twinkle, Twinkle, Little Star' as either normal or 'funny'. Presumably distortions that violated the child's own internal models of the songs, and that could be detected given the precision of the child's processing capabilities, would trigger 'funny' responses. If the child were relying solely on contour in responding to the songs, then alterations that preserved contour should not sound 'funny'. However, 'funny' responses to changes in pitch intervals where contour is preserved can be taken to indicate that the child is relying on more than just contour in judging the melodies. Adults, even with no musical training, are very sensitive to changes of pitch intervals in familiar melodies. Trehub *et al.* found that the children behaved like adults in rejecting versions of both of these tunes in which pitch intervals had been changed, as well as versions

that changed contour. For 'Twinkle, Twinkle' rejection on the basis of interval change was as great as for contour change, while for 'Happy Birthday' contour violations caused more rejections than interval violations. Thus for some well-known, familiar melodies four-and five-year-olds are able to notice changes in intervals from the models, as well as changes in contour.

Trehub *et al.* (1985) incidentally tested the notion that kindergarteners are sensitive to changes of key—to shifts in the tonal center and the set of pitches that make up the 'do-re-mi' scale underlying a melody. This tendency had been observed by Bartlett and Dowling (1980) as an increased tendency to reject a comparison melody the further it departed from a standard stimulus in terms of 'key distance' (a measure of shared pitches in the diatonic scale—the greater the number of shared pitches the smaller the distance). Trehub *et al.* observed such an effect as well, obtaining more 'funny' responses to far-key comparisons than to same-key comparisons (with near-but-different-key comparisons intermediate). This adds to our evidence that children in this age range are becoming sensitive to certain invariants of the culturally determined scale patterns.

The foregoing evidence shows that preschoolers are sometimes sensitive to pitch substitutions that alter the intervals of familiar tunes, and to transpositions of familiar tunes that take them into relatively distant keys using different sets of tonal scale pitches. Adults, especially musically trained adults, can also discriminate between melodies that are tonal—that conform to the invariants of a tonal scale pattern—and those that are not (Dowling 1978). I was curious to find out whether preschoolers would display sensitivity to the tonality vs. the atonality of melodies. Sensitivity to altered pitches in familiar melodies might simply reflect specific knowledge of certain well-learned tunes, and not reflect general knowledge of invariants of scale structure. However, sensitivity to 'atonal' alterations of pitch that violate scale invariants, as compared with tonal alterations that remain within the scale structure, can be taken as an indication that the child had some knowledge of the tonal structure of melodies in general—knowledge of the cultural invariants. Therefore, we conducted the following experiment.*

Preschoolers' sensitivity to atonal melodies

Method

The experimenter visited preschools and kindergartens in the Dallas area, and tested the children individually in isolated rooms in the schools. Eight

* I thank James C. Bartlett for helpful suggestions in the design of this experiment, and Melinda Andrews for carrying it out.

three-year-olds (that is subjects between the ages of 3.0 and 4.0 years), 12 four-year-olds, and 12 five- and six-year-olds served in individual sessions. The experiment was replicated with a group session for eight college students at UT/Dallas (mean age = 29.6 years), who divided evenly into those with two or more years of music lessons, and those with no musical training.

The stimuli were 16 brief melodies approximately 8 s long, presented at a rate of two crotchets per s (where a crotchet represents the most common note value of the melody). The melodies were derived from eight familiar tunes in the key of C major: 'Mary Had a Little Lamb', 'Frère Jacques', 'Yankee Doodle', 'Old Macdonald', 'Oh, Susanna', 'Good King Wenceslaus', 'London Bridge', and 'Waltzing Matilda'. From each tune two new melodies were derived: one tonal and the other atonal. The tonal derivatives were created by shifting the melodic pattern along the C major scale so as to preserve the contour and diatonic intervals, but alter the interval sizes among the notes. (All the tonal derivatives still either began or ended—and usually both began and ended—on one of the pitches of the tonic triad: C–E–G.) The atonal derivatives were created by placing the melodic patterns at analogous points on an 'atonal' scale designed to produce interval patterns not contained in either the major or the minor diatonic scales in Western music. This scale consisted of the set of pitches C–D flat–E–F–G flat–A flat–B—an interval set with half-steps between the first and second, third and fourth, fourth and fifth, and seventh and eighth degrees, augmented seconds between the second and third degrees and sixth and seventh degrees, and a whole-step between the fifth and sixth degrees. The purpose of this method of generating stimuli was to preserve the average interval size and the amount of pitch repetition characteristic of melodies familiar to the children. This was especially important in the atonal derivatives, where it would not have been as satisfactory simply to substitute non-scalar pitches for scalar ones in isolated instances. The mean interval sizes were 1.66 and 1.69 semitones/interval for tonal and atonal stimuli respectively, counting unisons (note repetitions) as zero semitones.

All 16 stimuli were presented to each subject. Two different random orders of the stimuli were tape-recorded using the 'clarinet' voice of a Yamaha synthesizer, and each tape was presented to half the subjects in each age group. Thus the two derivatives—tonal and atonal—of each seed melody were presented to each subject.

The experimenter brought a tape-recorder, two stuffed animals (rabbit and bear), and a 'puppet-theatre' screen to the school. At the start of the session the experimenter conversed briefly with the child, and asked the child to sing a song, most often 'Happy Birthday'. (For the younger children the experimenter suggested that it was the bear's birthday.) All the children except for four three-year-olds sang something, which the experimenter recorded. The experimenter sat behind the puppet-theatre

screen, and the child sat in front of it. The experimenter explained that the two animals liked different sorts of songs. (The animals' preferences were alternated from subject to subject. For older children who considered them too childish the animals were dispensed with.) One of the animals liked songs that had all normal notes in them. The experimenter played an example of a tonal melody, and displayed the animal that liked that type. The other animal liked 'funny' songs that had notes in them that sounded 'odd' or 'different from the other notes'. The experimenter displayed the other animal and played an example of an atonal melody. Then the experimenter presented the task in which the curtain of the puppet theatre would be drawn and the subject would listen to a melody. Behind the screen was the animal that liked that song, and the subject had to guess which animal it was. After the subject guessed, the curtain was opened to reveal which animal it really was. (This provided feedback for the trial.)

The songs the children taped at the start of the session were rated by 12 independent judges for 'how well in tune' the children sang. The children in each age group were divided at the median for those ratings into higher- and lower-rated singing groups. The four three-year-olds who did not sing at all constituted the lower-rated group for that age.

Results

Table 6.1 shows per cent correct judgements for the subjects with higher- and lower-rated singing in the three children's age groups, and for the adults. A 2-ratings $\times 3$ ages analysis of variance on the children's data showed only a main effect of song rating, $F\ (1,26) = 5.37$, $p<.05$. Children's performance in all the age groups was essentially at chance for those whose singing received low ratings, and was significantly better than that for the chidren with higher ratings of singing intonation.

Table 6.1 *Per cent correct responses discriminating tonal from atonal melodies distributed according to song performance (children) or musical experience (adults)*

	Group	
Age	Low Song Rating (inexperienced)	High Song Rating (experienced)
3 yr	50	58
4 yr	50	59
5–6 yr	46	61
Mean for children	49	59
adult	70	72

Discussion

The most interesting feature of these results is that children as young as three and four years, provided they were among the more competent singers, displayed the ability to respond to the degree of tonality of the stimuli. Presumably even at such early ages increased facility with simple musical materials—the songs learned at home and at school—goes hand in hand with facility in discriminating melodies on the basis of invariant properties such as conformity to standard scales. It seems plausible that nursery songs that emphasize the pitch content of the basic scales in the culture, without shifts of key or the introduction of altered pitches foreign to the key, would best facilitate perceptual learning involving the scale invariants. The next piece of evidence suggests that nursery songs are simple in just that way.

Tonal structure of nursery tunes

The best materials from which to learn the invariants of the tonal scale patterns are tunes in which those invariants are most clearly present; namely, tunes that introduce few alterations of pitch into the basic pattern. To the extent that nursery songs fill this need for simple learning materials for the scale system, we should expect them to be strongly tonal, and to contain relatively few departures from the key in which they start. Folk-songs from the same culture, but intended for adult singing, could be expected to contain more variant pitches departing from their initial keys. 'Art' songs, intended to be sung by advanced amateurs and professionals, should contain still more variation of pitch material. To test these possibilities I counted songs in those three categories that contained, and that did not contain, alterations of pitch which respect to the starting key of the song.

Method

I assembled a collection of 223 nursery songs from a group of books labelled as such by their editors (Seeger 1948; Moorat 1980; Beall and Nipp 1982). For adult folk-songs I used the 317 songs in Lomax (1975). And for art songs I used the 44 songs in Schubert's (1823, 1827) *Die schöne Müllerin* and *Die Winterreise*. I chose Schubert for this comparison because his songs, especially in these song cycles, have a folk-like, singable character, and are of the same general length and form as the songs in the other categories. That is, these songs of Schubert are as close as any in the Classical–Romantic tradition of European music to the European folk-song tradition.

Results

I categorized each song according to whether it contained alterations of pitch that departed from its initial key. The results are shown in Table 6.2. Clearly very few nursery tunes contain such departures, while the adult folk-songs contained more. All but two of the Schubert songs contained alterations. A chi-square on the 2×2 matrix involving nursery and adult folk-songs, altered or not, was signficant, chi-square (1)=45.38, $p<.01$.

Table 6.2 *Number of nursery, folk, and Schubert songs with and without pitches altered with respect to the starting key of the song*

	Nursery Songs	Adult Folk-songs	Schubert Songs
No Altered Notes	208	220	2
Altered Notes	15	97	42
Total	223	317	44

Discussion

Nursery tunes clearly differ, not only from Classical–Romantic art songs, but also from adult folk-songs in the culture, with respect to the simplicity of their tonal schemes. Nursery songs emphasize the repetition of strongly tonal patterns, and avoid the introduction of pitches that depart from the key established at the outset. They are thus ideal vehicles for perceptual learning of the invariants of the tonal scale pattern.

In passing, let me add a word about the differences between the adult folk-songs, one-fourth of which include altered pitches, and the Schubert songs. Generally, when a folk-song uses an altered pitch it is either as a chromatic passing tone, interpolated into the passage between two solidly tonal scale steps, or it involves playing with the differences between the major and minor (or other) modes, as with the alterations in the song 'Greensleeves'. Rarely do such alterations involve a change of key—a shift in the tonal centre and in the scale pattern. However, of the 42 songs in the Schubert sample that introduced alterations, 36 involved brief changes of key, typically modulations to the dominant. Thus the Schubert songs, simple and folk-like though they appear, contain not only more instances of altered pitches, but also a preponderance of altered pitches that signal shifts in the tonal structure of the song. Kessen (1981), in emphasizing the child's need for simple learning materials in acquiring basic knowledge of musical structure, points out the inappropriateness of the derivatives of tonally elaborate late-Romanticism for that function. From this comparison it

appears that even Schubert songs may be more complicated than is optimal for preschoolers' acquisition of the tonal system.

Musical experience and adult encoding

I wish to turn now to some new evidence bearing on the role of perceptual learning in the development of encoding schemes that reflect invariant patterns in musical structure. I will present evidence that even musically untrained listeners will, under certain circumstances, encode pitches in terms of the culturally defined pitch categories of the equal-tempered scale, as well as evidence that listeners with more training utilize more elaborate encoding strategies that involve diatonic pitch categories, defined within key structures.

Assimilation of quarter-steps

Even without specialized training in music, listeners use an encoding scheme for pitch arising from perceptual learning through exposure to their culture's 'tonal material'—the invariant describing the set of all possible pitch relationships in the culture (in Western music the 'chromatic' scale of all the semitones on the piano—Dowling 1978, 1982*b*, 1984*a*). This categorical encoding is apparent in the judgements of both musically trained and untrained listeners when judging pitches embedded in melodic contexts. In order to disclose this effect listeners must be put in a situation requiring rapid processing of tones, presumably via encoding guided by expectancies. As the quotation cited above from Haber (1966) suggests, listeners tend to be quite accurate when they can simply make direct comparisons between stimuli without using memory. However, following a familiar melody temporally interleaved with distractor tones presents them with a much more complicated problem. Previous results had shown that listeners can detect a familiar melody when its notes are temporally interleaved with the notes of a distractor pattern (at a rate of 8 or 10 notes/s in the same pitch range and of the same timbre and loudness, Dowling 1973). Recent results show that when listeners follow the pitch of a wandering tone in such a melody, and then compare its pitch with that of a subsequent probe tone, they make systematic errors (Dowling 1985). Those errors generally consist of judging half-step probes equal in pitch to actually presented quarter-steps, while making accurate responses to actually present half-steps. Thus quarter-steps appear to be encoded as neighbouring half-steps, while the half-steps appear to be encoded accurately.

Since listeners with no formal musical training show this assimilation effect of encoding quarter-steps as neighbouring semitones of the tonal

Improvisation: methods and models

JEFF PRESSING

Introduction

How do people improvise? How is improvisational skill learned and taught? These questions are the subject of this chapter. They are difficult questions, for behind them are long-standing philosophical quandaries such as the origins of novelty and the nature of expertise, which trouble psychologists and artificial intelligence workers today almost as much as they did Plato and Socrates in the fourth and fifth centuries BC.

In a previous article (Pressing 1984*a*) I summarized a number of general properties of the improvisation process on the basis of the diverse historical writings of artists, teachers, and musicologists. This material was integrated with precepts from cognitive psychology to sketch out the beginnings of a general theory of improvisation.

In this article a much more explicit cognitive formulation is presented, the first proper (though by no means necessarily correct) theory of improvised behaviour in music. The building of this theory has required input from many disparate fields with which the general musical reader may not be familiar. For this reason I begin with the survey of appropriate background research and its relation to improvisation. Some of these areas may initially seem distant from the topic at hand.

A survey of pertinent research

Some physiology and neuropsychology

Although our state of knowledge in these areas is far too meagre to have any definite repercussions for improvisation, there are a few facts which are at least strongly suggestive.

To begin with, improvisation (or any type of music performance) includes the folowing components, roughly in the following order:

(1) Complex electrochemical signals are passed between parts of the nervous system and on to endocrine and muscle systems;
(2) muscles, bones, and connective tissues execute a complex sequence of actions;
(3) rapid visual, tactile, and proprioceptive monitoring of actions takes place;
(4) music is produced by the instrument or voice;
(5) self-produced sounds, and other auditory input, are sensed;
(6) sensed sounds are set into cognitive representations and evaluated as music;
(7) further cognitive processing in the central nervous system generates the design of the next action sequence and triggers it.

– return to step (1) and repeat –

It seems apparent that the most starkly drawn distinctions between improvisation and fixed performance lie in steps (6) and (7), with possibly important differences in step (3). This chapter therefore inevitably focuses on these aspects.

The given steps are often collapsed into a three-component information-processing model of human behaviour which has ready physiological analogies: input (sense organs), processing and decision-making (central nervous system, abbreviated CNS), and motor output (muscle systems and glands).

Control of movement by the CNS is complex: the cerebral cortex sends signals to both the cerebellum and the basal ganglia, which process the information and send a new set of signals back to the motor cortex. The brainstem nuclei are also involved in details of motor co-ordination. It has been suggested that the basal ganglia and cerebellum have complementary roles, with the basal ganglia initiating and controlling slow movements while the cerebellum is active in the co-ordination of fast, ballistic movements (Sage 1977).

Motor signals from the cortex pass to the spinal cord and motor nuclei of the cranial nerves via two separate channels: the pyramidal and extra-pyramidal systems. These two nerve tracts illustrate the simultaneously hierarchical and parallel-processing aspects of CNS control, for they run in parallel but interconnect at all main levels: cortex, brainstem, and spinal cord. Hence while each tract has some separate functions there is a redundancy that can be used to facilitate error correction and motor refinement. Similar redundancy and parallel processing is found at lower levels of motor control. Alpha-gamma coactivation, for example, describes the partial redundancy of neural information sent to two distinct types of motoneurons, alpha and gamma, whose axons and collaterals terminate on the main skeletal muscles and the intrafusal muscle fibres, respectively.

The organization of behaviour has often been linked with the existence

of motor action units (or equivalent concepts), and their aggregation into long chains to develop more complex movements. The validity of the concept of motor action units can be seen mirrored physiologically in the existence of command neurons, single nerve cells in invertebrates whose activation alone suffices to elicit a recognizable fragment of behaviour. The effect is achieved by excitation and/or inhibition of a constellation of motoneurons (Bentley and Konishi 1978; Shepherd 1983). While there are no known single cells that fully trigger complex behaviour in mammals, populations of neurons in the brains of higher animals are strongly suspected of serving a similar function (Beatty 1975). It is therefore possible to speculate that skilled improvisers would, through practice, develop general patterns of neural connections specific to improvisational motor control.

Finally, it is of interest that neurological correlates have recently been discovered for a division of knowledge and memory into two separate categories: declarative and procedural. A degree of independence of these two types of memory (for facts or procedures) has been reported among amnesic and post-encephalitic patients for some time (for example Milner 1962; Brooks and Baddeley 1976). Typically, patients can not remember new facts, but are able to learn new motor skills over a period of time, yet without any awareness on successive days of having performed the tasks before. In recent studies, Cohen (1981) and Cohen and Squire (1981) have shown that declarative learning is linked to specific diencephalic and bitemporal brain structures. Unaware of this work, I drew a related distinction in a recent paper (Pressing 1984*a*) between *object* and *process* memory, based on the rehearsal strategies of improvising musicians. As Squire (1982) has pointed out, there are parallel distinctions in earlier writings: artificial intelligence (Winograd 1975), knowing how and knowing that (Ryle 1949), habit memory and pure memory (Bergson 1910), and memory with or without record (Bruner 1969). What is suggestive about these correlations is that physiological locations for some specific cognitive skills used in improvisation might very well exist.

Motor control and skilled performance

This area traditionally has centered around industrial skills, sport, typing, handwriting, specially designed laboratory tasks like tracking, and to a lesser degree music. It is a complex field of considerable relevance to improvisation, even though improvisation *per se* is scarcely mentioned. Therefore I first review general theories of motor control, and then delve into a number of special issues in skilled performance and skill development that are relevant here.

Theories of motor control and skill

The starting point for nearly all the existing theories is the three-stage information-processing model mentioned earlier, based on sensory input, cognitive processing, and motor output. To this must be added the notion of feedback (auditory, visual, tactile, or proprioceptive). Traditional 'open-loop' theories include no feedback, and hence no mechanisms for error correction. In its starkest form this theory is clearly inappropriate for improvisation; however, there is persistent evidence, dating back to the medical work of Lashley (1917), and including studies of insect behaviour and de-afferentiation techniques in monkeys that points to the existence of motor programmes that can run off actions in open-loop fashion.

In contrast stand 'closed-loop' theories, which contain feedback, and hence allow for the intuitively natural possibilities of error detection and correction. The closed-loop negative feedback (CLNF) model is one of the oldest. In this model the feedback (primarily auditory in the case of musical improvisation) is sent back to an earlier stage in the control system which compares actual output with intended output, producing a correction based on the difference between the two (see for example Bernstein 1967). Such closed-loop models have their historical roots in engineering models of servomechanisms, control theory, and cybernetics.

A wide variety of closed-loop formulations has been given. Gel'fand and Tsetlin (1962, 1971) used a mathematical minimization procedure to model the cognitive search for appropriate motor behaviour. Pew and Baron (1978) sketched out a theory of skilled performance based on optimum control (see also Kleinman *et al.* 1971). Powers (1973) proposed a hierarchy of motor control systems whereby the correction procedures of higher-order control systems constitute reference signals for lower-order systems. Another hierarchical model was given by Pew (1974), in which specific single movements are combined into sequences, and ultimately into various subroutines that make up goal-directed action. Actions are then organized and initiated by an executive programme (Fitts 1964). As is apparent, many such hierarchy theories are based on the application of computer programming principles (see Miller *et al.* 1960).

These ideas offer a more sophisticated understanding of motor behaviour, but they have serious limitations. They model motor learning either poorly or not at all, and are not based on empirical findings about human actions (Adams 1961). A closed-loop theory of motor *learning* was proposed by Adams (1971, 1976) in an attempt to rectify some of these problems. In this theory there are 'memory traces' which select and initiate movements and 'perceptual traces' which are representations of the intended movements, and are used as templates for error correction. A perceptual trace is gradually built up by repeated practice from feedback, knowledge of

results (often abbreviated KR), and error correction. Eventually the perceptual trace can function as an internalized goal, diminishing dependence on the externally based knowledge of results (Namikas 1983). Hence open-loop control characteristics are not completely excluded.

By the late 1970s the consensus was that both open- and closed-loop control must occur in skilled performance (Keele and Summers 1976; Delcomyn 1980; Paillard 1980; see Summers 1981 for a review). That is, movements are both centrally stored as motor programmes, and susceptible to tuning (adjustment) on the basis of feedback. Coupled with the well-established concept of *flexibility* characteristic of skilled (but not rote) performance (Welford 1976), this promoted approaches based on more abstract programming notions that brought the field closer to artificial intelligence (and made it more germane to improvisation).

In this spirit Schmidt (1975, 1976) proposed a theory of motor schemata that models both recall and recognition. The schema is considered to contain the general characteristics of a movement which must be organized in any given situation to satisfy environmental requirements and the goals of the performer. Context then guides the production of a series of motor commands that ultimately generate a spatiotemporal pattern of muscle actions. Feedback is based on a template-comparison idea.

Because schemata are not specific movement instructions but are 'generalized' motor programmes, this theory is capable of modelling novelty (at least in a very general way), which the others above could not (except Pew 1974, which also uses a schema notion). The possibility of novelty is also catered to by Schmidt's inclusion of degree of variability of practice conditions as one determiner of schema 'strength'. At its core, the 'novelty problem' is very close to that of improvisation.

Similar to schemata is the notion of action plan. Miller *et al* (1960) gave a general description of plans, while Clark and Clark (1977) described plans for language discourse, and Sloboda (1982) and Shaffer (1980, 1981, 1984) specified plans for playing music. As discussed by Shaffer (1980), a plan is an abstract homomorphism representing the essential structure of the performance and allowing finer details to be generated or located as they are needed during execution.

Other related theories include Allport's proposal of a system of condition-action units which are links between sensory calling patterns and categories of action (Allport 1980). Also related are adjustable control or description structures for artificial intelligence such as *frames* and *scripts* (see below).

This convergence of theory is useful in constructing a model of improvisation (see below). However, it remains rather unspecific, and has run far ahead of experiment. But as of this writing there seems only one alternative in the area of motor behaviour. This is the organizational invariant approach of Turvey, Kugler, Kelso, and others (Turvey 1977;

Kugler *et al.* 1980; see Kelso 1982 for further references). This approach draws on two sources: the ecological perspective of Gibson (1966, 1979) and the dissipative structure model of non-equilibrum thermodynamics (Prigogine 1967; Prigogine and Nicolis 1971). Essentially the theory de-emphasizes notions of cognitive process and control, replacing them with, in so far as is possible, 'organization invariants'. These organization invariants are characteristic constraint structures that allow the emergence of specific spatial relationships and dynamic processes in the behaviour of non-linear systems when the parameters controlling these systems fall in certain critical ranges. Thus if the human motor action apparatus is considered to be (as it certainly is) a non-linear system, characteristic properties of muscle groups and patterns of human limb co-ordination will naturally emerge from the constraints imposed by a given task situation (Kelso *et al.* 1981; Saltzman and Kelso 1983). The proposals are exciting, but their ultimate fate remains unclear. The theory is still being formulated, and comparable ideas from non-linear mathematics have infiltrated many fields in the last 10 years, with uneven results.

Organizational invariant theory seems also likely to apply primarily to the dynamics of motor programme execution, and not to the formulation of intentions and high-level decision-making (Wilberg 1983). Since these functions are vital elements in improvisation in any but an extreme mechanistic approach, the theory as it stands is not particularly suitable for improvisation modelling. Nevertheless, these ideas may be used in an understanding of the sources of behavioural novelty, and are discussed further below.

Some special issues relevant to improvisation

Skill classification Various dimensions of skill classification have been proposed and improvisation can be placed within these. Two possible categories are 'open' skills, which require extensive interaction with external stimuli, and 'closed' skills, which may be run off without reference to the environment (Poulton 1957). Solo improvisation is basically a closed skill, as it relies only on self-produced stimuli, whereas ensemble improvisation is more open. Other dimensions of skill classification are gross-fine, discrete-serial-continuous, complex-simple, and perceptual-motor (Holding 1981). Improvisation is a fine, complex skill, with both perceptual and motor components; continuous actions predominate, although there are also discrete and serial motor aspects. This last point varies somewhat with the nature of the instrument played.

It is important to also emphasize the contrast between unskilled and highly skilled performance. A vast majority of reported skill studies treat simple motor tasks like tracking, under an implicity reductionistic scientific methodology. It is increasingly acknowledged, however, that highly developed skills have distinctive emergent properties missed in these

earlier short-term studies, properties such as adaptability, efficiency, fluency, flexibility, and expressiveness (Welford 1976; Shaffer 1980; Sparrow 1983). These are vital components of improvisatory skill.

Feedback and error correction Feedback is a vital component in improvisation for it enables error correction and adaptation—a narrowing of the gap between intended and actual motor and musical effects. But feedback is also important for its motivational (Gibbs and Brown 1956) and attention-focusing effects (Pressing 1984*a*).

Feedback redundancy is an important concept for music. Aural, visual, proprioceptive, and touch feedback reinforce each other for the instrumental improviser, whereas the vocalist has only hearing and proprioception available (Pressing 1984*a*). Likewise the design of some instruments allows more precise visual feedback and more categorical kinaesthetic feedback than others. This is almost certainly why sophisticated improvisation using advanced pitch materials is more difficult on the violin than the piano, and extremely challenging for the vocalist. For every first-rate scat-singer in the world there must be 500 talented jazz saxophonists.

Feedback can also be considered to operate over different time scales. Thus short-term feedback guides ongoing movements, while longer term feedback is used in decision-making and response selection. Still longer term feedback exists in the form of knowledge of results (KR) for skills where external evaluation is present or result perception is not sufficiently precise or immediate. The importance of this for improvisation has been demonstrated by Partchey (1974), who compared the effects of feedback, models, and repetition on students' ability to improvise melodies. Feedback, in the form of playbacks of recordings of the students' own improvisations, was clearly superior to listening to pre-composed model melodies, or repetition, as an improvisation learning technique. In group improvisation, feedback loops would also operate between performers (Pressing 1980).

In view of the interconnectedness of the parts of the central nervous system, it is also clear that there exist internal feedback (and feedforward) loops not based on sensory processing (Brooks 1978). That is, if higher cognitive levels set the design of motor programmes while movement fine structure is specified in closed-loop fashion by lower levels of the CNS, notably the spinal cord, then copies of these lower level motor instructions are almost certainly sent directly back up to higher centres. In other words, there is some kind of central monitoring of efference. This would serve to increase overall processing speed and accuracy.

The role of errors in improvisation has been discussed previously (Pressing 1984*a*). It will simply be pointed out here that errors may accrue at all stages of the human information processing system: perception, movement/musical gesture selection and design, and execution. Minor

errors typically demand no compensation in following actions, whereas major errors typically do.

Anticipation, preselection, and feedforward These three concepts have to do with preparation for acton. Physiological recording of the Bereitschaft potential (BP) and contingent negative variation (CNV) (see Brunia 1980) now provides explicit support for the long-standing idea that higher cognitive control centres bias lower ones towards anticipated movements. This is therefore a type of feedforward, and has been described from various perspectives: spinal 'tuning' (Turvey 1977; Easton 1978), corollary discharge or efference copy (von Holst 1954), and preselection (see Kelso and Wallace 1978 for discussion).

The idea of preparation is very important for improvisation, where real-time cognitive processing is often pushed up near its attentional limits. It can be formally proved, for example, that only a control system with a model of disturbances and predictive power can become error free (Kickert *et al.* 1978). For improvised performance that aims at artistic presentation, where discrepancies between intention and result must be kept within strict bounds, practice must attempt to explore the full range of possible motor actions and musical effects, to enable both finer control and the internal modelling of discrepancies and correction procedures, including feedforward.

Hierarchy vs. heterarchy Because of influences of the physical sciences and control theory, an overwhelming majority of models for motor behaviour have used a hierarchical control system. However, the interconnectedness between difference locations in the CNS and the many documented types of feedack and feedforward processes mentioned above argue that this perspective is probably too narrow. Furthermore, explicit parallel-processing possibilities exist due to the separate pyramidal and extrapyramidal neural tracts, alpha-gamma coactivation, etc., as mentioned above. Hence other types of organization, referred to as heterarchical or coalition, have been proposed (McCulloch 1945; von Foerster 1960; Greene 1972; Turvey 1977). In this perspective, executive control of the system may be transferred between different 'levels' depending on the needs of the situation (Miller *et al.* 1960).

Time scales for the control of movement This is a subject with an enormous and complex literature. For background purposes in modelling improvisation a few points only seem sufficient.

Actual neural transmission times are on the order of tens of milliseconds. According to Davis (1957; see also Sage 1977), auditory stimulus activity reaches the cerebral cortex 8–9 ms after stimulation while visual stimulation involves a longer latency of 20–40 ms. Since the two neural pathways are of comparable length, this difference points to a greater

transmission speed for audition than vision. It should, however, be noted that the auditory system contains both ipsilateral and contralateral pathways, while the pathways of the visual system are exclusively crossed. The cortical response time for a movement stimulus appears to be on the order of 10–20 ms (Adams 1976).

Reaction time is the time taken for a sense stimulus to travel to the CNS and return to initiate and execute a largely pre-programmed motor response. Simple reaction time (RT) with only one chosen motor response typically fall in the range 100–250 ms, depending on conditions and sensory modality (Summers 1981). Auditory, kinaesthetic, and tactile reaction times have typically been found to fall in the range 100–160 ms (Chernikoff and Taylor 1952; Higgins and Angel 1970; Glencross 1977; Sage 1977), while visual reaction times have been considered longer, typically reported as at least 190 ms (Keele and Posner 1968). Reaction times for other sensory modalities seem to be in the range above 200 ms, while RTs involving choice of response are in general longer and are reasonably modelled by Hick's Law (Hick 1952). Kinaesthetic and tactile choice reactions seem also to be faster than visual (Leonard 1959; Glencross and Koreman 1979). Data on auditory choice RTs do not seem to be readily available.

Error correction (EC) times vary with sensory modality and context. EC times are important for improvisation because it may reasonably be argued that they reflect minimum times for decision-making that is expressive or compositional. Visual error correction is usually reported to be about 200 ms, whereas kinaesthetic EC can occur over intervals as short as 50–60 ms (Kerr 1982), as seen in reports on tracking tasks (Gibbs 1965; Higgins and Angel 1970). However, other recent work in the case of vision has found some instances of visual EC times down in the range near 100 ms as well (Smith and Brown 1980; Zelaznik *et al.* 1983). It seems likely that the time taken for error correction would be a function of the degree of invoked processing involvement; that is, motor programme construction would take more time than selection, while exacting criteria of discrimination or motor accuracy or a wide range of response choice would naturally increase EC time. Rabbitt and Vyas (1970) and Welford (1974) have enunciated this view, one which is well supported by the introspective reports of improvisers going back for many centuries (Ferand 1961).

Explicit information on auditory error correction times does not seem to be available, but it is possible to point out a general tendency in the above data. Namely, processing speed seems to be greatest for audition and touch/kinaesthesia, of all the possible sensory systems. These are precisely the elements involved in musical improvisation and provide a vivid psychological interpretation for the historical fact that music, of all art and sport forms, has developed improvisation to by far the greatest degree. Under this interpretation, human beings, as creative agents, have as a

matter of course drawn on the sensory systems most adapted to quick decision-making: in other words, a predilection for improvised sound manipulation might be genetically programmed. Of course, such an interpretation remains highly speculative.

Finally it should be noted that unexpected sensory changes requiring significant voluntary compensations require a minimum time of about 400–500 ms (Welford 1976). This is therefore the time scale over which improvising players in ensembles can react to each others' introduced novelties (about twice a second). Nuances in continuous improvised performance based on self-monitoring are probably limited by error correction times of about 100 ms (Welford 1976), so that speeds of approximately 10 actions per second and higher involve virtually exclusively pre-programmed actions (Pressing 1984*a*). An informal analysis of jazz solos over a variety of tempos supports this ball-park estimate of the time limits for improvisational novelty.

Timing and movement invariants Up to this point very little has been said about the timing of skilled performance, yet it is obviously a vital point. Considerable experimental work in the domains of fluent speech (Huggins 1978), typing (Shaffer 1978; Terzuolo and Viviani 1979), handwriting (Denier van der Gon and Thuring 1965; Viviani and Terzuolo 1980; Hollerbach 1981), generalized arm trajectories (Morasso 1983), and piano performance (Shaffer 1980, 1984) has established that invariant timing and spatial sequences, strongly suggestive of schemata, underlie skilled actions. Such performance rhythms, or 'hometetic' behaviour, as some have termed it, shows great tuneability: over wide variations in distance and overall time constraints, invariance of phasing and accelerations (equivalently, forces) can be observed (Schmidt 1983). By phasing is meant the relative timings of component parts of the entire movement sequence.

But it is also true that the relative timings of movement components can be changed intentionally, at least to a considerable degree. Hence the improviser has access to generalized action programmes (in both motor and music representation), which allow overall parametric control (time, space, force) *and* subprogram tuneability. This may well be responsible for the flexibility of conception characteristic of experienced improvisation.

Motor memory It has often been suggested that a distinct form of memory for action, called motor memory, exists. The subjective impression of improvisers (and other performers) is certainly that potentially separate yet often interconnected motor, symbolic, and aural forms of memory do exist. For a review of this extensive topic and its relationship to verbal memory the reader may wish to consult Laabs and Simmons (1981).

Skill development

All skill learning seems to share certain common features. In the early stages, a basic movement vocabulary is being assembled and fundamental perceptual distinctions needed for the use of feedback are drawn. In intermediate stages, larger action units are assembled, based on stringing together the existing movement vocabulary in accordance with the developing cognitive framework. These action units begin to enable predictive open-loop response. The ability to perceive distinctions is refined considerably, and internal models of action and error correction are developed. Expressive fluency begins to appear, characterized by a feeling of mindful 'letting go' (Schneider and Fisk 1983; Pressing 1984*a*). By the time advanced or expert stages have been reached, the performer has become highly attuned to subtle perceptual information and has available a vast array of finely timed and tuneable motor programmes. This results in the qualities of efficiency, fluency, flexibility, and expressiveness. All motor organization functions can be handled automatically (without conscious attention) and the performer attends almost exclusively to a higher level of emergent expressive control parameters.

In the case of improvised music these emergent control parameters are notions such as form, timbre, texture, articulation, gesture, activity level, pitch relationships, motoric 'feel', expressive design, emotion, note placement, and dynamics. There must also be a developed priority given to auditory monitoring over kinaesthetic and especially visual monitoring. This idea is supported by research on typists (West 1967), which showed that the dominant visual control used for optimal results in early stages of learning to type gave way later to reliance on tactile and kinaesthetic cues. It also seems likely that sensory discrimination and motor control functions make increasing use of higher order space–time relationships (velocity, acceleration) as skill learning progresses (Marteniuk and Romanow 1983).

The change from *controlled* processing to *automatic* motor processing as a result of extensive skill rehearsal is an idea of long standing (James 1890; Shiffrin and Schneider 1977), and it undoubtedly improves movement quality and integration (Eccles 1972). The accompanying feeling of automaticity, about which much metaphysical speculation exists in the improvisation literature, can be simply viewed as a natural result of considerable practice, a stage at which it has become possible to completely dispense with conscious monitoring of motor programmes, so that the hands appear to have a life of their own, driven by the musical constraints of the situation (Bartlett 1947; Welford 1976; Pressing 1984*a*). In a sense, the performer is played by the music. The same thing happens with common actions like walking and eating. As Welford (1976) has cogently pointed out, automaticity is therefore especially likely when the actions involved are always, or virtually always, accurate to within the

requirements of the task. Hence automaticity in improvisation can be frequent in both free and highly structured contexts, since task requirements are often self-chosen, but is more likely to be successful in musical terms for the less experienced player towards the free end of the specturm.

Schneider and Fisk (1983) have proposed an interesting corollary to the above, based upon a classification of tasks into those requiring *consistent* or *varied* processing: 'Practice leads to apparently resource free automatic productions for consistent processing but does not reduce (attentional) resources needed for a varied processing task.' (p. 129) This idea is appealing and perhaps widely valid, but is too simple to encompass the full complexity of improvisation. For part of the result of extensive practice of improvisation is an abstraction to greater and greater generality of motor and musical controls to the point where highly variable, often novel, *specific* results can be produced based on the automatic use of *general*, highly flexible and tuneable motor programmes. More irrevocable constraints causing attentional loading seem to be timing and interhand co-ordination (Pressing 1984*a*).

Another relevant area is the optimum distribution and nature of practice. Generalizations here are particularly hazardous (Newell 1981) and I will confine my comments specifically to improvisation.

The extremes of massed and distributed practice typically have complementary functions for the improviser. Distributed practice develops immediacy, and consistency of results under variable conditions, whereas massed rehearsal, by perhaps bringing to the player's awareness otherwise unperceived repetitive aspects of his or her music, enables the transcendence or improvement of stale musical design. One is reminded of the opinion of master trumpeter Miles Davis that his sidemen only really got loose in the last set of the night, after they had used up all their well-learned tricks (Carr 1982).

Variability of practice conditions is vital for improvisation, for obvious reasons, and this seems to be true of nearly all skilled behaviour (Schmidt 1983). Mental practice away from the instrument can be important for performers of fixed music, based on internal hearing of scores, but there seems very little record of its use in improvisation. This is presumably due to the intrinsically vital motoric link between performer and instrument for improvisation.

Techniques used by musicians to teach improvisation will be described below. However, some general principles of skill teaching are pertinent here. The successful yet contrasting approaches of the 'discovery' method and structural prescription (the use of instructions or demonstrations) may be mentioned. The basic trial-and-error idea of the discovery method probably requires little explanation; it has often been used as an industrial training procedure, where learning sessions are arranged so that trainees must make active choices which are normally correct, and which therefore

do not lead to ingrained errors (Welford 1976). Less formalized self-discovery techniques are certainly characteristic of much learning in the arts. But structural prescription is also a vital part of skill learning. For all but very simple skills, instructions seem particularly effective when kept simple, and when focusing on goals and general action principles rather than kinematic details (Hendrickson and Schroeder 1941; Holding 1965; Newell 1981). This certainly holds for improvisation. Probably too much intellectual detail both interferes with the fluid organization of action sequences, as mentioned earlier, and strains attentional resources.

Studies and theories of musical improvisation

A cognitive overview of much of this literature has been given earlier (Pressing 1984*a*, which includes references to dance and theatre), and will not be repeated here. Historical surveys of improvisation in Western music may be found in Ferand (1938, 1961), *The new Grove dictionary of music* (1983), and Pressing (1984*b*,*c*). These deal primarily with the period to 1900. Discussion of avant-garde improvisation since 1950 is included in Cope (1984). Non-Western musical improvisation is described by Reck (1983), Datta and Lath (1967), Wade (1973), Jairazbhoy (1971), and Lipiczky (1985) for Indian music; by Nettl and Riddle (1974), Nettl and Foltin (1972), Zonis (1973), Signell (1974, 1977), and Touma (1971) for various Middle Eastern traditions; by Béhague (1980) for Latin American musics; by Hood (1971, 1975), Sumarsam (1981) for gamelans and other stratified ensembles in Southeast Asia, and by Jones (1959) and Locke (1979) for Ewe music of Ghana. Park (1985) has described the improvisation techniques of Korean shamans, Avery (1984) structure and strategy in Azorean–Canadian folkloric song duelling, and Erlmann (1985) variational procedures in Ful'be praise song. Nettl (1974) has provided thoughtful general insights from the perspective of the ethnomusicologist.

In the twentieth century, prescriptive teaching texts on Western music improvisation are legion. Few, however, have the sorts of cognitive insights useful in model building, and almost all are concerned with the specifics of jazz (a small related number with blues and rock) or keyboard (particularly French-tradition organ) improvisation. The jazz texts are too numerous to survey fully here and are in any case mostly quite repetitious. Important perspectives are however given by Coker (1964, 1975), Schuller (1968), Baker (1969), Owens (1974), Liebman *et al.* (1978), Dobbins (1978), Howard (1978), Murphy (1982), and Radano (1985). Among the better organ and piano texts may be mentioned the works of Dupré (1925/37), Schouten (no date given), Gehring (1963), Berkowitz (1975) and Weidner (1984). Analytical and prescriptive texts which stand apart from the typical stylistic conventions above are the works of Bailey (1980),

Bresgen (1960), Sperber (1974), Stumme (1972), and Whitmer (1934). Except for Bailey, all of these take tonal music as their primary area of discourse. Discussions which emphasize free improvisation often take a more cognitive approach, but their usefulness is sometimes compromised by vagueness or subjectivity. Valuable readings in this area include Silverman (1962), Jost (1974), Parsons (1978), Bailey (1980), and special issues of *Perspectives of new music* (Fall–Winter 1982/Spring–Summer 1983, 26–111), the *Music educator's journal* (1980, **66**, (5), 36–147), *Keyboard* (1984, **10**(10)), and *The British Journal of Music Education* (1985, **2**(2)). Other works of interest are those on choir improvisation (Ehmann 1950, Ueltzen 1986), silent-film accompaniment (Hanlon 1975), dulcimer improvisation (Schickhaus 1978), and percussion gestures (Goldstein 1983).

Musical improvisation has also been considered as a vehicle for consciousness expansion and the tapping of deep intuitions. A full history of this 'transpersonal' approach would go back thousands of years to the sacred texts of many religions. Here I only survey recent Western opinion. Hamel (1979) has intelligently chronicled music of the avant-garde (for example Riley, Stockhausen) from this perspective. Laneri (1975) has developed a philosophy of improvisation based on different states of consciousness, featuring the concepts of synchronicity and introversion. The resultant music is primarily vocal, since the voice is considered the primal instrument. A powerful system of sonic meditation most applicable to local improvisation groups has been developed by Oliveros (1971). 'Sensing' compositions have been published by Gaburo (1968). An attempt to connect music, altered states of consciousness, and research in parapsychology has been given by Pressing (1980), while Galás (1981/82) has created a primal vocal music based on obsession, excessive behaviour, and trance states of severe concentration.

The approaches in the literature to the teaching of improvisation may be broadly grouped as follows. First, there is the perspective overwhelmingly found in historical Western texts, that improvisation is real-time composition and that no fundamental distinction need be drawn between the two. This philosophy was dominant in pre-Baroque times but had become rare by the eighteenth century. In practice this results in a nuts-and-bolts approach with few implications for the modelling of improvisation beyond basic ideas of variation, embellishment, and other traditional processes of musical development. A second approach, which historically took over as the first one waned, sets out patterns, models, and procedures specific to the improvisational situation, which, if followed by those possessing a solid enough level of musicianship, will produce stylistically appropriate music. In this category fall the many figured bass and melodic embellishment texts of the seventeenth and eighteenth centuries (for example Mersenne 1635; Quantz 1752/1966; Bach 1778/1949; Arnold 1965), as well as the riff

compendia and how-to-do-it books in the field of jazz (such as Coker, *et al.* 1970; Slonimsky 1975; Nelson 1966).

A third technique is the setting of a spectrum of improvisational problems or constraints. The philosophy behind this technique shows a clear contrast with the second approach above, as described by Doerschuk (1984), referring to the Dalcroze system.

> The art of improvisation rests on . . . a developed awareness of one's expressive individuality. This knowledge grows through interactive exercises with a teacher, whose function is not to present models for imitation, but to pose problems intended to provoke personal responses. (p. 52)

Jaques-Dalcroze (1921) seems to have pioneered this approach in our century with a revealing series of improvisation exercises for piano. These include composition-like problems in rhythm, melody, expressive nuance, and harmony; muscular exercises; imitation of a teacher; exercises in hand independence; the notation of improvisation just after performing it; and what may be termed an 'interrupt' technique. In this last technique the word 'hopp' is recited by the teacher, as a cue for the student to perform pre-set operations such as transposition or change of tempo during the performance. This technique is reminiscent of a much later suggestion by Roads (1979) that musical grammars used in improvisation might be 'interrupt-driven'. This idea is developed in the model below.

Parsons (1978) has made effective use of this third technique in a collection of short pieces by many different composers defined largely by improvisational instruction sets; he also presents a taxonomy of psycho-improvisational faults and recommended exercises for correcting them. A shorter multi-author collection of improvisational exercises is found in Armbruster (1984). Jazz fake books like the *Real book* (no listed authors or dates) or *The world's greatest fake book* (Sher 1983) may also be considered to act along the lines of this technique.

A fourth approach is the presentation of multiple versions of important musical entities (most commonly motives) by the teacher, leaving the student to infer completely on his or her own the ways in which improvisation or variation may occur by an appreciation of the intrinsic 'fuzziness' of the musical concept. This imitative self-discovery approach is found in the Persian *radif*, which is a repository of musical material learned in a series of increasingly complex versions by the aspiring performer (Nettl and Foltin 1972), and in Ghanaian traditions (K. Ladzekpo, personal communication), for example. A related procedure made possible by the use of recording technology in the twentieth century is for the student to directly copy a number of improvised solos by repeated listening to recordings, and from this extract common elements and variation procedures. Song-form based improvisations, in which solos consist of a number of choruses which repeat the same underlying chord

progression, are particularly suitable. This method has been widely used in jazz and blues since the end of the First World War.

A fifth approach is allied to the self-realization ideas of humanistic psychology. It is based on concepts of creativity and expressive individuality which go back in music explicitly at least to Coleman (1922), implicitly certainly to Czerny (1829/1983), and probably in a general sense at least to the Enlightenment. Important educational applications of this idea are found in the works of Carl Orff, Zoltán Kodály, Suzuki (see Mills and Murthy 1973), and particularly Jaques-Dalcroze (1976, 1930) and Shafer (1969). In the words of Jaques-Dalcroze,

> Improvisation is the study of direct relations between cerebral commands and muscular interpretations in order to express one's own musical feelings . . . Performance is propelled by developing the students' powers of sensation, imagination, and memory.
>
> (In Abramson 1980, p. 64.)

Little actual research on optimal techniques for teaching improvisation has been carried out. The important study by Partchey (1973) which showed the value of models and particularly of subsequent aural feedback in learning to improvise has already been mentioned above. Work by Hores (1977) has shown that visual and aural approaches to the teaching of jazz improvisation can be equally effective. Burnsed (1978) looked at the efficacy of design of an introductory jazz improvisation sequence for band students. Seuhs (1979) developed and assessed (by adjudication) a course of study in Baroque improvisation techniques. Bash (1983) compared the effectiveness of three different instructional methods in learning to improvise jazz. Method I was a standard technical procedure based on scales and chords. Method II supplemented this technical dimension with aural perception techniques which included rote vocal responses to blues patterns, blues vocalizations, and instrumental echo response patterns based on rote or procedures of generalization. Method III supplemented the same technical procedures of Method I with a historical–analytical treatment. All three methods gave improved results over that of a control group, and methods II and III, though no significant difference was found between them, were both superior to method I. The results show the value of specific theoretical and technical instruction, and also of its supplementation by relevant aural training or analyses of performance strategies used by virtuoso improvisers.

One final comment on improvisation teaching seems apposite. This is the fact that the optimally effective teacher is able to direct evaluative comments on several different levels. One is the technical—'Your notes don't fit the chord', 'The piano is lagging behind the bass', etc. Another is the compositional—'Try to develop that motive more before discarding it', 'Use more rhythmic variety in pacing your solo', 'Musical quotations seem

inappropriate in this free a context', etc. Yet another level is the use of organizing metaphor, a vital part of the tradition of jazz teaching—'Use more space', 'Dig in', 'Go for it', 'Play more laid-back', 'Don't force it—follow the flow', etc. Simple comments of this kind can be remarkably effective at removing improvisational blocks, when delivered at a proper time.

Pike (1974) has presented a brief but insightful phenomenology of jazz. His approach considers the projection of 'tonal imagery' to be the fundamental process in jazz improvisation. Tonal imagery is either 'reproductive' (memory-based) or 'productive' (creative). The improviser operates in a 'perceptual field' which acts as a framework in which the improviser's imagery appears and originates. This field includes not only the perception of external tonal events, but the perception of internal images, as well as the states of consciousness evoked by these images. Images in this field are combined, associated, contrasted, and otherwise organized. The phenomenological operations describing this are processes such as repetition, contrast, continuity, completion, closure, and deviation. Other aspects of improvisation defined by Pike include 'intuitive cognition', an immediate penetration into the singular and expressive nature of an image, and 'prevision', a glimpse into the developmental horizons of an embryonic jazz idea.

Although some of Pike's claims are open to question, for example his uncritical acceptance of concepts like Hodeir's 'vital drive' (Hodeir 1956), his short paper remains an important introspective analysis of the experience of improvisation. The only other extensive phenomenological treatment of improvisation seems to be Mathieu's (1984) study of musician/dancer duo performances. Other perspectives on the experiences of the improviser have been given by Milano (1984), in an interview with jazz pianist/psychiatrist Denny Zeitlin, and Sudnow (1978), who has produced a basic ethnomethodological description of learning to play jazz on the piano. Related philosophical issues have been raised by Alperson (1984) and Kleeman (1985/86).

Finally it may be proper to note that the computer age has spawned new hybrids of composition and improvisation. Fry (1980, 1982/83) has described music and dance improvisation set-ups using computer sensing and control devices. Chadabe (1984) has described a method of 'interactive composition' whereby movements of the hands in space near two proximity-sensitive antennas trigger and exert partial control over real-time computer sound generation. Interactive computer-based performance systems have also been used by trombonist George Lewis and a host of 'performance artists', including this writer. And recently available commercial software, such as the Macintosh-based *M* and *Jam Factory*, has an interactive improvisational component that seems rich with promise.

Oral traditions and folklore

The idea that traditional folk-tales from many cultures have underlying unities, which may be interpreted as narrative grammars, is a fairly well-established one (Propp 1927; Thompson 1946; Nagler 1974). Explanations of this fact have tended towards one or the other of two viewpoints.

A common (particularly European) perspective in the study of oral tradition and folklore has been a focus on their repetitive and imitative aspects, with the frequent assumption of an *Urtext* which has undergone historical and geographic transformation. A powerful opposing view, and one which seems increasingly relevant as a description of referent-based improvisation, is found in the 'formulaic composition' proposals of Milman Parry and Albert Lord (Parry 1930, 1932; Lord 1964, 1965).

Formulaic composition was derived from Milman's intense study of the Homeric epics, particularly the *Odyssey*, and given further support by research on Yugoslav folk-epic poetry conducted by Milman and Lord. It is also considered to be applicable to other oral epics such as *Beowulf* and the *Chanson de Roland*, and has been used to analyse Latvian folk-song texts (Vīķis-Freibergs 1984). In this view epic oral poetry is created anew at each performance by the singer from a store of formulas, a store of themes, and a technique of composition. There is no 'original' version; instead the tradition is multiform. A 'formula' is a group of words regularly employed under the same metrical conditions to express a given essential idea; it has melodic, metric, syntactic, and acoustic dimensions. By choosing from a repertoire of roughly synonymous formulas of different lengths and expanding or deleting subthemes according to the needs of the performance situation, the experienced performer is able to formulaically compose (in real-time, hence improvise) a detailed and freshly compelling version of a known song epic. As a result of the composition system, instances of pleonasm and parataxis are common.

The formulas considered as a group reveal further patterns. In the words of Lord (1964): 'the really significant element in the process is . . . the setting up of various patterns that make adjustment of phrase and creation of phrases by analogy possible' (p.37). In addition, the permutation of events and formulas may occur, as well as the substitution of one theme for another.

Yet the traditional singer does not seek originality with this technique, but heightened expression. Lord speculates that formulas originally grew out of a need for intensification of meaning or evocation. 'The poet was sorcerer and seer before he became artist' (Lord 1964, p. 67).

The relevance of formulaic composition to specific types of musical improvisation has recently been discussed by several writers. Treitler (1974) has argued that Gregorian chant was composed and transmitted in an analogous process to that used in the oral epics. Smith (1983) has used

the process to describe the constraints imposed on the song-based jazz performer, and has gone on to analyse piano improvisations by Bill Evans. Kernfeld (1983) has examined how far formulas may be used to describe the music of saxophonist John Coltrane. Reck (1983) has produced the evocative idea of a musician's 'tool-kit', in a mammoth study of five performances by South Indian musician Thirugokarnam Ramachandra Iyer. The tool-kit is considered to be piece-specific and to contain both individually chosen and culturally determined formulas, musical habits, models of improvisational and compositional forms, aesthetic values, and social attitudes.

The application of Parry–Lord theory to musical improvisation is thus a clear contemporary trend. The limits of its validity and usefulness are still open questions, and are probably linked to whether a satisfactory agreement can be reached on the principles to be used to define musical 'formulas'.

Intuition and creativity

These are two related concepts, each with a vast literature. Their connection with improvisation is undeniable, yet explicit mention of it in either field is rare. On the other hand, 'free' musicians and many music educators commonly use the two terms, but often without a very clear notion of just what is being discussed. This section attempts to bridge that gap.

The concept of intuition is much older than creativity, and it has separate philosophical and psychological traditions. Westcott (1968) has provided an excellent general survey, enumerating three historical approaches to philosophies of intuition. First comes Classical Intuition (for example Spinoza, Croce, Bergson), which views intuition as a special kind of contact with a prime reality, a glimpse of ultimate truth unclouded by the machinations of reason or the compulsions of instinct. Knowledge gained through this kind of intuition is unique, immediate, personal, unverifiable. The second approach, called by Westcott Contemporary Intuitionism (for example Stocks 1939; Ewing 1941; Bahm 1960), takes the more restricted view that intuition is the immediate apprehension of certain basic truths (of deduction, mathematical axioms, causality, etc.). This immediate knowing stands outside logic or reason and yet is the only foundation upon which they can be built. Knowledge gained through intuition constitutes a set of 'justifiable beliefs', which are nevertheless subject to the possibility of error. A third approach is positivistic (for example Bunge 1962) in that it rejects as illusory both the notions of immediacy and ultimate truth found in some earlier views. Rather, an intuition is simply a rapid inference which produces a hypothesis.

Of all these views, it is perhaps that of French philosopher Henri

Bergson (1859–1941) which shows the greatest affinities with the common metaphors of improvisation. Bergson saw intuition as a way to attain direct contact with a prime reality ordinarily masked from human knowledge. This prime reality is an ongoing movement, an evolving dynamic flux which proceeds along a definite but unpredictable course.

> The prime reality is referred to as 'the perpetual happening' or 'duration'. The mind of man, according to Bergson, is shielded from the perpetual happening by the intellect, which imposes 'patterned immobility' on prime reality, distorting, inmobilizing, and separating it into discrete objects, events and processes. In the perpetual happening itself, all events, objects, and processes are unified'
>
> (In Westcott 1968, p. 8).

In Bergson's view, the intellect can freely interact with the fruits of intuition (special knowledge and experience) to develop an enriched personal perspective.

The notion of tapping a prime reality is very similar to the improviser's aesthetic of tapping the flow of the music, as mentioned above. The same apparent process has been eloquently described with regard to the origins of folk-tales from many cultures by English writer Richard Adams:

> I have a vision of—the world as the astronauts saw it—a shining globe, poised in space and rotating on its polar axis. Round it, enveloping it entirely, as one Chinese carved ivory ball encloses another within it, is a second . . . gossamer-like sphere . . . rotating freely and independently of the rotation of the earth.
>
> Within this outer web we live. It soaks up, transmutes and is charged with human experience, exuded from the world within like steam or an aroma from cooking food. The story-teller is he who reaches up, grasps that part of the web which happens to be above his head at the moment and draws it down—it is, of course, elastic and unbreakable—to touch the earth. When he has told his story—its story—he releases it and it springs back and continues in rotation. The web moves continually above us, so that in time every point on its interior surface passes directly above every point on the surface of the world. This is why the same stories are found all over the world, among different people who can have had little or no communication with each other.
>
> (Adams 1980, p. 12.)

There is a clear convergence of imagery in this and other descriptions that points to a likely transpersonal component to improvisation.

The psychological perspectives on intuition are many and varied, but only two seem relevant here. The first is the widely occurring idea that intuition is a special case of inference which draws on cues and associations not ordinarily used (Westcott 1968). A similarity with certain theories of skill learning mentioned above is apparent. A second and wide-ranging approach is found in the recent work by Bastick (1982), which includes a search of over 2.5 million sources for common properties underlying intuition. After the identification and detailed analysis of some 20 of these

properties, Bastick ends up describing intuition as a combinatorial process operating over pre-existing connections among elements of different 'emotional sets'. These emotional sets apparently contain encodings, often redundant, of many different life events (intellectual activities, movement, emotion, etc.). By giving strong emphasis to the role of dynamics, bodily experience, and the maximizing of redundancy in encoding, and by a series of suggestive diagrams of intuitive processing, Bastick seems to be on an important track parallel to emerging ideas of improvisation.

Research in creativity is probably more extensive than that in intuition, for intuition is most commonly considered a subcategory of creativity. Creativity research in music education has been recently surveyed by Richardson (1983). The only clear relations to improvisation she found were in specialized educational methods and a growing tendency to use improvisation tests in assessing musical creativity. Vaughan (1971), Gorder (1976), and Webster (1977) have designed and implemented such tests, but results show uneven patterns of correlation between general intelligence, creativity, musicality, composition, and improvisation, and seem to have no clear consequences for improvisation modelling.

General studies of creativity abound, and follow many divergent paths. Two alone seem relevant here. Guilford's Structure-of-Intellect (SI) model proposed a taxonomy of factors of intelligence (Guilford and Hoepfner 1971 (and earlier references mentioned therein); Guilford 1977). These intelligence factors, which number 120, are classified along three dimensions:
thought content: visual, auditory figural, semantic, symbolic, and behavioural information;
kinds of operation performed on the content: cognition, memory, convergent production, divergent production, evaluation;
products (the results of applying operations to content): units, classes, relations, systems, transformations, and implications.
These classifications are related to improvisation in a general way, but despite their intuitive appeal, they have so far been fairly resistant to empirical verification.

Guilford further defined a set of six aptitudes for creative thinking: fluency, flexibility, originality, elaboration, redefinition, and sensitivity to problems. Torrance (1966) used this same set in designing a more open-ended approach to the testing and definition of creativity. Some of these six aptitudes are identical to the ones found in skilled performance above; they are considered here to be further guidelines for testing the plausibility of improvisational modelling.

Finally, Guilford and Hoepfner classified techniques of evaluation (in problem-solving), which they held to be due to appeals to logical consistency, past experiences, feeling of rightness, or aesthetic principles. Such a classification also has implications for improvisation (see model below).

Artificial intelligence

This field is concerned with programming computers to be intelligent problem solvers. The framework of action is usually formulated in terms of a problem space which must be searched for correct solutions. Since interesting problem spaces are nearly always too large to be investigated completely, a major focus of the field is the design of better heuristic search techniques. Coupled naturally with this are many methods and frameworks for the representation of knowledge.

There is traditionally no explicit mention of improvisation in the field. In making such a link, it seems clear that the successful application of artificial intelligence concepts to improvisation rests to a large degree on the appropriateness of considering improvisation to be a kind of problem solving. There is little doubt that such an analogy can be fruitful, particularly for referent-guided improvisation. For example, the process of improvisation may be divided up into a number of time points, and viewed as a succession of small problems, each of which is the production of an appropriate chunk of musical action at the current time point, where the constraints on action are the referent, goals, and musical actions at earlier time points. Alternatively, the time-scale may be drawn much coarser, and each complete improvisation may be considered a solution to a much more generally stated problem: for instances, improvise a chorus on 'I Got Rhythm' changes, within the constraints of be-bop style.

Before surveying the fruits of this approach it may be wise to spell out its limitations. Experientially, improvisation can seem to be far removed from problem solving. This is particularly so where the goals of the music making are exploration and process, rather than the presentation of artistic product. It is also very difficult to imagine how one could ever specify the 'problems' in freer types of improvisation with sufficient detail to allow specific artificial intelligence techniques to be used in modelling. Such problem formulations, even if possible, would be very personal, open ended, and sometimes contradictory.

With these provisos, we examine how various artificial intelligence problem-solving techniques might apply to improvisation. Search techniques come in several variants, including depth-first, breadth-first, and best-first. All use a generate-and-test procedure to find solutions to a problem. Clearly there are possible connections with improvisation. Generate-and-test could be applied to learning to improvise, where generation is sound production and testing is listening to generated music; or, it could describe internal cognitive selection processes, where testing is based on internal hearing of generated possibilities, before one is chosen as the actual musical output at a given time. Unfortunately with regard to this second interpretation there is a serious limitation: the inevitable use of back-tracking in the search processes cannot be very significant in improvisation

due to the cognitive limitations of real-time processing. The need of the improviser is for a good solution, not the best, for there is probably no single 'best' solution, and even if there were, it would take too long to find it. Therefore, the number of solution paths compared at any one step is probably very strongly limited, perhaps to two or three.

Another problem-solving technique is problem reduction: that is, reducing a problem to a set of subproblems. This is a common way to look at the teaching of improvisation, but seems less likely to apply to doing it, where integration of action is required. Of course there is no proof of this; we know far too little about the workings of the brain. Constraint satisfaction, on the other hand, is a technique whose principles seem to apply to improvisation. The constraints are the referent, goals of the performer, stylistic norms, etc. Finally, means-ends analysis is a technique that is based on comparing current and goal states. Because it involves considerable back-tracking, it is unlikely to apply to the improvisation process. Yet like other methods above, it seems relevant to the process of learning improvisational skill. In general, then, learning to improvise (that is, to structure musical impulses within aesthetic guidelines) is more like problem solving than is improvising itself.

Another main branch of artificial intelligence is knowledge representation. The relevance to improvisation seems clear, for any particular mode of knowledge representation makes it efficient to do certain things and inefficient to do others. And efficiency is what the improviser needs above all.

Knowledge representation in artificial intelligence is based on many ideas, including indexing, conceptual dependency, hierarchies, semantic nets, multiple representation, blackboards (actually a type of interprocess communication), frames, scripts, stereotypes, and rule models (Rich 1983; Lenat 1984). With respect to improvisation, many of these are more suggestive than readily applicable. Indexing, for example, is too artificial, whereas conceptual dependency, in which information is represented by certain conceptual primitives, is too strongly linked with natural language structure. Hierarchies have been discussed previously. Semantic nets are perhaps more promising: information is represented as a network of nodes connected to each other by labelled arcs, each node representing an object, event, or concept, and each arc a relation between nodes. Such a graph could be drawn for musical objects and events, but parametrically tuneable processes are not easy to represent, and this is a serious drawback.

Multiple representation, however, is an important idea, and one which is implicit in parallel-processing ideas mentioned earlier. The increased flexibility and efficiency possible with multiple representation argue very strongly for its inclusion in any model of improvisation. Gelernter (1963) successfully applied the idea to problems in plane geometry by using simultaneous axiomatic and diagrammatic representations. Another interesting application is the notion of the 'blackboard', an organization of the

problem space into multiple levels of representation, typically along a dimension indicating level of abstractness. Thus a spoken sentence may be processed at levels of acoustic wave form, phonemes, syllables, words, word sequences, phrases, etc. Each part of the blackboard is triggered automatically as relevant information comes in. Multiple representation also strengthens the possibilities for analogy, and promotes synergy, by which is meant the co-operative action of parts of a complex system (Lenat 1984).

The last four ideas mentioned above, frames, scripts, stereotypes, and rule models, are considered to be various types of schemata (Rich 1983). The use of the word here is slightly different from that in the area of motor behaviour (see Adams 1976 for a survey). Frames are used to describe collections of attributes of an object. A frame consists of slots filled with attributes and associated values. Like most slot-and-filler structures, frames facilitate the drawing of analogies. Ideas equivalent to the frame are found in the improvisation model below. Scripts are simply normative event sequences and in so far as they apply to improvisation have much in common with the generalized motor schemata described above. Stereotypes have their usual meaning and are parts of the norms of musical style, but are often avoided by the best improvisers. Rule models describe the common features shared by a set of rules which form the basis for a 'production system'. If the improvising musician is the production system, the important rules will be largely heuristic and the rules about rules may be termed metaheuristics. Some of these will be culturally and historically based, while others presumably reflect intrinsic properties of the cognitive apparatus. Serafine (1983) has presented an insightful discussion of this distinction from the standpoint of the cognitive psychologist.

In principle it should be possible to integrate appropriate artificial intelligence techniques to construct an expert system which improvises. One of the very few such attempts is the unpublished work of Levitt (1981), which dealt with jazz improvisation. The idea awaits further development.

A model of improvisation

Any theory of improvisation must explain three things: how people improvise; how people learn improvisational skill; and the origin of novel behaviour. It must also be consistent with the numerous recurring themes reviewed above. The model given here seems to satisfy these conditions.

How people improvise

The first part of this model describes the process of improvisation. It begins with the observation that any improvisation may be partitioned into a

sequence of non-overlapping sections. By non-overlapping it is simply meant that sounds are assigned to only one section, not that the sounds themselves do not overlap. Let each of these sections contain a number of musical events and be called an event cluster E_i. Then the improvisation I is simply an ordered union of all these event clusters. Formally,

$$\mathrm{I} = \{E_1, E_2 \ldots E_n\} \tag{1}$$

From a naïve analytical perspective there is a large number of ways such a partitioning could be made. Our first major assumption is that every improvisation is actually generated by triggers at specific time points $t_1, t_2 \ldots t_n$ that instigate the movement patterns appropriate to effect intended musical actions. Each time point is thus the point at which decided action begins to be executed. Note that it is schemata for action that are triggered, not precise movement details, and subsequent motor fine tuning based on feedback processes goes on after each time point. Often time points will have clear musical correlates, with adjacent event clusters being set off from each other by local musical boundary criteria; pauses, phrase junctures, cadences, grouping by sequence etc.; but this need not always be the case.

With this interpretation, equation (1) is a unique specification of the timing of central decision making made by the improviser. The improvisation may then be viewed as a series of 'situations', where the $(i+1)$th situation is confined primarily to the time interval (t_i, t_{i+1}) and entails the generation of the cluster E_{i+1} on the basis of the previous events $\{E_1, E_2, \ldots E_i\} \equiv \{E\}_i$, the referent R (if one exists), a set of current goals $\mathcal{G}$, and long-term memory M. The referent R is an underlying piece-specific guide or scheme used by the musician to facilitate the generation of improvised behaviour (Pressing 1984*a*). The process of event-cluster generation may then be written

$$(\{E\}, R, \mathcal{G}, M)_i \rightarrow E_{i+1}. \tag{2}$$

Decision-making in the $(i+1)$th situation may in principle extend well back before time t_i, depending on the degree of pre-selection used by the performer, and will also extend slightly into the future, in that fine details of motor control will be left to lower control centres and hence may occur after t_{i+1}.

Equation (2) applies strictly only to solo improvisation. The only changes with group improvisation are that, first, all performers will have their own distinct time-point sequences (even though they would often be partially correlated), and, second, players will normally interact. Equation (2) can be readily extended to apply to all K members of an improvisation ensemble by writing

$$(\{E\}, C, R, \mathcal{G}, M)_{i_k} \rightarrow E_{i_k+1}, \; k=1, \ldots K, \tag{3}$$

where subscripts refer to the kth performer, and C stands for performer k's cognitive representation of all previous event clusters produced by the other performers and any expectations of their likely future actions. For simplicity, we use the formalism of equation (2) and speak primarily in terms of solo improvisation in what follows, adding in the effects of other performers in a straightforward manner as needed at certain points.

Any given event cluster E has a number of simultaneously valid and partially redundant 'aspects'. Each aspect is a representation of E from a certain perspective. Most important are the acoustic aspect (produced and sensed sound), the musical aspect (cognitive representation of the sounds in terms of music-technical and expressive dimensions), and the movement aspect (including timing of muscular actions, proprioception, touch, spatial perception, and central monitoring of efference). Visual and emotional aspects normally also play a role, and in principle there may be others. Furthermore each aspect exists in two forms, intended and actual. Each intended form is specified at a specific time point: the corresponding actual form is constructed from subsequent sensory feedback. The gap between these two forms is reduced by sound training in musicianship and improvisation practice, but it never dwindles completely to zero. Hence in equation (2) or (3) the variable $\{E\}_i$ represents intended and actual forms of all aspects of event clusters E_1 to E_{i-1}, the intended form of E_i, plus, over the course of the time interval (t_i, t_i+1), increasing feedback on the actual form of E_i. By t_{i+1}, when central commands for E_{i+1} are transmitted, the ongoing nature of improvisation probably demands that integration of the intended and actual forms of E_i be virtually complete.

The details of the proposed model of what occurs in the $(i+1)$th situation, that is, the selection of E_{i+1}, are as follows:

(A) E_i is triggered and executed (it may spill on briefly to times $t>t_{i+1}$).

(B) Each aspect of E_i may be decomposed into three types of analytical representation: objects, features, and processes. An 'object' is a unified cognitive or perceptual entity. It may, for example, correspond to a chord, a sound, or a certain finger motion. 'Features' are parameters that describe shared properties of objects, and 'processes' are descriptions of changes of objects or features over time. At t_i this decomposition is based only on intended information (efference); by t_{i+1} much of the actual form of E_i, received through the senses and internal feedback, has been used to refine the cognitive representation of E_i. This may continue after t_{i+1}. Let this decomposition into objects, features, and processes (for each aspect) be represented by three variable-dimension arrays **O**, **F**, and **P**, and assume that they represent all information about E_i needed by the improviser in decision making.

(C) The structures of the three types of arrays are as follows. The object array is a $2\times N$ array where row 1 components label the objects present and row 2 gives their associated cognitive strengths s_k (explained below). The

feature and process arrays are typically non-rectangular. Their first rows consist of object and process labels respectively, and each column below that row is built up of a number of pairs of elements which give the values v_{jk} of associated features or process parameters and their corresponding cognitive strengths s_{jk}. The arrays are non-rectangular because different objects may possess different numbers of significant features or process parameters. The feature and parameter process values v_{jk} vary over ranges appropriate to their nature, whereas cognitive strengths s_{jk} are normalized to vary between 0 and 1. Cognitive strength is essentially an indicator of attentional loading, that is, the importance that the given factor has in the performer's internal representation. Thus even though certain features may be objectively present, as analysed by others, if the player does not use them in his or her cognitive representation, their s values would be zero. Sample object, feature, and process arrays for the following event cluster (a short trombone motive) are given by way of example (Fig. 7.1), for the musical aspect only. Considerable redundancy of representation has been set out in the process array.

(D) Production of E_{i+1} occurs primarily on the basis of long-term factors (R, $\mathscr{G}$, stylistic norms, and ongoing processes), and by evaluation of the effects and possibilities of E_i. There seem to be only two methods of continuation used: associative or interrupt generation. In associative generation the improviser desires to effect continuity between E_i and E_{i+1} and picks new arrays $\mathbf{O}_{i+1}$, $\mathbf{F}_{i+1}$, $\mathbf{P}_{i+1}$ whose set of strong cognitive components includes all or nearly all of the strong cognitive components of $\mathbf{O}_i$, $\mathbf{F}_i$, and $\mathbf{P}_i$, with the parameter values of these shared components being directly related (as described in (E) below). In other words the E_i components with high s values carry their information on in some way to E_{i+1}. These new arrays act as a set of constraints which determine, in conjunction with various generation processes, the musical actions generated for E_{i+1}. The relative importance of different constraints in the generation process is indicated by their respective cognitive strengths s_k and s_{jk}. Note that the E_{i+1} arrays may contain new strong components (constraints) that were previously weak or completely absent. In particular, it is possible to add a new independent musical process to a continuing one to produce an associative continuation which has a clear sense of novelty (e.g. the introduction of a new part in polyphonic music). In the case of interrupt generation the improviser has had enough of the event train ending with E_i (for whatever reasons) and breaks off into a different musical direction by resetting a significant number of strong components of $\mathbf{O}_{i+1}$, $\mathbf{F}_{i+1}$, $\mathbf{P}_{i+1}$ without any relations to E_i except possibly those chosen to be normative with regard to style in the piece, or intrinsic to the referent (if present) or goals. Clearly, the more strong components that are reset, the greater the sense of interruption.

Object array **O**

$$\mathbf{O}=\begin{pmatrix} \text{N} & \text{G} & \text{R} & \text{N} & \text{S} \\ \tfrac{1}{2} & \tfrac{1}{2} & \tfrac{1}{2} & 1 & 1 \end{pmatrix}$$

*Range

Fig. 7.1. Possible object, feature, and process arrays corresponding to a short trombone motive.

(E) Associative generation is based on either similarity or contrast. In the case of similarity all or nearly all important (important as determined from the vantage point of the improviser) array components stay approximately the same. In other words, for those components v_{jk} with s_{jk}'s signicantly above zero at time $t=t_i$, $(v_{jk})_{t_i} \approx (v_{jk})t_{i+1}$. Significant object array components behave analogously. In the case of constrast-type associative generation, at least one strong component of either the feature or process arrays must either move from near one end of its possible range of values to near the opposite end, or cross some perceptually significant boundary. Meanwhile, all other strong components change either very

little or not at all. Examples are when a group of high notes is followed by a group of low notes, or an accelerando changes of decelerando, or bright timbres are replaced by dull timbres. The idea behind this classification is that the most powerful and general types of improvisational control are those that are cued to features and processes. The objects, though a crucial part of the entire procedure, are at the same time often merely the very familiar musical clothing of cognitive action space.

(F) Interrupt generation is based on the resetting of all or a significant number of the strong array components without regard to their values in the current event cluster E_i. A decision to interrupt brings to an end a sequence of related event clusters, say $K = \{E_{i-r}, E_{i-r+1}, \ldots E_i\}$, where the number of event clusters in this 'event-cluster class' is $r+1$. Hence interrupt decisions partition the entire improvisation into A discontinuous event-cluster classes K_α, so that the formal design of the piece becomes

$$I = \{K_1, K_2 \ldots K_A\}. \tag{4}$$

Each event-cluster class K_α contains at least one event cluster, and may be defined in terms of the strong components of the object, feature, and process arrays shared by all the member event clusters. If these special components are represented as $\mathbf{O}_s^\alpha$, $\mathbf{F}_s^\alpha$, and $\mathbf{P}_s^\alpha$, then K_α is defined by $(\mathbf{O}_s, \mathbf{F}_s, \mathbf{P}_s)^\alpha$. One of the sets $\mathbf{F}_s^\alpha$ and $\mathbf{P}_s^\alpha$ must be non-empty. If $(\mathbf{O}_s, \mathbf{F}_s, \mathbf{P}_s)^\alpha =$ or $\approx (\mathbf{O}_s, \mathbf{F}_s, \mathbf{P}_s)^\beta$, for some β not immediately following α, we have recursion in formal design of the improvisation. Under these assumptions the process of improvisation may be sketched diagrammatically as in Fig. 7.2.

(G) The choice between association and interrupt generation may be formally modelled by a time-dependent tolerance level for repetition, $L(t)$. An interrupt tester, whose inputs are presumably the time since the onset of the K_α event cluster class, $(t-t_{i-r})$, and the size and nature of K_α, computes the degree of current repetition, $Z(t)$, and if $Z(t) \geqslant L(t)$, institutes an interrupt generation, so that $Z(t)$ jumps to a low value. Otherwise associative generation continues. Diagrammatically this is shown in Fig. 7.3 for the same improvisation as in Fig. 7.2.

(H) Once $\mathbf{O}_{i+1}$, $\mathbf{F}_{i+1}$, and $\mathbf{P}_{i+1}$ are selected for all relevant aspects, tuneable cognitive and motor subprogrammes are set in motion that generate, on the basis of these higher constraints and current motor positions, a specific action design. At this point we have reached t_{i+1} and this loop of the process $(E_i \rightarrow E_{i+1})$ is complete. By iteration, then, the entire improvisation is built up. The starting point E_1 may be considered a situation of interrupt generation (where E_0 is silence) and the final event cluster E_n is simply a second case of interrupt generation where E_{n+1} = silence, after which the improvisation process is turned off.

These, then, are the salient features of the model in outline. They are diagramatically displayed in Fig. 7.4.

Next we look more deeply at certain critical stages of the improvisation

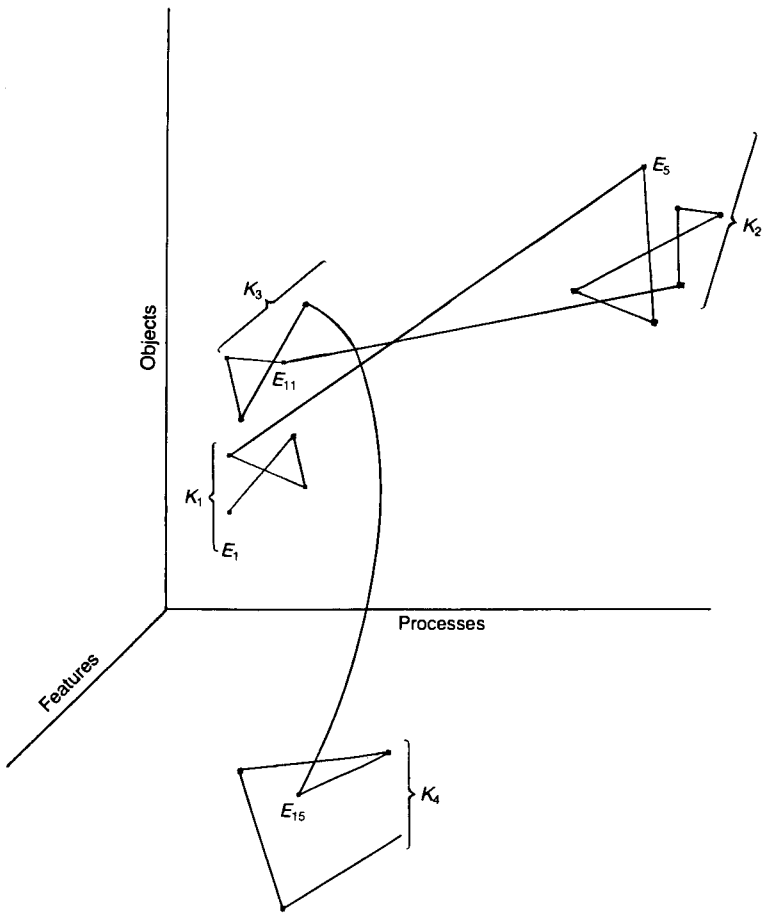

Fig. 7.2. An improvisation in musical action space, showing four event-cluster classes, and form ABA'C.

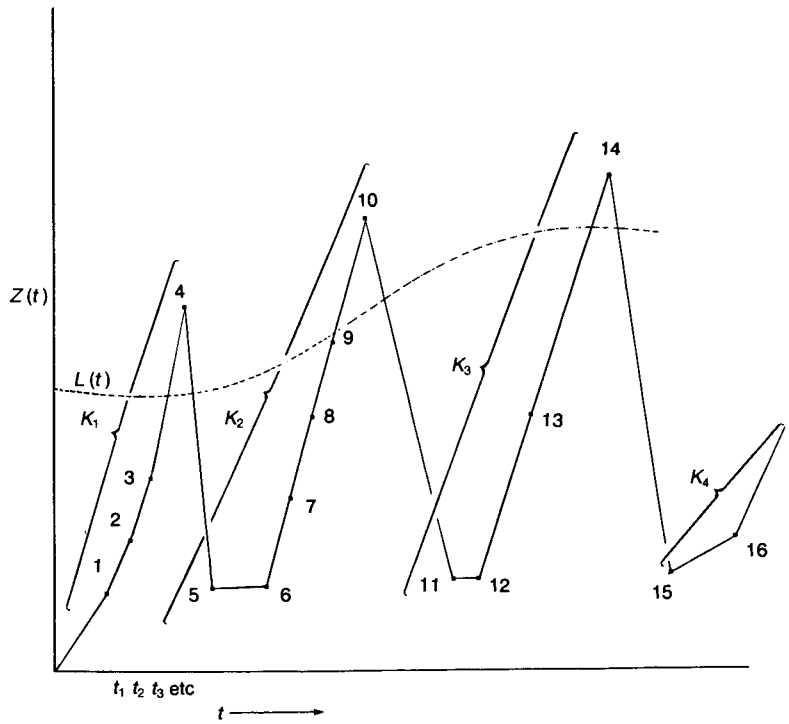
model. To begin with, it is characterized throughout by extensive redundancy. There is first of all redundancy between the aspects of each event cluster. The performer knows, for example, that certain motor actions involved in striking a kettle drum (motor aspect) will correspond to a particular sound (acoustic aspect), with associated musical implications (musical aspect). Furthermore, each aspect is decomposed into extensive object, feature, and process representations which contain considerable redundancy. For example, the musical motive of Example 7.1 may be pitch encoded as the objects $D^2F^2A^2B^2$, or as the object $B\phi$ diminished 7 chord in first inversion, or as a diatonic sweep to the leading tone in the key of C major, or as a ii ϕ diminished 7 chord in a minor, or as an ascending contour, and so forth. Its features include melodic motion by seconds or



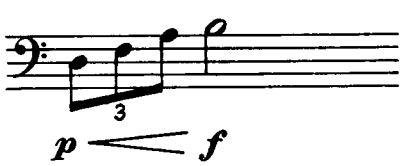


Fig. 7.3. Interrupt generation via the repetition functions L and Z.

thirds, diatonic note choice, the degree and speed of crescendo, rhythmic regularity of attack, certain values of finger force and velocity used by the performer, and so forth. Many processes could be implicated to generate the given motive: arpeggiate a Bϕ diminished 7 chord, pick notes consistent with a triplet feel in C major, move the fingers 4321 of the left hand in such a fashion as to depress keys on the piano, and so forth. If the nature of improvisation entails the seeking out of a satisfactory trajectory in musical action space, such redundancy of description and generation allows maximal flexibility of path selection, so that whatever creative impulse presents itself as an intention, and whatever attentional loadings

Example 7.1

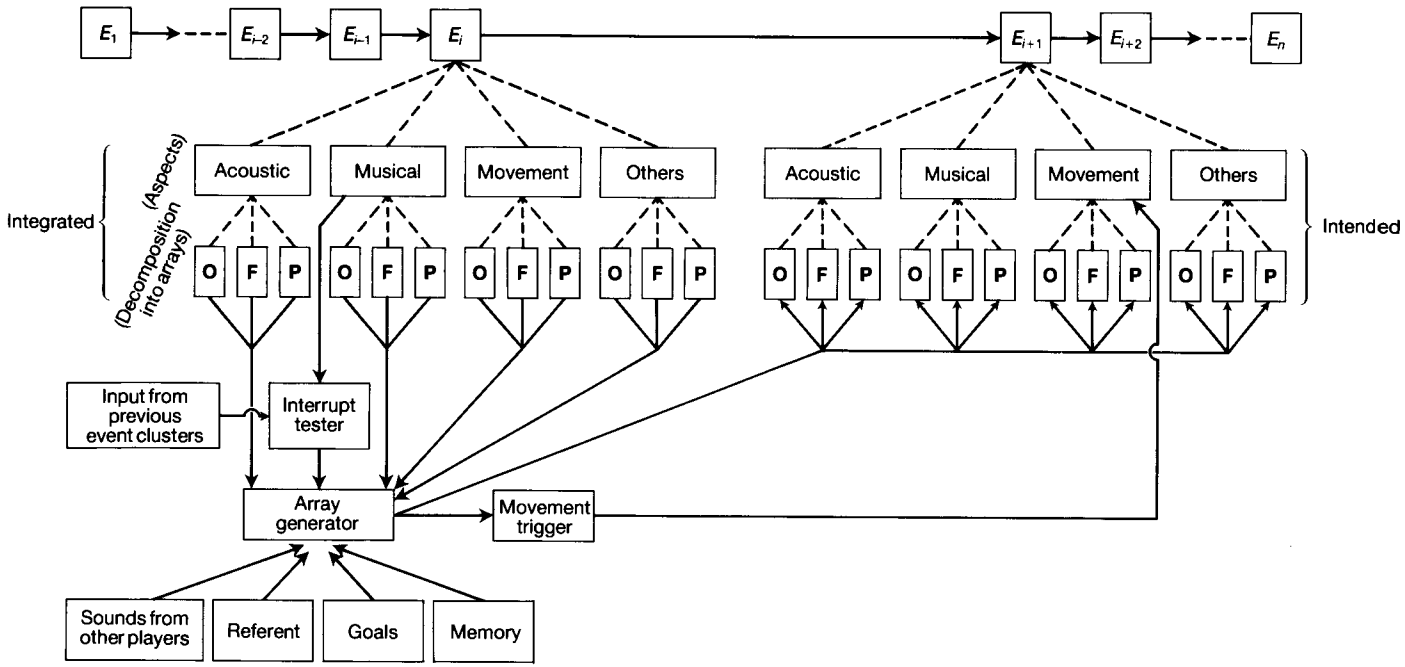

Fig. 7.4 The improvisation model in diagrammatic form. Only the process $E_i \rightarrow E_{i+1}$ (intended) is detailed. Each event cluster E_i is present in a number of partially redundant aspects, and each of these is decomposed into object, feature, and process arrays. Largely on the basis of musical representation a decision about type of continuation is made by an interrupt tester. In accordance with this decision an intended array decomposition is generated, with input from E_i arrays, referent, goals, and memory. This decomposition acts as a set of constraints in the generation of musical action, and production of E_{i+1} is subsequently begun by a movement trigger at t_{i+1}.The diagram detail shows what happens in the time interval (t_i, t_{i+1}), so that the indicated decomposition of E_i is integrated (that is, intended plus actual forms of E_i are combined), whereas the indicated decomposition of E_{i+1} is intended (no feedback has been received yet). Hence **O**, **F**, and **P** at time point t_{i+1} do not have indicated outputs.

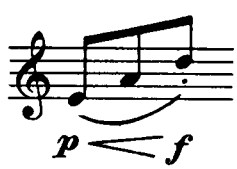
may be set up, some means of cognitive organization and corresponding motor realization will be available within the limiting constraints of real-time processing.

Such extensive redundancy I take here to mean that control of event production is heterarchical, and may potentially shift rapidly from one cognitive control area to another. Indeed this must be considered the most effective strategy for improvisation. Experientially it very probably corresponds to 'letting go', or 'going with the flow' as described earlier, whereby central hierarchical control, identified here with conscious monitoring of decision making, yields to heterarchical control (and corresponding unconscious allocation of attention).

Next we look further at the object, feature, and process arrays that are critical in the representation and generation of event clusters. First of all it may well be asked how such arrays are formed. The answer given here is based on an ecological perspective, which considers that the capacity to extract or create such arrays is neurologically innate, but that they are only brought into being by interaction with the environment. More specifically, cognitive objects are inferred to exist on the basis of perceived invariance in sensory input over time, and boundedness in a space (whether physical, musical, or abstract). Features are tuneable parameters and come to be abstracted on the basis of perceived similarity or contrast in sensory input. Processes come about from perceived change in an object or along a feature dimension with time.



Thus over the course of one's life new arrays and array components are constantly being created by new perceptions and new perceptual groupings. During any given improvisation at most very few new features or processes will be created, and only a limited number of new objects. In general, though, this is one source of novel behaviour: the evolution of movement control structures for newly discovered objects, features, and processes. However, there seems to be another, probably more common source of behavioural novelty: the motor enactment of novel combinations of values of array components. This second possibility is shown for example by considering a child musician who has learned motor actions corresponding to the distinctions loud/soft and fast/slow separately, but without encountering soft and fast simultaneously. By combining these two dimensions an action novel to the child's experience can result. Furthermore, the results of such novel parametric combinations need not be so predictable. If we recall that the human performance system is non-linear, then, as mentioned above in the paragraphs on organizational invariant theory, novel, strikingly different behaviour may follow when controlling system parameters assume certain novel combinations of ranges. It can further be shown mathematically that behaviour described as 'chaotic' may occur under such conditions (Li and Yorke 1975; May 1976), even for simple systems. This perspective has led to a biomathematical analysis, for example, of many so-

called 'dynamical' diseases, including schizophrenia, AV heart block, epilepsy, and some haematological disorders (see Guevara *et al.* 1983 for a survey). The point with regard to improvisation is that the same sort of smooth parametric tuning can be used to generate abrupt intentional novelties in movement and musical expression. The integration of the results of novel ranges of array components is presumed to be handled by control structures of the CNS responsible for timing and smoothness of action.

During any given improvisation, when possible object, feature, and process array types are basically fixed, novel sensory input will be analysed and assigned to existing categories, or, if the fit is too poor, into existing categories plus deviations. In this model such a description is also considered to apply to the generation of action. That is, novel actions are built primarily by distorting aspects of existing ones. This sheds light on the organizing power of the metaphor, mentioned earlier, since it may be considered to be a global link across categories, one that facilitates movement integration. In other words, the image or metaphor enables the co-ordinated modification and resetting of whole classes of array components in a fashion ensuring spatial and temporal coherence.

The central core of the model is the generation of a new set of array components for E_{i+1} from those preceding it. To make this process clearer, we now look at two examples.

(1) Let E_i be

Example 7.2

played by the right hand at the piano.

Above are a number of possible improvisational continuations, based on attentional emphasis (that is, cognitive strength) given to the mentioned array components (see Fig. 7.5). Emphasis given to a particular component means that it will guide the generation of subsequent events. The type of arrays emphasized are also indicated; note that this is not uniquely determined, since the model makes a feature of redundancy. Continuations 1–8 exemplify associative continuation, with numbers 7 and 8 more abstract than the others, while number 9 is interrupt based.

Continuation	Emphasized components used for continuation	Type of arrays
1	key of A major; quaver durations	**O,F,P**

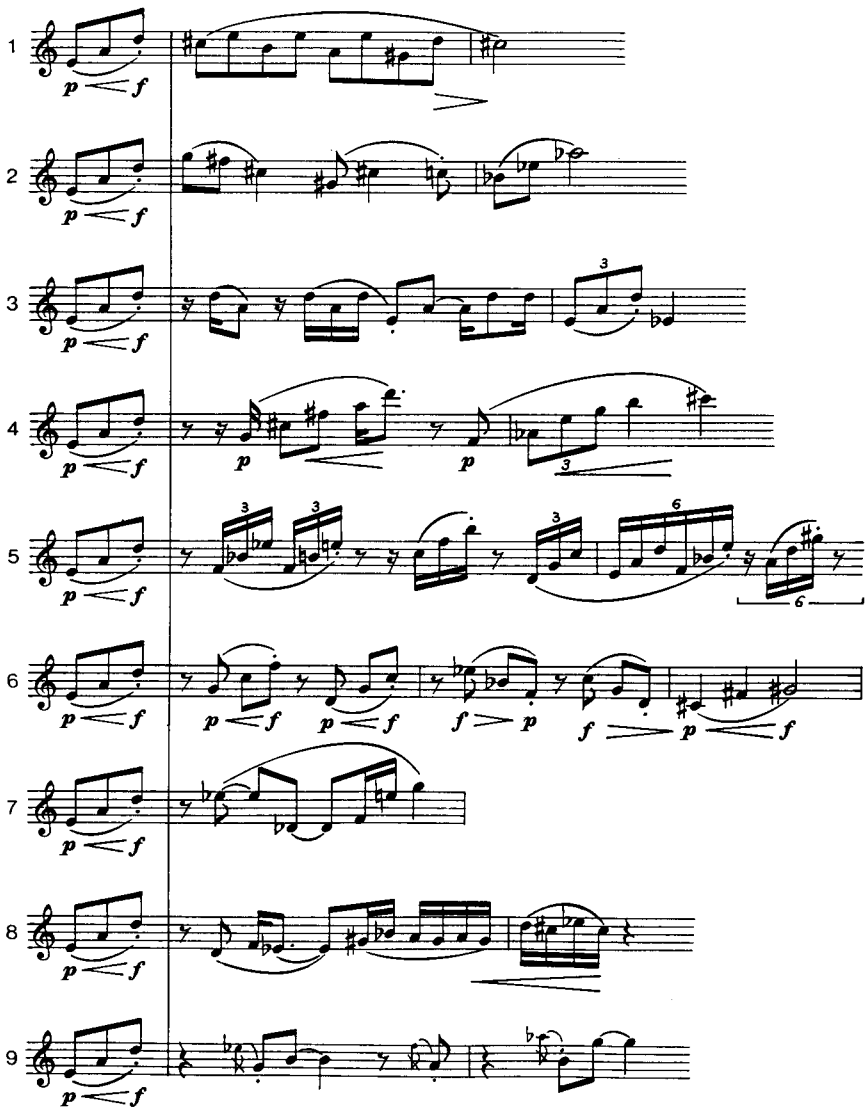


Fig. 7.5. Examples of continuation of an event cluster under the emphasis of selected array components.

2	perfect fourth interval	**F**
3	notes E, A, D; rhythmic displacement	**O,P**
4	melodic contour	**O,F**
5	motor generation with right-hand fingers 1, 2, and 4	**O,F**

6	gesture (note use of contrast), perfect fourth interval	**F,P**
7	phrase design (antecedent/consequent), interval class 2	**F**
8	notes E, A, D: chromatic decoration	**O,P**
9	interrupt generation: new motive	**O,F,P**

If the same line had been played on flute, the continuations might all have been very similar except for continuation number 5, which has as its constraint focus the actual movement patterns for manipulating the instrument.

(2) Here we consider an event cluster less clearly tied to structural-historical processes. Let E_i be a segment of sounds produced by a single slow tilting and rotation of a tambourine one-quarter filled with a single layer of small lead shot. E_i is a coloured noise sound which subjectively is reminiscent of distant ocean waves or rain. Some possible continuations are then as follows:

Continuation	Description	Type of arrays
1	continue tilt but speed up rotation of tambourine	**F,P**
2	shake tambourine from side to side	**F,P**
3	stop motion of tambourine	**F,P**
4	toss lead shot in air and catch it	**F,P**
5	perform a drum roll on the bottom of the tambourine skin with fingers of the right hand	**O,F,P**

Continuations 1 and 2 are of associative type, whereas 3, 4, and 5 are interrupt type. Notice that here description emphasizes the motor aspect, since there is no extensive tradition of music theory which applies to such a sound source.

If these examples succeed in illustrating how continuations may be constructed, they are mute on the details of how one continuation comes to be chosen over all other possible ones. What has been said so far is only that, in associative generation, a set of constraints is produced associatively, while in interrupt generation the set of strong constraints on action includes uncorrelated resetting. Obviously, event generation is informed by a vast panorama of culturally and cognitively based musical processes and stylistic preferences (motivic development, phrase design, historical forms, transposition, rhythmic design, etc.). But a considerable degree of residual decision-making remains, as for example the choice of array components that will be singled out to act as strong constraints or to be reset. How are such residual decisions made?

It does not seem possible to give a final answer to this question, for it has

at its ultimate root the question of volition and hence the mind-body problem, about which there is no general philosophical agreement in our culture or even among scientists. There is also no conclusive empirical evidence to support one view or another, despite the opposing claims of some positivists and phenomenologists. It seems useful therefore to characterize a number of strategies of explanation for the residual decision-making mentioned above, and subsequently explore what possibilities exist for experimentally decided among them.

It is first of all possible to take the intuitive perspective, that the individual acts best when he or she merely taps a certain powerful source that dictates the course of musical action in a naturally correct fashion, one that may not be analysable or predictable in physical or musical terms. Although this perspective is usually transpersonal and may seem romantic to some, this does not imply that it is untestable and therefore unscientific.

A second perspective is to assume that this residual decision making actually reflects the effects of individual free will. In other words, the improviser is a unique conscious entity, and residual decision making rests to some degree on internal variables not predictable even in principle from a fully detailed knowledge of the physical-state variables of the improviser and his or her environment.

A third perspective is the physicalist one. Here complex decision making is seen to be an emergent property of the fantastically complex physical system known as a human being, in interaction with a series of environments. Free will in this perspective is either illusory, or simply a somewhat misleading metaphor for certain complex characteristics of the system. There are a number of models possible within this perspective for residual decision making: interactive control with lower CNS centres, network statistical voting models, distributed memory-type models, decision making based on fuzzy logic, etc.

Fourth and last is the perspective of randomness. Here the unconstrained residual decision making is simply modelled by use of random generators. As the improviser becomes more and more expert through practice and more and more control procedures are built up, random processes need to be invoked less and less frequently and overall error levels decrease, perhaps approaching a minimum threshold.

To experimentally distinguish between these points of view a high resolution improvisation transcription system has been built here at La Trobe University. Co-worker Greg Troup and myself, as well as technical staff of the departments of psychology and music, have designed and set up the apparatus. It is a synthesizer-based system, using modified MIDI format, and enables detailed recording, to millisecond resolution, of musical actions at a keyboard. It is also possible to input sound from other (non-keyboard) instruments. Simultaneously as music is recorded a videotape of the performance can be made. The results of this investigation

are not yet complete and will be reported elsewhere, but it seems likely that the limits of validity of intuitionist and random perspectives will be determinable. There seems to be, however, no obvious experimental design that will decide between the physicalist and free-will perspectives. Hence the two may be considered co-existing formulations. The problem in deciding between the two rests with setting up the repeatable conditions which should theoretically lead to the same 'improvised' result in the hard-core physicalist model and to a different improvised result under conditions of free will. But since each event potentially affects all those that follow, all initial conditions are intrinsically unrepeatable.

The development of improvisational skill

The modelling of this process remains in a less developed state and only a brief discussion is included here. Its starting point is the emergent results of practice found in all types of skill, as mentioned earlier: improved efficiency, fluency, flexibility, capacity for error correction, and, less universally, expressiveness. But there are at least two additional components of improvisational skill: inventiveness and the achievement of coherence. In more fixed skills these are less important, since inventiveness provides few tangible advantages, and coherence is built in by the rigidity of the task demands.*

The specific cognitive changes that allow these properties to develop in improvised musical behaviour are considered to be:

(1) an increase in the memory store of objects, features, and processes—in musical, acoustic, motor (and other) aspects;

(2) an increase in accessibility of this memory store due to the build-up of redundant relationships between its constituents and the aggregation of these constituents into larger cognitive assemblies;

(3) an increasingly refined attunement to subtle and contextually relevant perceptual information.

The build-up and improved access to memory of points (1) and (2) is presumably central to any learning process. In the language of the model of this chapter this involves the use of extensive redundancy, and also the aggregation of memory constituents (objects, features, processes) into new cognitive assembles which may be accessed autonomously. Because such a procedure can presumably be nested to arbitrary depth, very complicated interconnected knowledge structures may develop.

This last idea is not new here. It has a considerable history and has been most clearly outlined for the purposes of this paper by Hayes-Roth (1977), who generalized an earlier model of Hebb (1949). The central feature of

* It is interesting to note that these two skills push in opposite directions, for inventiveness comes from the commitment to avoid repetition as much as possible, while coherence is only achieved by some degree of structural unity, which is only possible with repetition.

aggregation of memory elements Hayes-Roth termed *unitisation*, and her knowledge-assembly theory was built up around the presence of elemental 'cognitive units'. In the terminology of this chapter these are object, feature, and process array components. In knowledge-assembly theory such cognitive units are associatively activated and may combine to form assemblies, whose 'strengths' are increasing functions of recency and frequency of activation, and decreasing functions of their own complexity. From these strengths are derived probabilities and speeds of activation. There is a level of redundancy appropriate to improvisation in this model, since for example a cognitive unit may be activated individually or as part of a larger assembly of cognitive units. In her paper, Hayes-Roth shows that knowledge-assembly learning theory is consistent with a large body of experimental results. It is also consistent with the introspective reports of improvisers and the review given above of improvisation teaching methods. But a decision on the superior applicability of this theory to improvisation over those of other related formulations must rest upon experimental work as yet undone. For this reason I give no further speculation.

The third point mentioned above may be elaborated as follows. The refinement of improvisational skill must depend partly on increasing the efficiency of perceptual processing to allow the inclusion of more and better-selected information in the improviser's decision-making procedures. The need for this efficiency is imposed by every performer's more or less limited individual capacity, per unit time, to process novel sensory input. It seems likely that practice leads to the increasingly efficient use of information in two ways: by reducing the effective amount of information by the recognition of patterns of redundancy in the sensory input, and by focusing attention increasingly on the information that is most relevant for producing a successful improvisation. The increased use of such subtle and 'higher-order' information leads to the higher-order skill characteristics mentioned earlier. The main differences in this process between fixed and improvised actions may be said to reside in the nature of the attention focus used in the two situations. The fixed-skill situation evolves towards a minimal size attention set, whereas the unpredictability of improvisation demands that the attention focus remain wide. To go beyond such insufficiently specific observations experimental work is clearly required.

Conclusions

This chapter has attempted to illuminate the process of musical improvisation by first examining the modelling tools available from a number of different disciplines. Based on this examination, a cognitive model has then been presented for the process itself, followed by a brief discussion of its relation

to improvisational skill acquisition. The central features of the model are as follows. It is reductionist, in that cognitive structures of processing and control are considered to be broken down into aspects (acoustic, musical, movement, etc.), each of these into types of analytical representation (objects, features, processes), and each of these into characterizing elements (array components). At the same time the model is synergistic and capable of behavioural novelty, due to the extensive redundancy of the cognitive representations and the distributed and non-linear character of the outlined control processes. The extensive presence of feedback and feedforward contributes to this. The fundamental nature of the improvisation process is considered to be the stringing together of a series of 'event clusters' during each of which a continuation is chosen, based upon either the continuing of some existing stream of musical development (called here an event-cluster class) by association of array entries, or the interruption of that stream by the choosing of a new set of array entries that act as constraints in the generation of a new stream (new event-cluster class).

The model seems to be specific enough to allow its use as a basis for the design of 'improvising' computer programs. Work in this direction is in progress. At the same time some fundamental philosophical questions remain about the origin of certain kinds of decision making in any such model, and four types of answers to these have been outlined: intuition, free will, physical causation, and randomness. Some of these alternatives should be distinguishable on the basis of experimental work currently in progress at our laboratories, which also has as its aim the testing of the basic assumptions of the model. This will be described in subsequent publications.

Experimental research into musical generative ability*

MÁRIA SÁGI and IVÁN VITÁNYI

One of the projects carried on for about 15 years in the Institute for Culture of Hungary has been concerned with analysing human creative faculties; in particular, artistic creativity. We have been concerned to discover the place, role, and modes of creativity in Hungarian culture, and we have attempted to relate different levels of creativity to economic, social, and educational factors. Our empirical studies have been extended to differnt arts, including music, fine arts, fiction, and poetry.

This chapter describes part of our research into musical creativity. Music is a particularly suitable idiom for our purposes. Its abstract character makes it easy to react to on many different levels. Also, music has deeply penetrated many different social groups, thus 'pre-conditioning' a wide range of subjects for giving relevant responses. In addition, the wide use in Hungarian education of the Kodály method has placed great importance on the practical development of musical creativity.

The music-psychological research to be described below was provoked by the view widespread in the literature both of the psychology and the sociology of art that two kinds of artistic experiences can be distinguished: that of the creator and that of the receiver. This is a view we do not share. Proponents of this view tend to argue that only a narrow group in contemporary society takes a creative part in music (for example from Hungary's population of 10 million, taking into account all the composers of popular songs and rock music, only about 2 to 3000; that is 0.02 to 0.03 per cent).

A contrasting view is provided by Weber's (1921) and Blaukopf's (1972) ideas on the role of sound systems. According to them, the systems of musical structures adopted by a composer form a language, a semiotic system to which the most ingenious composer can merely add something and which he is unable to create himself.

* A short summary of part of this study was published earlier in *Contribution to the Sociology of the Arts* (1983), ISA Research Committee 37, pp. 242–9. Research Institute for Culture, Sofia.

Of course, there are different levels of composing ability. In particular, we can distinguish between *constructive* and *generative* forms of composing ability. We do not wish to dwell at length on the general theoretical issues of creativity because our aim is to describe our empirical investigation. Let us simply note that we agree with authors like Taylor (1959) who distinguish levels of creativity. We consider creativity as consisting of two main types: constructive creativity (which is—in the stricter sense of the term—artistic creativity) and generative creativity.

We speak about constructive creative ability in music where the composer gives a final form to an original opus by means of conscious work, employing and (partly) reshaping the elements and rules known to him. By generative composing we mean a largely unconscious or intuitive variational application of the elements and rules which does not result in a final opus of unchangeable form but merely in a new variant. We have adapted this term from Chomsky's (1965) 'generative linguistic ability'. Generative linguistic ability means that with the knowledge of a definite number of elements and of a definite number of generative rules all the speakers of a language can produce an indefinite number of sentences. That is exactly how generative musical ability acts: with a definite number of elements (stock of sounds) 'and a definite number of generative rules' an indefinite number of melodies can be constructed.

Historical evidence of generative musical ability is readily available. We see this in the way that folk-songs take shape, are transformed, and are sung time and again by folk-singers. We may legitimately ask, however, if, through the destruction of traditional popular art, the generative musical ability of mankind may not have been destroyed as well. Has the pervasive music-supplying apparatus of radio, television, cinema, music-halls, and restaurants killed the ability of man to compose music for himself? This was the question to which the following investigation sought a reply.

Procedure

Exploration

Prior to undertaking the musical tasks subjects were engaged in a personal discussion to put them at ease. The subjects gladly discussed their lives, past and present, their general views on life, their relations to the world and the arts, and their general and artistic tastes.

Examination of generative musical ability

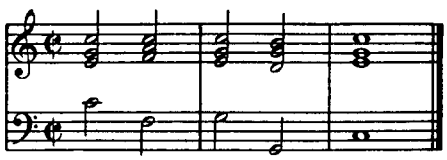
Subjects were asked to make immediate sung improvisations to poems.

One was Sándor Petőfi's (mid-19th century) '*Falu végén kurta kocsma*' ('Little inn outside the village') in the style of a folk-song.

Falu végén kurta kocsma,	At village end a small saloon,
Oda rug ki a Szamosra,	That is where Szamosra hangs out,
Meg is látná magát benne,	He would even be able to see himself in it,
Ha az éj nem közeledne.	If night was not approaching.
Az éjszaka közeledik,	Night is coming,
A világ lecsendesedik,	The world grows quiet,
Pihen a komp, kikötötték,	The ferryboat rests, they have tied it out,
Benne hallgat a sötétség.	In it the darkness remains silent.
	(*translation by Dr Thomas Kabdebo*)

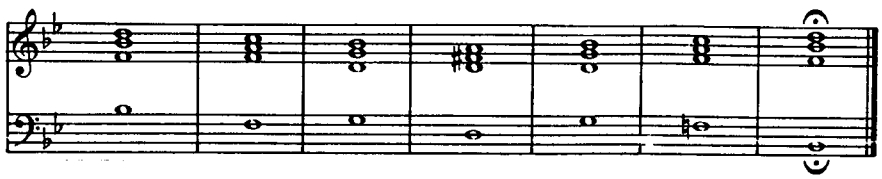
Two other poems were chosen to represent the Hungarian poetry of the twentieth century: Endre Ady's poem '*A Kirsztusok mártirja*' ('The Martyr of the Christ').

	Literal translation
Vad, nagyszerü rajongást oltott	The brooklet's bank has infused in me
Az Érnek partja én belém	A worship wild and passionate,
Csupa pogányság volt a lelkem,	Of paganism my soul was brimful
Gondtalan vágy és vak remény	Carefree desire and blind of hope.
Forgott körültem zagyva módon	Turning confusedly around me
Lármával, vadul a világ	The world was clamorous and wild.
És én kerestem egyre-egyre	I was searching unfalteringly
Valami nagy Harmóniát.	In it some major Harmony.



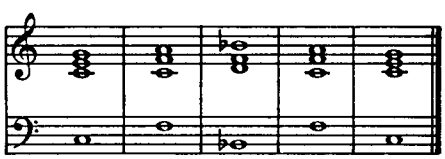
and eight lines of Attila József's '*Óda*' ('Ode').

Óh, hát miféle anyag vagyok én,	O what kind of matter am I
hogy pillantásod metsz és alakit?	that your glance cuts and shapes me?
Miféle lélek és miféle fény	What kind of soul and what kind of light
s ámulatra méltó tünemény,	and what kind of amazing phenomenon am I
hogy bejárhatom a semmiség ködén	that in the mist of emptiness I can walk around
termékeny tested lankás tájait?	the gentle slopes of your fertile body?
S mint megnyilt értelembe az ige,	And like the word entering into an enlightened mind
alászállhatok rejtelmeidbe.	I can enter into its mysteries . . .
	(*translation by Dr Thomas Kabdebo*)

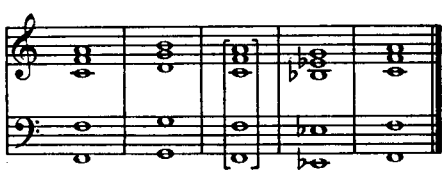


The fourth poem was the lyric of a hit song.

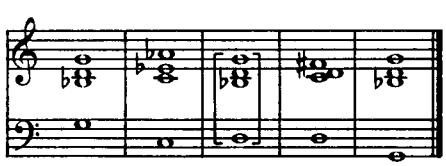
Subjects were also asked to make improvisations to simple harmonic progressions; first to the familiar I–IV–V–I, then to the more sophisticated progressions, including some typical of Bartók (see Examples 8. 1–7).



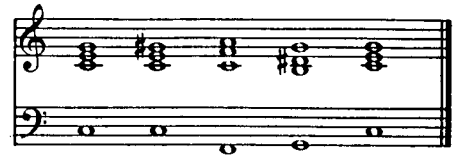
The sense of tonality of the subjects was examined by asking them to improvise completions to three melodies (see Examples 8. 8–10). Each was



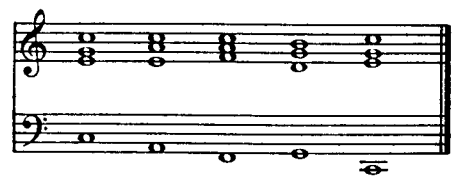
Example 8.1



Example 8.2

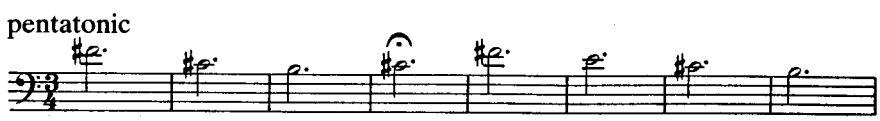


Example 8.3

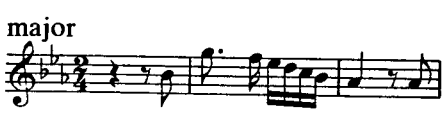


Example 8.4

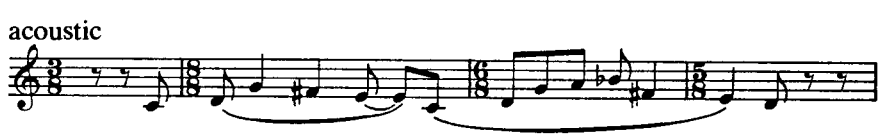
Example 8.5



Example 8.6



Example 8.7



in a different mode: pentatonic, major, and acoustic (or overtone). The latter, often used by Bartók, produces scales such as C–D–E–F♯–G–A–B flat–C.

Example 8.8. Bartók.

Example 8.9. Mozart.

Example 8.10. Bartók.

Tests of tonal awareness

Some additional receptive tests of tonal awareness were administered, but the results of these tests are not considered here.

The subjects

The experiment was conceived on a large scale, with 220 subjects in 11 samples, after a pilot study with 20 peasants from a Hungarian village, Aradva'nypuszta.

Our hypothesis is that any person, whether musician or not is capable of composing music such as a song verse, using the musical patterns and structures provided by his/her daily musical environment (radio, TV, singing, etc.). Some musicologists have challenged our view. This is why our sample included untrained subjects from different age groups and social strata. A few control groups were selected from those studying or having studied music.

The impact of European musical culture arose as a separate issue which was studied by examining control groups consisting of students in Budapest of non-European (Asian, African, Latin American) origin.

The 11 samples are shown in Table 8.1.

Table 8.1 *Subject samples used in the experiment.*

Group No.	Age	Laymen	Age	Those having studied music
1/2	13	pupils	13	music pupils
3	17	middle school pupils	–	–
4	17	apprentices	–	–
5	20–25	industrial workers	–	–
6/7	20–25	university students	20–25	conservatory students
8	about 40	industrial workers	–	–
9/10	about 60	industrial workers	about 60	industrial workers singing in choirs
11	20–25			non-European students

Although the experiment involved a great deal of work (each person was tested for two to three hours), we succeeded in examining 20 persons in each of the 11 samples.

Before the beginning of the experiments a dispute over principles arose: many musicologists said we were embarking upon an impossible enterprise, that it was inconceivable that laymen might be able to perform the task. However, the result of the investigation has corroborated the correctness of our assumption.

Three thousand four hundred and twenty tunes, the length of folk-songs were recorded. If all subjects had succeeded in completing all the musical tasks, 3740 tunes could have been recorded. However, in several cases the subjects could not complete some of the tasks; for instance, they could not improvise tunes to the poems of Ady and József. This also happened when the chords proved too difficult to inspire a tune. The subjects were never forced to produce melodies since a negative result was also considered an important indicator in the experiment.

The tape-recorded music was transcribed into musical notation by 10 professional musicians whose transcriptions (both notes and bar lines) were checked by two independent judges; first by a colleague, then by a specialist, a former collaborator of Bartók. This was followed by a qualitative analysis of the tunes based on Bartók's method of folk-song classification. The analyses thus obtained were collated with the musical tastes obtained from the questionnaires and with the tests of tonal awareness. The entire work lasted eight years, from 1972 to 1980, including the analysis of the material in some 1300 pages and the writing of a 600-page book. (The book is now in press and will be published by the Hungarian Academy of Sciences.)

The scope of this chapter does not allow us to give a full description of the experiment but we can present our conclusions concerning the existence of a concrete level of generative musical creativity by means of the improvisational tests.

Results

In our experiment we endeavoured to study the phenomenon of musical creative ability by using new methods. Our work displayed all the positive and negative aspects of a pilot study and this was why keen attention had to be paid to methodology. In such situations the first tasks to be performed include the testing of the method applied and, if possible, its validation. If we have been able to prove, to a reasonable extent, that it is possible and worthwhile to follow this path, our work would have achieved its main purpose.

We feel that certain achievements can already be seen. In the following we shall summarize these results and inferences, and in certain cases we would like to add a few reflections which are not strictly entailed by the results, but which we are encouraged to propound in view of the relatively large amount of accumulated material.

Generative abilities in the universe of music

First of all, we have to note that the persons questioned willingly

could not really grasp the content and the message of the poems by Ady and József, their reasoning, their lyric world; this lack of understanding was indicated by frequent misreadings. The other is that, simultaneously with this, they could not grasp the structure of the poem and create an adequate form.

Thus, it may be said that the ideal form for most experimental subjects is the four-line song form; this is what they can best grasp, learn, and create. Those who know it better, repeat the first verse. The less accomplished cannot do this, but they endeavour to do so. And when they are faced with more difficult contents and poetic forms, they attempt to approach them from the angle of this ideal form; therefore they solve the task in an inadequate manner.

Melodic features

Very much like for the structure, a clear picture was gained also for melodics: 60–70 per cent of the improvisations made for the Petőfi, Ady, and József poems were in the minor or major scales, minor character always having priority, as shown in Table 8.2.

Table 8.2 *Use of major and minor modes*

	Poem		
	Petőfi	Ady	József
Total responses	198	132	117
Major	38	18	17
Minor	64	45	32
Major and minor mixed	24	41	26
Total major and minor	126	104	75
as % of all responses	63	74	63

If we deduct the control groups (the musicians and foreign students) from the full sample, that is, if we only consider the improvisations of the Hungarian non-musicians, the proportion of the minor and major tunes is even higher (Petőfi songs 65 per cent, Ady songs 81 per cent, Attila József songs 66 per cent). Whereas non-professionals tend to stay in the same mode, young professionals tend to switch between different modes.

In the case of the Petőfi song, many subjects produced improvisations which had a folk-song character. The number of strictly pentatonic tunes (see Appendix, p. 286, Example 8.11) (10) was the highest here, which, together with the tunes having a mainly pentatonic character (25) accounted for 17 per cent of all the tunes. Modal tunes were similarly high

The concrete level of generative musicality

It was not our purpose merely to prove musical generative ability, but also to measure its concrete form and level. The collected data may serve as a basis for drawing certain general conclusions. We shall endeavour to describe the most general features valid for almost all the groups and which, therefore, best characterize the musical disposition of the subjects of our experiment.

Morphological features

We shall draw some general conclusions about the structure of the tunes improvised for the poems. The majority of the responses are characterized by strophic musical thinking on a level extending to the production and understanding of four-line musical forms. As soon as this limit has to be exceeded, they become uncertain.

Most subjects sang a strophic tune to the excerpt from the Petőfi poem. Forty-three subjects closely followed the strophic structure in the second verse (that is, they repeated the tune of the first verse with very little alteration); 47 endeavoured to achieve this but did not quite succeed; 54 sang two different verses of four lines each; another 30 considered the whole of the excerpt (eight lines) as a four-line tune and sang one musical line for each two lines of the poem. Thus, 174 of the 198 subjects were found to be capable of creating a more or less adequate form. The tendency to use the strophic structure is well illustrated by the fact that subjects tended to repeat the same musical line at different points in their song. Thirty per cent of the subjects used just four musical lines, 52 per cent used three, four or five lines for construction. The proportion of subjects using six, seven, or eight lines, or just one line, was 18 per cent.

The excerpt from the poem by Ady was more difficult. The test passage, of eight lines, was interpreted as such by only 44 of the 132 subjects; 63 subjects formed two four-line verses, while 20 created four two-line verses. Therefore, it seems that an eight-line strophe is more difficult to grasp, and even more difficult to structure, than a four-line verse. Many of the seemingly eight-line structures were quite loose in form and were not regular strophes.

Finally, the excerpt from the poem by Attila József was interpreted as an eight-line structure by most (70 of 117) subjects, for whom it was too difficult to establish a suitable system of interrelations between the lines. Thirty-two people created two four-line verses, while 15 created four two-line verses.

This may be due to two interrelated reasons. One is that most subjects

could not really grasp the content and the message of the poems by Ady and József, their reasoning, their lyric world; this lack of understanding was indicated by frequent misreadings. The other is that, simultaneously with this, they could not grasp the structure of the poem and create an adequate form.

Thus, it may be said that the ideal form for most experimental subjects is the four-line song form; this is what they can best grasp, learn, and create. Those who know it better, repeat the first verse. The less accomplished cannot do this, but they endeavour to do so. And when they are faced with more difficult contents and poetic forms, they attempt to approach them from the angle of this ideal form; therefore they solve the task in an inadequate manner.

Melodic features

Very much like for the structure, a clear picture was gained also for melodics: 60–70 per cent of the improvisations made for the Petőfi, Ady, and József poems were in the minor or major scales, minor character always having priority, as shown in Table 8.2.

Table 8.2 *Use of major and minor modes*

	Poem		
	Petőfi	Ady	József
Total responses	198	132	117
Major	38	18	17
Minor	64	45	32
Major and minor mixed	24	41	26
Total major and minor	126	104	75
as % of all responses	63	74	63

If we deduct the control groups (the musicians and foreign students) from the full sample, that is, if we only consider the improvisations of the Hungarian non-musicians, the proportion of the minor and major tunes is even higher (Petőfi songs 65 per cent, Ady songs 81 per cent, Attila József songs 66 per cent). Whereas non-professionals tend to stay in the same mode, young professionals tend to switch between different modes.

In the case of the Petőfi song, many subjects produced improvisations which had a folk-song character. The number of strictly pentatonic tunes (see Appendix, p. 286, Example 8.11) (10) was the highest here, which, together with the tunes having a mainly pentatonic character (25) accounted for 17 per cent of all the tunes. Modal tunes were similarly high

in number, primarily those in the Dorian and Aeolian modes (that is, those nearest to minor), and so were those in the Phrygian and Mixolydian modes, which mainly occurred in turns and cadences. In the case of young workers we also met Lydian-acoustic turns (with raised fourth). All these modes are characteristic of folk-songs.

We obtain a similar picture when considering the stylistic characteristics of the tunes. The total of folk-song-based improvisations reached 32 per cent (see Appendix, p. 287; Examples 8.12 and 8.13). But by including those conceived in the style of the popular Hungarian art (see Appendix, p. 288, Example 8.14), the ratio reached 51 per cent. One may hesitate about how to categorize intonations typical of Hungarian popular songs; if these are attached to the two former types it may be said that 72 per cent of the subjects related their improvisations to a style that in some way originates from current Hungarian national music culture. About half of the remaining 28 per cent endeavoured to use non-Hungarian (that is, non-Oriental) intonations (see Appendix, p. 288, Example 8.15) which are related to European art music, while the other half—not being able to tackle the problem—produced a few melodic fragments based on seconds.

A different picture is obtained from improvisations to the Ady poem. Here the highest rate is represented by tunes in minor-like and major-like scales (78.7 per cent), presumably because this poem did not make a folk-song-like impression. Therefore, the number of pentatonic tunes and phrases, as well as of modal tunes and phrases, descreased considerably. However, the rate of compositions with a mixture of minor and major increased, from 18 per cent in Petőfi songs to 39 per cent in Ady songs. In the majority of the cases this reflected uncertainty which led to the dissolution of the classical major-minor polarity. The result of this seems to be a tendency to turn towards tunes that reflected a 12-note scale, not only in the case of the musicians, but also in that of the musically untrained middle school students and the apprentices.

Similar differences are found with regard to styles. Only nine of the tunes were folk-music-like in character (7 per cent) and only seven had the character of composed folk-songs (5 per cent). The impact of Hungarian popular song and operetta increased (26 per cent), as well as that of school songs, marches, pop, and religious songs (see Appendix, p. 289, Example 8.16). None of these styles is particularly appropriate from the Ady poem; they may all derive from the endeavour to present the contents of the poem in music different from that used for the Petőfi poem and for this purpose an intonation subjects happened to remember was applied. Only 24 tunes (18 per cent) show the composer actually tried to find a modern tonality.

The tunes created for the Attila József poem yield again different pictures. The rate of minor-like and major-like tunes again decreased, to approximately the level of those improvised to Petőfi songs, but presumably for other reasons. We may be justified in presuming that the József poem

had an even more remote content for the majority of the experimental subjects. They understood all the words but they could not grasp the sentences. However, there were some who obtained a feeling of the ballad, more so than in the case of the Ady poem, and this might be the reason for the repeated increase in the number of pentatonic and modal tunes and phrases, and for the unexpected appearance of other archaic structures (possibly from musical subconsciousness). This is how Lydian modes, Phrygian cadences, and whole-tone and acoustic scale fragments appeared; one experimental subject produced a pentatonic structure based on the 3/2/3/2 intervals (A–F sharp–E–C sharp–B descending structure with fourth structuring). The rate of tunes nearing dodecaphony had increased even compared to the Ady songs. The other reason for the decrease in the number of melodies using major–minor tonality was the increasing number of improvisations close to speech, almost pre-modal owing to uncertainty, based on seconds and varying one or two tones.

An even more complex picture is shown by the analysis of the styles. The rate of styles that are in no way suitable for formulating the musical material of this poem increased considerably. The rate of second-by-second tune fragments is 27 per cent, the same structure somewhat more fancifully conceived is 3.3 per cent, march tunes make up 5.6 per cent, pop 10 per cent, and all these combined constitute nearly half of the improvisations (47 per cent). This is followed by tunes of the Hungarian art song and operetta type (23 per cent) and by the composed folk-song (8 per cent) which can not be considered fit for the 'Ode' either. The rest is inspired by folk-songs, including songs reaching back to ancient tunes (8 per cent), and some initiatives resembling modern composed music (14 per cent). (See Appendix, p. 289, Example 8.17.)

On tune completion (Examples 8.8–10 above) we found that the same number of people (58 per cent) could complete both the major tune (Mozart) and the pentatonic melody (Bartók). In the case of the acoustic tune, not one single subject managed to complete the music without deviating from the tonality.

Tonal-functional thinking on an elementary level

A general characteristic of improvisation related to minor–major tonality is a stereotyped level of tonal-functional thinking. Sixty-two per cent of the Petőfi songs, 57 per cent of the Ady songs, and 40 per cent of the Attila József songs fit a simple functional structure, either the simplest T–S–D–T cadence (I–IV–V–I), or the T–D or T–S variants of functions.

We obtained similar results from improvisations to sequences of chords (or harmonic sequences, in other terms). As shown in our following analysis, the subjects could improvise on different levels to the seven sequences of chords (Examples 8.1–7 above). The improvisations were

rated according to the degree to which they corresponded to the accompanying chords, according to traditional rules of harmony.

Based on the level of solution the seven sequences of chords could be separated into the following groups:

(1) An outstanding place is due to the harmonic sequence shown in Example 8.1, the classical I–IV–V–I cadence. Here, not only is the proportion of good solutions high (45 per cent), but the number of tunes harmonically unrelated to the chords is low (38 per cent). Also the number of variants that may be considered real improvisations is the largest; such tunes do not simply follow one or the other part, but create elaborations by arpeggiating the chord (18 per cent) and by flourishes. (See Appendix, p. 290, Example 8.18.)

(2) The second group includes harmonic sequences examples 8.2, 8.5, and 8.7. Example 8.2 comes into this group presumably because all the parts create suitable and understandable descending-ascending motifs. Example 8.7 is in this group because the addition of VI (in I–IV–V–I) extends harmonic sequence Example 8.1 in a manner that is familiar from hit songs; and Example 8.5 because the minor-character given by the Naples chord renders it accessible due to its romantic connotation. The number of good solutions in these three harmonic sequences is high. Example 8.2 inspired 41 per cent successful improvisations, 8.5 44 per cent, and 8.7 39 per cent. Despite this, we must distinguish these harmonic sequences from Example 8.1, because in these cases the proportion of unrelated and bad solutions is larger (38, 44, and 36 per cent) and even the acceptable responses include a larger number of tunes that merely follow the top part (that is, in unison) rather than being real improvisations.

(3) The third group includes harmonic sequences Examples 8.3, 8.4, and 8.6, which proved to be the most difficult ones. The rate of acceptable answers was 35 per cent for Example 8.6, 33 per cent for 8.3, and 31 per cent for 8.4. Sixty-four, 67, and 69 per cent of the experimental subjects could only sing notes completely unrelated to the chords. In the case of sequence 8.3, the problem was presumably caused by the flattened seventh degree; in Example 8.6 the source of problems (although popular in romantic music) was chromatics. A special place is occupied by sequence 8.4 which suggests Lydian-acoustic modality and therefore remains uninterpretable for most of the experimental subjects. In these three sequences of chords even the good solutions follow the parts, with only a few exceptions.

Rhythm

The analysis of the rhythmic structure of the improvisations requires a preliminary note. All three poems or excerpts involve parlando-like rhythmic structures. None of our examples would adequately fit a giusto

(strict) rhythmic tune. Thus, we could achieve only a partial evaluation of sensitivity to rhythm, but this was enough to draw some conclusions.

The highest rate of parlando rhythm was created for the Petofi excerpt: a total of 103 (51 per cent). The vast majority of these had good prosody interpreting the 'ancient eight' in a 6+2 division. This provided for several intonations, between the explicitly old-style folk song and the style of the Hungarian popular song. Seventy songs (27 per cent) were prepared in a strict rhythm: however, the majority did not suit the poem, but were done with wrong prosody. The three-fourths rhythm was often used, though it can only forcibly be applied to the poem. The same can be said of march-like and hit song rhythms, as well as of repeated crotchets or quavers. It is, however, noteworthy that bound rhythms were primarily used by young people, and among them mainly by those attending special music elementary school and by the students of the vocational school. Finally, only 13 per cent belonged to the mixed category, who changed from free to bound rhythms and back.

In the Ady excerpt the proportion of improvisations in strict rhythm was the same (34 per cent). These were used mainly by the young, but now from all the categories. The proportion of free rhythms was 27 per cent, and most improvisations conformed to the prosodic and rhythmic requirements of the poem. The rate of mixed rhythms increased (39 per cent). Half of these (19 per cent) were still characterized by suitable prosody; these were basically parlando songs with bound scanning sections. The other half (nearly 20 per cent) endeavoured to impose some known style of Hungarian popular song (or of opera arias) on the poem, but the music turned out to be incompatible with the text due to the complexity of the latter.

Finally, in the performance of the 'Ode', the rates were again different. Here the rate of strict rhythms increased to 43 per cent, that of mixed rhythms remained unchanged (37 per cent), and that of the free-parlando rhythms decreased (25 per cent). Despite all this, the best rhythmic solutions were those in the free category and this was chosen most often by the music students. Others (peasants from Aradva'nypuszta, members of the workers' choirs) formulated parlando-recitativo hymn-like songs, or opera excerpts, selected ways with which they could best approach the poem according to their own knowledge. In this case, the mixed rhythms meant mainly infeasible tasks and a resort to scanning (the tune mostly moved in seconds here). The strict rhythm was again the 'solution' of the young in hit-like, march-like isorhythmic, or triplet-like style.

All this indicates that the subjects have a strong inclination for parlando-strict polarity which corresponds not only to the traditions of Hungarian folk-song but also has its equivalents in Hungarian popular song as well as in the style of hit music. This duality, naturally, also applies to art music but here there are far many more transitions and sepithese in genre than in

current music. However, for the experimental subjects this wealth is unattainable; thus, when they are faced with a task that cannot be solved either with a folk-song-like parlando or a march, they become uncertain. It is especially important to note that parlando is so closely linked to folk-songs (and to Hungarian popular songs) that it can hardly be applied to the Ady and József poems. The young (even pupils of music elementary school) are less acquainted with folk-song than older people, and that is why their improvisation is dominated by a march-like and a hit-like character.

Conclusions

Altogether, these data demonstrate a certain parallel with Bernstein's (1970) sociolinguistic investigations and might lay the foundation of a kind of sociomusicological attitude. Bernstein makes a distinction between a tied-to-context and an elaborated method of use of the language. The situation in music is similar—the difference being that music as a language is less generalized or is generalized in a different way.

Our observations concerning the state or generative musical ability relate to our investigations regarding the development of popular music. In our opinion, generative ability determines also the spectrum of receptive experience. We listen in a distinct way to music that does not exceed the limits of our own generative musical ability. And so we can distinguish three degrees of musical receptive capacity:

(1) In the first degree, nearly the whole of the music listened to is interpreted in terms of structures that can be handled by the generative musical ability of the receivers themselves. This will be realized, for instance, in popular and beat music. Here the receiver can become identified with music. He feels as if he were able to make it himself.

(2) In the second degree, receptive generative musical ability does not comprise the whole of the composition received, only some of its elements. That is how for instance a listener with little formal musical education listens to, say, Beethoven's Symphony No. 5. The listener, being able to translate only a few elements—for example, the melody—to his own language, will understand the symphony only partially. The practice of everyday musical life proves, however, that he can enjoy it even in this case.

(3) Finally, in the third degree, the 'vocabulary' of the listener's generative musical ability and the composition listened to have nothing in common: in such cases no receptive experience comes about. These are the impressions of a listener brought up on Classical and Romantic music when hearing the works of, say, Webern or Bartók (not to speak of Boulez,

Stockhausen, or Ligeti). He does not meet a single familiar structure: he feels as though he were in a barren desert.

Our research not only revealed the attraction of the younger generation to pop music but also proved that this new type of investigation was a much more negotiable and applicable method in music psychology than the usual investigation of musical tastes. We can say that almost all the 11 groups had a specific musical characteristic or aspect which accorded with their different social backgrounds, and these musical attitudes definitely tally with the actual musical tastes and practices of the social strata in question.

Young children's musical representations: windows on music cognition

LYLE DAVIDSON and LAWRENCE SCRIPP

Soon after children begin to speak, they begin to make marks on paper. At first, these marks form primitive depictions of everyday objects—flowers, houses, the family dog, and pictures of mummy and daddy. Later, marks change their meaning. For example, scribbled marks, which formerly stood for a stream, might now each represent a 'list' of things to get at the store. Gradually individual letters are formed and words begin to take shape. When children enter formal schooling, much effort is devoted to mastering the conventions of the written language, the importance of keeping the letters in a straight line, the common forms of spelling, word order, and grammar. Eventually, children's ability to make meaning from and express themselves in written language becomes a sign of understanding, an index of intellectual ability and perhaps even of station in life.

In music, the case is very different. Parents know that young children take great delight in listening to music, singing songs, and inventing songs of their own. However, they rarely suggest that their children write out songs they know. Performance ability alone is taken as the index of musical ability. Unlike language, mastery of the written form of music is neither viewed as necessary for musical ability, nor as an index of musical understanding. However, in music, as in language, the ability to represent relationships among elements in various ways is a more powerful measure of understanding than relying on performance or speech alone.

This raises many questions for those interested in young children and music. Is it possible that young children's invented marks or pictures could contain any musical meaning? Or is it possible that writing the words of a song could also convey some rhythmic grouping, melodic contour, or musical structure? Without training in standard music symbol systems, children are forced to invent symbol systems in order to indicate the musical features of a song or phrase. Thus, interpreting children's early symbolic representations of music is the initial task. It is only by finding

ways to understand these unique symbol systems that we can begin to look at the range of sophistication in their representational knowledge of music and for possible patterns of development.

While some findings have been reported about the child's representational knowledge of music during these early years (Bamberger 1980, 1982; Upitis 1985), recent researchers in developmental and cognitive psychology have shown more interest in the music perception and performance skills of young children. Drawing from Piaget's notion of discrete and ordered stages of cognitive development, researchers in music report considerable evidence for different levels of perceptual development (Gordon 1965; Petzold 1966; Zenatti 1969; Dowling 1982) and performance development (Werner 1948; Pflederer 1964; McKernon 1979; Davidson 1985) in pre-aldolescent children. It is our contention that for a more complete knowledge of children's understanding of music, their representations of music are critical 'windows' for viewing their musical cognitive development. For example, by asking children to write down a song they know 'so that someone else can sing it', we can find evidence of those musical features children think are most important for remembering 'how the tune goes'. Viewing the same children's musical representations over time, we can witness the development of their understanding of pitch, rhythm, or phrase relationships in the songs they know.

Consider the closing phrase of the common nursery tune 'Row, Row, Row Your Boat' (Fig. 9.1).

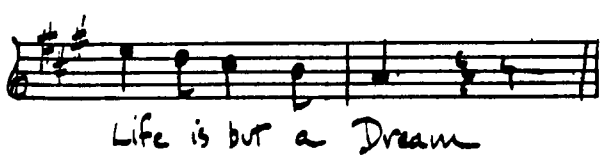

Fig. 9.1. Closing phrase of the song 'Row, Row, Row Your Boat'.

As a participant in our longitudinal study of young children's music notations, Janet provides remarkably clear representations of this musical phrase (Fig. 9.2). At age five Janet enactively traces only the rhythmic groupings of the 'fast and slow notes' while later (age six) she provides precise seriated lines that represent the melodic contour of the phrase ('the small lines are the higher notes'). Finally (age seven), she *simultaneously* suggests the rhythmic grouping and the melodic contour of the song (using the added dash to indicate rhythmic grouping and the layout of the words in a downward slope for the melodic contour), and additionally provides the text of the phrase.

This example illustrates three premises of this chapter. First, young

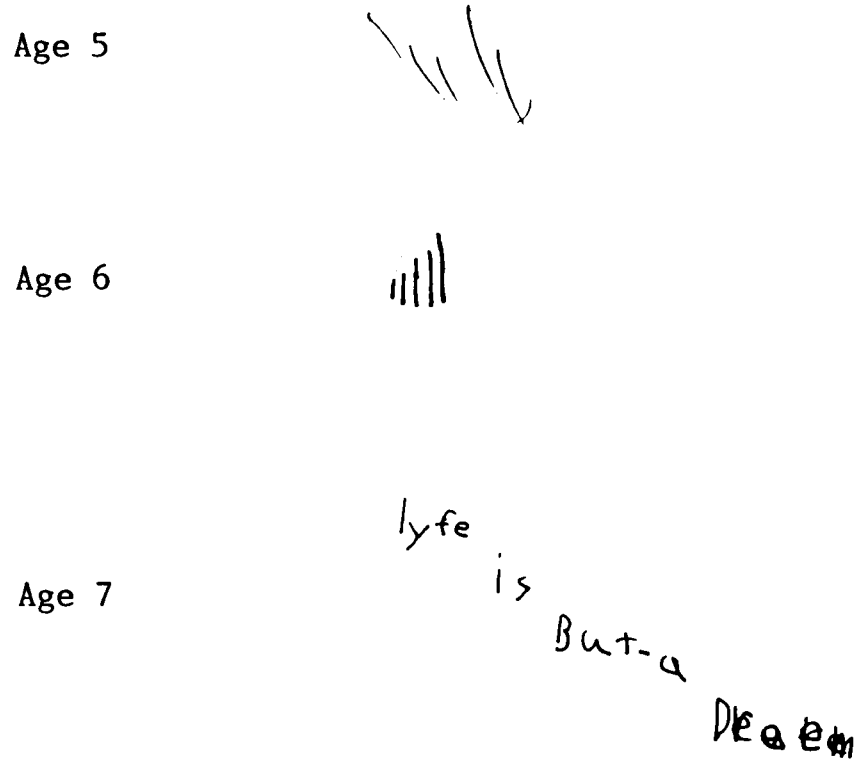

Fig. 9.2. Closing phrase of the song 'Row, Row, Row Your Boat' as represented by Janet at ages 5, 6, and 7.

children, untrained in music notation, can invent rich and articulate representations of the songs they know. Like many other children between the ages of five and seven, Janet effectively represents a wide range of musical features in her notations. Second, children's music notations reveal crucial insight into their understanding of music at various stages of musical cognitive development. Powerful developmental trends can be seen in Janet's and other children's notations as they increasingly specify and combine the rhythm and pitch dimensions of a single phrase. Between the ages of five and seven their notations become strikingly articulate and multi-dimensional. Third, taking both representational and performance development into account, musical pitch emerges as the primary component of children's musical cognitive development by the age of seven. Janet, typical of most young children we saw, increasingly focused on pitch relationships in her music notations and performance.

The study of young children's notations reported in this chapter offers a

wide-ranging view of their representations of music. While several recent studies have considered older children's (ages 8–12) spontaneous representations of rhythmic fragments (Bamberger 1980, 1982) and instructional effects in children's notations (Walker 1981; Upitis 1985), no previous study has explicitly looked at the early longitudinal development of younger children's spontaneous musical notations across various rhythmic, melodic, and structural contexts. Before looking at this new evidence we will first consider in more detail what music psychologists have found in music perceptual, performance, and representational development in children. Drawing on general models of cognitive development, we will piece together a 'three-dimensional view' of music cognition in which children's representations will play a vital role.

Towards a three-dimensional view of young children's musical development

In the past, studies of musical development have been largely influenced by behaviourist, associationist, and atomist psychology. As a result, music psychologists traditionally tended to focus on extremely local stimulus-response tasks in music perception and performance. In music perception tests (Seashore 1919), for example, children were typically asked to discriminate two narrowly differentiated frequencies as 'same' or 'different' without regard to their musical temperament (within a standard scale) or their melodic context. Similarly, in music performance, research (Hattwick and Williams 1935) focused on children's ability to match individual pitches or to reproduce extremely short melodic phrases. Although this early research documented changes in children's perceptual or performance acuity with isolated pitches or melodic fragments, it offered little insight into children's ability to discriminate or produce pitch or rhythm patterns within broader, more realistic musical contexts.

More recently, studies in music perception and performance have taken a more global, cognitive approach. Current research in music perception, for example, has focused on children's developing ability to recognize melodic patterns within wider and more tonal contexts (Gordon 1965; Dowling 1982). Children were asked to recognize short melodies as 'same or different' depending on pitch transpositions or alterations of the contour (directionality) of the phrase. Results indicate that children at the age of five typically do not recognize two melodic fragments as the 'same' if the pitches are not identical in both fragments. However, by the age of eight, an important 'cognitive shift' occurs. Children now can recognize pitch relationships betwen two melodies as the 'same' even though the actual individual pitches of each melody are not shared (Pflederer 1964; Dowling 1982). Children's perception of music by the age of eight is now understood

as operating within an increasingly stable *tonal system* where the musical scale and a tonic reference are used to store melodic 'information'.

A 'cognitive shift' occurs in children's performance abilities as well. Whereas young toddlers approach the task of singing melodies by means of loosely structured pitch 'contour schemes' (Davidson 1985), six- or seven-year-olds sing familiar and invented songs with increasingly discrete and stable pitch reference (Werner 1948; McKernon 1979). The music transcriptions in Fig. 9.3 show performance development typical of most young children between the ages of four and seven. Jeannie, at the age of four, sang the melody of 'Twinkle, Twinkle, Little Star' without reference to the major scale system. By the age of six, however, her singing rivals adult performance standards.

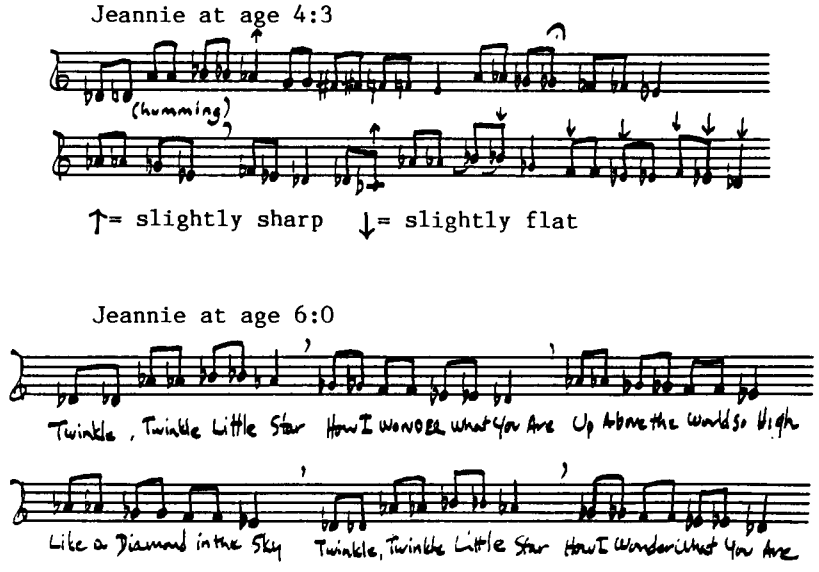

Fig. 9.3. Two versions of 'Twinkle, Twinkle, Little Star' by Jeannie.

Taking two dimensions together—perception and performance—we can characterize children's musical development as progressing rapidly through parallel stages of increasingly systematic knowledge. This development is measured by the emergence of a stable tonal framework. This is in contrast to rote imitation of musical fragments or perception of isolated pitches. From this 'two-dimensional' point of view we can see that untrained children between the ages of four and seven develop into surprisingly sophisticated musical listeners and performers.

Still, important questions remain regarding the depth of children's

musical understanding. For example, although children may be able to simultaneously perform the rhythms, pitches, and text of a familiar song, we know very little about which of these components children themselves regard to be most important to represent. In fact we have no idea whether young children primarily attend to more central components (rhythm and pitch) or to the relatively peripheral aspects (words or story-line) of the music they sing. Nor do we know how these patterns may change with age. Questions such as these are not easily answered with the research techniques traditionally used in studying young children's music perception and performance development. By turning to yet another dimension, children's initial representations of their performance knowledge, we may be able to better understand the roots of their developing musical comprehension.

Music and representational development in children

Psychologists researching cognitive development in other domains have interpreted children's representations from several different points of view. Children's drawings, for example, have been used as evidence for levels of mental development (Werner 1948). From this point of view representational development occurs as a result of general mental development which Werner believes proceeds 'from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation and hierarchic integration' (1957). Piaget, particularly with his study of children's knowledge of spatial relations (Piaget and Inhelder 1956), used young children's representations to show precisely ordered levels of cognitive development. Piaget argues that children's representations are the product of what children 'know' rather than what they 'see'. To substantiate this claim, in later research, he asked young children to make drawings of a set of seriated vertical lines from memory, and reported positive development in their drawings *without perceptual intervention* six months to one year later (Piaget and Inhelder 1973). These drawings suggest that children later had access to a more intellectually advanced 'cognitive lens' which allowed them to *refocus* on their stored mental images. Other psychologists report that children's representations can also reflect stages of cognitive strategies (Bruner 1973) and levels of cognitive development within artistic domains (Goodnow 1977; Gardner 1980). Olson (1970) reports the importance of children co-ordinating pencil and papr skills with their perceptual skills in order to explore the link between cognitive skills and their representation.

Clearly children's representations are of critical value to a wide range of psychologists studying cognitive development within various domains. Similarly, children's music representations are crucial to our understanding of their musical cognitive development. Only very recently have music

psychologists begun to view this 'third dimension' of children's musical cognitive development.

Cognitive processes and children's representation of simple rhythms

By asking young children and musically untrained adults to perform simple rhythms and then later represent them, Bamberger (1980, 1982) allows us to glimpse the 'cognitive structures' children use to express their understanding of music. Bamberger's research suggests that writing down rhythms involves a 'figural-formal transaction' (Bamberger and Schon 1977). That is, when representing these rhythmic fragments, notators may attend to the more figural properties (for example the motivic groupings formed by adjacent 'fast' and 'slow' notes) or to the more formal/metric properties (for example the organization of the surface patterns with respect to an underlying pulse) of the target phrase. Bamberger reports a developmentally ordered typology of symbols used by her subjects in respect to either side of this 'transaction'.

Bamberger reports that four- and five-year-old children typically represent simple rhythms (1980) using primitive enactive scribbling to trace the action of the rhythmic performance. Later on, children (age six or seven) use early 'figural' representations that group the surface units by duration, or notations that merely record the number of events in the phrase. Only after training is there evidence for a 'cognitive shift' towards a system where figural grouping can become subsumed by a formal/metric system classifying beat units, rhythmic patterns, and their co-ordinations. Bamberger reports:

> Results indicate that musically untrained adults and older children (9–12) seem to develop the capacity only to make figural drawings: metric/formal drawings are made almost solely by those with the trained ability to read standard music notation. (1980, p. 172)

Bamberger's work provides an intriguing first view of young children's music representational development. We can see categorically different processes in young children's notations as they discover ways of restructuring their performance knowledge of simple rhythms. Through this cognitive 'window' we begin to see how musically untrained children (without knowledge of a conventional code) represent the complex and sometimes conflicting musical dimensions of surface patterns, underlying metric pulse, and their possible co-ordinations in 'simple' rhythmic phrases.

However, Bamberger's research also raises vexing questions concerning children's musical cognitive development. Considering children's music representations within the larger framework of cognitive development, we need to ask why young children without musical training are unable to develop beyond the 'figural' representations of simple rhythms while

'formal' development apparently occurs in other domains (Flavell 1963; Furth 1969). Within the domain of music, on the other hand, we need to know why children's music representations of rhythm apparently lag behind the more developed levels of their pitch perception and performance described earlier. Because we only have evidence detailing children's representations of short rhythms, we have no way of directly comparing the development of tonality in children's perception and performance with their representational development. In sum, Banberger's work offers an enlightening point of departure for assessing children's music representations. A wider-ranging study is needed in order to get a more complete picture of children's music representational development.

In the next sections we will report findings from the Harvard Project Zero notations study (Wolf *et al.* 1986), the first longitudinal study to look at children's (ages five to seven) music notations across a wide range of musical contexts. We begin by describing in some detail the structure of the research.

The research design: children's representations of musical content across various contexts

In this study we asked 39 musically untrained children to perform a wide variety of tasks. In the spring of each of three years, we requested the children (over two separate sessions) to reproduce short rhythmic or melodic patterns, recall a familiar song ('Row, Row, Row Your Boat'), and learn a short, unfamiliar song. At the beginning of each session it was explained that all the items were to be written down in their 'own music book'. To ensure that each child had a secure performance knowledge of the items, a pattern of phrase of the song was repeated either until the child made a correct performance or until the level of performance had stabilized. Afterwards, children were asked, 'Write the song down on your paper so that someone else who doesn't know the song can sing it back.' For those who objected to the task of writing down a song they'd known since they were 'babies', it was suggested that they should write down the song carefully for children from 'other countries' who might not know the song. They were also told they might use any mark they wished to write down the music if it helped them remember the sound of the rhythms or melodies. The children were allowed as much time as they needed to write in their 'music books'.

Immediately upon completing their notations, children were asked to perform each item while reading from their 'music books'. The experimenter explained that he wanted to 'see if the music book would work for someone who couldn't remember the clapping or the singing'. Later on in the session the experimenter asked each child to read back the notations in the 'music book' in random order to determine whether or not children were using

their own notation rather than recalling the target items by rote. At the end of the final session, each child was asked to explain or demonstrate 'how the music book works'. Each session was about 20 minutes long.

The materials for the tasks were simple. Two cassette tape-recorders were used, one to play the pre-recorded musical examples, and one to record the child's performances for future transcription and scoring. Children were each given a 12″ × 18″ piece of white drawing paper and a choice of coloured felt-tipped markers with which to notate their performances. When the task was completed (and after the child had left) the experimenter freely added comments to the notation (in pencil) or recorded remarks that might serve to clarify the child's process of making the notation.

Rather than simply focussing on one set of materials, this research design allows us to analyse children's representational as well as performance development across various musical contexts: rhythm patterns, pitch patterns, a familiar song, and a new song (see figure 9.16). These four different contexts share the same pitches or rhythms. In designing our study we structured our tasks to provide answers to the following broad questions:

(1) What is the general nature of young children's (five to seven) musical representations?

(2) What musical dimensions are young children able to extract from the melodic fragments or familiar songs they are asked to write down?

(3) What evidence is there for development in young children's music notations from the ages of five to seven?

(4) How does context affect children's notations of music?

In following sections we will analyse the notational responses to the familiar song task. First, we will show how young children use an extremely wide range of invented and borrowed graphic symbols to create increasingly sophisticated notational systems. Second, we will examine their ability to extract and code various musical dimensions without the use of standard musical symbols in their music representations. Finally, we will present evidence of representational development in children's ability to increasingly specify various musical dimensions such as phrase strucure, musical units, rhythmic pulse and grouping, and pitch contour. This allows us to appreciate the remarkably rich and articulate knowledge of music which many of these young children can express through their invented notations.

Borrowed symbols and invented systems: young children's first notations of song

Children approached the task of writing down a familiar song with great earnestness. For five-year-olds, the task of choosing an appropriate symbol

for representing music involves a good deal of personal investment. Many openly confided they didn't know how to do it and it was not uncommon to observe children pause several minutes in silence before writing down their first mark. Careful not to prompt young children towards a particular set of graphic symbols, we witnessed an extraordinary range of symbol use. More importantly, we saw how they adapted and organized various families of graphic symbols into *symbol systems* that map various musical dimensions of their songs.

We have grouped the children's notations of song into five symbol systems: the *pictorial*, *abstract patterning*, *rebus*, *text*, and *combination/ elaboration* symbol systems. Although these systems can be identified largely by their ingredient graphic symbol types, our analysis will focus primarily on which features of the song were coded and how they were organized within the notation.

The pictorial system

This system features a variety of pictures, icons, and images that young children use to record the song 'Row, Row, Row Your Boat'. These evocative 'picture drawers' represent the song with a drawing that can effectively render the title of the song, the look of a 'music book' or a 'person singing', or perhaps the entire story-line condensed into one salient image. Because these 'picture notations' do little more than record the song as a global event or action, this system usually remains a primitive and ineffective system of notation. Indeed, the pictorial system probably best meets the common adult expectations of the 'artistic', yet notationally untutored, child.

Emily's notation is a particularly good example of the limitations of her particular symbol system (Fig. 9.4). After observing Emily carefully drawing a rich landscape of rippling water, clouds, and a prominent boat, we asked her how 'to read the song' from this picture. Patiently explaining 'the book isn't finished yet', she turned the paper over, folded it in half, and began drawing the notes that 'belong' in her 'music book'. Although the picture of the boat may remind us of the title of the song and the notes drawn inside tell us that it is a music book, there is little here to help us remember how the tune goes. Alas, these notes appear to have all the 'look' but little of the substance of standard music notation.

The abstract patterning system

This system usually features lines and dots which children use to represent the melodic units ('notes') of the song and record the rhythmic groupings, underlying pulse, melodic contour, or phrase structure. Due to the ambiguous nature of these symbols, it is often difficult to tell at first which

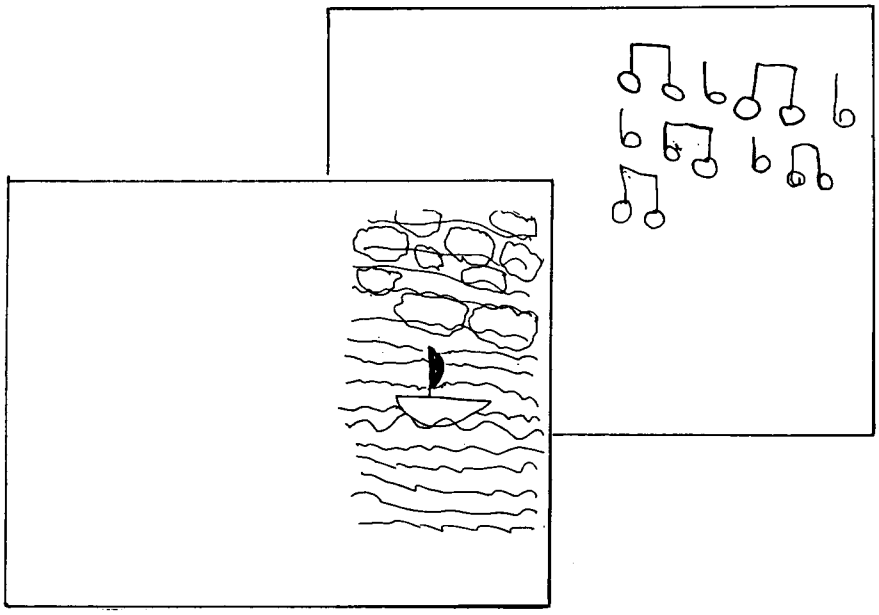

Fig. 9.4. Emily's (age 6) pictorial system.

musical dimensions of the song are being coded, but it is clear that these 'abstracters' are primarily concerned with the rhythmic and melodic *relationships* of the notes of the song rather than being content with merely representing the story-line or the text.

As is typical with 'abstracters', no conclusive interpretation of Janet's notation (Fig. 9.5) can be made without a transcript. What at first appears to be an arbitrary set of seriated vertical lines turns out to be an elegant system for recording pitch relationships in the song. And, once we understand that the smaller 'sticks' indicate the higher notes, we can track through the entire system with little difficulty. We see that the structural boundaries of the musical phrases are indicated not only by gaps in the notation (that is, musical 'rests'), but also by the corresponding intervallic pitch relationships recorded throughout the song (for example, the last note of phrase 1 appears to be equivalent to the first note of phrase 2 or, more remarkably, the first note of phrase 1 seems equivalent with the last note of phrase 3 and the first note of phrase 5). In fact, after Janet performed her notation while pointing at the lines, she spontaneously announced that the last phrase 'is just like the first one'!

The rebus system

This system usually features elaborate and flexible *alternations* of icons,

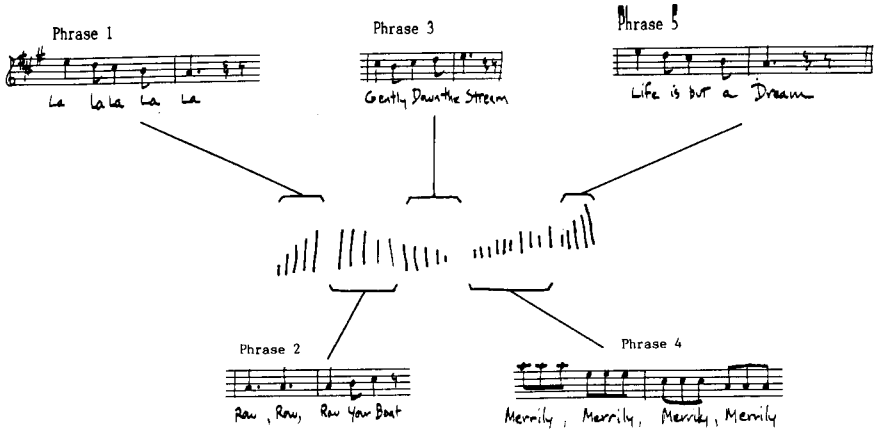

Fig. 9.5. Janet's (age 6) abstract patterning system with corresponding phrases of 'Row, Row, Row Your Boat' in standard notation.

conventional signs, and words children use to record the text of the song. While 'rebus makers' effectively depict the text or illustrate the lyrical content of the song, they can also occasionally reveal the underlying pulse (word stress) or pitch direction (contour) of the tune.

At first glance, it appears that Aaron (Fig. 9.6) has freely selected letters, words, and icons only to track the lyrics of the song. With closer inspection, however, we see that there are occasional omissions of the text, which suggest a focus on the rhythmic organization of the words as well. In phrase 2, for example, Aaron redundantly draws three 'rowing boats' and spells out the word 'boat' while leaving out the word 'your'. Apparently Aaron is concerned more with notating the underlying *pulse* (or stress) of the rhythm than with merely recording all the 'units' of the text. Phrase 5 shows a similar understanding of musical pulse as the stressed words are depicted and the 'weak beats' appear to be deliberately left out. In phrase one, he shows sensitivity to the longer duration of the final 'la' and explains that the last 'la' is 'different from the rest'. Typical of rebus makers, Aaron inconsistently yet imaginatively suggests various salient dimensions of the song in his notations.

The text system

This system features the words, letters, or imitations of conventional language symbols children use to record the text of the song. Although these children seem primarily concerned with simply 'writing down the words', they also often take advantage of graphic layout devices to code

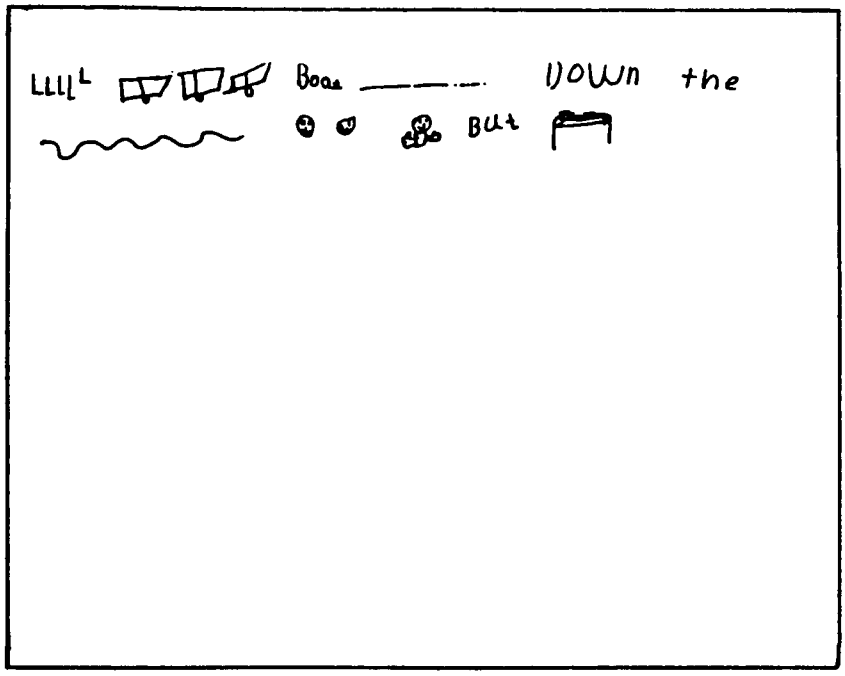

Fig 9.6. Aaron's (age 6) rebus system.

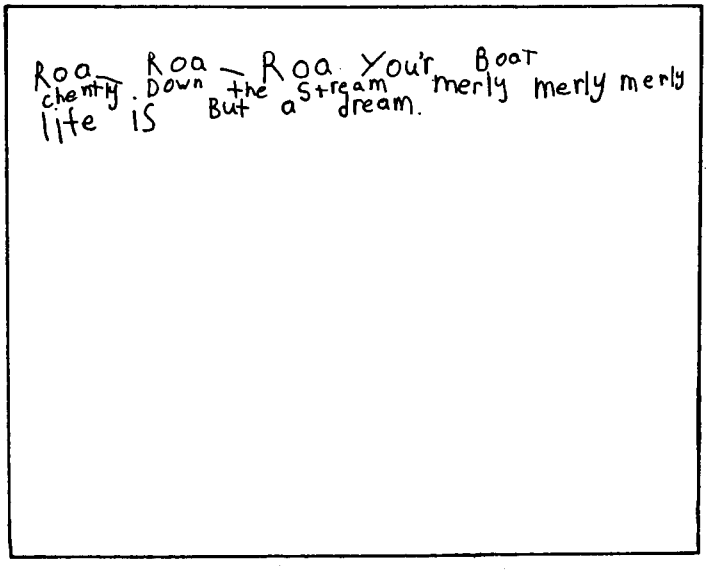

Fig. 9.7. Eleanor's (age 6) text system.

the verse structure, the direction of pitch, or the rhythmic grouping of the song.

Eleanor's notation (Fig. 9.7) is typical of most text notators. Eager to show off her newly learned writing skills, she quickly wrote down the words of the song. Although her transcription of the lyrics is almost impeccable, more importantly, the notation also clearly reveals her attention to the phrase structure of the song. Looking closely at the text system we see that she uses 'carriage returns' and additional space between 'stream' and 'merly' to show the individual lines of the text. Also she provides elongating marks after the first few words ('*Roa*') and demonstrates their purpose to the experimenter by gesturing the pulse and sustain while singing the opening phrase. Like most text systems, however, this notation has fallen considerably short of a consistent, systematic representation of rhythmic or pitch dimensions of song.

The combination/elaboration system

This system features *simultaneous* use of abstract symbols and words to represent the text and musical dimensions together. Unlike the pictorial and rebus system, this system does not utilize pictures or icons, nor does it primarily focus on the lyrical content of the song. 'Elaborators' are children who consistently employ abstract symbols to modify the text to show how the words are to be sung. 'Combiners' are children who record both the text and abstract patternings of the 'notes' as two separate and equally necessary ingredients of the song.

Mary's notation (Fig. 9.8) demonstrates both approaches children used in constructing their combination/elaboration system. Like most 'elaborators' Mary records the text first and later modifies these 'notes' with marks (arrows) showing relative pitch direction. Like most 'combiners' she works through one entire system first and then fashions a separate series of marks to be read simultaneously with the first. In this case Mary uses abstract symbols to represent the 'long and short notes' of the song. As with all children using combination/elaboration notation, Mary is embarking on an ambitious path: the integration of the melodic and lyrical content.

In sum, what is more impressive in these examples of children's symbol systems is the sophistication with which they approach the task of

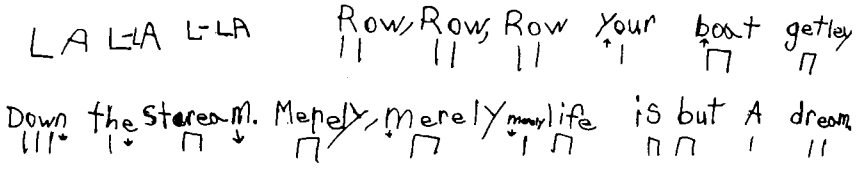

Fig. 9.8. Mary's (age 6) elaboration and combination system.

representing music. Using highly individual symbol systems these children can successfully code not only the song title, the story, and the text, but also the melody's more salient musical features—its underlying rhythmic pulse, pitch contour, or phrase structure. In the most gifted of notators we see children attending to several musical dimensions *at once*, constructing highly elaborated or elegantly patterned descriptions of the song. Recognizing the wide range of symbol use and the degree of sophistication with which children employ these symbols to write down a familiar song, new questions can be addressed: What changes in symbol use occur with age? Can these changes be ordered into developmental sequences?

Signs of development: preliminary evidence for children's emerging musical cognition in their representations of song

The sections that follow present evidence for development trends in young children's representational knowledge of music between the ages of five and seven. In this section we will only look at children's developing notations of the familiar song 'Row, Row, Row Your Boat'. In later sections, we will look at children's notation of a single phrase across various musical contexts.

Our data show that children between the ages of five and seven not only change radically in their choice of symbol systems to represent songs, but also show a dramatic increase in the level of sophistication of their notations. Examples from our entire sample of children's songs can be organized in the following developmental sequence:

Age 5—children (who may not have the option of writing words) primarily use pictures and abstract symbols to show musical structure or the units of the phrase.
Age 6—children primarily use abstract or language symbols and sometimes organize the units to show either underlying pulse, rhythmic grouping, or melodic contour.
Age 7—children combine and modify language with abstract symbols and consistently show multiple features of the music with particular attention to melodic contour.

Janet's and Mary's song notations (Fig. 9.9) between the ages of five and seven provide clear examples of this developmental sequence.

Mary's initial pictorial system exemplifies the average child's notation at the age of five. Although she makes a clear distinction between the introductory phrase and the rest of the song, little attention is given to the musical units within the phrases of the song.

Janet's precocious abstract notation at age five and Mary's elaborate rebus at age six are both typical of the average six-year-old's attention to

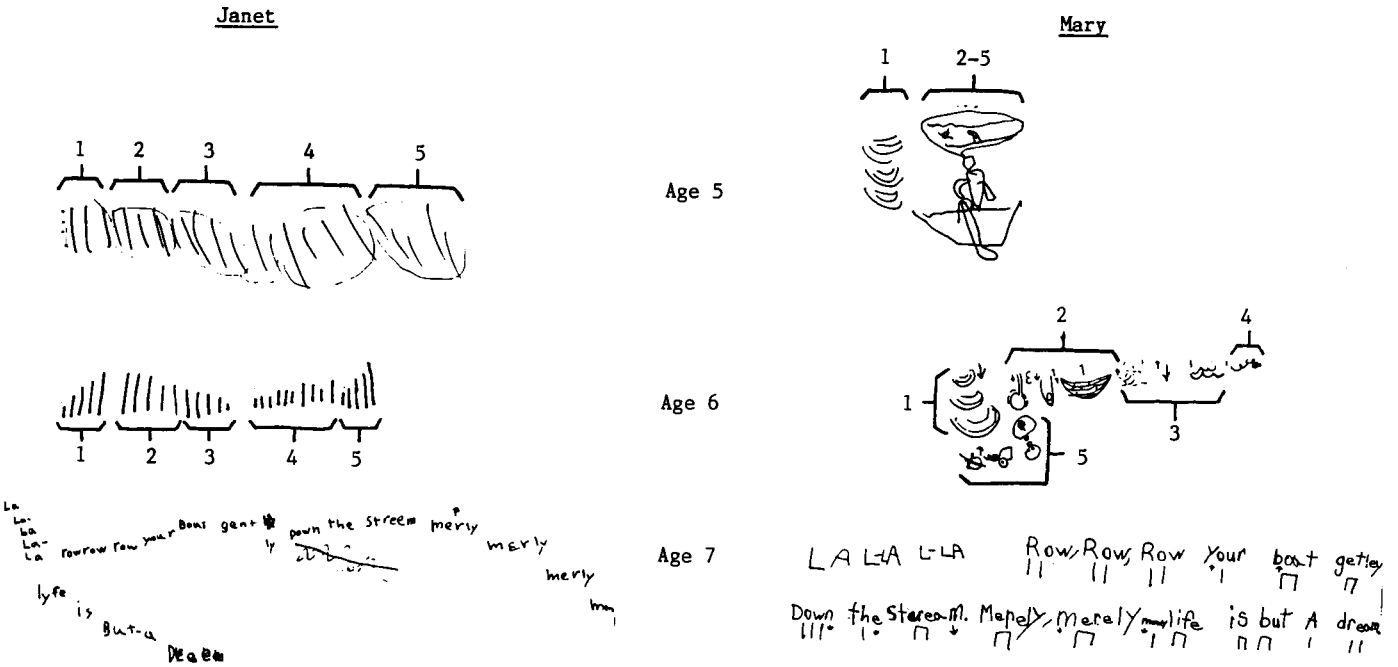

Fig. 9.9. Janet's and Mary's notations of the song 'Row, Row, Row Your Boat' at ages 5, 6, and 7 (phrases numbered as in standard notation).

the rhythmic organization of the units of the song. Here Janet provides an enactive tracing of the musical units with some semblance of their rhythmic pulse (phrase 1) or grouping (phrases 2 and 5); Mary clearly depicts the words of the text that receive the underlying pulse or stress (phrases 1, 3, and 5).

Both Janet and Mary anticipate the average seven-year-old child's attention to melodic contour at age six but without using language symbols. More typically, the average seven-year-old uses the combination/elaboration symbol system to record the text of the song while *simultaneously* providing indications of melodic contour.

The symbol system sequence

Janet and Mary are both examples of particularly fluent and richly sophisticated notators. As different as their 'tracks' of development at first appear, the notations of these two children suggest that the pictures or abstract patterns used to represent songs at age five will later be superseded by words combined or modified with abstract symbols. Data from the entire sample (n=39) over three years provide considerable evidence for this developmental trend in children's symbol system use.

An analysis of figure 9.10 shows that most children (69 per cent) use either the *pictorial* or *abstract patterning* systems to represent songs at age

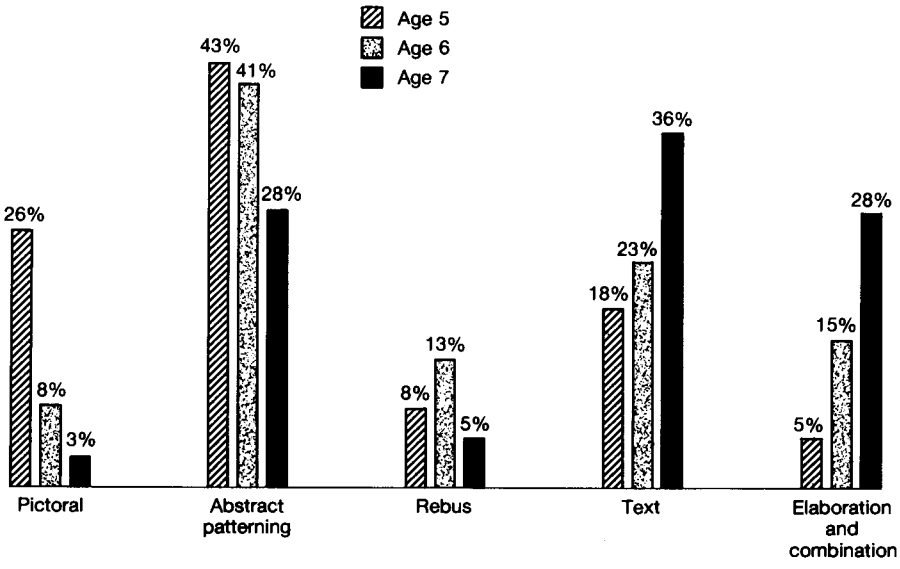

Fig. 9.10. Change in use of symbol systems for representing the song 'Row, Row, Row Your Boat' by children ages 5–7.

five while a majority of children (64 per cent) are using either the *text* systems or *combination/elaboration* systems by the age of seven. Statistical analysis supports the notion of these ordinal trends in symbol system choice with age [Friedman Chi-square = 9.94, 2 df, $p<0.007$, $n = 39$].

Probing further into this 'symbol system' sequence, two findings are particularly important to our understanding of the children's music representational development. First, since we assumed that most five- and six-year-old children would draw pictures to represent the song, the predominant use of abstract patterning systems throughout these early years was totally unexpected. Although young children receive considerable instruction with language literacy skills and are encouraged to draw, many feel compelled to use a totally different set of invented symbols to represent music. This suggests that the average five- or six-year-old perceives music as a separate domain, requiring its own particular symbol system uniquely suited to the task of representing musical features.

Second, although young children increasingly abandon pictorial systems and employ their newly acquired writing skills to transcribe the text of the song, many find language symbols insufficient for the task of representing the song. Surprisingly, children insist on representing important musical features as well as the words of the song. This is particularly signficant at age seven when there is a dramatic increase of elaborating marks or abstract patternings in conjunction with text.

This sequence illuminates significant trends of symbol system development. In the next section we will look at development in levels of extraction of musical dimensions in children's notations and possible correlations with symbol system or performance development.

Representational development in song

Analysing children's representational development in song, we coded children's notations according to the musical dimensions they were able to extract and represent. In the dimension of musical pitch, we predicted a simple sequence of development. We assumed that children would at first code the *units* (notes) of the phrase (level 1), and later indicate the *melodic contour*, or directionality, of these units (level 2), with a few older children eventually mapping the *intervallic boundaries* of these melodic contours (level 3). Although we did not expect many children to code exact pitch relationships, that is, *regulated pitch* (level 4), this was the next logical step in pitch representation. This was confirmed throughout the various contexts of our pitch tasks.

In rhythm, the sequence predicted was unconfirmed by our data. Originally we assumed that children would first code *units* (level 1), followed by the *grouping* of the units (level 2), the *underlying pulse* of the phrase (level 3), and finally the rhythmic grouping regulated by pulse, that

is, *pulse plus grouping* (level 4). This sequence was based on Bamberger's (1982) research which suggested that untrained children first attend to 'figural' features of rhythm (the grouping of fast and slow notes) while only a few later attempt a more 'formal' regulation of the rhythmic figures. We were unable to confirm this finding. Surprisingly, we found many children representing the underlying (metric) pulse or stresses of the text before providing any indication of the (figural) grouping of these units. As a result, our notational sequence for rhythm allows for selecting *either* grouping or underlying pulse as an intermediate step towards simultaneously constructing both pulse and surface groupings of rhythms.

The following examples (Fig. 9.11) of the introductory phrase of our song shows how children achieved various notation levels in rhythm and in pitch.

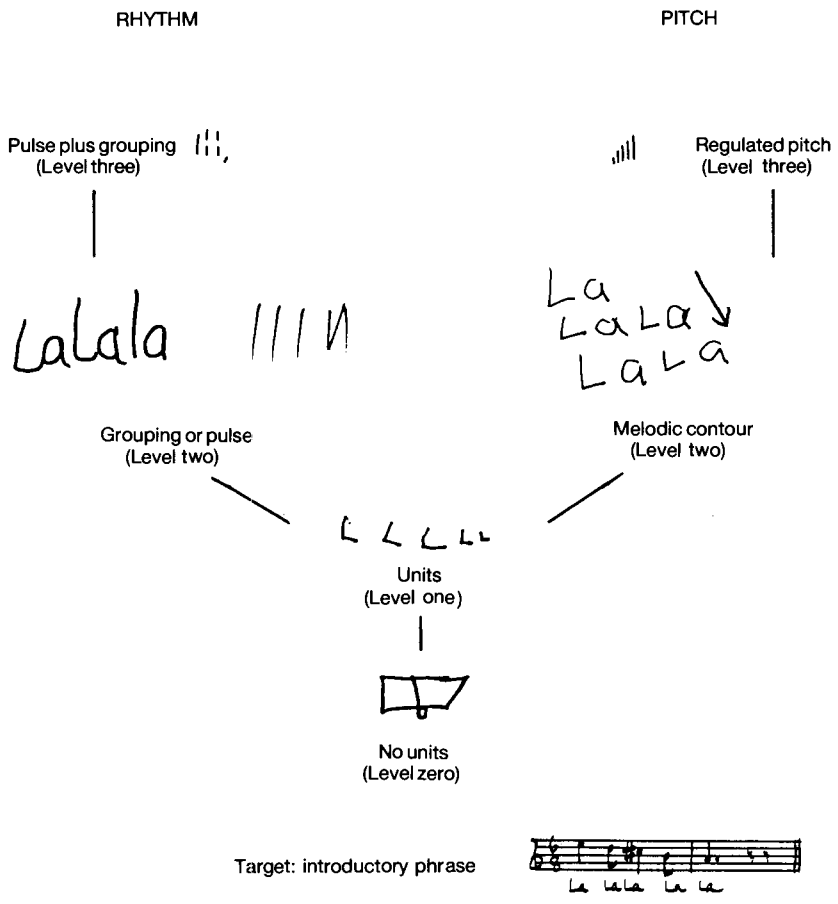

Fig. 9.11. The ordinal notation levels for pitch and rhythm.

Overall, we scored children's notations according to the level of the rhythm or pitch they consistently (three out of five phrases) encoded in their representations of song. A summary measure of notational consistency in rhythm and in pitch was achieved by calculating an average score produced by these levels. Looking at the mean notation scores in Fig. 9.12 we see that, on the average, children at ages five and six were able to represent the song only at the level of musical units. At age seven, however, there is a dramatic increase in representational skills as children demonstrate higher levels of rhythmic structure (that is, grouping or pulse) or pitch relationships (for instance, melodic contour or relative interval boundaries) in their notations of song.

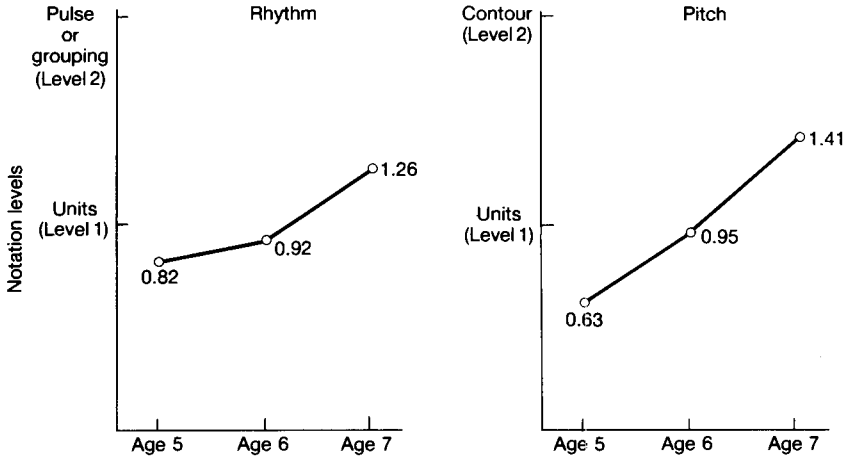

Fig. 9.12. Mean notation scores for rhythm and pitch in song by children ages 5–7.

Development in levels of representation of pitch can be clearly contrasted with representation of rhythm. Repeated measures one-way ANOVA suggests highly significant improvement in pitch notation levels [Friedman Chi-Square 20.55, df 2, $p<0.00005$] while improvement in rhythm notation levels appears to be relatively weaker [Friedman Chi-Square 6.62, df 2, $p<0.05$] over the three-year period. From these results it appears that young children are increasingly able to develop notations that consistently show the melodic contour rather than the surface rhythms or underlying pulse of the song.

Instead of looking at children's choice of graphic symbols as a measure of their notational sophistication, we can view children's music representational development in song independent of their choice of symbol systems. If we factor out children's symbol system choices, we are in a better

position to assess the relationship between young children's level of performance and levels of representational skills using familiar songs.

Analysis of the relationship between symbol system choice and level of notational sophistication shows decreasing correlation with age. In Fig. 9.13, we see that the more 'advanced' symbol systems (for example text or elaboration and combination systems) predict better notation scores in rhythm and pitch at age five but correlate less strongly a year later. In other words, one can expect five-year-olds to achieve higher levels of notation only if they are using a more sophisticated symbol system. In contrast, by the age of seven there are no significant correlations between children's notation scores and their choice of symbol system. In other words, the level of notation achieved and the symbol system used become increasingly independent for older children.

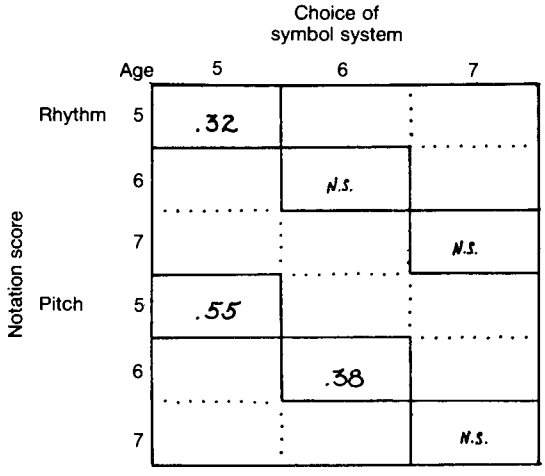

Fig. 9.13. Matrix showing significant ($p<0.05$) rank correlation coefficients (Kendall Tau) between symbol system choice and notation scores in children's notations of song.

Surprisingly, children's choice of symbol system in representing songs comes to have little bearing on development in notation. The more sophisticated the level of children's representations, the less of a factor the choice of specific symbol system becomes. In other words, the vehicle of expression becomes less visible with development.

Musical performance and representational development in song

Throughout the three-year study, we observed the development of children's performance knowledge of the song 'Row, Row, Row Your

Boat'. For rhythm, children were scored according to their ability to reproduce accurately the *number of units*, steady *underlying pulse*, the *surface grouping*, or the co-ordination of *underlying pulse plus the rhythmic grouping* of a phrase of the song. With respect to pitch, the children were scored according to their ability to match the *initial pitch*, the *melodic contour*, the *interval boundary*, and the *key* (scale) of the phrase.

From Fig. 9.14 one can assess performance development in rhythm and pitch in terms of the percentage of items accurately matched by children between the ages of five and seven. Performance in both rhythm and pitch improves over the three-year period but, as we take a closer look at these overall performance scores, we see strikingly different profiles of development. In contrast to reproducing the rhythm, the task of accurately singing the pitches of a familiar song proves to be initially far more difficult. Whereas five-year-old children, on the average, reproduced the rhythm measures with 85 per cent accuracy, approximately half of the pitch measures were matched accurately. With age, however, this gap narrows considerably, suggesting that either rapid and substantial improvement in pitch accuracy occurs in contrast to rhythm, or that rhythmic development is more precocious and thus its growth is less dramatic over the course of our study.

Statistical analysis supports the notion of rapidly improving pitch in children's performance development. Repeated measures one-way ANOVA and Duncan Multiple Comparison procedures (Cody and Smith 1985) suggests highly significant [$p<0.001$] improvement in both rhythm and pitch over the three-year period. Comparisons between years show significant [$p<0.05$] improvement in rhythm between the ages of six and seven while pitch dramatically progresses in each of the three years. As in representational development, longitudinal growth in young children's performance accuracy in song between the ages of five and seven apparently is best viewed within the dimension of pitch.

At no point in the three-year study did performance skills correlate significantly with children's choice of symbol system to represent music. Apparently, the ability of children at ages five through seven to accurately sing a tune or clap a rhythm in no way predicts their choice of graphic symbols to notate the music. This finding allows us to better appreciate music research as a domain uncontaminated by conventional symbol systems that may influence young children's ability to represent their understanding of that domain. Furthermore, it underscores the initial independence of children's notational and performance abilities.

In Fig. 9.15 one can view the developing relationships between performance and representational knowledge of the song. When the dimensions of pitch and rhythm are combined, we see significant correlations between performance skills and level of representational knowledge only at the age of seven. This suggests that children, as they

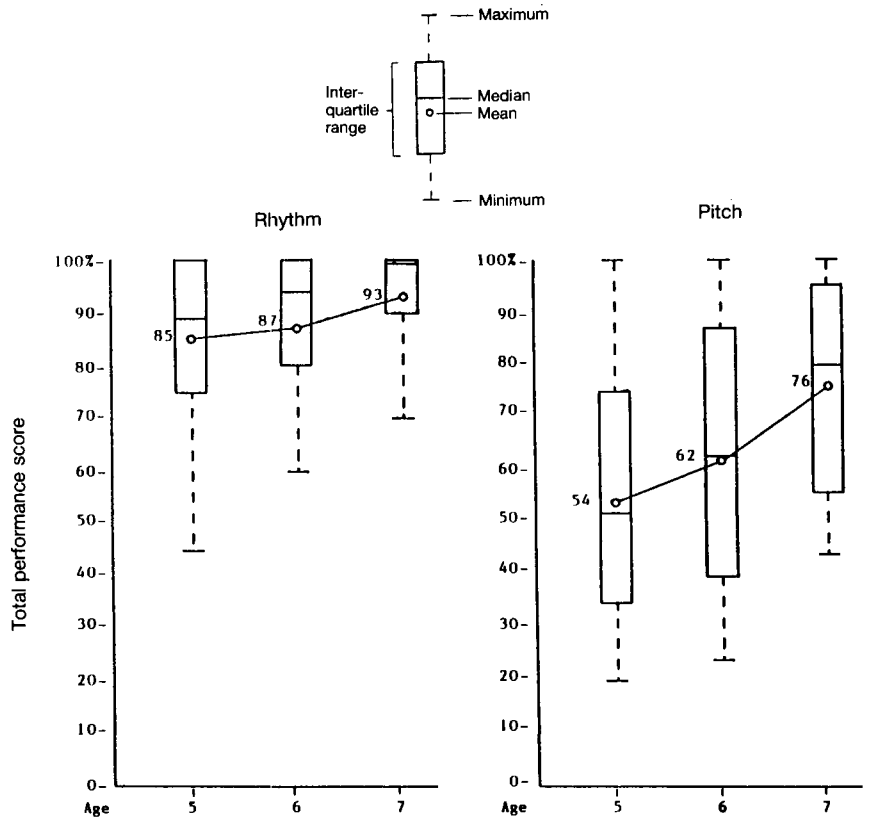

Fig. 9.14. Performance scores for rhythm and pitch in song by children ages 5–7.

develop, are increasingly able to draw on their performance knowledge in their representations. However, looking at pitch and rhythm separately, we see that pitch development in notation and performance increasingly correlates with age, whereas correlations are decreasing with respect to rhythm. This suggests that children's understanding of pitch is more closely linked to their developing representational knowledge of song than is their understanding of rhythm.

In sum, although there is substantial evidence for developmental trends in children's choice of symbol systems and in the level of sophistication of children's notation of songs, it appears that these are both increasingly independent 'tracks' in young children's representational development. However, as children's representations become more sophisticated, their level of representation increasingly corresponds to their performance knowledge of the song. This suggests, by the age of seven, the emergence

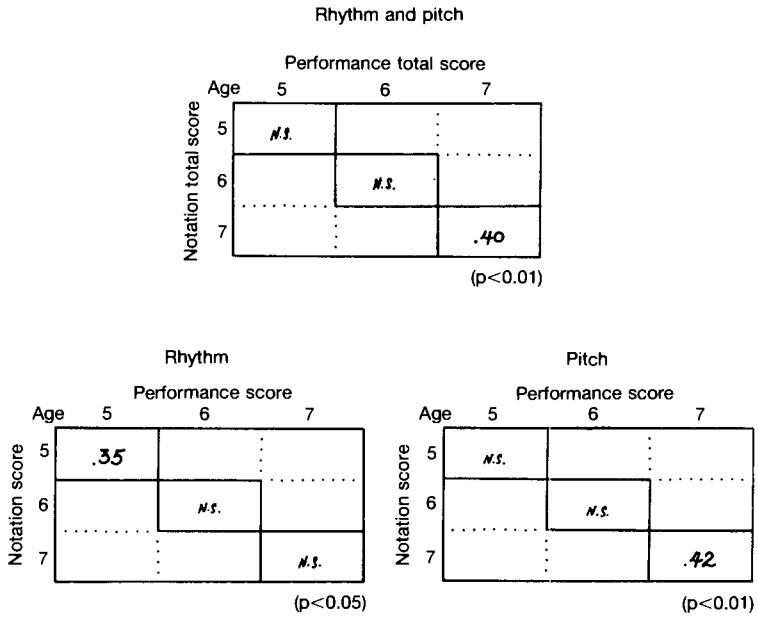

Fig 9.15. Matrices showing rank correlation coefficients (Spearman) between performance and notation scores in rhythm and pitch in children's song.

of a 'cognitively unified' domain of musical intelligence (Gardner 1984), where children's knowledge of musical performance and representation become increasingly yoked together. In both representational and performance knowledge of song, the dimension of pitch appears as the most stabilizing and powerfully predictive measure of children's musical development.

In the next section we look at children's notation of a single phrase across various musical contexts. Looking closely at their use of graphic symbols, we see young children's increasing sensitivity to the context of a phrase. Analysing the level of sophistication in their representations of a single phrase, we witness the increasingly powerful and consistent coding of musical features regardless of musical context. We also find more evidence establishing pitch as the primary factor in young children's developing musical cognition.

Making the difference: a closer look at young children's representations across musical contexts

Although we have seen developmental stages in children's notations of

song, a closer view of their development is needed in respect to a wider range of musical contexts. Children's music representations may profoundly differ according to *performance attributes* (is the phrase sung or clapped?), *structural presentation* (is the phrase an isolated pattern or embedded within a song?), or *familiarity* (is the phrase familiar or newly learned?).

In our sessions we asked children to perform and notate a single five-note phrase in five distinctly different contexts : (A) as an *isolated rhythmic fragment*, (B) as an *isolated melodic fragment*, (C) as an *added introductory phrase to a familiar song*, (D) as a *concluding phrase of a familiar song*, and (E) as a *concluding phrase of an unfamiliar song*. As we can see from Fig. 9.16, these five contexts contain virtually identical pitch and rhythmic musical motives.

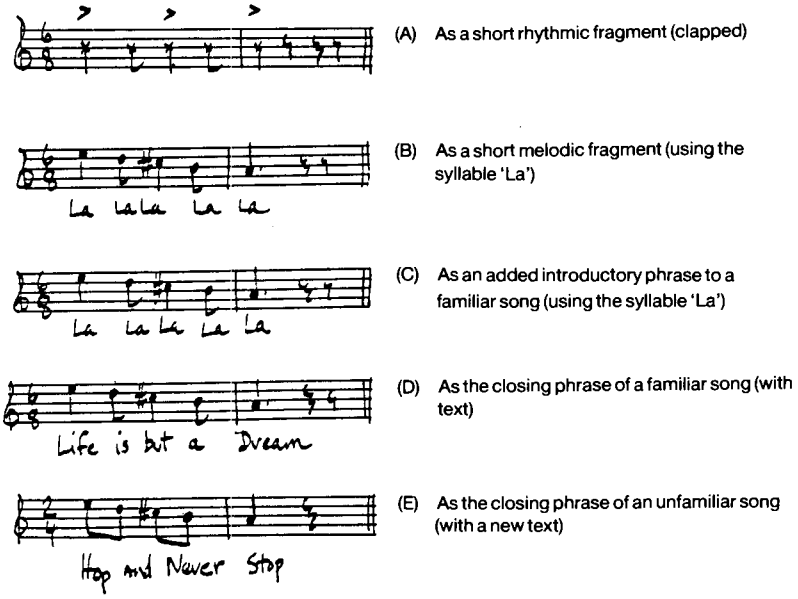

Fig. 9.16. The five musical contexts of a single musical phrase.

Using this single phrase as a control, we explore the ways in which young children are responsive to musical context. In particular, we contrast developmental trends in notation within the context of isolated rhythmic or pitch fragments with trends occurring within the structure of a whole song. Also, we want to know the effect of text on children's musical representations. Comparisons between no text (clapping), a generic text (the syllable 'la'), the text in a familiar song, and the text of a recently

learned song allow us to see how text may confound young children's attention to the musical features of a song. Finally, we can see which musical features children are apt to represent *regardless* of musical context. This last question may help us understand which dimensions of music are most important to (or less easily ignored by) young children.

Choosing graphic symbols for a single phrase: evidence for the increasingly 'context sensitive' musical child

Analysing notations of a single phrase, we again see the broad developmental trends discussed in the analysis of children's notations of a familiar song. These trends include the dramatic decrease of icons and pictures, the increase of words and mixed symbols with age, and the relatively consistent use of abstract lines and dots (Fig. 9.17). More importantly, we see evidence for increasing sensitivity to musical context.

Children use *icons* less often with age, perhaps because they consider musical context when they choose these symbols. From Fig. 9.17 below we see that chldren ages five and six are just as likely to use icons to represent the single phrase in the context of isolated rhythm or pitch pattern as they are within a familiar or newly learned song. In other words, young children consider these symbols unconstrained by musical context and increasingly inappropriate for music representation.

This finding substantially contrasts with the children's increasingly 'context-sensitive' use of *abstract lines and dots* and *letters and words*. At first, children use these symbols equally often across the various musical contexts, but, in the succeeding years, there is a great deal of fluctuation of use, depending on the musical context. In particular, children use lines and dots more often for short rhythm patterns (with no pitch or text), less often for isolated or introductory melodic phrases (with generic text 'la la la'), and least often for verses (using the lyrics) of a familiar or unfamiliar song. This effect is increasingly pronounced with age. Children also use letters and words with increased context sensitivity but in opposite contexts: these symbols appear more often in phrases of the song, less often in isolated pitch patterns, and rarely in rhythm patterns.

Although language symbols appear as an obvious choice for representing a phrase within the context of a familiar song, we also see the sudden emergence of *mixed symbols* (usually combining words with abstract symbols or signs) with seven-year-olds, particularly in the context of isolated melodic patterns. Observing the relatively profuse use of mixed symbols in pitch patterns compared with relatively scant use with the identical phrase used as an introduction to the song, we see evidence for young children's increasing sensitivity to the structural aspects of song.

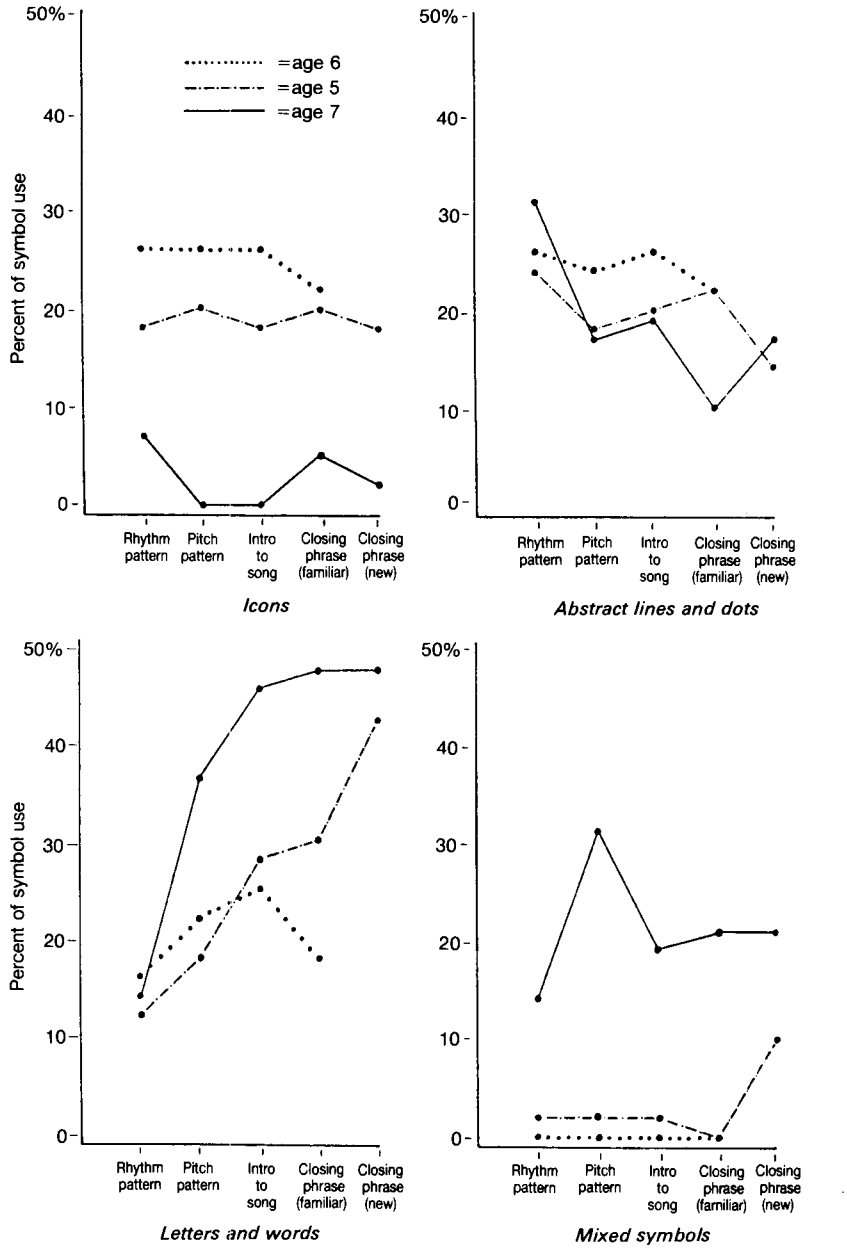

Fig. 9.17. Use of the four major graphic symbol types in a single phrase across five musical contexts by children ages 5–7.

Summarizing children's use of graphic symbols *by age*, we see an increasingly wider range of sensitivity to musical context. At the age of five, children's range of symbol use is surprisingly broad, yet relatively context-independent. At this age children use a large repertoire of symbol types of grasp the musical phrase. By the age of seven, however, a remarkably distinct profile of children's sensitivity to musical context emerges as children consistently choose language or abstract symbols (and their combinations) according to the context of the phrase. Looking across *context* at this age, we see children predominantly using abstract symbols for rhythm patterns, abstract and language symbols for pitch patterns, and mixed symbols for phrases within new or familiar songs.

As we trace Mary's notations of the single phrase through three years we encounter a clear example of this developmental sequence. In her notations we see a consistent use of abstract symbols for the rhythm patterns at all ages, while language and mixed symbols increasingly appear in the remaining contexts (Fig. 9.18).

Controlling for the structural context of the phrase, we see the symbols chosen for phrases as isolated patterns are markedly different from those chosen for phrases functioning within the song. We see a contrast in graphic symbols chosen for rhythmic fragments as opposed to pitch patterns. Continuing this analysis of a single phrase across the five contexts, we can take a closer look at children's ability to represent pitch and rhythmic content.

Evidence for the increasingly divergent paths of rhythm and pitch in representational development

In our previous analysis of young children's representational development we contrasted their growth in notating the rhythmic and pitch dimensions of a familiar song. On the average, we saw the power of children's notations in both rhythm and pitch significantly expand from musical units (at age five) towards the organization of these units into rhythmic pulse or grouping and melodic contour (at age seven). We noticed also that growth in music representation and performance was particularly powerful in pitch. In our present analysis of the single phrase across five musical contexts we will see a telling clarification of this finding.

Comparing children's notations of musical dimensions across contexts we find that developmental trends in rhythm and pitch very different (Fig. 9.19). Whereas rhythmic levels are relatively unstable across contexts, pitch levels are much more stable. And, while representational development in rhythm occurs in spurts across years, growth patterns in pitch are unambiguous and increasingly substantial. Additionally, these tendencies are increasingly pronounced with age.

Although children at age five can organize the rhythmic units in the context

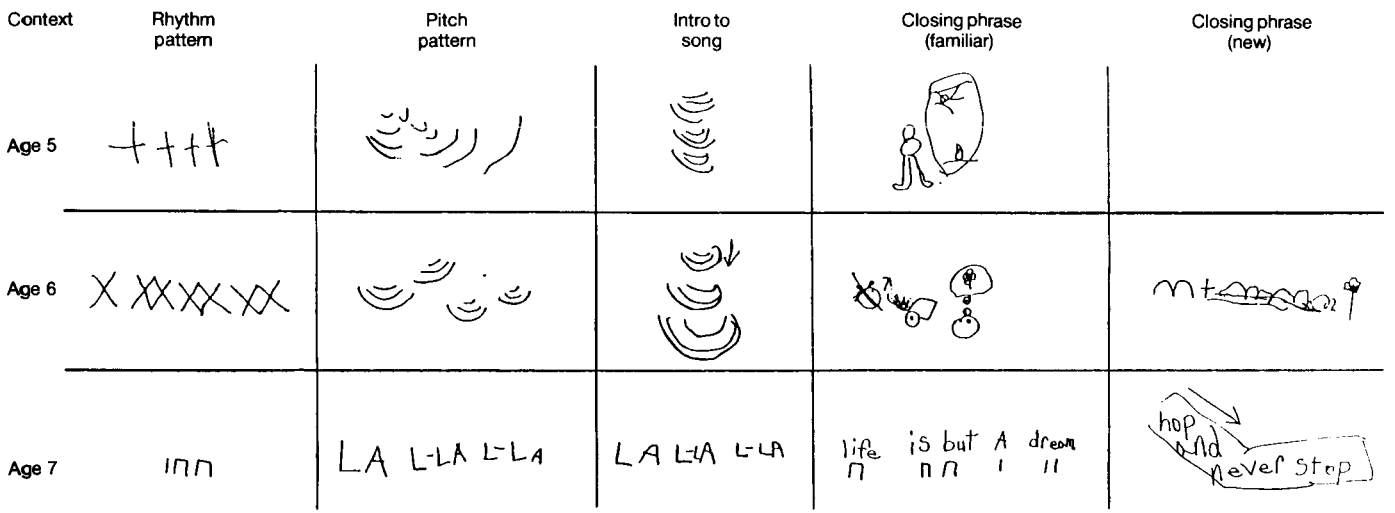

Fig. 9.18. Mary's notation of a single musical phrase across five contexts at ages 5–7.

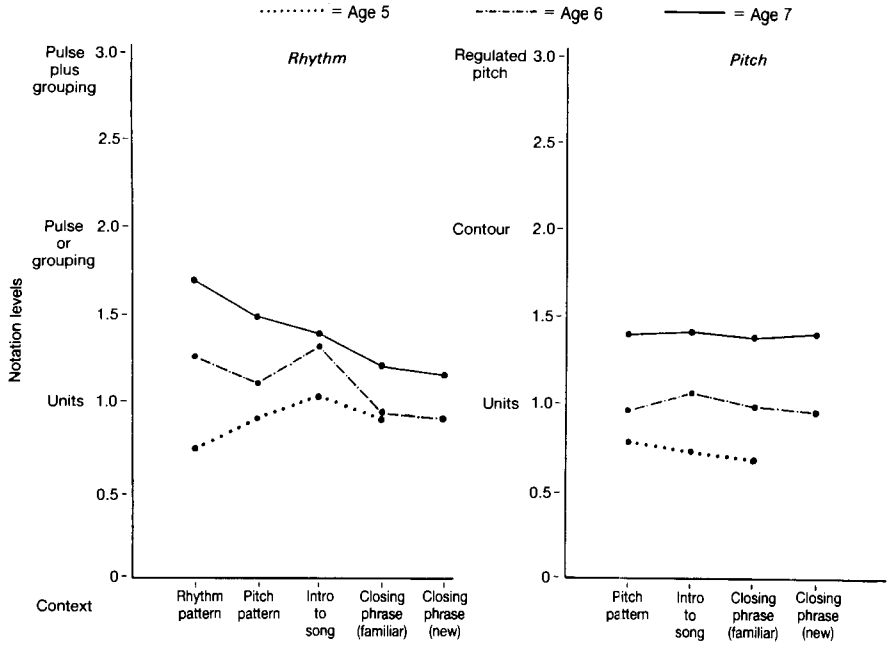

Fig. 9.19. Mean notation scores for rhythm and pitch in a single phrase across five musical contexts by children ages 5–7.

of a song, later they reveal their most sophisticated understanding of rhythmic features within the context of isolated rhythm patterns. Accordingly, statistical analysis of rhythmic notations using one-way repeated measures ANOVA reveals highly significant development [$p<0.0001$] over the three-year period *only* for isolated rhythm patterns. In this context it is not unusual to see seven-year-olds representing rhythmic grouping and the underlying pulse *simultaneously*. However, as soon as the dimension of pitch is introduced to the phrase, the notation of rhythmic pulse or grouping appears less often. This decline continues as the rhythmic features of the phrase competes with those features of pitch, text, and song structure. Although seven-year-olds continue to develop higher levels of rhythmic complexity in their musical representations, these only occur in the context of isolated rhythm patterns.

On the other hand, children's developing representations of pitch appear regardless of musical context. Whether the phrase occurs as an isolated melodic pattern, as an added introduction phrase with generic syllables, or as a phrase in a familiar or unfamiliar song, children attend to pitch equally well at every level of development. When compared to rhythm, pitch

development appears universally stable and increasingly robust with age. Statistical analysis in pitch notations using one-way repeated measure ANOVA shows highly significant [$p<0.002$] growth over the entire three-year period in all of the contexts.

This stable representation of pitch is most impressive at the age of seven. The average child is no longer content to code units of the phrase without providing some indication of melodic contour. Many children are now concerned with higher levels of organizing and formatting pitch as they invent ways of regulating the placement of notes so that intervallic or even scalar relationships can be represented. Furthermore, representing this level of pitch is important to the child in every musical context.

As we trace Janet's notations of the single phrase at age five and six, we see a clear example of the preference children generally give to pitch (Fig. 9.20). At age five, Janet represents the units of the phrase in the context of isolated patterns while tracking the underlying pulse (context (C)) or rhythmic grouping (context (D)) in song. At age six, she is primarily concerned with showing melodic contour except with isolated rhythm patterns. At age seven, she again consistently represents the melodic contour of the phrase, while occasionally adding indications of rhythmic grouping.

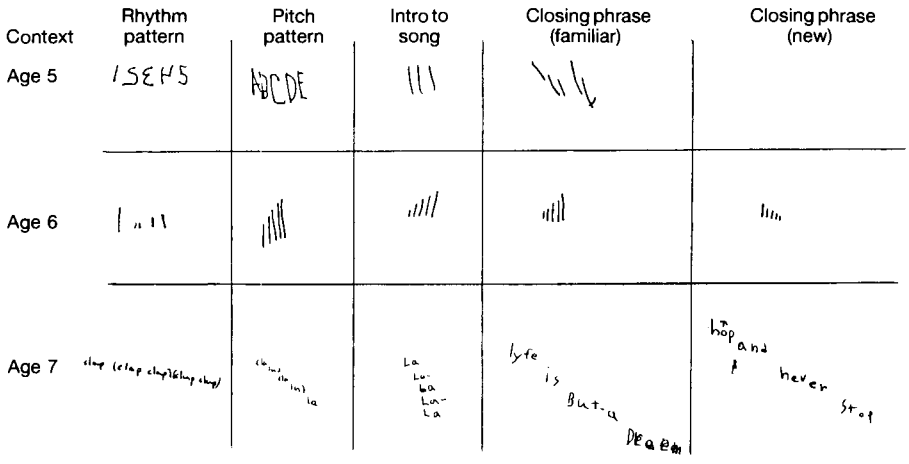

Fig. 9.20. Janet's notation of a single phrase across five musical contexts at ages 5–7.

Correlational analysis provides another way of viewing the diverging patterns of association between levels of rhythm and pitch representation. As seven-year-olds develop more complex representations of the phrase,

notations of pitch in all contexts are highly correlated, while rhythm notation levels are not. This strongly suggests that once children are able to record melodic contour in one context they are likely to retain this level of pitch representation throughout various contexts.

Remarkably, only children's notations of *isolated* rhythm patterns are highly correlated with the level of sophistication of pitch. Those who represent more sophisticated notational levels of isolated rhythm patterns tend to be the same ones who do well at representing pitch in their notations of short melodic fragments or phrases of songs. These findings reveal a distinctive profile of their musical understanding. Although clearly these children *can* represent the complex patterning of rhythmic relationships, when pitch is present they more often *choose* to notate the melodic contour. This switch of attention places rhythm and pitch in a figure-ground relationship, that is, the rhythmic 'figure' in isolation becomes 'ground' when pitch is introduced into the context of the phrase.

Looking briefly at the relationship between performance skills and ability to represent rhythm and pitch across contexts, we see additional evidence for the developing link between children's performance abilities and their representations of music. As children grow older and develop more sophisticated representations of pitch, they appear increasingly able to draw upon their performance knowledge. Surprisingly, this is not the case with their representation of the rhythmic content of the phrase. At first, correlations between performance scores and notation scores are practically nonexistent. By the age of seven, however, children's performance scores almost all significantly correlate with notation levels of pitch across virtually every context. Again, this is not the case with rhythm.

In sum, this 'across context' analysis of children's ability to attend to increasingly sophisticated levels of rhythm and pitch in their notations provides a rare 'composite' image of their implicit understanding of music. By looking at their notations of a single phrase across a wide range of musical contexts, we see the representation of pitch as their primary focus of attention. Although children can produce remarkably sophisticated representations of isolated rhythmic patterns during this time, we witness the dramatic emergence of pitch as the musical ingredient most consistently important to young children.

Again we witness the divergent paths of rhythm and pitch in young children's representational development. Although rhythm appears as the initial focus of focus of children's notations, pitch emerges as the increasingly cohesive underpinning of representational development. Not only is development more striking within pitch, but representational development with pitch can now be seen as extremely stable within a wide range of musical contexts and graphic symbols. We also find that representation of pitch—particularly in the context of songs—is increasingly tied to the performance knowledge of young children.

Conclusion

Originally, in this chapter, we were concerned with the relationship of representational development to perceptual and performance development in the domain of music. For the most part, earlier studies in musical development concentrated on perception and performance. Although this research shows that young children progress considerably in their ability to recognize or discriminate melodic patterns, or in their ability to produce or imitate short melodic fragments, it may be that children's musical cognitive development is best viewed by their symbolic representations of music. Simply put, although dogs can recognize melodic calls and birds can create and reproduce tuneful ditties, human musical development is uniquely tied to symbolic 're-presentations' of the music we hear and perform. Therefore, through young children's first musical representations we can begin to view the uniquely human inception of musical cognitive development.

The age range of five to seven has been documented by many development psychologists (White 1970) as a period of considerable change in most children's learning and perception modes. Past research in musical perception and performance shows that music cognition is no exception. In our study of children's representation of musical features across a full range of contexts, we have documented dramatic developmental trends in their use of symbols, the level of sophistication of their notations, and their selective attention to musical features depending on the context. These trends appear particularly between the ages of six and seven. These findings root music cognition more firmly within the framework of general cognitive development than originally thought. Children not only reveal an increasingly systematic representation of musical features, they also increasingly draw on their performance knowledge when inventing their notations.

More importantly to psychologists of music, by studying the divergent paths of development in rhythm and in pitch we gain a more precise understanding of the course of musical development between the ages of five and seven. As these children's notations become more sophisticated, our results suggest the emergence of pitch as a prime ingredient of musical cognitive development. Pitch emerges as the most robust component of musical cognitive development, independent of musical context or symbol choice in representation, and increasingly associated with development of performance skills. We speculate from these findings that, as pitch development occurs with age, it becomes increasingly independent of the language, kinaesthetic, or number skills that confound our assessment of musical development in young children. For example, although performing the words of a well-known song may at first help control the rhythmic

surface of the performance, it does not predict the ability to sing these words with pitch. On the other hand, as children get older, the ability to reproduce 'pitch in song' increasingly predicts the ability to notate pitch in all contexts. Pitch, therefore, appears to be an essential 'core' ingredient of

In music education, we view these results as important to our understanding of the developing child. This study reveals that young children, without explicit musical training in notation, can represent an increasingly sophisticated understanding of the music they perform. While recognizing the *success* of performance training at an early age (for instance Suzuki training), we must also pay attention to the musical *understanding* of young children. For example, music teachers might be better off assessing children's sensitivity to musical features by looking at their invented representations of music rather than at their reproduction of music symbols. Also, music educators might restructure the focus and timing of musical training in accordance with these developmental findings. We would emphasize the assessment of pitch development as a critical focus in young children's musical training.

Finally we strongly urge the continued exploration of young children's understanding of music. The early development of music perception, performance, and symbolic representation can only help us better understand the early roots of human cognition. Contained in children's spontaneous notations of short nursery songs are glimpses of growing minds at work. As we better understand children's extraordinary invented symbol systems for music, we discover how they mindfully abstract and reconstruct an increasingly rich and integrated world of musical understanding.

Acknowledgements

This research was supported in part by grants from the Carnegie Corporation, Rockefeller Foundation, and the Spencer Foundation. The work was carried out in the Cambridge, Mass, Public Schools and at the Cambridge Friends School. We are grateful to the teachers, children, and parents who helped us to pursue our interest in musical cognition. For their careful and critical readings of early drafts, we thank Howard Gardner and Jeanne Bamberger. John Willet's command of non-parametric statistical techniques aided us greatly in our data analysis. We are also indebted to Martha Davis-Perry, Joan Meyaard, Dennie Wolf, Joe Walters, and Rena Upitis for their suggestions and assistance.

Cognitive constraints on compositional systems

FRED LERDAHL

In this chapter I explore the relationship between composing and listening. I begin with a problematic story, draw some general conclusions, introduce relevant concepts from Lerdahl and Jackendoff (1983) and related work, propose some cognitive constraints on compositional systems, discuss 'pitch space', and explain why serial (or 12-tone) organizations are cognitively opaque. Most of these topics deserve fuller treatment than is given in these pages. My concern here is just to lay out a basic, if wide-ranging, argument.

I am not interested in passing judgement on the composers and compositions that are mentioned, particularly not on the remarkable work by Boulez that I use as a representative example. The thrust of my argument is psychological rather than aesthetic. But since aesthetic issues inevitably impinge on the discussion, I treat them briefly at the end.

Hidden organization in *Le Marteau sans Maître*

Boulez's *Le Marteau sans Maître* (1954) was widely hailed as a masterpiece of post-war serialism. Yet nobody could figure out, much less hear, how the piece was serial. From hints in Boulez (1963), Koblyakov (1977) at last determined that it was indeed serial, though in an idiosyncratic way. In the interim listeners made what sense they could of the piece in ways unrelated to its construction. Nor has Koblyakov's decipherment subsequently changed how the piece is heard. Meanwhile most composers have discarded serialism, with the result that Koblyakov's contribution has caused barely a ripple of professional interest. The serial organization of *Le Marteau* would appear, 30 years later, to be irrelevant.

This story is, or should be, disturbing. There is a huge gap here between compositional system and cognized result. How can this be?

One might suppose that the impenetrability of *Le Marteau's* serial organization is due to insufficient exposure. After all, the piece was

innovative; listeners must become accustomed to novel stimuli. Such has been the traditional defence of new art in the face of incomprehension. One might refine this view by pointing out that there is little repetition in *Le Marteau*. The lack of redundancy perhaps overwhelms the listener's processing capacities. Comprehensibility, then, is arguably a consequence both of the degree of conditioning to the materials and of the number and variety of events per unit time. (Is it a coincidence that *Le Marteau* was composed in the heyday of behaviourism and information theory?)

But this explanation is inadequate. For one thing, competent listeners to *Le Marteau*, even after many hearings, still cannot even begin to hear its serial organization. For many passages they cannot even tell if wrong pitches or rhythms have been played. The piece is hard to learn by ear in a specific sense; its details have a somewhat statistical quality. Conditioning, in short, does not suffice. For another thing, *Le Marteau* does not feel structurally complex in the way, for example, that compositions by Beethoven or Schoenberg do. Vast numbers of nonredundant events fly by, but the effect is of a smooth sheen of pretty sounds. The listener's processing capacities, in short, are not overwhelmed.

This is not to deny the influence of exposure and redundancy on comprehensibility. But these factors do not go far enough; they do not address issues of specific organization. Cognitive psychology has shown in recent decades that humans structure stimuli in certain ways rather than others. Comprehension takes place when the perceiver is able to assign a precise mental representation to what is perceived. Not all stimuli, however, facilitate the formation of a mental representation. Comprehension requires a degree of ecological fit between the stimulus and the mental capabilities of the perceiver.

Experienced listeners do not find *Le Marteau* totally incomprehensible, but neither, I would argue, do they assign to it a detailed mental representation. This is why the details of the piece are hard to learn and why the piece does not in the end feel complex. The serial organization that Koblyakov found is opaque to such structuring.

Of course a musician of Boulez's calibre would not use a compositional system without drawing crucially upon his musical intuition and experience. Music-generating algorithms alone have always produced primitive outputs; not enough is known about musical composition and cognition for them to succeed. Boulez had the intellectually less ambitious goal of developing a system that could just produce a quantity of musical material having a certain consistency. He then shaped his materials more or less intuitively, using both his 'ear' and various unacknowledged constraints. In so doing, he listened much as another listener might. The organization deciphered by Koblyakov was just a means, and not the only one, towards an artistic end.

The degree to which *Le Marteau* is comprehensible, then, depends not

on its serial organization but on what the composer added to that organization. On the other hand, the serial procedures profoundly influenced the stimulus structure, leading to a situation in which the listener cannot form a detailed mental representation of the music. The result is a piece that sounds partly patterned and partly stochastic.*

Compositional and listening grammars

It will be useful to put these observations in schematic form. Let me introduce the notion of a *musical grammar*, a limited set of rules that can generate indefinitely large sets of musical events and/or their structural descriptions. Such a grammar can take the form of (a) or (b) in Fig. 10.1. (The rectangles stand for sets of rules, the ellipses for inputs and outputs of rules.) In (a), the rule system generates the events of a passage or piece, and in the process provides some sort of specification (the 'input organization'). In (b), the sequence of events is taken as given, and the role of the rule system is to assign a structural description to the sequence.

Our discussion of *Le Marteau* suggests that there are two kinds of musical grammar at work here. The first is the *compositional grammar*, consciously employed by Boulez, that generated both the events of the piece and their serial organization as discovered by Koblyakov. This grammar is an instance of (a) in Fig. 10.1. The second kind is the *listening grammar*, more or less unconsciously employed by auditors, that generates mental representations of the music. This grammar is an instance of (b) in Fig. 10.1; the events themselves are present when *Le Marteau* is played.

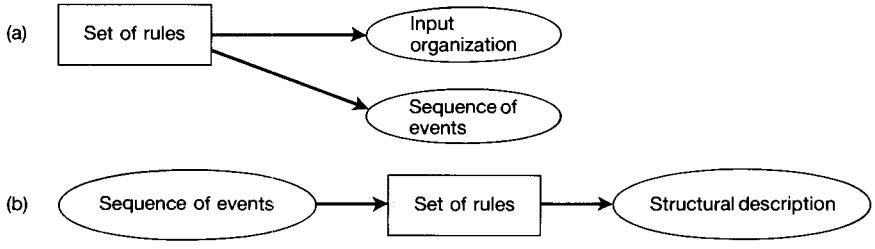

Fig. 10.1

* In *Structures*, Book I (1952), Boulez flirted with 'algorithmic composition', and in *Pli selon pli* (1958–61) he incorporated aleatoric elements; so *Le Marteau* lies *en route* in his dialectic of determinism and chance (see Boulez 1964). His interest in algorithmic composition continues to the extent that for a while there was a research group at IRCAM pursuing it. For six months in 1981 I was part of that group, though in my project the purpose of the computer program was not to compose but to assist composers in composing, much as a word processor assists writers (see a brief description in Lerdahl 1985). Many of the ideas expressed in this essay grew out of that experience, for which I remain deeply grateful.

Fig. 10.2 summarizes these remarks. The diagram shows that the compositional grammar generates the sequence of events and the manner in which they are specified. Only the sequence of events, however, is available as input to the listening grammar: the listener hears the acoustic signal, not its compositional specification. The listening grammar then generates the mental representation that comprises the 'heard structure' of the piece. Note that Fig. 10.2 incorporates both (a) and (b) of Fig. 10.1.

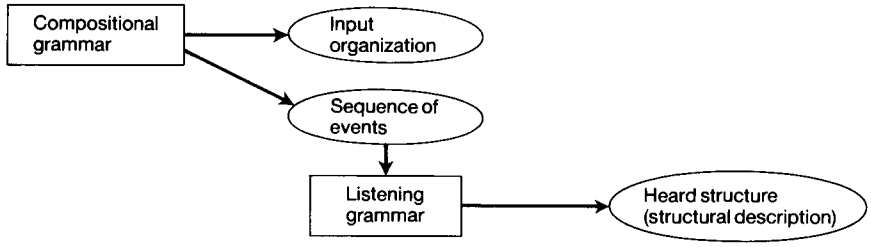

Fig. 10.2

This account is complicated by the fact that, as noted above, Boulez created *Le Marteau* not only through serial procedures but through his own inner listening. In the process he followed constraints that, while operating on the sequence of events produced by the compositional grammar, utilized principles from the listening grammar. This more elaborate picture is drawn in Fig. 10.3.

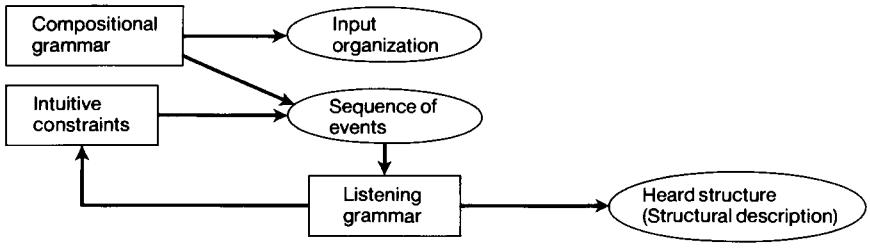

Fig. 10.3

Observe that none of the arrows in the diagram are inputs to the 'compositional grammar'. This component is inaccessible to the rest of the system. Hence it becomes quite possible for the 'compositional grammar' to be unrelated to the other rules, the 'listening grammar' and 'intuitive constraints'. If this happens, the 'input organization' will bear no relation to the 'heard structure'. Here, then, lies the gap between compositional system and cognized result with which we began.

This situation exists not only for *Le Marteau* but for much of

contemporary music. I could have illustrated just as well with works by Babbitt, Carter, Nono, Stockhausen, or Xenakis. This gap is a fundamental problem of contemporary music. It divorces method from intuition. Composers are faced with the unpleasant alternative of working with private codes or with no compositional grammar at all. Private codes remain idiosyncratic, competing against other private codes and creating no larger continuity—so that, for example, 30 years later the serial organization of *Le Marteau* becomes irrelevant even to other composers.

Natural and artificial compositional grammars

Where does a compositional grammar come from? The answer varies, but a few generalizations may be helpful. Let us distinguish between a 'natural' and an 'artificial' compositional grammar. A natural grammar arises spontaneously in a musical culture. An artificial grammar is the conscious invention of an individual or group within a culture. The two mix fruitfully in a complex and long-lived musical culture such as that of Western tonality. A natural grammar will dominate in a culture emphasizing improvisation and encouraging active participation of the community in all the varieties of musical behaviour. An artificial grammar will tend to dominate in a culture that utilizes musical notation, that is self-conscious, and that separates musical activity into composer, performer, and listener.

The gap between compositional and listening grammars arises only when the compositional grammar is 'artificial', when there is a split between production and consumption. Such a gap, incidentally, cannot arise so easily in human language. People must communicate; a member of a culture must master a linguistic grammar common to both speaking and hearing. But music has primarily an aesthetic function and need not communicate its specified structure. Hidden musical organizations can and do appear.

A natural compositional grammar depends on the listening grammar as a source. Otherwise the various musical functions could not evolve in such a spontaneous and unified fashion. An artificial compositional grammar, on the other hand, can have a variety of sources—metaphysical, numerical, historical, or whatever. It can be desirable for an artificial grammar to grow out of a natural grammar; think, for example, of the salutary role that Fux (1725) played in the history of tonality. The trouble starts only when the artificial grammar loses touch with the listening grammar.

In the Western tradition the trouble began with the exhaustion of tonality at the turn of the century. Anything became possible. Faced with chaos, composers reacted by inventing their own compositional grammars. Within an avant-garde aesthetic it became possible to believe that one's own new system was the wave of the future. Boulez's generation was the

last to believe this. To a younger generation these systems have come to seem merely arbitrary. The avant-garde has withered away, and all methods and styles are available to the point of confusion.

One can react to this situation by giving up on compositional grammars and relying solely on ear and habit—on the 'intuitive constraints' of Fig. 10.3. But composing is too difficult for such a solution; there are too many possibilities. Or one can react by reverting to earlier 'natural' styles, a move that condemns one to a parasitic relationship with the past. Both reactions are common these days, and both are motivated by the desire to avoid the gap between composing procedure and what is heard.

My own reaction as a composer has been less to avoid than to confront this gap. These were my initial ground rules: (1) a compositional grammar is necessary; (2) it need not be nostalgic; (3) our musical culture is too fragmented and self-conscious for a natural grammar to emerge; but (4) an artificial grammar unresponsive to musical listening is unacceptable. It was inevitable, I concluded, that early attempts at artificial grammars—say, from the 1920s to the 1950s—were defective in their relation to listening. Not enough was known about musical cognition; the basic questions had not even been framed. Beginning around 1970, however, a new perspective became possible through the simultaneous decline of the avant-garde and rise of cognitive psychology. Contemporary music had lost its way. What other foundation was there to turn to than the nature of musical understanding itself? In other words, I decided that a compositional grammar must be based on the listening grammar. Fig. 10.4 illustrates this by adding a dashed arrow to the flow chart of Fig. 10.3. In principle this arrow integrates the compositional grammar into the overall framework, rather than leaving it isolated from input.

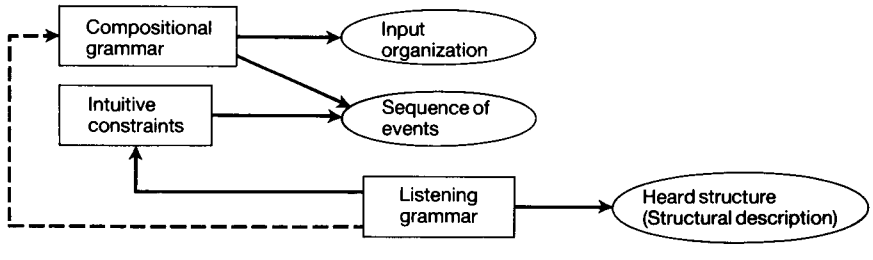

Fig. 10.4

But for this proposal to have substance, a great deal must be known about the listening grammar. Hence it became necessary to develop a detailed theory of musical cognition (Lerdahl and Jackendoff 1983). Such a theory, I reasoned, could provide the basis for artificial compositional grammars that could be intellectually complex yet spontaneously accessible

to mental representation. The commonality of compositional and listening grammars could produce a rich yet transparent music.

Theoretical overview

This is not the place to describe the specifics of Jackendoff's and my theory. I propose only to outline some of its general features. The reader should bear in mind, however, that the theory is concrete and detailed.

Our theory models musical listening within the framework of some standard methodological idealizations. Assuming (1) an experienced listener, (2) the psychoacoustical organization of the physical signal into a 'musical surface' comprising a sequence of discrete events, and (3) a final-state knowledge of the sequence, the theory predicts structural descriptions from musical surfaces by means of a set of rules that ideally corresponds to the 'listening grammar' of Figs. 10.2–4. See Fig. 10.5; and note that the theory is 'generative' in the sense of (b) in Fig. 10.1. The predictions of the rules are testable by introspection and, in principle, by experiment.*

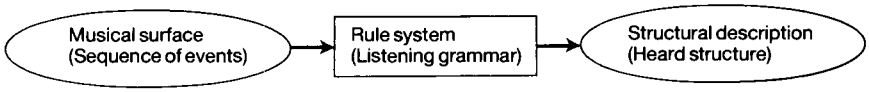

Fig. 10.5

As a practical matter the theory focuses on Classical tonal music, but most of the rules appear to have a more general psychological basis and therefore to be applicable to other idioms as well. The extent of the universality of the rules is an empirical question. Again for practical reasons, the rules assign structural descriptions only to the hierarchical aspects of musical structure, neglecting 'associational' dimensions such as motivic processes and timbral relations (but see Lerdahl 1987). By 'hierarchy' is meant the strict nesting of elements or regions in relation to other elements or regions. The theory claims that, if the signal permits, the listener unconsciously infers four types of hierarchical structure from a musical surface: *grouping structure*, or the segmentation of the musical flow into units such as motives, phrases, and sections; *metrical structure*, or the pattern of periodically recurring strong and weak beats associated with the surface; *time-span reduction*, or the relative structural importance of

* Deliège (1985) has experimentally verified—and, in a few cases, improved upon—the local grouping preference rules of the theory. Todd (1985) has used the time-span reductional component of the theory to model expressive timing at cadences in performance. Palmer and Krumhansl (in press) have found empirical support for predictions made by the metrical and time-span components.

events as heard within contextually established rhythmic units; and *prolongational reduction*, or the perceived pattern of tension and relaxation among events at various levels of structure. Both kinds of reduction are described by structural trees. The prolongational component incorporates aspects of Schenker's (1935) theory.

For the most part these four hierarchies interact as shown in Fig. 10.6. From the grouping and metrical structures the listener forms the rhythmic units, or *time-span segmentation*, over which the dominating-subordinating relationships of time-span reduction take place; and from the time-span reduction the listener in turn projects the tensing-relaxing hierarchy of prolongational reduction. Thus the mapping from musical surface to prolongational structure is indirect. In addition, both kinds of reduction depend for their operation on *stability conditions* among pitch configurations as considered 'out of time'. These conditions, which also can be described hierarchically (Krumhansl 1983; Bharucha 1984*b*), are internal schemata induced from previously heard musical surfaces and brought to bear on the in-time event sequences described by the reductions.

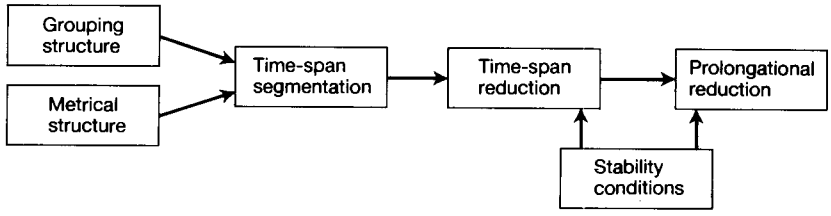

Fig. 10.6

For each of the four organizations there is a set of *well-formedness rules* that defines the conditions for hierarchy. Well-formed structures can be modified in limited ways by *transformational rules*. These two rules types are abstract in that they only define formal possibilities. By contrast, a third rule type, *preference rules*, registers particular aspects of presented musical surfaces and selects which well-formed or transformed structures in fact apply to those surfaces. The preference rules, which do the bulk of the work of the theory, do not generate categorically right or wrong analyses but instead predict descriptions as more or less coherent. When the preference rules reinforce one another, the analysis is stable and the passage in question is judged as stereotypical: when they conflict, the analysis is unstable and the passage is judged as ambiguous or vague.

In summary, the theory asserts that (1) the listener has at his disposal a number of hierarchical organizations possessing certain formal properties, and (2) the listener unconsciously attempts to assign the most stable overall description (or descriptions) by means of preferential principles that activate and interact in response to specific features of musical surfaces.

Constraints on event sequences

What does Jackendoff's and my theory have to say about closing the gap between compositional system and cognized result? Let me explore this question by proposing, in this and the following two sections, a number of psychologically plausible constraints on compositional grammars. These constraints will give substance to the dashed arrow in Fig. 10.4. Then I will use the constraints to explain why serial organizations are not easily learnable.

We begin with a presupposition of the theory, namely that the musical surface breaks down into individual events. Certain recent musical developments (pioneered for instance by Ligeti) have tended to blur distinctions between events. Sensuously attractive though this blurring may be, it inhibits the inference of structure.

> *Constraint 1*: The musical surface must be capable of being parsed into a sequence of discrete events.*

It is hardly fortuitous that our theory concentrates on hierarchies. Most of human cognition relies on hierarchical structuring (Miller *et al.* 1960; Simon 1962; Neisser 1967). Studies in music psychology have indicated that the absence of perceived hierarchy substantially reduces the listener's ability to learn and remember structure from musical surfaces (Deutsch 1982). It does not suffice for the input organization to be structured hierarchically; such in fact is the case for *Le Marteau* (Koblyakov 1977). It is the relationship to the listening grammar that matters.

> *Constraint 2*: The musical surface must be available for hierarchical structuring by the listening grammar.

As suggested above, there are four ways that the listening grammar can structure event sequences hierarchically. Let us return to Fig. 10.6 and consider what is needed at the musical surface for these organizations to come into play.

Segmentation into groups is accomplished at local levels largely by detection of *distinctive transitions* in the musical flow. A distinctive transition corresponds at a less fine-grained level to the principles by which events themselves are perceived as discrete rather than continuous. It is a change in some musical dimension, such as greater distance in attack points or shift in dynamics, timbre, or register, with respect to an immediate context that is relatively invariant. From this it follows that constant change will not give rise to salient distinctive transitions; nor of course will

* This formulation skirts the issue of simultaneous sequences of discrete events, an area that has been researched as 'auditory stream segregation' by Bregman and his associates (see McAdams and Bregman 1979 for a review).

no change at all. Babbitt and Reich have something in common after all. The steady-state quality of both their musics is due to a paucity of distinctive transitions, hence of grouping boundaries.

> *Constraint 3*: The establishment of local grouping boundaries requires the presence of salient distinctive transitions at the musical surface.

The other factor creating local groups is repetition or, more generally, *parallelism* of musical units. Repetition is an obsession of minimalism. But without distinctive transitions such groups produce only 'flat' hierarchies; that is, the repetitions are not heard within larger groups to any depth of embedding. Groups of groups tend to arise rather through the reinforcing action of distinctive transitions and parallelisms, often supplemented by a third principle of *symmetry* (the approximately equal division of a larger time span). At global levels parallelism becomes the overriding grouping principle: listeners try to hear parallel passages in parallel places in the overall structure.

> *Constraint 4*: Projection of groups, especially at larger levels, depends on symmetry and on the establishment of musical parallelisms.

Much contemporary music avoids symmetry and parallelism. Indeed, in the 1950s and 1960s literal repetition was widely regarded as aesthetically inexcusable. But symmetry and especially parallelism are basic ingredients of any complex grouping structure. The reliance on these principles in Classical tonal music and in various ethnic musics is not necessarily a sign of lack of invention but is an essential technique for the creation of deeply embedded groups.

We turn now to metrical structure. A well-formed metre is a looping pattern of equidistant beats occurring at multiple hierarchical levels. A beat at any metrical level is felt to be strong if it is also a beat at the next larger level. Depending on the musical idiom, the criterion of equidistance may be loosened, but not to the extent of abandoning all sense of periodicity. A musical idiom typically has available a limited repertory of well-formed metrical possibilities.

When hearing a musical surface, the listener seeks an optimal fit between the accents perceived directly from the signal and the repertory of available metrical structures. These *phenomenal accents* arise from local stresses such as sforzandos, changing bass notes and chords, contextually long events, and so forth. Insofar as possible, the onsets of phenomenal accents are aligned with relatively strong beats. In other words, the listener looks for maximal periodicity in the musical signal.

Great regularity in phenomenal accents produces a rhythmic quality of stability and squareness. In much rhythmically vital music, however, many

phenomenal accents are forced to align with weak beats, creating cross-accents or syncopations. But if there is very little regularity to the phenomenal accents, the listener may not be able to infer any metrical structure. Most music is metrical, and the immediate location of events is established largely in relation to this or that strong or weak beat. An inability to assign a metrical grid weakens the precision of location of events, resulting in a quality of suspended rhythm.

Constraint 5: The establishment of a metrical structure requires a degree of regularity in the placement of phenomenal accents.

Much contemporary music, even if notated traditionally, avoids regularity of phenomenal accents and does not give rise to a sense of metre. Complicated rhythms can cancel as well as create structure. An interesting case is Carter's practice of establishing two or more simultaneous tempos. Each such tempo corresponds to a single metrical level, or pulsation, but usually does not evoke a hierarchy of strong and weak beats. Carter contracts metrical depth in order to focus on multiple speeds. However, two or three simultaneous tempos cannot be taken in as readily as the four or five metrical levels that are commonplace in a march or waltz. Musical cognition has a bias for hierarchical organization. Simultaneous tempos instead produce independent organizations competing for attention. The difficulties in attending to more than one such organization are well known (Cherry 1953) and are ameliorated only if the vertical correspondences are coherent (Sloboda 1985), a condition that only partly obtains in this case. The situation is analogous to that of harmonically controlled versus uncontrolled polyphony.

The grouping and metrical structures come together (via well-formedness rules) to form the time-span segmentation. Details aside, it should be intuitively obvious that events are heard and thought of within such units. We normally speak of an event at small levels in terms of this or that beat, at larger levels in terms of this or that phrase or section. If the grouping or metrical structure is impoverished, then so too is the time-span segmentation.

Constraint 6: A complex time-span segmentation depends on the projection of complex grouping and metrical structures.

Various passages of *Le Marteau*, in which no metrical structure is apparent and the groups are not deeply embedded, provide a contrary illustration. Because of the consequent lack of hierarchical time-span segmentation, the sense of these passages is of a flurry of events followed by a pause, then another flurry and another pause, like beads on a string. Each flurry tends to become one complex 'event' rather than an organized sequence of events. The phrase is replaced by a sonorous object extended in time. (This is one way of explaining why, despite its generally fast tempos, *Le Marteau* feels slow.)

The notion of an extended sonorous object filled with inner movement is a compelling one, especially in light of recent developments in computer music. Here lies an unexpected link beteween *Le Marteau* and Boulez's recent work, *Répons*. But from the perspective of musical cognition, one must ask how the inner movement of an object receives structure. We have returned to Constraint 1, the issue of musical surfaces as discrete events. If the listener can assign any rich internal structure to the sonorous object, it must be perceived as consisting of 'subobjects'. But if the subobjects are to be experienced as aspects of one object, they cannot be too discriminable or allow salient structuring.

The time-span segmentation must be highly structured for a complex event hierarchy to emerge—something not achieved, and perhaps not tried for, in *Le Marteau, Répons*, or indeed most contemporary music. Since 'events' in music are usually pitch events, event hierarchies are normally pitch hierarchies. A unified pitch hierarchy is an instance of tonality (broadly defined), the stability conditions for which will be discussed in the next two sections. For now let us assume stability conditions and review the projection of event hierarchies from musical surfaces.

The two kinds of reduction are complementary descriptions of event hierarchies. In the time-span reduction, the listener compares the relative stability of events within each time-span segment. The less stable event in a segment is judged as subordinate to, or as an elaboration of, the more stable event. This process continues recursively from local to global levels of the time-span segmentation until an entire time-span tree is built up. The relative stability of events within a span is determined partly by rhythmic position, for example whether an event occurs on a strong beat or cadences a group. But the main determinant of domination or subordination within a span is the set of stability conditions.

> *Constraint 7*: The projection of a time-span tree depends on a complex time-span segmentation in conjunction with a set of stablility conditions.

A little thought-experiment will demonstrate the necessity for both the time-span segmentation and the stability conditions for the hearing of an event hierarchy. Imagine the pitches of *Le Marteau* plugged into the rhythms of Beethoven's Fifth Symphony. The hierarchical time-span segmentation would largely be erased by the lack of any concomitant pitch articulation, and, in any case, the absence of stability conditions would prevent the inference of any pitch hierarchy. Or, conversely, imagine the pitches of the Fifth Symphony plugged into the rhythms of *Le Marteau*. The potentially hierarchical pitch structure would be garbled by the lack of supportive time-span segmentation (including the absence of any metrical structure or patterned grouping structure). In short, rhythm and pitch must work in concert if there is to be any time-span reduction.

The prolongational reduction derives from the time-span tree and, again, from the stability conditions. Although this is the most important of the ways in which events relate to one another, its description is rather technical and abstract, and so will be avoided here. Suffice it to say that in this component events connect hierarchically in terms of progression and continuity, creating *prolongational regions* that act in structural counterpoint to the time-span segmentation (see Lerdahl and Jackendoff 1983 for a detailed treatment).

> *Constraint 8*: The projection of a prolongational tree depends on a corresponding time-span tree in conjunction with a set of stability conditions.

Before continuing, it would be well to emphasize how interdependent the contraints are that have been listed so far. Most of them call on their immediate predecessors. Thus a hierarchy of events (Constraint 2) requires a musical surface that has been parsed into events (Constraint 1); the recursive segmentation of the surface into rhythmic units (Constraint 6) cannot take place without the establishment of grouping and metrical structures (Constraints 3–5); the relative structural importance of events (Constraint 7) cannot be assessed without the time-span segmentation (Constraint 6); and the representation of how events depart and return (Constraint 8) demands an evaluation of their function in the rhythmic structure (Constraint 7). The requirement of projecting event hierarchies to the listener has brought a great deal in its wake.

Constraints on underlying materials

We turn now to the stability conditions underlying the two reductions. Generally, a stability condition says, 'Musical context aside, this structure is judged as more stable than that.' Stability conditions interact like preference rules, sometimes reinforcing and sometimes conflicting with one another. In Classical tonality, for example, a triad in root position is more stable than a triad in first inversion, and a I chord is more stable than a V chord. These conditions reinforce one another when the judgement is between a I and a V^6, but conflict when the judgement is between a I^6 and a V. In actual music such conflicts are resolved by context: on the assumption that the two events come up for comparison in the same unit (time-span segment or prolongational region), the reductional preference rules decide which event is more stable on the basis of rhythmic position, linear function, and other factors.

Stability conditions are contingent on the basic materials and properties out of which the event structure of a piece is made. In Classical tonal music, for instance, the basic materials include the diatonic scale, which

has certain internal and transpositional properties that can project judgements of relative stability (of which more below). Musical idioms vary in these respects. It is possible though rare for the basic materials not to be used in a way that gives rise to stability conditions: one can imagine a treatment of the diatonic scale where all scale degrees are functionally equivalent and the circle of fifths is not employed. Similarly, both Bach and Schoenberg used the well-tempered chromatic scale, but only the former carved it up so as to induce clear judgements of relative stability among pitch configurations; the latter instead sought a noncentric musical universe in which the 'twelve tones . . . are related only with one another' (Schoenberg 1941). However, since learning and memory depend on hierarchical structuring (Constraint 2), and since event hierarchies depend on stability conditions (Constraints 7 and 8), it follows that stability conditions are cognitively advantageous.

What are the constraints on stability conditions? First, there must be a fixed collection of sonic elements (normally pitches; but see Lerdahl 1987). The assumption of such collections might go unremarked except that in electronic music they are fairly rare. When there is a virtual infinitude of sonic possibilities, it is hard for a composer to select and stick with a limited collection. Non-selection, however, means no syntax.

> *Constraint 9*: Stability conditions must operate on a fixed collection of elements.

A fixed collection should not be thought of as completely rigid. First, an element of a collection need only be perceived categorically (Burns and Ward 1982); otherwise a slightly mistuned pitch would cause havoc. Second, as long as the categories remain the points of reference, there can be embellishing or sliding within or between categories (as in microtonal inflexions in Indian music or string glissandos in Western music).

The elements of a collection can be placed along a dimension to form a scale. The intervals of a scale have general size limitations: they must be large enough for adjacent elements to be easily discernible, but not so large as to use up excessive space along the continuum.

> *Constraint 10*: Intervals between elements of a collection arranged along a scale should fall within a certain range of magnitude.

Constraints 9 and 10 are analogous to Constraint 1 (the requirement of discrete events). Both cases provide the building blocks for further organization, Constraints 9 and 10 for stability conditions and Constraint 1 for event hierarchies. A fixed collection with moderate interval sizes allows other stability conditions to emerge. In surveying some of these, let us assume that the collections are pitch collections—as opposed, say, to drums or synthesized timbres.

Most pitch collections take advantage of the 2:1 frequency ratio of the

octave, so that in one respect pitches reduce to 'pitch classes'. There are 88 pitches on the piano but only 12 pitch classes. Thus, in addition to giving a recurring structure to the overall collection, the octave decreases to a more manageable size the memory load for elements of the collection.

> *Constraint 11:* A pitch collection should recur at the octave to produce pitch classes.

The octave can be divided up in innumerable ways. A common route has been to make a collection beginning with other small-ratio intervals and progressing gradually to intervals with larger ratios. From the present perspective, this route is advantageous because the resultant intervals provide a broad and graduated palette of *sensory* consonance and dissonance. Sensory consonance and dissonance can in turn form the basis for *musical* consonance and dissonance, where in a general sense consonance is equivalent to stability and dissonance to instability. Thus a seventh in Classical tonal music resolves to a sixth not just out of cultural convention but because the syntactical resolution is supported by sensory experience.

The claim is not that pitch configurations exhibiting relative sensory consonance must necessarily be more stable in musical contexts than those exhibiting relative sensory dissonance. The reverse can occur contextually, and shows up in the reductions where appropriate. Rather the claim is that the stability conditions will be relatively ineffectual unless they are supported by sensory consonance and dissonance. Stability conditions in which a seventh is supposed to be more stable than a sixth would contradict sensory experience and would not lead to event hierarchies of any depth of embedding.

Strictly speaking, these remarks hold for fundamentals with harmonic partials, such as produced by the voice and by all instruments in which the source is periodically excited. For intervals with very small ratios, the partials of the respective fundamentals are largely reinforcing, creating the sensation of consonance. Sensory dissonance, or 'roughness', arises when frequencies (whether of fundamentals or of partials) interfere within a critical bandwidth, which extends in most musical registers from a fraction of a semitone to a little less than a minor third (Plomp and Levelt 1965). The critical bandwidth is a consequence of the resolving power of the hearing mechanism in the peripheral auditory system. One could also invoke pattern-recognizing templates of the central auditory system, such as proposed in Terhardt (1974); these for present purposes lead to the same conclusion.

> *Constraint 12*: There must be a strong psychoacoustical basis for stability conditions. For pitch collections, this entails intervals that proceed gradually from very small to comparatively large frequency ratios.

However, as is well known, small interval ratios—whether in just or Pythagorean tuning—present problems for the transposition of intervals and chords. A reading of Partch (1949) might additionally suggest that the number of pitches and intervals in such a collection can become alarmingly large. An alternative route that avoids these problems is to divide the octave into equal intervals. The collection then permits equivalence under transposition, and the pitches and intervals to be learned are limited.

> *Constraint 13*: Division of the octave into equal parts facilitates transposition and reduces memory load.

But these advantages are offset by the fact that almost all equal divisions of the octave lead to interval ratios that are complex and that do not easily round off categorically to simple ratios. As a result the intervals give a small range of sensory consonance and dissonance, and Constraint 12 is not satisfied.

The 12-fold division of the octave (and to a lesser extent the 19-fold division; see Yasser 1932) is an exception: its intervals are sufficiently close to just intervals to be useful; that is, the deviations from just intonation are not large enough to cause serious roughness from otherwise consonant intervals. The slight loss in distinctions in sensory consonance and dissonance is compensated for by the possibility of unfettered transposition. The familiar chromatic scale has presumably survived so well because it meets the demands of both Constraints 12 and 13.

At this point two routes are available, one viewing the chromatic collection (or set) essentially as a whole, the other thinking of it as material for subsets that have various musical and psychological properties. Let us review these alternatives.

One can evoke stability conditions directly from the chromatic set through a selection and patterning of different degrees of sensory consonance and dissonance. For example, Debussy's and Bartók's harmonies often 'modulate' among chord types of varying degrees of dissonance. Schoenberg was at least tacitly occupied with such a notion both early and late in his career: early, notably in the First Chamber Symphony (1906), where the basic dissonant-to-consonant progression is from a chord built in fourths to a whole-tone chord to a triad; late, in the 12-tone works of the 1940s that include tonal features, particularly at cadential points. Hindemith's (1937) theory of 'harmonic fluctuation' is based on a similar idea, generalized on a supposedly psychoacoustic foundation to embrace all possible sonorities. It is profitable to view harmonic progression in the work of Machaut and other fourteenth-century composers in such a light. Much of my own work also fits in this category.

The other route is taken by the Classical tonal system, in which the referential sonority is always the triad. Various versions of the triad alone do not project adequate differences in sensory consonance and dissonance.

Stability conditions among triads are instead achieved through the use of subsets of the chromatic set, notably the diatonic. (Historically, of course, the diatonic scale precedes the chromatic, and until Wagner it was musically paramount as well. It can be illuminating, however, to view the diatonic in terms of the chromatic.)

Balzano (1980, 1982) shows through a group-theoretic analysis that only certain equal-interval sets—the 12-fold among them—lead to subsets incorporating the psychologically important criteria of intervallic 'uniqueness', scale-step 'coherence', and transpositional 'simplicity'. All three criteria have to do with location in 'pitch space'. The first criterion demands a unique 'vector of relations' for each pitch in a subset, so that the listener can orient himself unambiguously in relation to the other pitches. For example, each scale degree of the asymmetrical diatonic subset of the chromatic set has a non-duplicating intervallic relation to the other scale degrees. In contrast, the octatonic subset (alternating half- and whole-steps), which has been widely used in this century, is not 'unique', since its vector repeats four times in an octave (this is the 'charm of impossibilities' described in Messiaen 1944). The second criterion ensures that the intervals of a scale proceed in an orderly manner, so that, for instance, the same distance is not traversed by one step in one part of a scale but by two or more steps in another part. The harmonic minor scale, not to mention more extreme examples, would thereby be disqualified, since the augmented second between the sixth and seventh scale degrees is equal in distance to the minor thirds that elsewhere take two steps to traverse; this presumably explains why the scale is avoided melodically in much diatonic music. The third criterion ensures orderly transposition of a subset. The diatonic subset, for example, drops one pitch and adds another as it transposes along the circle of fifths, so that distance in transposition correlates with the number of pitches shared in two diatonic scales.

> *Constraint 14*: Assume pitch sets of *n*-fold equal divisions of the octave. Then subsets that satisfy uniqueness, coherence, and simplicity will facilitate location within the overall pitch space.

Balzano surprisingly demonstrates that in the 12-fold chromatic set only the pentatonic and diatonic subsets satisfy all three criteria. He advances this rather than traditional psychoacoustical explanations as the reason for the cultural ubiquity of these scales; and he recommends that the few other *n*-fold divisions of the octave that permit these features (such as the 20-fold set) be explored for their musical potential. However, none of the other candidates approximates just intonation. The real cognitive appeal of the chromatic set, I would argue, is that only here do Constraints 12, 13 and 14 all converge intact. The structural features of the pentatonic and diatonic subsets would appear to be correspondingly special. (For discussion relating to this section, see Sloboda 1985; Dowling and Harwood 1986.)

Pitch space

I referred above to 'pitch space'. I want now to examine this notion with the purpose of extracting a few more constraints on stability conditions.

A number of cognitive psychologists, notably Longuet-Higgins (1978) and Shepard (1982), have proposed multidimensional representations for pitch relations.* The basic idea is that in a tonal framework pitches are cognized as relatively close to or far from one another, and that these distances can be represented geometrically. To take the simplest case, pitches are heard as proximate in terms of both pitch height and pitch class, so at least a two-dimensional representation is necessary. Another dimension can be added to account for fifth-relatedness; and so on. One can think of these representations as internalized maps. Just as cities are close to or far from home and can best be reached via some roads rather than others, so it is with tonal relations.

> *Constraint 15*: Any but the most primitive stability conditions must be susceptible to multidimensional representation, where spatial distance correlates with cognitive distance.

The geometric pitch spaces proposed in the psychological literature seem promising, but I have lingering doubts. First, granting the insights provided by Balzano (1982) and Shepard (1982), it remains odd that the chromatic collection is taken as the basis for the diatonic music they seek to explain. A second and related point is that, in pursuit of geometric symmetry, these models tend to come up with more regularity than diatonic music warrants. For example Longuet-Higgins's (1978) array has a major-third axis, and Shepard's (1982) double helix is made up to two strands of whole-tone scales. But only the semitone and perfect-fifth interval cycles are relevant to diatonic music, which is in many ways asymmetrical. Other interval cycles do not begin to assume musical significance until nineteenth-century chromaticism.

These questions lead me to suggest a complementary pitch space that has a reductional rather than a geometric format. This space is musically obvious yet has explanatory power. I take the lead from Deutsch and Feroe (1981), who speak of different pitch 'alphabets'—chiefly the chromatic, diatonic, and triadic—that the tonal listener 'highly overlearns' from previously heard musical surfaces. This in itself is an important point, since without repeated exposure to such regularities, listeners could not spontaneously organize new input in terms of them.

* Actually, there is a long tradition in music theory for such models, dating back to Weber (1824) and his eighteenth-century predecessors; see Werts (1983). Schoenberg's (1954) chart of regions, which has been cited in the psychological literature, can be traced through Riemann back to Weber.

Constraint 16: Levels of pitch space must be sufficiently available from musical surfaces to be internalized.

Deutsch and Feroe show that memory load is greatly reduced if tonal melodies are structured by means of their alphabets. As their formalism suggests, such alphabets are hierarchically related as in Fig. 10.7: the octave level *a* elaborates into the perfect-fifth level *b*, which elaborates into the triadic level *c*, which elaborates into the diatonic level *d*, which elaborates into the chromatic level *e*. In addition, pitches at higher levels in the hierarchy are more stable than pitches that do not appear until successively lower levels. This correlates with Krumhansl's (1979) experimt results. So Fig. 10.7 includes a partial representation of stability conditions.

Fig. 10.7

This pitch space circumvents the reservations mentioned above. First, the overall orientation is not chromatic. Non-well-tempered distinctions can be incorporated merely by expanding the content of level *e*, leaving the other levels untouched. Second, level *e* expresses an equal interval cycle and other unwanted equal divisions of the octave are absent.

As chords and diatonic collections change, so too must the hierarchy in Fig. 10.7. For example, in the framework of a IV chord in C major, levels *a*, *b* and *c* would shift respectively to F–F, F–C–F, and F–A–C–F. If the diatonic collection changes to that of F major, level *d* would also shift, with B flat replacing B. The structure of this shifting pitch space demands further representation, perhaps geometic in format, but we will not pursue this here.

Each level in Fig. 10.7 can be thought of as a scale with stepwise motion occurring between adjacent members. An octave is a step away at level *a*, as is a fifth at level *b*; an arpeggiation proceeds by step at level *c*; diatonic and chromatic progressions are by step at levels *d* and *e*. A skip is a progression between two elements that requires more than one step for traversal. This step/skip distinction is important for establishing cognitive distance, and was implicit in Constraint 14 above.

Fig. 10.7 can further be seen as expressing preferred melodic routes via the Gestalt laws of proximity and good continuation. A preferred route is one that is 'complete', where completeness is defined as a stepwise

progression at any level that begins and ends at elements represented at the next higher level. Thus a complete chromatic progression must begin and end on diatonic pitches, and so on. Anything else—a chromatic appoggiatura, for instance—is felt as 'incomplete'. Generally, incompleteness is more acceptable at the start than at the end of a progression; unstable elements must be subsequently 'anchored' (Bharucha 1984).

> *Constraint 17*; A reductionally organized pitch space is needed to express the steps and skips by which cognitive distance is measured and to express degrees of melodic completeness.

The notion of completeness ties in significantly with current music theories that are otherwise dissimilar. Meyer's (1973) and Narmour's (1977) implication-realization theory depends exactly on the space in Fig. 10.7: a stepwise motion at any level implies the next step at that level; such an implication can be realized or not, as the case may be. And Schenker's (1935) central conception of the *Zug*, a diatonic progression bounded by pitches of the prolonged harmony, falls out as a special case of completeness at levels *c* and *d* in Fig. 10.7. Other Schenkerian concepts (coupling, arpeggiation, the initial ascent, the *Urlinie*, the *Bassbrechung*) can be illuminated in related fashion. Completeness appears to be the basic voice-leading principle in Classical tonal music.

Two general psychological points may be inserted here. First, even if—as at the fifth, triadic, and diatonic levels—intervals along a level are psychoacoustically unequal, they are cognitively equal because they are steps at that level. Second, because each of these levels constitutes a category in terms of which the next level is understood, Miller's (1956) restrictions on memory load ('seven plus or minus two') are easily met, something not accomplished by the single category of the chromatic set.

Finally, Fig. 10.7 reflects certain psychoacoustic facts. In general, a descent from level *a* to level *e* brings increasing sensory dissonance. Level *a* gives the 'virtual pitch' (or root) of the collections in levels *b* and *c* (Terhardt 1978). Level *b* serves as the harmonic norm for medieval music and various ethnic musics, level *c* for Classical tonal music. Level *d* provides the melodic basis for many musical idioms, with level *e* offering inflectional possibilities. Thus between levels *c* and *d* there appears a conceptual line separating harmony and melody. This differentiation may in part stem from the critical bandwidth, since for most registers steps at level *c* fall outside the bandwidth and steps at level *d* fall inside.

Fig. 10.7 embodies all of the constraints on stability conditions enumerated in the last two sections: fixed collections with appropriate interval sizes (Constraints 9 and 10); octave equivalence at level *a* (Constraint 11); increasing sensory dissonance from level *a* to level *d* (Constraint 12); equal division of the octave at level *e* (Constraint 13); uniqueness, coherence, and simplicity at level *d* (Constraint 14—and,

incidentally, uniqueness and coherence at level *c*); multidimensional representation expressing cognitive distances (Constraint 15); levels of pitch space that are easily induced from a wide variety of musical surfaces (Constraint 16); and steps, skips, and degrees of melodic completeness at multiple reductional levels (Constraint 17). The cultural persistence of the many musical idioms relating to Fig. 10.7 may be due to this convergence.

Some of these constraints seem to me binding, others optional. Constraints 9–12 are essential for the very existence of stability conditions. Constraints 13–17, on the other hand, can be variously jettisoned. The resulting stability conditions may be weaker, but they can still lead to hierarchically rich music. For example, South Indian music approximates just intonation and does not modulate, thereby ignoring Constraint 13 and part of Constraint 14; Debussy, Bartók, and others have developed consonance-dissonance patterns directly from the total chromatic, thereby ignoring Constraints 14–17. It will be fascinating to discover how the new sound materials of computer music will be able to meet these constraints. In all probability the new materials will bring additional requirements into play. Meanwhile there remains ample leeway within the chromatic collection and within the constraints listed above for music as yet unimagined.

Cognitive opacity of serialism

Now we are in a position to see why serial organizations are inaccessible to mental representation. Rather than explore the subject through the idiosyncratic serialism of *Le Marteau*, I will refer to elementary aspects of the Classical 12-tone system, which has been more widely influential (Schoenberg 1941). I will give three causes for serialism's cognitive opacity.*

Before proceeding, I must emphasize that the issue is not whether serial pieces are good or bad. As with tonal music, some serial pieces are good and most are bad. Nor am I claiming that listeners infer no structure at all from musical surfaces composed with serial techniques. What listeners in fact infer from such surfaces is an interesting question, one that deserves theory and experiment in its own right. But this is not the issue here. The issue is why competent listeners do not hear tone rows when they hear serial pieces.

The first reason is that serialism is a permutational rather than

* It must be said that, if only from the evidence in Schoenberg's 12-tone sketches (Hyde 1980), Schoenberg's (1941) account of the 12-tone system is partly misleading. Plainly he used the system not just to generate rows but to create certain systematic but non-serial relationships among subsets. This, however, does not affect my argument, which concerns the cognitive opacity of serial structures (tone rows) as such.

elaborational system. Pitch relations in virtually all 'natural' compositional grammars are elaborational. Take for example the pitch sequence B–E–F sharp. It is easy to imagine any number of melodic embellishments internal to the sequence. This typically happens when children sing and performers improvise. Like the syntax of a sentence (Chomsky 1957), musical elaborations can continue recursively to an indefinite level of complexity; for example, sonata form is an expansion of the Classical phrase (Schenker 1935: Rosen 1972; Lerdahl and Jackendoff 1983). This feature enables pitch relations to be described hierarchically by a tree notation.

Serialism instead depends on specific orderings of the elements of a set. Distinctions arise from permutations of the elements; for example, the inversion of a 12-tone row has the same 12 pitch classes but in a different order. The order position of the elements is therefore essential to the identity of individual set forms. From this it follows that internal elaboration of any element by other elements will undermine a set form. Consider the row of Schoenberg's Violin Concerto (1936), shown in Fig. 10.8 with order numbers given above. The sequence B–E–F sharp appears at order numbers 3–5. If one wanted to elaborate E, say, with G or with B flat–A, creating the sequences B–E–G–E–F sharp or B–E–B flat–A–E–F sharp, the integrity of the row would be destroyed, since G, B flat, and A have order positions elsewhere in the row. A tone row is not an elaborational structure. (The same point could be made with reference not to elements but to the intervals between elements.)

Order number:	0	1	2	3	4	5	6	7	8	9	10	11
12-tone set:	A	B♭	E♭	B	E	F♯	C	C♯	G	A♭	D	F

Fig. 10.8

The little research that has been directed towards serialism (as in Francés 1958; Dowling 1972; Deutsch 1982; Bruner 1984) supports the contention that permutational structures are hard to learn and remember. Since other human activities are not organized in such a fashion, it is hardly surprising that the issue has in general been ignored by psychologists. The situation reminds me, though, of Chomsky's (1965) observation that many logically possible grammatical constructions never occur, such as forming interrogatives from declaratives by word reversal or by exchange of odd and even words. There is unfortunately no one on whom to test these linguistic counter-examples. Music offers a unique opportunity in this regard. Surely children can be found who have been raised on a steady diet of serial music. Do they identify tone rows? A negative answer will provide strong counter-evidence concerning the structure of musical cognition, and may suggest inherent limitations on cognitive organization in other domains as well.

Ironically, Schoenberg was much preoccupied with the issue of compre-

hensibility. I suspect this is one reason why in his 12-tone phase he adopted Classical motivic, phrasal, and formal structures. As a result, his serial music satisfies the rhythmic Constraints 3–6. But the permutational basis of his pitch organization assures a gap between the compositional and listening grammars.

It is of course possible to organize the combinations and sequences of individual rows on a hierarchical rather than permutational basis. Boulez, Babbitt, and others have done just that. But these higher-level hierarchies are extremely difficult to cognize in a hierarchical fashion because their underlying basis, the row, remains non-tree-like. There are further reasons as well, which brings us to the other causes of serialism's cognitive opacity.

The second cause is the avoidance of sensory consonance and dissonance as an input to the system (Constraint 12). This avoidance in turn stems from the historical collapse of the stability conditions underlying Classical tonal pieces. The pre-serial atonal period had established an aesthetic in which hierarchical pitch relations gave way to purely contextual, associative ones. The 12-tone system reinforced this trend through constant reshuffling of the total chromatic and through constant repetition of the intervallic patterns of the row. Concerned about the natural basis of his new aesthetic, Schoenberg (1911, 1941) invoked the doctrine of the 'emancipation of the dissonance': consonance and dissonance are not opposites but are on a continuum determined by the overtone series; dissonances are harder to comprehend than consonances; but aquaintance with the more remote overtones has made dissonant intervals just as comprehensible as consonant intervals; so now intervals may be treated as equally consonant (or dissonant). Babbitt (1965) goes a step further, debunking the overtone series as a basis for pitch systems and claiming that consonance-dissonance distinctions among intervals are entirely contextual in origin.

Neither Schoenberg nor Babbitt distinguishes between sensory and musical consonance and dissonance. Though the details of pitch perception are not fully resolved, there is no doubt about the objective existence of sensory consonance and dissonance. For intervals between pitches with harmonic partials, the degree of sensory dissonance bears an important relationship to the overtone series, by virtue of the degree of interference among partials within the critical bandwidth. Thus far Schoenberg, at least, is right. What one does with this musically is another matter. Classical tonality founds musical consonance and dissonance largely on sensory consonance and dissonance (partial exception must be made for the perfect fourth, the minor triad, and so on). Serialism, on the other hand, treats intervallic combinations in terms of the row and in effect defines musical consonance and dissonance out of existence (with the glaring exception of the octave: pitch classes are needed). But this strategy, while perfectly logical, does not neutralize sensory consonance and dissonance. The sensory dissonance of a seventh remains greater than that of a sixth,

regardless of the musical purposes to which these intervals are put.

There is an important psychological consequence: by ignoring sensory distinctions, serialism creates musical contexts that are not apprehended hierarchically. One pitch or hexachord may be associated with another pitch or hexachord, but these relationships are not easily heard in a dominating-subordinating manner. The requisite intuitions of stability and instability are missing. And because hierarchies are not inferred, tone rows and their combinations are difficult to comprehend (Constraint 2).

The third cause is that serialism does not induce a pitch space where spatial distance correlates with cognitive distance (Constraint 15). Assume for simplicity that serial pitch space looks like the 'combinatorial' space shown in Fig. 10.9 for Schoenberg's Violin Concerto. Here the first six pitch classes of the inverted set, transposed up five semitones, are identical to the second six pitch classes of the prime set, though in a different order. For a variety of reasons such a space was useful to Schoenberg (see Schoenberg 1941). A complete 12-tone pitch space would include transpositions of this and other relationships, just as the tonal space of Fig. 10.7 would have to be enlarged for other chords and regions.

P0:	A	B♭	E	B	E	F♯	C	C♯	G	A♭	D	F
I5:	D	C♯	A♭	C	G	F	B	B♭	E	E♭	A	F♯

Fig. 10.9

One might suppose that a 'step' in such highly chromatic music is a semitone. But this is not reflected at all in the pitch space of Fig. 10.9. Or, more in the spirit of the row, one might say that a 'step' occurs from any pitch class to any horizontally adjacent pitch class. But in this case step distance varies wildly from one adjacency to the next, and there is no correlation with psychoacoustic (log frequency) distance. In short, serialism does not incorporate any psychologically coherent notion of step and skip. The listener consequently has difficulty locating a pitch as close to or far from another pitch.

Further causes of serialism's cognitive opacity could be adduced, such as its failure to provide consistent exposure from piece to piece to a limited number of 'alphabets' (Constraint 16). But the main points have been addressed. We turn now to some aesthetic issues that have been lurking behind this entire discussion.

Comprehensibility and value

There is no obvious relationship between the comprehensibility of a piece and its value. Many masterpieces are esoteric, while most ephemeral

music is all too comprehensible. On the other hand, if a piece cannot be understood, how can it be good? Most would agree that comprehensibility is a necessary if not sufficient condition for value.

Care must be taken with this formulation in three respects. First, comprehension presupposes listening competence for the music in question. This competence varies with ability and especially with exposure, but is not less real for that. Second, comprehension pertains to the listening grammar rather than to the compositional grammar. A serial piece may be understood in non-serial ways. Third, we are talking about intuitive rather than analytic comprehension. Along the lines of Fodor (1983), the mind's music module must be able spontaneously to form mental representations of musical structure from musical surfaces. This is quite different from using the all-purpose reasoning faculty to figure out the structure of a piece.

With these provisos in mind, I think the above formulation stands. Appreciation depends on cognition. I now want to go an aesthetic step further.

> *Aesthetic Claim 1*; The best music utilizes the full potential of our cognitive resources.

This seemingly innocuous statement carries weight because a great deal is becoming known about how musical cognition works. I have outlined aspects of this understanding in the constraints presented above. Following them will not guarantee quality. I maintain only that following them will lead to cognitively transparent musical surfaces, and that this is in itself a positive value; and, conversely, that not following them will lead in varying degrees to cognitively opaque surfaces, and that this is in itself a negative value.

This stance can be refined through the notion of musical 'complexity', which is to be contrasted with musical 'complicatedness' (Lerdahl 1985). A musical surface is complicated if it has numerous non-redundant events per unit time. Complexity refers not to musical surfaces but to the richness of the structures inferred from surfaces and to the richness of their (unconscious) derivation by the listener. For example, a grouping structure is complex if it is deeply embedded and reveals structural patterns within and across levels. The derivation of such a structure is complex if all the grouping preference rules come into play and if they conflict with one another to a certain degree. (Total reinforcement of the rules would produce a stereotypical grouping structure; total conflict would create intolerable ambiguity.) I take complicatedness to be a neutral value and complexity to be a positive one. Many musical surfaces meet the various constraints, but only those that lead to complexity employ 'the full potential of our cognitive resources'.

All sorts of music satisfy these criteria—for example, Indian raga,

Japanese koto, jazz, and most Western art music. Balinese gamelan falls short with respect to its primitive pitch space. Rock music fails on grounds of insufficient complexity. Much contemporary music pursues complicatedness as compensation for a lack of complexity. In short, these criteria allow for infinite variety, but only along certain lines.

I find this conclusion both exciting and—initially, at least—alarming. It is exciting because psychology really does have something substantive to say about how music might be; here is the foundation I was seeking. It is alarming because the constraints are tighter than I had bargained for. Like the old avant-gardists, I dream of the breath of other planets. Yet my argument has led from pitch hierarchies (Constraints 7–8) to an approximation of pure intervals (Constraint 12), to diatonic scales and the circle of fifths (Constraint 14), and to a pitch space that prominently includes triads (Constraint 17).

However, the constraints do not prescribe outworn styles. Rather they provide a prototype (Rosch 1975). Let me first give an uncontroversial rhythmic example. A musical surface in which the note values are multiples of 2 is intrinsically more stable and easier to cognize than one in which the note values are multiples of 7 and 11. This does not mean that the latter surface is somehow impermissible. It instead amounts to the observation that, because of the resultant ease in forming a metrical structure, note values that are multiples of smaller prime numbers are easier to process and remember, and therefore that multiples of 2 (or 3) inevitably remain a cognitive reference point for more complicated rhythms. I claim that a similar situation holds for pitch: the structure in Fig. 10.7 (with its hierarchically organized octave, fifth, triad, and diatonic scale) remains a reference point for other kinds of pitch organization, not because of its cultural ubiquity but because it incorporates all of the constraints developed above. I take this as a given, with or against which a composer can play creatively. Of course one may opt for a less constrained pitch space. But if a composer chooses the space represented by Fig. 10.7, I am sure there are innumerable and radically new ways to use and extend it. The future is open.

My second aesthetic step was discussed above; I list it here only for completeness.

> *Aesthetic Claim 2*: The best music arises from an alliance of a compositional grammar with the listening grammar.

This claim does not exclude the artifice hidden in a Bach fugue or a Brahms intermezzo. Such artifice is rooted in the bedrock of a 'natural' compositional grammar. At our present musical juncture, however, composers would do well to heed the claim.

This claim carries with it a historical implication. The avant-gardists from Wagner to Boulez thought of music in terms of a 'progressivist'

philosophy of history: a new work achieved value by its supposed role *en route* to a better (or at least more sophisticated) future. My second aesthetic claim in effect rejects this attitude in favour of the older view that music making should be based on 'nature'. For the ancients, nature may have resided in the music of the spheres, but for us it lies in the musical mind. I think the music of the future will emerge less from twentieth-century progressivist aesthetics than from newly acquired knowledge of the structure of musical perception and cognition.

From collections to structure: the developmental path of tonal thinking

LYLE DAVIDSON and PATRICIA WELSH

Imagine three musicians composing a piece. Each is seated at a piano; manuscript paper is on the music rack; pens are alongside. The first musician plays some notes on the piano, erases a few notes he has already scribbled on the manuscript paper, and replaces them with new ones. He continues in this manner until he finally completes the melody. After completing it, he plays it on the piano, immediately starts revising it, rubbing out whole sections. He stops before finishing and goes for a walk. The second musician spends some time staring at the blank manuscript paper, plays a few notes over and over on the piano, and after a few false starts writes out the complete melody on paper. During the final playing of the melody on the piano his finger slips and he hits a 'wrong' note. Immediately, he is interested in his mistake. He incorporates the 'error' into his written melody, replacing the original note. The third musician scans the page, checks the pen, thinks a moment, and writes out the melody without hesitation, as if taking down dictation.

These three working styles represent those of well-known composers. It is easy to imagine Beethoven, Stravinsky, and Mozart hard at work, creating significant musical compositions, solving complex musical problems. But at the same time, it is difficult to imagine the thought processes which supported their efforts. We know only that each composer had a very different working style and the working styles themselves tell us very little beyond the fact that there are different ways of composing.

If we replay the scene, and specify the task, 'compose a melody which starts in one key, modulates to a specific key, and returns to the original key at the end', our interpretation of these working styles changes. We expect composers of the stature of Beethoven, Stravinsky, or Mozart to be able to dash off such a melody easily. However, it is easy to imagine

inexperienced musicians having trouble with this task. Young musicians writing such a melody might show working styles very much like those described. Furthermore, the working styles now take on additional meaning. Under these circumstances, it is relatively easy to imagine the working style of the beginner, the intermediate, and the expert. Different working styles can reflect different levels of skill.

Tasks similar to this one are common in music schools. While the writing of melody is rarely studied, work in harmony and counterpoint focuses on specific aspects of composing within a tonal framework. These studies are a standard part of professional training for the classically oriented musician. However, little is known about the mental and cognitive processes which support different orientations to the musical task of writing a melody which modulates. There are two reasons for this. First, melody writing has not been systematically studied. Second, in music schools, musicians tend not to be interested in the processes involved in arriving at solutions to musical problems, but only in musically successful products.

Perception and production of tonality

While musicians are more interested in production, psychologists take a different tack. They focus on the perception of tonality by untrained individuals. Several studies have compared the recognition of melodic shapes which form tonal patterns to those which form atonal patterns (Frances 1958; Dowling and Fujitani 1971; Zenatti 1975; Cuddy and Lyons 1981). These studies consistently report that tonal patterns are easier to process, recognize, and recall than atonal patterns. Still other work suggests the presence of tonality plays a central role in our perception and cognition of richer musical contexts. Research indicates that the components of melodic textures are easier to grasp when they are in the context of closely related keys than in more distantly related keys (Sloboda and Edworthy 1981).

Apparently, little training is needed to establish highly useful tonal schemata when perception is required. Krumhansl (1979) shows that scales are highly stable mental structures even for untrained listeners. Her work also suggests that relationships between keys parallel those of the notes of the diatonic scale (Krumhansl *et al.* 1982). Taken together, these various studies indicate that tonality and scales are powerful psychological structures which play an important role in our comprehension and enjoyment of music.

It seems clear that adults spontaneously employ the principles of tonality when they perceive melodic structures. But we should not assume that they spontaneously use that same tonal knowledge when they invent or compose even simple melodies. Indeed, except for the work of Bamberger,

we know very little empirically about how the perception of tonality is employed in the construction of tonal musical structures.

Bamberger (1986) finds that children construct tonal melodies on a set of bells in very different ways. For example, when constructing melodies from a chromatic collection of bells, some subjects physically separate the bells with pitches which do not 'fit' the tune they are attempting to play from those bells that sound notes in the tune. In doing so, they place the bells in the order in which they are played in the melody. Performance of the melody then means playing the bells in order from left to right. Another strategy these subjects use when making a tune is to select one bell for each sound of the melody. For example, the first three notes of 'Row, Row, Row Your Boat' would require three different bells using this strategy, even though all three notes are the same and could be played on a single bell.

In contast to those subjects, subjects of another group first position the bells to make a scale, then play the tune in an action path which maps the sequence of pitches of the melody on to the pitches of the scale pattern. Similarly, these same subjects simply restrike one bell to produce repetitions of pitches. Bamberger suggests that these very different strategies for finding the notes for an already known tune reflect the different levels of musical knowledge held by novice and gifted children.

Domains as arenas for solving problems

Psychological research makes it clear that developmental studies of skill and cognition have much to offer for developing a more articulated understanding of a domain. Differences between the responses of subjects with different levels of ability provide windows on the subskills and foundations of specific skills involved in relatively simple tasks. For example, looking at the difference between novice and expert chess players has told us much about the nature of the knowledge required for the game, its representation, and how chess players use that representation to process new bits of information, make decisions, and orient themselves to subtle differences in patterns of information (DeGroot 1965, 1966). The tools of cognitive psychology and artificial intelligence have been used to look at other domains as well (Simon 1979).

The information gained in these studies is due in part to the use of protocols and protocol analysis and in part to the design of the questions guiding the interpretation of the protocols (Simon 1979). While this paradigm is not traditionally experimental, it has been extraordinarily useful in unravelling various aspects of cognition—for example, the creative process (Perkins 1981). Perkins observed poets in the process of

writing poems, and he highlights the role of everyday perception, reflection, and production in the creative process.

Combining the approach taken by Perkins, and including a developmental component, we can define and unravel still more of the mysteries of tonality. A great deal can be learned by studying musicians in the process of writing a modulating melody. Comparing musicians who have a sophisticated knowledge of tonality with those who do not can shed light on the underlying constructs of tonality. A musically and psychologically interesting task, it provides an opportunity to see how novices and experts think in a key, weaken one tonal centre, and strengthen another.

In addition to identifying developmental profiles, we hoped to be able to identify various problem-solving strategies. One might expect to find strategies in musical composition similar to those reported in studies of general problem solving (Johnson-Laird and Wason 1977), especially since the use of 'means-ends analysis' (breaking the larger composition problem into a series of subproblems) is routinely taught as a strategy in harmony and counterpoint classes. One might anticipate other heuristic procedures for compositional problem solving as well.

We also wondered about the prerequisites for the tonal understanding necessary for a simple composing task. Is the ability to play an instrument sufficient to enable one to compose melodic shapes which reflect tonal knowledge? Does the tonal knowledge acquired with advanced performance ability transfer to the composition of a tonal melody?

Novice and expert solutions to a musical problem

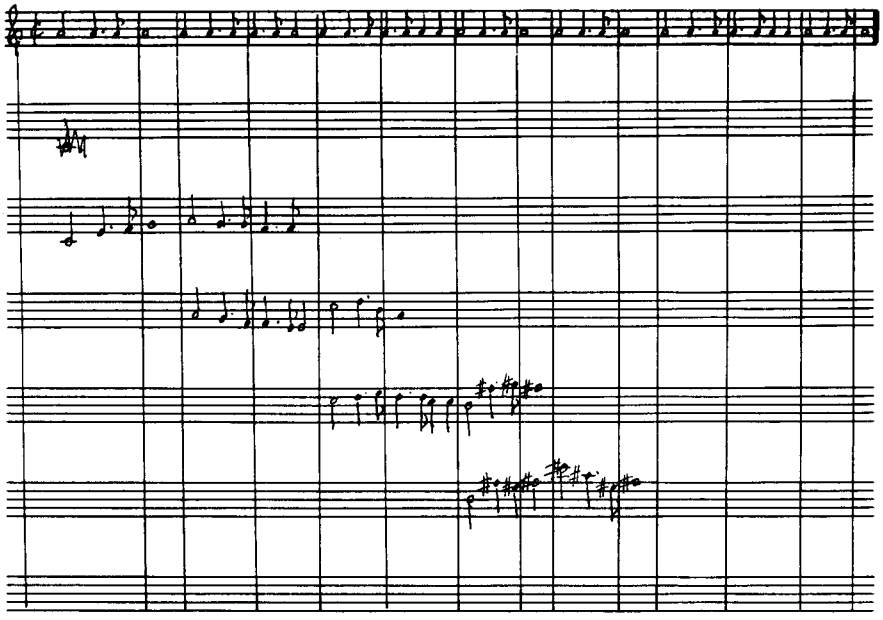
We chose a composition task because it allowed us to observe the process of constructing tonal relationships. Many different ways of observing subjects composing modulating melodies were considered before the final version was designed. One approach considered was that of asking students who were studying composition to allow us to observe while they wrote melodies which modulated. This task would provide subjects who were accustomed to writing, but it would not allow us to control for individual differences which might arise between composition students over issues of metre, key, rhythm, length, phrase structure, or style. More importantly, it failed to recognize the possible biasing which personal writing habits might introduce into the task. For example, one composer might not be accustomed to writing tonal music at all while another might be acustomed to making melodies that were tonal but which moved only to certain keys and not others. For these reasons, we decided two things—first, not to include composers in the study and second, to control for variables which were not central to the issue of tonality. These variables included the length of the melody and the rhythmic durations to be used.

The rhythm of the melody was controlled by using a rhythmic structure modelled on the first section of the march by Schubert, Op. 27 No. 1. The rhythmic pattern, in 2/2 metre, was 14 measures long. The rhythmic shape allowed different interpretations of the phrase structure while providing the opportunity for constructing melodic motives. This rhythmic pattern

Example 11.1

created a 'shell' which the subjects filled in with notes they determined to be necessary to fulfil the requirements of the task.

It was also necessary to specify the nature of the modulation. If we left the modulation unspecified, we ran the risk of every one making a favourite and presumably well-practised key shift, or relying on their memory of a specific modulation from a specific piece as a model. Because we wanted to draw out the principles on which beginners and more experienced music students relied, we decided to ask for a relatively rare and unpractised modulation.



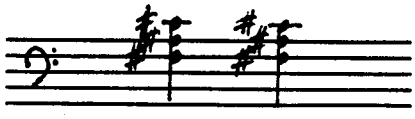
We controlled for the modulation by requesting a melody which would move from the tonic to the key a tritone away and back to the tonic. This provided three specific areas within the task where tonal thinking could be observed: the opening of the melody (to determine how the first key was established), the transition into the new key (to observe how the stability of the first key was undermined and the second key established), and finally, the ending of the melody (to determine how the return to the first key was negotiated). Interest was sharply focused on the areas in which the key was established or undermined. In this way, we could observe the ebb and flow of tonal support around specific points of reference.

Conditions of the study

Ten music students took part in the study. They were all performers and were assigned to one of two groups. Five students were in their first year of conservatory study (we shall refer to this group as 'beginners'). Their average age was 20, and they had studied an instrument, on average, for six years. The second and more experienced group of students had an average age of 22 and all had undergone two years of training at the conservatory (we shall call these students 'experienced').

At the beginning of the session individual students were seated at a piano and given a sheet of 12-staff manuscript paper. The rhythmic pattern was written in the second space of the top staff. The remaining staves were sectioned into measures corresponding with those of the rhythm, but were

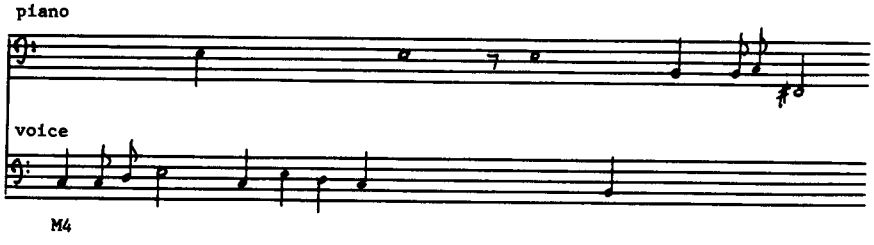
otherwise blank. All subjects were asked to 'use the rhythmic pattern at the top of the page and write a melody starting in the key of C major, passing through the key of F sharp major, and closing in C major.' A pen was provided and subjects were instructed to make all revisions in the measure immediately below their initial choice (see Example 11.2). They were requested not to cross out any of their work. The subjects were asked to talk aloud as they worked and to explain what they were considering at each step of the process; they were also instructed to use the piano whenever they wished. The task had a time limit of 30 minutes; subjects were not informed of this limit, but were stopped after 30 minutes had elapsed. The entire session was tape-recorded and an observer was present.



Example 11.2

Later, the second author made a transcription of each session which organized the student's activity in a chronological manner. The transcriptions were based upon the tape-recordings of the sessions, the notes of the observer, and the music manuscript pages on which the students notated their melodies and made their revisions.

Below is an excerpt from the transcript of a beginning student. The transcription excerpt begins just after this student has completed the first four measures of his melody. He has written those measures in C major.



When the student replays material already written down it is designated beneath the music as M1, M2, etc., for measure 1, measure 1, and so forth. In all examples of playing or singing, the rhythmic notation is proportional and reflects only relative durations.

Example 11.5

Writes measure 5

The sessions were analysed on the basis of categories which took into account several aspects of the composition process. These categories focused upon working procedures, rhythmic and tonal considerations, and the overall success of the activity and its final melody. The specific categories were:

(A) Size of the working unit
(B) Generation of new melodic material
(C) Integration of rhythm into the working process
(D) Use of motivic relationships
(E) Orientation to the first key
(F) Transition to the new key
(G) Return to the home key
(H) Efficiency of the modulation process
(I) How a key is defined
(J) Strategies
(K) Success of melody

The analysis was carried out by the two authors independently; a high degree of reliability was achieved. For measure (J), strategies, the transcripts were examined for evidence of strategies and both scorers had to agree on the specific strategy being used. For measure (K), success of melody, seven musicians rated the melodies independently. The definitions of each analytic category and the findings for each category are presented in the results section which follows.

Results

In this portion of the paper, we first consider general features of the working style. These features are the size of the working unit, sequence and manner in which melodic material is generated, the role of the rhythm in the process of constructing the melody, and the degree to which motivic relationships are used in the melody. After we examine the profile of working styles, we consider the issues of tonality. The tonality measures discussed include the orientation to the first key (C major), the location of the cadences (in C and F sharp), the location of the first indication of key change (in C and F sharp), and how tonalities are defined while composing this melody. Finally, after the discussion of strategies used while composing the melody, we consider the transfer of knowledge of tonality acquired through performance to the compositional task.

General working style

Size of the working unit

One of the findings from the 'novice-expert' literature suggests that the

amount of organized information at an individual's disposal is dependent, at least in part, on the level of that individual's experience (DeGroot 1965, 1966). The key word is 'organized'. The expert sees patterns of organized information where the novice sees only unrelated details. In music composition, the amount of information an individual works with at any single moment can also be an index of the level of development. Presumably, the novice will be able to work with only the immediate context or next note, while the more developmentally advanced musician will be able to chunk information into larger units and to work more efficiently—projecting further ahead and reflecting further back while at the same time holding the moment of focus in place. This makes it possible for the expert to consider immediate contextual issues and the degree to which a specific instance is forecast by earlier moments of the composition, and to develop a higher degree of motivic organization than the novice would be able to achieve. Consequently, we kept track of the size of the frame of reference within which individuals worked. We refer to this as the 'size of the working unit', which measures the area to which a subject made either verbal or behavioural reference during the task. There are five levels in this measure: (1) note-to-note, (2) measure-to-measure, (3) two-measure chunks, (4) three-measure chunks, and (5) whole phrases.

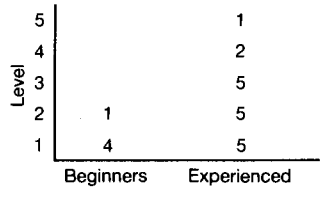

Fig. 11.1. Size of the working unit.

The size of the working unit proved to be a useful measure for distinguishing among the subjects. The scores reflect the magnitude of the differences between the first-year students and those in the more experienced group. Four of the five beginners used only the note as a working unit, while the third-year students all used two entire measures as a working unit at least once during the session. Furthermore, the more experienced subjects used much more variation in the size of the unit they employed when they constructed their melodies. At some time during the task, all of the third-year students used the next note, and one- and two-measure chunks. In addition, two of these subjects once used a three-measure unit, and one spoke in terms of an entire phrase. In contrast, the first-year students were less flexible in their ability to look ahead and to use units of various sizes. Specifically, four of the beginners usually looked

only to the next note. One was able to occasionally use a whole measure as a unit of focus.

Generation of new material

The order or sequence in which a mature composer might work on a piece is largely unexplored. Obviously, one can work in many different ways. One might work on different places at once, shuttling back and forth between one area and another throughout the compositional process; another might systematically write in a front-to-back order. There is no reason to expect that one procedure is superior to another. However, one might expect to see evidence of more back-and-forth movement (more flexibility) in the experienced students, but more beginning-to-end movement (less flexibility) in the beginning students.

When we looked at the sequence in which the new material was generated we saw two different patterns. The beginners normally worked in a left-to-right order, usually playing back only within a local context. The experienced students also worked left-to-right, but when they played back their results they were careful to connect the new material to larger chunks—the previous measure or phrase—or even to the beginning.

How composers generate new ideas or the next chunk of music is also largely unexplored. Sloboda's analysis of his own compositional process is one of the few attempts to look systematically at this important issue (Sloboda 1985). We did observe the first-year students generating new ideas, but the processes of the experienced students proved to be more elusive.

The first-year students' reliance on an enactive, sensory-motor mode of generating new melodic material was striking. They would often begin by playing or writing out a melodic shape and then get stuck. Once stuck, they would abandon their plan and start to explore ways of getting from the note they last wrote down to the next one of the rhythmic pattern. Remarkably, they often did this by letting their fingers sound the notes between two goal pitches, sometimes slowly playing all the semitones between. It is immediately striking that *all* of the first-year students, but *none* of the third-year students, let their fingers lead in this way when searching for the next note or bit of melody.

It was more difficult to determine how the experienced students were generating new material. They would more often consider the next part of the rhythmic pattern, and then write out or play a fully developed bit of melody. Clearly, they were able to consider the contextual constraints and generate pitch shapes and integrate them into the rhythmic pattern, as well as reflect on the effect without committing themselves to a solution.

Integration of rhythm into the working process

The ability to integrate the given rhythm into the compositional process

proved to be another useful index of difference between the two groups. When the beginners were engaged in the process of generating melody, they ignored the given rhythm entirely. On the other hand, all of the more experienced students used the given rhythm in the compositional process. In addition, when playing the completed melody at the end of the task, none of the beginners played the pitches consistently in rhythm, while the experienced students always played their melodies back in rhythm.

Use of motivic relationships

The rhythmic shape given as a control in this study suggests many possible motives and therefore allows the possibility of establishing and strengthening the formal relationship between the opening and the ending of the piece. The use of melodic motives is not only a powerful means of achieving structural unity and contrast, but their use also reflects the ability to think in larger structural chunks.

One of the beginners and four of the experienced students used the rhythmic pattern as a source of motivic material.

How a tonality is defined

The centre of the study was tonality. Measures of tonal thinking included the orientation to the first key, transition to the new key, return to the home key, the relative efficiency of the modulation process, and how a key was defined. Other topics included the degree of difficulty in changing key and the way in which notes were used to define a key in the introduction as well as during the composition of the melody.

Orientation to first key

During the first moments of the task, students were in the process of defining the problem for themselves; trying out different ways of establishing the first key and testing the distance to the second key. Five behaviours occurred during the opening:

(1) Establishing the key by repeating the tonic note of the scale;
(2) Establishing the key by extending the duration of the tonic note of the scale;
(3) Establishing the key by using tonal formula, for example, scale degree motion from 7 to 1;
(4) Establishing the key by using scalar motion;
(5) Establishing the key by using the notes of the scale to suggest long-range tonal relationships, specifically by starting on a weaker portion of the scale, thereby preparing a smoother transition to the new key.

There was a sharp distinction between the two groups on this measure.

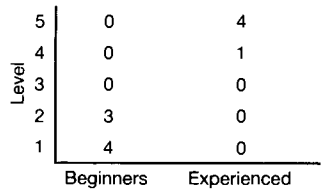

Fig. 11.2. Orientation to the first key.

Entrance of the modulation

Each student had to determine from the given rhythmic structure where critical tonal shifts had to be made in order to meet the modulation requirements of the task. The location of first indication of modulation is important because it provides an index of how the problem is interpreted, how the boundaries of key are determined, and how the moment of modulation is defined.

Six of the 10 students (three of the beginners and three of the experienced students) placed their first accidental in measure 4; no one used an accidental before measure 4. Four students placed the first accidental of their modulations after measure 4.

Most students tended to make the first move of the modulation in the fourth measure. This suggests they recognized the traditional phrase structure implicit in the rhythmic pattern.

Location of cadence in F sharp

The location of the cadence in F sharp is critical. If it occurs too early, the second key is too prominent. On the other hand, if it appears too late in the melody there is not enough time to get back smoothly to the home key of C major. The rhythmic structure suggests a cadence would be best placed at measure 8. All of the beginning students made a cadence in F sharp at measure 8. Three of the experienced students also made the cadence in this measure.

Return to the home tonic and the ending

This measurement has three levels. Level one places the moment of modulation at bar 8, and level two places the moment of modulation at bar 10, while level three indicates the modulation took place at some other point (see Fig. 11.3).

Economy when making a modulation

We expected that students who did not have strong and flexible representations of tonal structures would find it difficult to make a

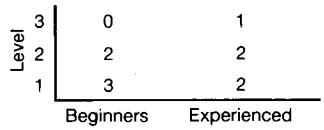

Fig. 11.3. Return to the home tonic.

modulation. They would not be able to easily and quickly create the tonal shift necessary to effect a new key. Consequently, we anticipated that the first-year students would use many more trial-and-error attempts to make a modulation than the more experienced subjects. We measured the students' efficiency by counting the number of notes played between the first written accidental and the cadence in the new key. There was a significant difference between the two groups of students.

The first transition was defined as the area between the first written accidental in the first section (C major) and the cadence goal on the key of F sharp major. The beginners played or hummed an average of 232 notes while composing this portion of their melody, while the experienced students averaged only 72 notes.

The second transition was defined as the area between the cadence on F sharp and the clear statement of C major at the end of the piece. Beginners sounded an average of 132 notes in the course of writing this section, in contrast to an average of 92 notes for the experienced students. The first-year students had great difficulty negotiating the shift of keys from C major to F sharp major, and somewhat less difficulty moving from F sharp major back to C major. Interestingly, the experienced students had somewhat more difficulty returning to C major than moving away from it.

Definition of key

There are five levels in this measurement. These levels chart the distance between between treating notes as mere collections of pitches to simultaneously considering the tonal value of each note in relation to both keys required for the task.

Level (1) Collection of notes without any specific order; key is defined by an aggregate of pitches common to the scale but not necessarily used in a way that suggested a tonal framework.

Level (2) Key defined only by local emphasis on the tonic of the scale; other notes of the scale are ignored. Focus is created by the (frequency of occurrence or) repetition of the tonic note, or by the duration of the tonic triad.

Level (3) Key defined by the use of a scheme (any of several functional chunks such as 'leading tone' function, or triad shape). This level is an

extension of level (2), in which the knowledge of a triad or a scale degree function is fixed, for example, scale degree 7 is transposed as a unit with sd 1 (7–1 in C, then 7–1 in F sharp), or as a triad (1–3–5 in C [C–E–G], then in F sharp [F sharp–A sharp–C sharp]).

Level (4) Key defined by using specific transferable relationships within the context of different keys. Specifically, this includes the use of dominant-to-tonic relationships, and the use of pitches as part of small scalar fragments. This reflects an understanding of the relation of pitches to a local tonic.

Level (5) This level shows the use of single pitches to suggest different scales. A pitch may be chosen because of its relation to the local tonic *and* the target or goal tonic. A common example of this level is to start the melody on a weak scale degree, thereby heightening the likelihood of a smooth transition to the second key. Pitches are chosen which can suggest the local tonic while forecasting other tonics, scales, and scale degree functions, for example using sd 6 (A) as a starting point because it can also function as sd 3 in F sharp minor.

Figure 11.4 shows the frequency of use for each level by each group.

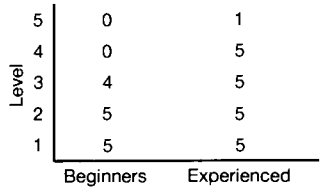

Fig. 11.4. Definition of key.

To summarize the results of looking at working styles, clearly, there are differences between groups. It is possible to show contrasting profiles of the two groups on the basis of the differences between them on a variety of measures. The groups differed significantly in the number of notes which they used to make the transition between the two keys. There were also differences in the ability to separate the identity of a note when it had a specific function, for example, a note as a leading tone, and the function of 'leading tone' in general. The beginning students had difficulty finding the leading tone of F sharp major because they tended to confuse it with the leading tone of the scale of C major. Similarly, none of the beginning students were able to use the note 'B' to mediate between the two scales (even though it is the single common tone between the two keys). In contrast, the members of the more experienced group were easily able to find and use the common tone as a means of entering or leaving either key.

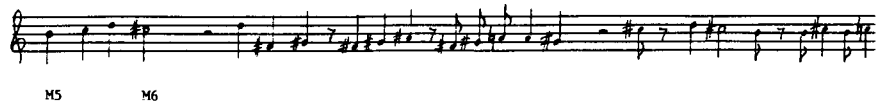
Strategies

The differences in working styles, defined by the size of working unit, the work sequence, and the integration of rhythm and pitches when composing the melody, were supported by a wide range of strategies. Several strategies have family resemblances which enable us to group them into categories.

The strategies can be arranged to form a three-step scale from the least sophisticated (level (1)) to the most sophisticated (level (3)). The less advanced strategies tend to rely only on local features or single, uncoordinated attributes, while more advanced strategies require the ability to consider moments of the task from the perspective of the structured whole.

First-level strategies

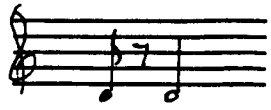
The first level contains the strategies used by the five beginning students. These are the most local of all the strategies observed, and they tend to focus on single attributes. They include the use of repetition of a single note, a heavy reliance on the use of sensory-motor or finger knowledge when finding new notes, and the use of a simple 'next-to' rule which defines the extent the beginners look ahead or back when they co-ordinate the notes on which they are currently working. That is, the beginners tended to compare what they were working on with only the immediate notes rather than phrase-length units.



One striking characteristic of this level of strategy is the reduction of the working unit to the immediate context. The field of vision and hearing appears to be restricted to the notes on either side of the one(s) being worked on at the moment. It is especially difficult to achieve a high degree of integration when working in this bit-to-bit manner. Only by ignoring the rhythmic durations of notes is it possible to weigh each note in relative isolation. Because each note occupies the same amount of attention, the effect of shorter and longer durations on the tonal weight a pitch may receive is either not realized or not taken into account during the composition process. It is easy to observe that the beginners fail to understand the tonal implications of the given rhythmic series.

Sounding a note and repeating it is an early means of either establishing a tonally weighted note, such as the tonic note of a scale, or of filling up a space of musical time. Another beginning strategy is the reliance on whatever falls under the fingers when generating new material. The uncritical acceptance of melodic shapes which appear to grow out of finger motion alone, and which appear to be unconnected to whatever has been generated during the previous chunk, is surprising.

The transcript excerpt (Examples 11.6–12) shows many characteristic behaviours of the beginners. Most important is the reliance on the finger



knowledge to find new notes of the melody. It also shows the small unit within which the beginners work, and the comment at the end suggests the importance of the number of occurrences of F sharp as a means of defining the F sharp major tonality. This student has just completed writing measure 6 and is starting to explore possible ways of continuing the melody into measure 7.

Hums:

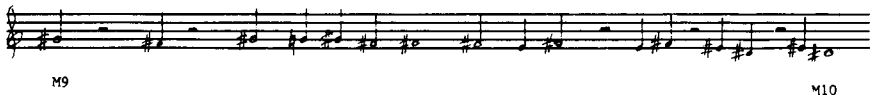
Example 11.12

'Only two F sharps'. Gotta get more than two out of this! OK?'



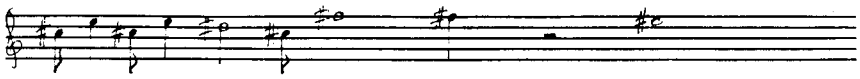
Second-level strategies

Three of the experienced students used second-level strategies which feature various local rules. Unlike level (1), however, this level prescribes the use of chunks of material which are larger than individual notes. These chunks consist either of portions or scales or of triads.

The least-developed aspect of this level is the use of a descending semitone motion from a goal pitch in one measure to a goal pitch in another measure. This is similar to the sensory motor exploration of the first level. The difference between the two strategies is that the sensory motor strategy appears to have no clearly directed goal, while the descending semi-tone motion has specific boundaries forming its top and bottom pitches. Thus there is a feeling of intentional design guiding the use of this strategy.

In the example below, the G sharp in measure 9 forms the top pitch and D sharp at the end of excerpt forms the final pitch of what becomes measure 10. This experienced student plays the entire completed portion of the melody before he explores the next chunk.

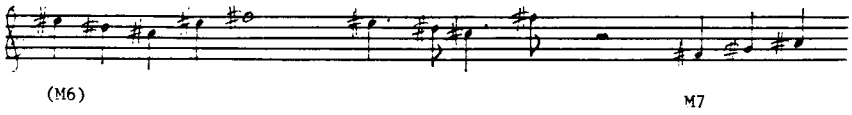
Plays:



Example 11.13

6 seconds silence
Writes measure 11

A slightly more elaborate strategy is the use of a specific tonal function such as the leading-tone-to-tonic motion. Successful use of this step shows that the subject can easily locate the critical scale degrees (7 and 1) in C major *and* in F sharp major. These are usually co-ordinated with a specific rhythmic motive as well, knitting the whole into a coherent melodic shape.



The most advanced of these local rules uses fragments of scales to introduce the modulation. The next example shows the use of a 'leading-tone' strategy to approach the new key and the use of scale fragments (the upper tetrachord of F sharp major: C sharp, D sharp, E sharp, and F sharp).

Plays:

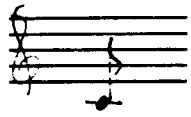
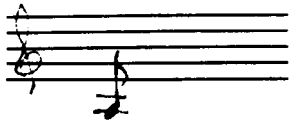
Example 11.15



20-seconds silence
'OK, this is what I'll do, you see?'
Writes measure 6 and 7

Third-level strategies

Two of the experienced students used strategies which were very different from those of the other students. Students at this level easily talk about their plans and strategies, and often forecast the success of an expected solution—all before sounding a note. These students were able to balance the focal and the subsidiary aspects of the task and integrate the particular shapes into a coherent and whole melody. For example, students at this level looked at the rhythmic shape, thought about the two keys, and then stated a specific plan which would take the melody from C major to F sharp major, for example, through the intermediary key of A major.



'So this is just the rhythm?' (*points to the page*)
Observer: 'Yes, that's the rhythm'.
'It's just the melody?'
Observer: 'Right.'

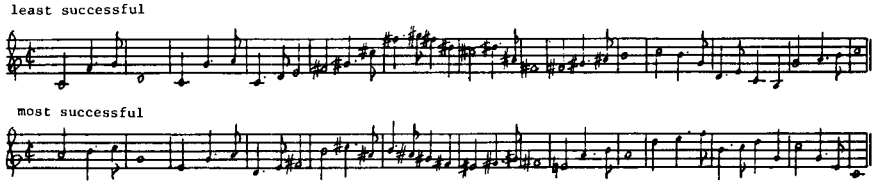
Example 11.20



39 seconds silence in which she writes measures 1, 2, 3, and 4
'OK. What I'm going to do is go from C major to a minor to, um, F sharp major.'

Characteristically, individual decisions at the note-by-note level are assessed in terms of their overall effect on the design. These students' ability to maintain the most global perspective while considering the local situation is evident from the use of a hypothesis-testing model throughout the task. The model appears to have four steps, *hypotheses*, *test*, *try out in context*, and *evaluate* (accept or reject). The similarity to the TOTE (Test–Operate–Test–Exit) model described by Miller, *et al.* (1960) is obvious.

Success of melody

Is it possible that composing a successful melody is the result of pure inspiration? If this is the case, one might expect to find little correlation among the factors of experience and the most successful of these melodies. On the other hand, to the extent that writing a successful tonal melody is dependent on rules of composition, one can expect the more experienced students to write more successful melodies. In an attempt to consider these questions, we asked a group of seven professional musicians to judge the melodies. Some of the musicians were college teachers while others were freelance musicians; all had a great deal of performing experience. We asked them to place the melodies in rank order from most to least successful. The judges were not told about the students or the study, and the melodies were presented in random order. The results are interesting because they shed more light on the role of formal knowledge in music. The resulting rank order of the melodies showed a high correlation with the experience of the student (Spearman Rho, $r = 0.86$). This means that the more sophisticated the strategies used in the process of composing the melody, the more likely judges were to consider it a successful melody. This suggests that experience, including theoretical knowledge of tonality, does indeed play a role in the creation of a more successful melody.

The melodies below were judged the least successful and the most successful respectively.

Example 11.21

Summary and discussion

Looking at the working styles and the strategies employed by members of the two groups suggests that a developmental stance combined with a problem-

finding/problem-solving approach is a very useful way of investigating musical questions. Examining how a task is represented, and determining the role a representation plays in forming strategies, operations, and definitions of goals, sheds light on even such a simple task as adding notes to a rhythmic pattern.

Representation of the problem

The beginning and experienced music students' representations of the task were very different because of their distinctive knowledge states. The dimensions of their different knowledge states are seen in the particular ways members of the two groups defined keys and integrate rhythm into the composing process.

At a verbal level all the students appeared to have the problem well defined. For example, the beginning and experienced students understood the keys to be used as C major and F sharp major without difficulty. However, the meaning supporting the text was very different for the two groups. The beginning students defined keys with single notes (usually the tonic) or the tonic triad. This suggests their schema for key is limited to rather simple and static units. The notes of these units are not hierarchically integrated with other notes of the scale, but simply exist as part of a familiar collection of tones. In contrast, the experienced students relied on more dynamic and structured tonal schemata which supported the hierarchical relationships implicit in scales and scalar fragments. They were able to 'lift out' overlapping portions of different scales, co-ordinating and integrating them into a tonal blend which linked the two.

Similarly, the difference rhythm played in the representation of the task was striking. Although the rhythm was specified for everyone, only the third-year students used it when constructing their melodies. The beginning students appeared not to include rhythm in their representation of the task, since they focused exclusively on the pitches of the melody. The beginners even ignored the rhythm when playing back their final version, as if slowly testing each note as they played the entire melody through. Again in contrast to the beginners, the experienced students used the rhythm at every stage of the task, making it clear that their concept of melody included rhythm *as well as* pitch.

There was a striking difference between the groups in their choice of when to edit the melody. Members of the third-year group characteristically edited measures and phrases of the melody immediately, while they were composing. This reflects their ability to work on precise moments within a larger framework as evidenced by their not needing to listen when they had finished working and not wanting to make revisions once they had completed the melody. This was very different from the editing behaviour of the beginning students. Characteristically, they did not assess the effect of

their melodic accretions until the final performance of the melody. They usually played the melody the last time as though they were listening carefully to the effect of the whole shape. After that performance, they would often pick up the pen again and make 'corrections'. Usually, only a few notes were changed and, confident of their work, they usually did not perform the entire melody a second time to check their revisions.

In summary, members of the two groups see the task differently. Beginners do not have many ways to define a tonality, whereas the more sophisticated musicians employ very different ways of establishing key centres. The beginners fail to see rhythm as a central or crucial factor in constructing a tonality or designing a tonal melody. This leads them to an unsatisfactory definition of key, because they fail to realize the importance of placing more important notes of the key on longer and/or more accented moments of the rhythmic series. In sharp contrast, experienced subjects were keenly aware of the role rhythm plays in contributing to the tonal weight of a note, both during the composition process and during the playing of the final melody.

Defining the limits of the problem of making a modulation around the use of appropriate triads is very different from defining the problem as involving the use of scales. While the triad definition has the virtue of being simple, that focus tends to make melodies which are abrupt in their shifts. The scale definition does not place a limit on the nature of melodic materials (one can use triads and stepwise scalar motions), and at the same time allows abrupt as well as smooth moments of transition. Seeing the problem of establishing a key as requiring units of two or three notes of the scale (for example, scale degrees 7 and 1, or a triad) is very different from interpreting it as based on a concept of a collection of seven pitches which exist in specific hierarchical tension.

Clearly, having alternative representations of the problem is an advantage. It was possible to see the task essentially as a problem of linking tonic triads, making a harmonic progression, or locating a specific tonic note, scalar fragment, or scale. The beginners characteristically had fewer alternative representations, while the experienced subjects not only had a wider range of representations, but were able to move among them, selecting an approach which seemed appropriate for a given moment.

Representation of the problem and strategies employed

Each representation of the problem defines and limits the range of operations used to arrive at solutions. For the problem solver, the formulation of a plan of action or strategy depends on how the problem is understood and represented. For the researcher, understanding the dimensions within which the problem solver is working makes it possible to

observe and evaluate the set of actions or operations which the problem solver hopes will lead to a solution of the problem.

The task we presented was open ended in so far as the moment of modulation was not defined. An algorithmic or rule-governed approach, even though it might lead to a solution, was not used by anyone. On the other hand, there were a wide variety of heuristic approaches to the problem. The most local strategies included the use of finger patterns and semitone chromatic pitch motion, the identification of a specific tonal relation such as the leading tone, and the use of a tone common to both keys as a pivot point. More advanced strategies included the use of melodic shapes, contours, and motives (sometimes in melodic sequence), as well as the hypothesis–test–incorporate–evaluate model. Finally, the most advanced and long-range strategies included the hypothesis-testing operation in conjunction with verbal statement of means, and the ability to plan future areas of focus.

Characteristically, the beginners were unable to design or construct a strategy except at the most local level. Consequently, they usually added notes to their melody without a long-range plan or design in mind. If they began with a plan, it was usually only temporary since they were often unable to transform it into a flexible heuristic attitude. Because of this, their attempts either looked as though there was no plan at all, or like perseveration, since they would use the same unsuccessful strategy over and over. In contrast, the most experienced students were able to use means-ends analysis, and even use a generate-test model.

Two levels of tonal thinking: enactive vs. reflective processes

First-year students, the beginners, were generally unable to reflect on the task without enactively sounding out each step of a solution. Their reliance on their fingers when finding the next notes of their melody was particularly striking. Their knowledge of tonality appeared to have not yet been integrated into a flexible working system. They were aware of individual notes or triads but not able to use them in larger functional contexts. Their goals emerged as they worked. They were in constant conflict between an explicit local context within which they were working and the implicit global context imposed by the task definition. It was symptomatic of this conflict that they were unable to reflect on and evaluate the focal moment in terms of the whole product.

These students also tended to work from front to back in note-to-note or one-measure units and with little regard for the rhythmic shape of the melody either during construction or during the playback at the end of the session. They were unable to talk about their strategies or goals until after they had finished solving a specific problem. They were unable to assess the effect of choices they made during the process of writing the melody. They

also had trouble keeping the context in focus while they were making additional bits of melody. Similarly, they seemed to have a limited awareness of the final shape of their melody since they were frequently surprised when they played their melody at the end of the session. They used one of three strategies: using the leading-tone-to-tonic relationship as a means of entering a key; using the root-position triad to either stand for a key or as a reference point for a key; and relying on finger movement over the keyboard as a means of exploring for new notes and expanding the melody.

Third-year students, the experienced group, were able to reflect on the dimensions of the problem and solve much of it before they committed themselves to a specific version on paper. Two of them had to be requested to play their final melodies. Their tonal knowledge was integrated into a rich and flexible working system. They had an understanding of tonality which included awareness of how scale degrees functioned and how even distant key areas could be related. They were able to define their methods and their goals in advance of starting to work on them. They were able to work on a local problem while evaluating it in terms of the whole.

Like the beginning students, they also worked from front to back, but the experienced students more often worked in larger chunks (normally one-, two-, and three-measure units). They were able to talk about their strategies and goals in advance of the immediate working context. In addition, they quickly integrated the pitches into the rhythmic pattern provided at the top of the page. Since they used significantly fewer notes (and relied less on trial and error) they appeared to be relatively sure of the effect of their choices while they were constructing the melody. When they played their melody at the end of the session, they appeared to be satisfied with the result. This suggests they already knew how it was going to sound. They were able to plan an approach to the problem and adjust it to changing contexts as they worked through the task. Significantly, they were able to make sections of melody without losing the context of the whole melodic shape. Two in this group used a clear hypothesis-testing model when they worked. Specifically, they would generate a melodic fragment and test it out in isolation of its context. If it satisfied their criteria, they would integrate it into the already composed section by playing it and evaluating it. On the basis of its effect within the context of the whole shape, they would either accept it and integrate it into the melodic line, or throw it out and start again.

One final question remains. On the basis of this study, what is the relation between perceptual knowledge of tonality and the knowledge of tonality required for production? The results of this study strongly suggest that the composition of a tonal melody requires a qualitatively different understanding of tonality than does the perception of tonality. Surprisingly, it appears that even the years of practice involved in studying an instrument

fail to provide the breadth and depth of knowledge required for a tonal composition task like the one in this study. It seems that problem solving in a domain like music is fundamentally different from problem solving in a domain like chess. In chess, one is either a novice or an expert. In music, unlike chess, one can be both expert and novice at the same time, depending on whether the task is a performance task or a composition task, a perception task or a production task. The musicians in this study were all gifted performers. Only the older group approached the level of tonal knowledge which was necessary for the successful solution of the melody-writing task. That group had received two additional years of intensive training in the charged musical environment of a conservatory.

In light of this, we see there is a great deal of difference in the knowledge which supports each of the working styles described in the opening of this chapter, especially when we are considering less than fully mature composers. While a master composer may appear at times like a beginner, for example, proceeding on a note-to-note level or making revisions after a 'final' playing, on the basis of this study it is likely that the master composer has a much richer representation of the task and has strategic procedures which are more flexible than perhaps even the relatively advanced student. More than that, the results of this study indicate some of the milestones occurring along the developmental path which leads from beginning to advanced levels of tonal knowledge. We see that the definition of a task like writing a melody is very different for musicians at different levels of development. We see that these differences play an important role not only in the definition and goals of the task, but also in the strategies employed and in the quality of the results.

Acknowledgements

This research was supported in part by grants from the Carnegie Corporation, Rockefeller Foundation, and the Spencer Foundation. The authors wish to thank members of the Thursday Night Group and especially Erin Phelps and Joan Meyaard for their assistance.

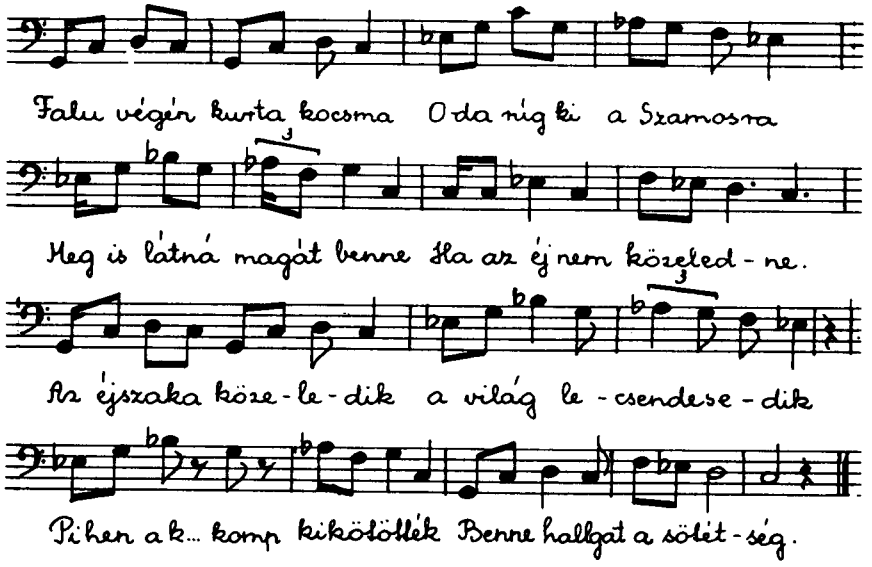
Appendix (Chapter 8)

Example 8.11. Conservatory student, 24 years old.

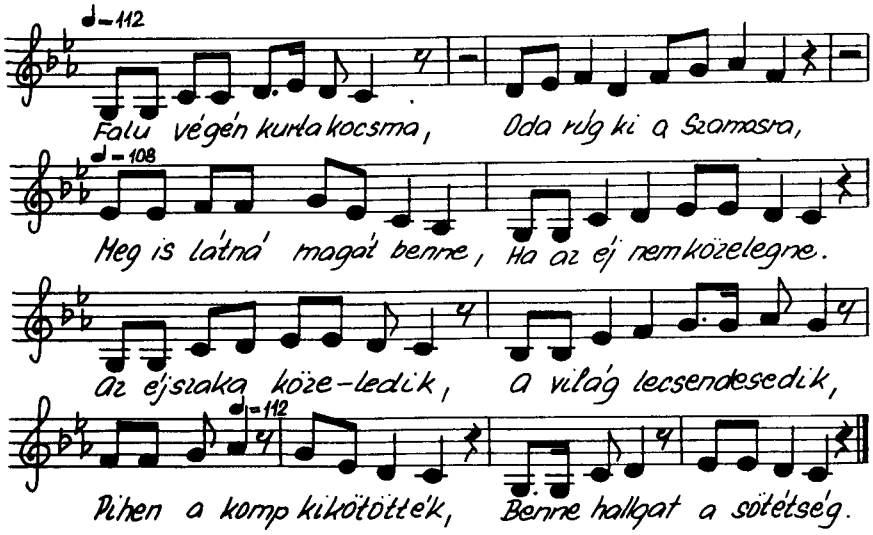
Form: A A_v^5 B C
A A_v^5 B_v C_v
Tonality: pentatonic



Example 8.12. Music pupil, 13 years old.

Form: A^5 A B A_v
A^5 A B A_v

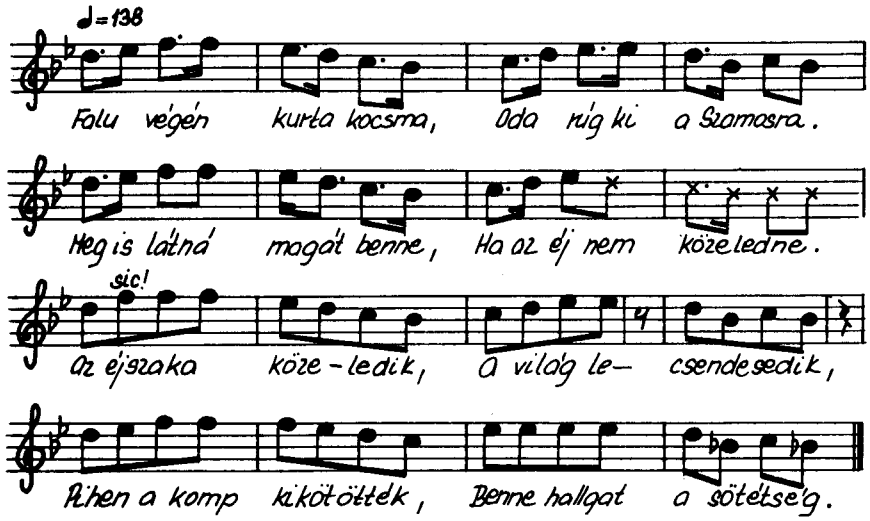
Tonality: minor + pentaton old style, folk-song like



Example 8.13. Peasant, 47-year-old-man.

Form: A B B_v C
A B_{v_2} $_v$B C

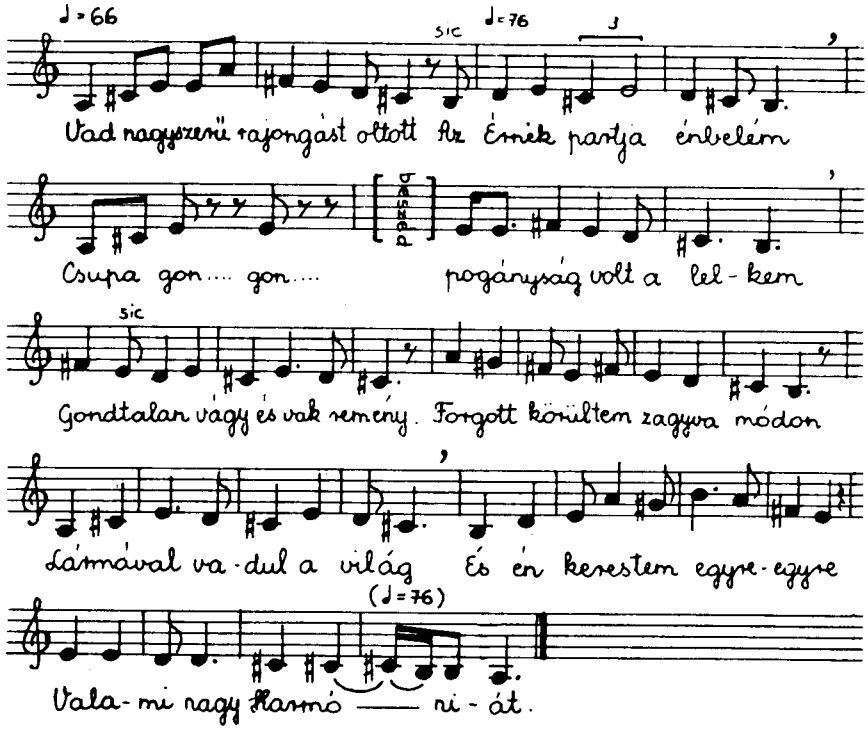
Tonality: in dome-structure C-minor, E flat major, E flat major, C minor



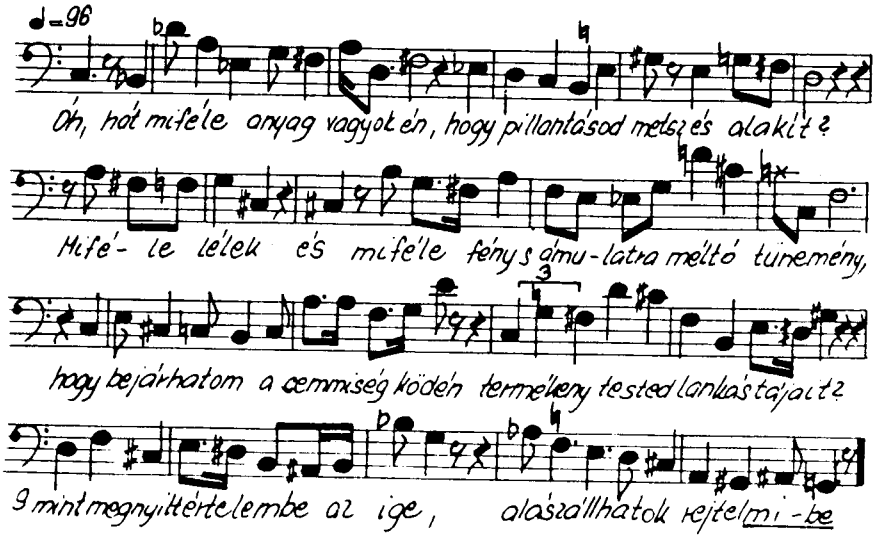
Example 8.14. Industrial worker, 30 years old.

Form: A B C A_v
A_v A_v^3 D A_v

Tonality: minor in composed folk song style example for tonality minor

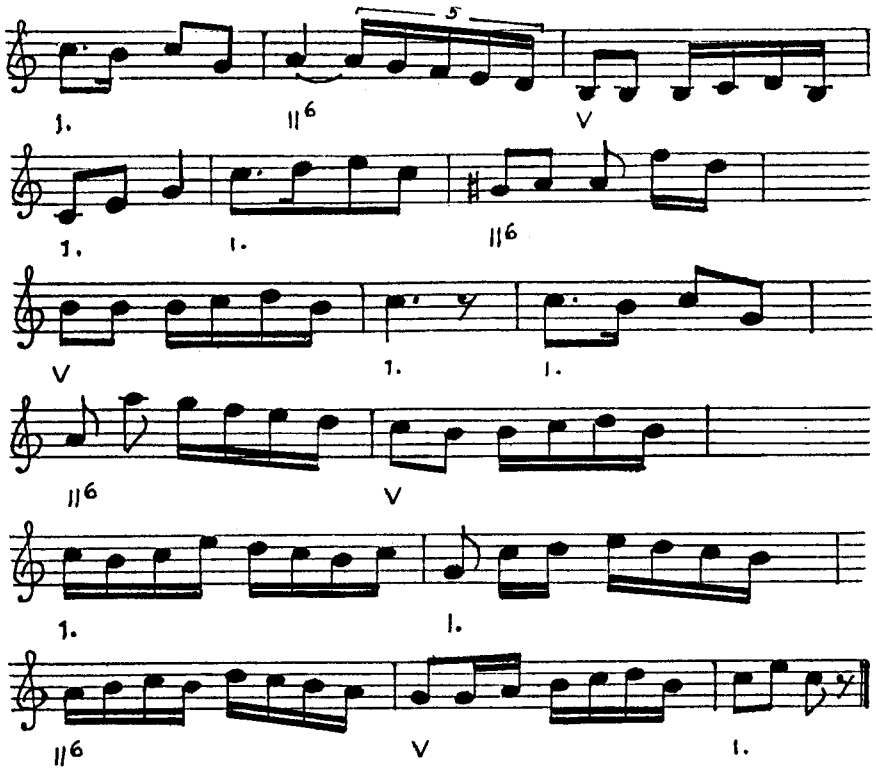


Example 8.15. Pupil, 13 years old.



Form: A A_{2v} A A_{2v}
A_v A_2 A B

Tonality: major pentachord in 'non-Hungarian intonations', i.e. hit song style



Example 8.16. Peasant, 52-year-old woman.

Example 8.17. Apprentice, 17-year-old boy.

Example 8.18. Grammar school pupil, 17 years old.

Whereas most of the literature in the psychology of music has focused on the processes involved when listening to music, little has been written about the processes involved in making music.

Re-issued by popular demand, and for the first time in paperback, *Generative processes: the psychology of performance, improvisation, and composition* brings together leading figures in music psychology to present pioneering studies of the processes by which music is generated.

The book looks at the generation of expression in musical performance, the problems of synchrony in ensemble performance, the development of children's song, rehearsal strategies of pianists, improvisational skill in trained and untrained musicians, children's spontaneous notations for music, formal constraints on compositional systems, and compositional strategies of music students.

Edited by a leading authority on music psychology, the book will be of great interest to cognitive and developmental psychologists, as well as music educators and musicologists.

PREFACE

Musical Perceptions is an introduction to the perception and cognition of music for readers in music and psychology. It presents a spectrum of the current research, and describes some of the many developments that have occurred in the perception and cognition of music over the last decades. This book includes twelve contributed chapters that discuss musical meaning, philosophical perspectives of music, comparisons beween music and language, the importance of music theory in perceptual research, research in musical development and music performance, the perception of melodies, tonality and rhythm, and the application of neural network models in music perception. The contributors' chapters give a detailed description of their research. I have prefaced each chapter with an introduction to provide a general background in which to place the significance of the contributor's research (John Sloboda contributed the introduction to his own chapter).

Because *Musical Perceptions* aims to foster a closer interaction between the artistic, the pedagogical, and the scientific aspects of music perception research, it includes contributions from both musicians and psychologists. Undoubtedly, the question "How do we perceive music?" is the main theme of this book. But there is also a second question, more difficult to answer, that underlines its intent: "How does music perception give rise to musical meaning?" Although the material discussed here offers only a small glimpse into the current vast literature on music perception and cognition, the reader will find the many references useful for more in-depth study.

I have tested the chapters that follow in my classes because they reflect the topics I teach in my perception of music courses at the Juilliard School, the Manhattan School of Music, and in the department of psychology at New York University. I am very grateful to my students for their comments and suggestions. In addition to being used in psychology of music courses (be they offered in music or in psychology departments), this volume could also be used in courses in the philosophy and the acsthetics of music, music education, and music theory.

The book opens with three chapters that address the perception of music from a philosophical perspective. Chapter 1 by Leonard Meyer, reprinted from *Emotion and Meaning in Music*, is of historical significance, and Meyer's ideas are still at the heart of the psychology of music today. Meyer explains how a listener may listen to music from several philosophical positions. Furthermore, Meyer shows how the melodic, rhythmic, and harmonic organization of music gives rise to musical meaning.

In Chapter 2, I describe comparisons between the perception of music and the perception of language at the phonetic, syntactic, and semantic levels. My

intent is not to underline the obvious similarities between the two, but to use the comparisons to point out what is intrinsically unique to music. Nicholas Cook's contribution (Chapter 3) offers a music theorist's view on music perception research, and his criticisms are thought-provoking. Cook argues that many studies in music perception are experiments in ear training strategies that do not reflect what music listeners actually do when they listen to music.

Chapters 4, 5, and 6 focus on musical development and music performance. Lyle Davidson (Chapter 4) traces the development of songsinging from the young child to the adult, and discusses the perceptual changes in tonal relationship that a student in music school undergoes. Davidson proposes that we do not yet have a comprehensive view of musical development because we fail to learn from the uncoordinated data we already have at hand. For Jeanne Bamberger (Chapter 5), listening to music in a new way enriches one's understanding of music. She elegantly describes how music students acquire new ways of listening to a piece when sharing with each other their descriptions of the piece.

In Chapter 6, John Sloboda brings new insights to research on music performance. Specifically, Sloboda examines recent studies that evaluate the ability to play notated solo compositions expressively, and the musical intentions of the performers. In addition, Sloboda discusses musical talent, practicing, and other factors that may be considered biographical precursors of musical excellence.

Aspects of the perception of melody and tonality are addressed in Chapters 7, 8, and 9. Jay Dowling (Chapter 7) defines the features that make a melody perceptually relevant. Drawing from his extensive research in this area, Dowling explains the perceptual strategies that we engage in when listening to tonal, atonal, and transposed melodies. Butler and Brown (Chapter 9) propose that the perception of tonality is influenced by the temporal organization of the pitches and not by the pitches themselves. They show experimentally that the frequency with which certain musical intervals are heard within a piece is what conveys information about the tonality of that piece.

In Chapter 9, Jamshed Bharucha demonstrates the relationship between tonality and expectation. Specifically, he explains the cognitive processes that underlie tonal expectation and their acquisition, and differentiates between the musical expectations that are related to the general style of a piece and those that are related to an actual composition. Moreover, Bharucha illustrates how musical expectations may be investigated with the application of neural networks.

Both Chapters 10 and 11 address the perception of rhythm and timing, but from different perspectives. While Sternberg and Knoll (Chapter 10) report on the ability of musicians to perceive, produce, and imitate microrhythmic patterns in the context of a laboratory setting, Shaffer and Todd (Chapter 11) describe the ways in which pianists reproduce rhythms while playing actual performances at the piano. In chapter 12, I address the importance of developing more studies in the perception of music that use as stimuli compositions from the musical repertoire rather than aesthetically impoverished laboratory sounds. Ul-

timately, research in the perception of music should help us understand the meaning and the aesthetics of music.

ACKNOWLEDGMENTS

My students are a very important part of my life. It is with them that I share my love for music and my interest in understanding how music is perceived. Their questions and comments have given me insights in the meanings of music, and have presented me with new perspectives. I thank all of them. It was a milestone for me to read the transcript of Leonard Bernstein's lectures *The Unanswered Question: Six Talks at Harvard.* As a musician and as a teacher, I thank the late maestro for what I learned.

Many colleagues have helped me with various aspects of this book. I acknowledge with deep gratitude the late Louis Gerstman, professor of psychology at the City College and the Graduate Center of the City University of New York, and a musician at heart. His enthusiasm and expert advice helped me envision how my lectures on the perception of music could become the book now at hand. In addition, I thank John Lewers, a dear friend, for the exchanges of ideas we have had since our student days; Edgar (Ted) Coons for his guidance and friendship; and Thomas Bever for introducing me to the literature in the perception of music. My thanks also to John Sloboda, David Butler, Leonard Meyer, David Burrows, Kendall Durell Briggs, Jerry Kerlin, Michael Palij, Valerie Bernhardt, Joan Bossert, and Paul Schlotthauer. Jane Gottlieb, the chief librarian at the Juilliard School, was very gracious in answering all my questions and in discussing many references at length.

Above all, I am grateful to my mother and to my husband, John G. J. Ritter, for their support.

Philosophical Perspectives

1

Emotion and Meaning in Music

LEONARD B. MEYER

Introduction

Leonard B. Meyer, one of the most important figures in the field of music aesthetics, has been pivotal in the growth of the psychology of music for almost four decades. The historical importance of his first book, *Emotion and Meaning in Music,* 1956, is evident in the frequency with which it is quoted, and in the impact that the theories it set forth have had on the psychology of music as a whole. *Emotion and Meaning in Music* focuses primarily on the moment-to-moment processes that take place in listening to total compositions and argues that the central meaning of music is to be found in the structural interplay of its elements and forms, rather than in associations to nonmusical events. Specifically, Meyer considers what kind of patterning underlies music, what implications are suggested by its melodic, rhythmic, and harmonic organization, and how these implications are realized or not realized in the ongoing sequence of events.

Meyer's writings address musical meaning from a psychological perspective. His theories are grounded in Gestalt psychology and information theory. The laws of Gestalt psychology (e.g., good continuation, similarity, common fate) relate to patterns in any modality, be it visual, auditory, or tactile, and provide explanations for the fact that some patterns seem particularly "good" or "complete" (the reader may wish to consult Rudolph Arnheim's *Art and Visual Perception,* 1969, for an in-depth discussion of Gestalt psychology; see also the introduction to Dowling's chapter 7 in this volume). The principles of information theory offer parameters for understanding how much information

Reprinted from L. B. Meyer, *Emotion and Meaning in Music.* Chicago: University of Chicago Press, 1956. Used by permission.

the listener can possibly derive when listening to music. (The works of Moles, 1966, Kraehenbuehl and Coons, 1959, Coons and Kraehenbuehl, 1958, and Youngblood, 1958, provide a background in information theory and music). In this vein, a style is a system of probabilities; the music, as it unfolds, sets the probabilities for what will happen next. The listener who is aware of the style may successfully predict what will follow, thus deriving a satisfactory meaning from the music. Deviations from the musical norms violate the listener's expectations and create patterns of tension and resolution.

Meyer's theories of meaning in music (1956) *preceded* a great deal of psychological research in meaning and emotional responses (see Gaver & Mandler, 1987; Mandler, 1984; Schachter & Singer, 1962). Psychologists (Mandler, 1984; Schachter & Singer, 1962) have shown that a subject's knowledge of a stimulus is of paramount importance in determining his or her emotional reactions to that stimulus. Meyer's theories of expectation and resolution in music have been found to be empirically valid (Schmuckler, 1989).

The first chapter of *Emotion and Meaning in Music* addresses music from a philosophical point of view. Music can have an intrinsic "absolute" meaning or can have an extrinsic "referential" meaning. Furthermore, the meaning of music may be interpreted from the viewpoint of the "formalist" (i.e., the listener who values the abstract patterning of music in and of itself) or from the viewpoint of the "expressionist" (i.e., the listener who views music as a means to express emotions). Meyer claims that a philosophy of music may legitimately endorse either of the opposing positions on each dimension. For example, an absolute expressionist (Meyer himself is an absolute expressionist) is a listener who believes that musical meaning is intrinsic in the music, and who derives an emotional meaning from understanding the interplay of the musical relationships.

We reprint the first chapter of *Emotion and Meaning in Music* not only because of its historical importance but to bring into focus the importance of having a philosophical perspective in addressing questions about the perception of music and to emphasize the historical importance of the book. Like Meyer, we believe that the philosophical positions of listeners may influence their perception of music. Research in the psychology of music asks what people perceive, but seldom have the subjects' philosophical views been taken into account. Studying what subjects report when hearing music should go hand in hand with asking questions about their philosophical perspective of music.

Meyer's latest book, *Style and Music: Theory, History, and Ideology,* 1989, further develops his belief that a musical style is a result of human choices that develop because of psychological, cultural, and musical constraints.

Past Positions as to the Nature of Musical Experience

Composers and performers of all cultures, theorists of diverse schools and styles, aestheticians, and critics of many different persuasions are all agreed that music has meaning and that this meaning is somehow communicated to both participants and listeners. This much, as least, we may take for granted. But what constitutes musical meaning and by what processes it is communicated has been the subject of numerous and often heated debates.

The first main difference of opinion exists between those who insist that musical meaning lies exclusively within the context of the work itself, in the perception of the relationship set forth within the musical work of art, and those who contend that, in addition to these abstract, intellectual meanings, music also communicates meanings which in some way refer to the extramusical world of concepts, actions, emotional states, and character. Let us call the former group the "absolutists" and the latter group the "referentialists."

In spite of the persistent wrangling of these two groups, it seems obvious that absolute meanings and referential meanings are not mutually exclusive: that they can and do coexist in one and the same piece of music, just as they do in a poem or a painting. In short, the arguments are the result of a tendency toward philosophical monism rather than a product of any logical opposition between types of meaning.

Because this study deals primarily with those meanings which lie within the closed context of the musical work itself, it is necessary to emphasize that the prominence given to this aspect of musical meaning does not imply that other kinds of meaning do not exist or are not important.

On the contrary, the musical theory and practice of many different cultures in many different epochs indicates that music can and does convey referential meaning. The musical cosmologies of the Orient in which tempi, pitches, rhythms, and modes are linked to and express concepts, emotions, and moral qualities; the musical symbolisms depicting actions, character, and emotion, utilized by many Western composers since the Middle Ages; and evidence furnished by testing listeners who have learned to understand Western music—all these indicate that music can communicate referential meanings.

Some of those who have doubted that referential meanings are "real" have based their skepticism upon the fact that such meanings are not "natural" and universal. Of course, such meanings depend upon learning. But so, too, do purely musical meanings—a fact that will become very clear in the course of this study.

Others have found the fact that referential meanings are not specific in their denotation a great difficulty in granting status to such meanings. Yet such precision is not a characteristic of the nonmusical arts either. The many levels of

connotation play a vital role in our understanding of the meanings communicated by the literary and plastic arts.

Let us now make a second point clear, namely, that the distinction just drawn between absolute and referential meanings is not the same as the distinction between the aesthetic positions which are commonly called "formalist" and "expressionist." Both the formalist and the expressionist may be absolutists; that is, both may see the meaning of music as being essentially intramusical (nonreferential); but the formalist would contend that the meaning of music lies in the perception and understanding of the musical relationships set forth in the work of art and that meaning in music is primarily intellectual, while the expressionist would argue that these same relationships are in some sense capable of exciting feelings and emotions in the listener.

This point is important because the expressionist position has often been confused with that of the referentialist. For although almost all referentialists are expressionists, believing that music communicates emotional meanings, not all expressionists are referentialists. Thus when formalists, such as Hanslick or Stravinsky, reacting against what they feel to be an overemphasis upon referential meaning, have denied the possibility or relevance of any emotional response to music, they have adopted an untenable position partly because they have confused expressionism and referentialism.

One might, in other words, divide expressionists into two groups: absolute expressionists and referential expressionists. The former group believe that expressive emotional meanings arise in response to music and that these exist without reference to the extramusical world of concepts, actions, and human emotional states, while the latter group would assert that emotional expression is dependent upon an understanding of the referential content of music.

The Present Position and Criticism of Past Assumptions

The present study is concerned with an examination and analysis of those aspects of meaning which result from the understanding of and response to relationships inherent in the musical progress rather than with any relationships between the musical organization and the extramusical world of concepts, actions, characters, and situations. The position adopted admits both formalist and absolute expressionist viewpoints. For though the referential expressionists and the formalists are concerned with genuinely different aspects of musical experience, the absolute expressionists and the formalists are actually considering the same musical processes and similar human experiences from different, but not incompatible, viewpoints.

Broadly speaking, then, the present investigation seeks to present an analysis of musical meaning and experience in which both the expressionist and the formalist positions will be accounted for and in which the relationship between them will become clear.

Past accounts given by the proponents of each of these positions have suffered from certain important weaknesses. The chief difficulty of those who have adopted the absolutist expressionist position is that they have been unable to account for the processes by which perceived sound patterns become experienced as feelings and emotions. In fact, strange as it may seem, they have generally avoided any discussion of emotional responses whatsoever. These shortcomings have led to a general lack of precision both in their account of musical experience and in their discussions of musical perception.

But, at least, the expressionists have recognized the existence of problems in their position. The formalists, on the other hand, have either found no problems to recognize or have simply turned the other way, seeking to divert attention from their difficulties by attacking referentialism whenever possible. Yet the formalists are faced with a problem very similar to that confronting the expressionists: namely, the difficulty and necessity of explaining the manner in which an abstract, nonreferential succession of tones becomes meaningful. In failing to explain in what sense such musical patterns can be said to have meaning, they have also found themselves unable to show the relation of musical meaning to meaning in general.

Finally, this failure to explain the processes by which feelings are aroused and meanings communicated has prevented both groups from seeing that their positions should make them allies rather than opponents. For the same musical processes and similar psychological behavior give rise to both types of meaning; and both must be analyzed if the variety made possible by this aspect of musical experience is to be understood.

Readers familiar with past studies in the aesthetics and psychology of music will perhaps note that much of the earlier work in these fields is not discussed in this study and that many traditional problems are ignored. This neglect stems from the conviction that the assumptions and orientation of this literature have proved sterile and are today untenable. Since this literature has been explicitly and cogently criticized by such writers as Cazden,[1] Farnsworth,[2] and Langer,[3] only a brief comment on these earlier assumptions seems necessary here, in the hope that the position of this book will thereby be clarified.

The psychology of music has, since its beginnings, been plagued by three interrelated errors: hedonism, atomism, and universalism. Hedonism is the confusion of aesthetic experience with the sensuously pleasing. As Susanne Langer writes:

> Helmholtz, Wundt, Stumpf, and other psychologists . . . based their inquiries on the assumption that music was a form of *pleasurable sensation*. . . . This gave rise to an aesthetic based on liking and disliking, a hunt for a sensationist definition of beauty. . . . But beyond a description of tested pleasure-displeasure reactions to simple sounds or elementary sound complexes . . . this approach has not taken us. . . .[4]

The attempt to explain and understand music as a succession of separable, discrete sounds and sound complexes is the error of atomism. Even the meager achievement which Mrs. Langer allows to studies of this kind must be still further depreciated. For the tested pleasure-displeasure reactions are not what most of the psychologists tacitly assumed them to be: they are not universals (good for all times and all places) but products of learning and experience.

This is the third error, the error of universalism: the belief that the responses obtained by experiment or otherwise are universal, natural, and necessary. This universalist approach is also related to the time-honored search for a physical, quasi-acoustical explanation of musical experience—the attempt, that is, to account for musical communication in terms of vibrations, ratios of intervals, and the like.

These same errors have also plagued music theory. Attempts to explain the effect of the minor mode of Western music, to cite but one example, in terms of consonance and dissonance or in terms of the harmonic series have resulted in uncontrolled speculations and untenable theories. Even those not thus haunted by the ghost of Pythagoras have contributed little to our understanding of musical meaning and its communication. For, on the whole, music theorists have concerned themselves with the grammar and syntax of music rather than with its meaning or the affective experiences to which it gives rise.

Today we are, I think, able to take a somewhat more enlightened view of these matters. The easy access which almost all individuals have to great music makes it quite apparent that a Beethoven symphony is not a kind of musical banana split, a matter of purely sensuous enjoyment. The work of the Gestalt psychologists has shown beyond a doubt that understanding is not a matter of perceiving single stimuli, or simple sound combinations in isolation, but is rather a matter of grouping stimuli into patterns and relating these patterns to one another. And finally, the studies of comparative musicologists, bringing to our attention the music of other cultures, have made us increasingly aware that the particular organization developed in Western music is not universal, natural, or God-given.

Evidence as to the Nature and Existence of the Emotional Response to Music

Any discussion of the emotional response to music is faced at the very outset with the fact that very little is known about this response and its relation to the stimulus. Evidence that it exists at all is based largely upon the introspective reports of listeners and the testimony of composers, performers, and critics. Other evidence of the existence of emotional responses to music is based upon the behavior of performers and audiences and upon the physiological changes that accompany musical perception. Although the volume and intercultural

character of this evidence compel us to believe that an emotional response to music does take place, it tells us almost nothing about the nature of the response or about the causal connection between the musical stimulus and the affective response it evokes in listeners.

Subjective Evidence

From Plato down to the most recent discussions of aesthetics and the meaning of music, philosophers and critics have, with few exceptions, affirmed their belief in the ability of music to evoke emotional responses in listeners. Most of the treatises on musical composition and performance stress the importance of the communication of feeling and emotion. Composers have demonstrated in their writings and by the expression marks used in their musical scores their faith in the affective power of music. And finally, listeners, past and present, have reported with remarkable consistency that music does arouse feelings and emotions in them.

The first difficulty with this evidence is that, taken at its face value, without benefit of a general theory of emotions as a basis for interpretation, it yields no precise knowledge of the stimulus which created the emotional response. Because music flows through time, listeners and critics have generally been unable to pinpoint the particular musical process which evoked the affective response which they describe. They have been prone, therefore, to characterize a whole passage, section, or composition. In such cases the response must have been made to those elements of the musical organization which tend to be constant, e.g., tempo, general range, dynamic level, instrumentation, and texture. What these elements characterize are those aspects of mental life which are also relatively stable and persistent, namely, moods and associations, rather than the changing and developing affective response with which this study is concerned.

Much confusion has resulted from the failure to distinguish between emotion felt (or affect) and mood. Few psychologists dealing with music have been as accurate on this point as Weld, who notes that: "The emotional experiences which our observers reported are to be characterized rather as moods than as emotions in the ordinary sense of the term. . . . The emotion is temporary and evanescent; the mood is relatively permanent and stable."[5] As a matter of fact, most of the supposed studies of emotion in music are actually concerned with mood and association.

Taken at face value the introspective data under consideration not only fail to provide accurate knowledge of the stimulus (music) but they cannot even furnish clear and unequivocal information about the responses reported. For several reasons the verbalizations of emotions, particularly those evoked by music, are usually deceptive and misleading.

Emotions are named and distinguished from one another largely in terms of the external circumstances in which the response takes place. Since, aside from the often fortuitous associations which may be aroused, music presents no exter-

nal circumstances, descriptions of emotions felt while listening to music are usually apocryphal and misleading. If they are to be used at all, they must be analyzed and considered in the light of a general theory of the relation of musical stimuli to emotional responses.

Second, a clear distinction must be maintained between the emotions felt by the composer, listener, or critic—the emotional response itself—and the emotional states denoted by different aspects of the musical stimulus. The depiction of musical moods in conjunction with conventional melodic or harmonic formulas, perhaps specified by the presence of a text, can become signs which designate human emotional states. Motives of grief or joy, anger or despair, found in the works of baroque composers or the affective and moral qualities attributed to special modes or *rāgas* in Arabian or Indian music are examples of such conventional denotative signs. And it may well be that when a listener reports that he felt this or that emotion, he is describing the emotion which he believes the passage is supposed to indicate, not anything which he himself has experienced.

Finally, even where the report given is of a genuine emotional experience, it is liable to become garbled and perverted in the process of verbalization. For emotional states are much more subtle and varied than are the few crude and standardized words which we use to denote them.

In this connection it would seem that many of the introspections supplied by subjects in the studies made by Vernon Lee, C. S. Myers, Max Schoen, and others contain a large amount of what psychiatrists call "distortion." For example, when a subject in an experiment by Myers reports that while listening to a particular musical selection she had "a restful feeling throughout . . . like one of going downstream while swimming,"[6] she is obviously translating unspeakable feelings into symbolic form. The interpretation of such symbols is the task of the psychiatrist, not the music critic. To the music critic such introspections show only that some response, not necessarily a specifically musical one, was present. For it is always possible that the thoughts and reveries thus revealed are without any relation to musical experience. The musical stimuli may have functioned merely as a kind of catalytic agent, enabling the response to take place but playing no controlling part in shaping or determining the experience and figuring nowhere in the end result, except perhaps negatively.

Objective Evidence: Behavior

The responses of listeners can also be observed and studied objectively. Two general categories of observable responses can be distinguished: (a) those responses which take the form of overt changes in behavior and (b) those responses which take the form of less readily observable physiological changes. Such objective evidence, though it undoubtedly avoids the difficulties of the verbalization of subjective feelings and emotions, presents other difficulties no less perplexing.

In the first place, emotional responses need not result in overt, observable behavior. As Henry Aiken points out,[7] one of the special characteristics of our responses to aesthetic objects is the very fact that, due to our beliefs as to the nature of aesthetic experience, we tend to suppress overt behavior. Furthermore, as an important adjunct to this point it should be noted that emotion-felt or affect is most intense precisely in those cases where feeling does not result in or take the form of overt behavior or mental fantasy. This is clear as soon as one considers the tendency of human beings to "work off" or relieve emotional tension in physical effort and bodily behavior. In short, the absence of overt emotional behavior, particularly in response to aesthetic stimuli, is no indication as to either the presence or force of emotional responses.

However, even where overt behavior is present, its interpretation is difficult and problematical. When, on the one hand, overt behavior is the product of particularly powerful emotional tensions, it tends to be diffuse, generalized, or chaotic. Extreme conflict, for example, may result in either motionless rigidity or frenzied activity; weeping may be the product of either profound grief or extreme joy. Unless we have accurate knowledge of the stimulus situation beforehand, such behavior can tell us little or nothing as to the significance of the response or of its relation to the stimulus.

On the other hand, when emotional behavior does become differentiated it tends to be standardized—to become part of more general patterns of social behavior. Thus although the philosophical aspect of the stimulus situation, the fact that an aesthetic object is being considered, tends toward the suppression of overt behavior, the social aspect of the stimulus situation permits and at times indeed encourages certain standardized types of emotional behavior. This is apparent in the conduct of performers and audiences alike. The jazz performer and his audience, for example, have one mode of socially sanctioned emotional behavior; the concert performer and his audience have another. The difference between the two is more a matter of conventionally determined behavior patterns than it is a matter of musical differences.

Such behavior must be regarded at least in part as a means of communication rather than as a set of natural, reflex reactions. It indicates and designates not only appropriate mental sets but also the proper (i.e., socially acceptable) modes of response. Once this sort of behavior becomes habitual, and it does so very early in life, then it may be activated by the social aspects of the stimulus situation alone, without regard for the stimulus itself. In short, given no theory as to the relation of musical stimuli to affective responses, observed behavior can provide little information as to either the nature of the stimulus, the significance of the response, or the relation between them. For conduct which might to an observer appear to indicate the presence of an emotional response might in point of fact be the result of the subject's day dreams, his observation and imitation of the behavior of others, or his beliefs as to the kind of behavior appropriate and expected in the given social situation.

Objective Evidence: Physiological Responses

On the physiological level music evokes definite and impressive responses. It "has a marked effect on pulse, respiration and external blood pressure. . . . [It] delays the onset of muscular fatigue . . . [and] has a marked effect upon the psychogalvanic reflex. . . ."[8] In spite of the fact that these changes are the very ones which normally accompany emotional experience, the significance of these data is not completely clear. Two principal difficulties are involved.

To begin with, no relation can be found between the character or pattern of the musical selection evoking the response and the particular physiological changes which take place. These changes appear to be completely independent of any particular style, form, medium, or general character. The same responses will take place whether the music is fast or slow, exciting or soothing, instrumental or vocal, classical or jazz.

Because tonal stimulation is a constant factor of all musical stimuli, Mursell is led to conclude that the power of "tone as such" must be the cause of the physiological changes observed.[9]

There is, however, another constant involved in the perception of music; namely, the mental attitude of the audience. The listener brings to the act of perception definite beliefs in the affective power of music. Even before the first sound is heard, these beliefs activate dispositions to respond in an emotional way, bringing expectant ideomotor sets into play. And it seems more reasonable to suppose that the physiological changes observed are a response to the listener's mental set rather than to assume that tone as such can, in some mysterious and unexplained way, bring these changes about directly. For while the relationship between mental sets and physiological changes has been demonstrated beyond doubt, the effect of "tone as such" has not.

This does not imply that the presence of a physiological environment, which is a necessary condition for the arousal of emotion, is not a significant fact. The existence of this necessary condition increases the likelihood that emotional responses do take place—a fact which some critics have sought to deny. What this analysis indicates is that not only are these physiological adjustments pre-emotional, as Mursell would admit, but they are also premusical.

Furthermore, even the conclusions just reached about the significance of the physiological data are probably an exaggeration, if not from a psychological point of view, at least, from a logical one. For such adjustments not only accompany affective responses, but they are also concomitants of clearly nonemotional responses.

In the light of present knowledge it seems clear that though physiological adjustments are probably necessary adjuncts of affective responses they cannot be shown to be sufficient causes for such responses and have, in fact, been able to

throw very little light upon the relationship between affective responses and the stimuli which produce them. The situation is concisely summarized by Rapaport:

> (a) On the basis of the material surveyed nothing can be definitely stated as to the relation to "emotion felt" of physiological processes concomitant with emotions. Proof has not been offered to show that the usually described physiological processes are *always* present when emotion is felt. (b) Nothing is known about the physiological processes *underlying* emotional experience. However, sufficient proof has been adduced that neither the James-Lange theory nor the hypothalamic theory explains the origin of "emotion felt." (c) The investigations into the physiology and the neural correlates of emotional expression are of importance; their relation to the psychic process designated as "emotion felt" is the crucial point of every theory of emotions. However, the knowledge concerning this relation is so scant that investigations into the influence of emotions on other physiological processes will have to be based rather on what is known about the psychology of emotions.[10]

There is one basic problem with all the objective data discussed: namely, that even when affective experiences result in objective adjustments, whether behavioral or physiological, what can be observed is not the emotion-felt, the affect, but only its adjuncts and concomitants, which in the case of behavior tend to become standardized and in the case of physiological changes are not specific to emotion. What we wish to consider, however, is that which is most vital and essential in emotional experience: the feeling-tone accompanying emotional experience, that is, the affect.

Here we face a dilemma. On the one hand, the response with which we are concerned is profoundly and permanently subjective and hence of necessity concealed from the scrutiny of even the most scrupulous observers; and, on the other hand, we have found that the subjective data available, taken by themselves, provide no definite and unequivocal information about the musical stimulus, the affective response, or the relation between them. This difficulty can be resolved only if the subjective data available, including the responses of the readers and the author of this study, can be examined, sifted, and studied in the light of a general hypothesis as to the nature of affective experience and the processes by which musical stimuli might arouse such experience.

Such a hypothesis is provided by the psychological theory of emotions. For although much work undoubtedly remains to be done in the field of emotional theory, there appears to be general agreement among psychologists and psychiatrists at least as to the conditions under which emotional responses arise and as to the relationship between the affective stimulus and the affective response.

The Psychological Theory of Emotions

Since the physiological changes which accompany emotional experience, whatever their importance, do not provide a basis for differentiating affective from

nonaffective states, the differentia must be sought in the realm of mental activity.

However, not all mental responses are affective. We speak of dispassionate observation, calm deliberation, and cool calculation. These are nonemotional states of mind.

If we then ask what distinguishes nonemotional states from emotional ones, it is clear that the difference does not lie in the stimulus alone. The same stimulus may excite emotion in one person but not in another. Nor does the difference lie in the responding individual. The same individual may respond emotionally to a given stimulus in one situation but not in another. The difference lies in the relationship between the stimulus and the responding individual.

This relationship must first of all be such that the stimulus produces a tendency in the organism to think or act in a particular way. An object or situation which evokes no tendency, to which the organism is indifferent, can only result in a nonemotional state of mind.

But even when a tendency is aroused, emotion may not result. If, for example, a habitual smoker wants a cigarette and, reaching into his pocket, finds one, there will be no affective response. If the tendency is satisfied without delay, no emotional response will take place. If, however, the man finds no cigarette in his pocket, discovers that there are none in the house, and then remembers that the stores are closed and he cannot purchase any, he will very likely begin to respond in an emotional way. He will feel restless, excited, then irritated, and finally angry.

This brings us to the central thesis of the psychological theory of emotions. Namely: Emotion or affect is aroused when a tendency to respond is arrested or inhibited.

Supporting Theories

In 1894 John Dewey set forth what has since become known as the conflict theory of emotions.[11]

In an article entitled "The Conflict Theory of Emotions,"[12] Angier shows that this general position has been adopted, in more or less modified form, by many psychologists of widely different viewpoints. For instance, the behaviorists, who emphasize the excitement and confusion which disrupt behavior as important characteristics of emotional conduct, would seem to be describing objectively what others view as the result of inner conflict. But the difficulty with examining emotions from the point of view of behaviorism is that, as we have seen, emotion may be felt without becoming manifest as overt behavior.

MacCurdy, whose own attitude is psychoanalytical, points out that it is precisely "when instinctive reactions are stimulated that do not gain expression either in conduct, emotional expression, or fantasy, that affect is most intense. It is the prevention of the expression of instinct either in behavior or conscious thought that leads to intense affect. In other words the energy of the organism, activating an instinct process, must be blocked by repression before poignant

feeling is excited."[13] MacCurdy's analysis involves three separate phases: (a) the arousal of nervous energy in connection with the instinct or tendency;[14] (b) the propensity for this energy to become manifest as behavior or conscious thought once the tendency is blocked; and (c) the manifestation of the energy as emotion-felt or affect if behavior and conscious thought are also inhibited. Of course, if the stimulation is so powerful that the total energy cannot be absorbed by either behavior or affect alone, both will result.[15]

It is obvious that a shift of emphasis has taken place in the statement of the theory of emotions. Dewey and his followers tended to stress the conflict or opposition of tendencies as being the cause of emotional response. MacCurdy and most of the more recent workers in the field believe that it is the blocking or inhibiting of a tendency which arouses affect. Actually the concept of conflict through the opposition of simultaneously aroused conflicting tendencies may be regarded as a special and more complicated case of the arrest of tendency.

This point was made in Paulhan's brilliant work, which in 1887, almost 10 years before Dewey's formulation, set forth a highly sophisticated theory of emotions. "If we ascend in the hierarchy of human needs and deal with desires of a higher order, we still find that they only give rise to affective phenomena when the tendency awakened undergoes inhibition."[16]

However, more complex phenomena are possible as the result of "the simultaneous or almost simultaneous coming into play of systems which tend toward opposite or different actions and which cannot both culminate in action at the same time; always provided that the psychical systems brought into play do not differ too widely in intensity. . . ."[17] Such a situation results, according to Paulhan, in an emotion or affect characterized by confusion and lack of clarity.

In other words, in one case a tendency is inhibited not by another opposed tendency but simply by the fact that for some reason, whether physical or mental, it cannot reach completion. This is the situation of the inveterate smoker in the example given earlier. In the other case two tendencies which cannot both reach fruition at the same time are brought into play almost simultaneously. If they are about equal in strength, each tendency will block the completion of the other. The result is not only affect, as a product of inhibition, but doubt, confusion, and uncertainty as well.

These latter concomitants of conflict are of importance because they may themselves become the basis for further tendencies. For to the human mind such states of doubt and confusion are abhorrent; and, when confronted with them, the mind attempts to resolve them into clarity and certainty, even if this means abandoning all other previously activated tendencies.

Thus confusion and lack of clarity, growing out of conflicting tendencies, may themselves become stimuli producing further tendencies—tendencies toward clarification—which may become independent of the originally conflicting tendencies. Such tendencies need not be definite in the sense that the ultimate resolution of the doubt and confusion is specified. Some resolution of the confusion may be more important than this or that particular solution, assuming that

the final result is not in conflict with other aspects of the stimulus situation or other mental sets.

Furthermore, it should be noted that uncertainty and lack of clarity may be products not only of conflicting tendencies but also of a situation which itself is structurally confused and ambiguous. This is of capital importance because it indicates that a situation which is structurally weak and doubtful in organization may directly create tendencies toward clarification. Delay in such a generalized tendency toward clarification may also give rise to affect.

Although the main tenets of the psychological theory of emotions have been widely accepted, there have, needless to say, been criticisms of the theory. In the main these have come from those who have sought, as yet without success, to account for, describe, and distinguish emotions in purely physiological terms. The theory of emotions, it is objected, does not tell us what an emotion is; it does not tell us precisely what takes place in the body to make us feel.

This objection, though valid, is irrelevant for our purposes. For just as the physicist long defined magnetism in terms of the laws of its operation and was able to deal with the phenomena without knowing the nature of the magnetic states so, too, the psychologist can define emotion in terms of the laws governing its operation, without stipulating precisely what, in physiological terms, constitutes feeling—what makes affect felt.

The Differentiation of Affect

Thus far we have considered emotion as though it were a general, undifferentiated response, a feeling whose character and quality were always more or less the same. While there is a good deal of evidence for this view, it is nevertheless clear that in common speech and everyday experience we do recognize a variety of emotional states—love, fear, anger, jealousy, and the like.[18] The whole problem of whether undifferentiated feelings, affects per se, exist, of their relation to differentiated emotional experience, and of the basis for such differentiation is of importance in the present study. For while music theorists and aestheticians have found it difficult to explain how music designates particular emotions, they have found it almost impossible to account for the existence of less specific affective experience.

Were the evidence to show that each affect or type of affect had its own peculiar physiological composition, then obviously undifferentiated feeling would be out of the question. However, Woodworth's summary of the work in this field makes it clear that this is not the case.[19]

The evidence in the case of "emotional (affective) behavior" (the term which will henceforth be used to designate the overt and observable aspects of emotional conduct) is more complex. Much emotional behavior, though habitual and hence seemingly automatic and natural, is actually learned. Because this aspect of behavior serves in the main as a means of communication, it will be called "designative (denotative) behavior." To this category belong most of the postural

sets, facial expressions, and motor responses accompanying emotional behavior. Though designative behavior is definitely and clearly differentiated, the differentiation is not a necessary one and indicates nothing as to the possible differentiation of the affect itself.

Other aspects of affective behavior, such as skeletal and muscular adjustments, have been said to be automatic, natural concomitants of the affective response. These will be called "emotional reactions." Supposing that such automatic reactions do exist, a fact that has been debated, it has not been definitely shown that they are differentiated as between types of affective experience.

However, even if it were demonstrated that emotional reactions were differentiated, this would not necessarily prove or even indicate that the affects which they accompany are also differentiated. For the reaction is a response made to the total emotion-provoking situation and not necessarily a product of affect itself. In other words, it may well be that such automatic behavior is called forth by the peculiar nature of the objective situation rather than by the operation of the law of affect itself. Were this the case, such a reaction would be independent of affect and might indeed take place, as does designative emotional behavior, in the absence of affect.

The suppositions that behavior reactions are essentially undifferentiated, becoming characteristic only in certain stimulus situations, and that affect itself is basically undifferentiated are given added plausibility when one considers the following:

a. The more intense emotional behavior is, and presumably therefore the more intense the affective stimulation, the less the control exerted by the ego over behavior and the greater the probability that the behavior is automatic and natural.

b. The more intense affective behavior is, the less differentiated such behavior tends to be. In general, the total inhibition of powerful tendencies produces diffuse and characterless activity. For example, extreme conflict may result in either complete immobility or in frenzied activity, while weeping may accompany deepest grief, tremendous joy, or probably any particularly intense emotion.

c. Thus the more automatic affective behavior is, the less differentiated it tends to be.

It seems reasonable then to conclude that automatic reflex reactions not only fail to provide reasons for believing that affect itself is differentiated but the evidence seems to point to just the opposite conclusion.

Finally, our own introspective experience and the reports of the experiences of others testify to the existence of undifferentiated emotions. It is affect as such which Cassirer is discussing when he writes: "Art gives us the motions of the human soul in all their depth and variety. But the form, the measure and rhythm, of these motions is not comparable to any single state of emotion. What we feel in art is not a simple or single emotional quality. It is the dynamic process of life itself."[20]

The conclusion that affect itself is undifferentiated does not mean that affective experience is a kind of disembodied generality. For the affective experience, as distinguished from affect per se, includes an awareness and cognition of a stimulus situation which always involves particular responding individuals and specific stimuli.

Not only do we become aware of and know our own emotions in terms of a particular stimulus situation but we interpret and characterize the behavior of others in these terms. "When an organism is in a situation which results in a disturbed or wrought-up condition, then the situation plus the reaction gives us the name or word which characterizes the whole as a specific emotion. The reaction itself is not sufficient to differentiate the emotion, the character of the situation is involved in this differentiation."[21]

Thus while affects and emotions are in themselves undifferentiated, affective experience is differentiated because it involves awareness and cognition of a stimulus situation which itself is necessarily differentiated. The affective states for which we have names are grouped and named because of similarities of the stimulus situation, not because the affects of different groups are per se different. Love and fear are not different affects, but they are different affective experiences.

Awareness of the nature of the stimulus situation also seems to be the real basis for the distinction which Hebb draws between "pleasant" and "unpleasant" emotions. According to the present analysis, there are no pleasant or unpleasant emotions. There are only pleasant or unpleasant emotional experiences. This is of importance in understanding the distinction made by Hebb.

According to Hebb, the difference between pleasant and unpleasant emotions lies in the fact that pleasant emotions (or, in our terminology, pleasant emotional experiences) are always resolved. They depend "on first arousing apprehension, then dispelling it."[22] But were this actually the case we could only know whether an emotion were pleasant or unpleasant after it was over. Yet, surely, we know more than this while we are experiencing affect. The pleasantness of an emotion seems to lie not so much in the fact of resolution itself as in the belief in resolution—the knowledge, whether true or false, that there will be a resolution. It is not, as Hebb seems to assert when he cites as pleasurable the "mildly frustrating or the mildly fear-provoking,"[23] the control actually exercised over a situation which distinguishes pleasant from unpleasant emotions. It is the control which is believed to exist over the situation.

The sensation of falling through space, unconditioned by any belief or knowledge as to the ultimate outcome, will, for instance, arouse highly unpleasant emotions. Yet a similar fall experienced as a parachute jump in an amusement park may, because of our belief in the presence of control and in the nature of the resolution, prove most pleasurable.

The foregoing analysis is of genuine importance in the present study because it explains and accounts for the existence and nature of the intangible, nonreferential affective states experienced in response to music. For insofar as the

stimulus situation, the music, is nonreferential (in the sense that it pictures, describes, or symbolizes none of the actions, persons, passions, and concepts ordinarily associated with human experience), there is no reason to expect that our emotional experience of it should be referential. The affective experience made in response to music is specific and differentiated, but it is so in terms of the musical stimulus situation rather than in terms of extramusical stimuli.[24]

In the light of this discussion it is evident that, though it is wrong to assert, as some have done, that emotions exist which are *sui generis* musical or aesthetic, it is possible to contend that there are emotional experiences which are so.[25] By the same token, however, any number of emotional experiences can be grouped together so long as their stimulus situations are in some respects similar. Musical affective experiences, for example, might be differentiated into operatic, orchestral, baroque, and so forth. But the most significant distinction would still lie in the fact that musical stimuli, and hence musical affective experiences, are nonreferential.

Emotional Designation

Although emotional behavior is frequently characterless and diffuse, often it is differentiated and intelligible. Even without knowledge of the stimulus situation, motor behavior, facial expression, tone of voice, and manner of speaking can tell us not only that an individual is responding in an emotional way but also something of the character of his feelings or, more accurately, of the character of his affective experience.

Differentiated behavior, as we have seen, is not an automatic or a necessary concomitant of affect itself or even of affective experience. The more automatic behavior is, the less likely it is to be differentiated. Differentiation involves control, and control implies purpose.

The purpose of emotionally differentiated behavior is communication. The individual responding, having an affective experience or simulating one, seeks to make others aware of his experience through a series of nonverbal behavioral signs. Because the gestures and signs which differentiate such behavior are purposeful, this mode of behavior will be called "emotional designation" or "designative behavior."[26]

Such signs not only act as cues for appropriate behavior in the social situation but are probably, at least in part, aimed at making other individuals respond in an empathetic way. As the saying goes: Misery loves company. And so do other emotional states. Not only do we dislike physical isolation, but we want to share our emotional life with others. And, indeed, such sharing does take place. For an observer, recalling a situation in his own experience similar to the one signified by the behavior of another, may respond to the remembered situation in an affective way. Though designative affective behavior may, through constant use, become habitual and automatic so that it is almost invariably called up as part of

the total emotional response, it is not basically a necessary concomitant of the response but one brought into play as a result of a desire to communicate.

Designative behavior is differentiated largely by custom and tradition. It varies from culture to culture and among different groups within a single culture. This does not mean that there are no features of such behavior which are natural and widespread. In all probability there are. However, three points should be kept in mind: (1) There is no real evidence to show that there is only one single natural mode of behavior relevant to a given stimulus situation. When alternative modes of behavior are possible, cultural selection probably determines the composition of any particular pattern of affective designation. (2) Whatever natural tendencies toward a particular pattern of behavior exist may be altered or suppressed by the demands of the larger behavior patterns of the culture. (3) Even where natural behavior is retained in the pattern of emotional behavior, it inevitably becomes codified and standardized for the sake of more efficient communication.

Above all, we understand and make appropriate responses to designative behavior as a total behavior pattern, not just to some features of it, whether natural or otherwise. As a total pattern designative behavior is a cultural phenomenon, not a natural one. It is, in the final analysis, learned.

This is important as it takes most of the sting out of the criticism that music which attempts to designate emotional states depends for its effect upon the learning of conventional signs and symbols. For this fact is not peculiar to music but is characteristic of all emotional designation. If one excludes such designation as a legitimate means of musical communication, one must by the same token exclude it as a means of human communication in general.[27]

The Theory of Emotions Related to Musical Experience

An Assumption

An examination of the psychological theory of emotions was made because the evidence furnished by the introspections of musicians, aestheticians, and listeners and the objective data gathered from the observation of behavior and the study of the physiological responses to musical stimuli did not yield reliable information about the musical stimulus or the affective responses made to it. Implicit in this examination was an assumption which must now be made explicit: Though the stimulus situation may vary indefinitely, the conditions which evoke affect are general and are, therefore, applicable to music. In other words, it was assumed that the law of affect, which states that emotion is evoked when a tendency to respond is inhibited, is a general proposition relevant to human psychology in all realms of experience.

This assumption does not, however, imply or stipulate that musical affective experiences are the same as the affective experiences made in response to other stimulus situations. Musical experience differs from nonmusical or, more specifically, nonaesthetic experience in three important ways.

First, as we have seen, affective experience includes an awareness and knowledge of the stimulus situation. This being so, the affective experience of music will differ from other types of affective experience, particularly insofar as musical stimuli are nonreferential.

Second, in everyday experience the tensions created by the inhibition of tendencies often go unresolved. They are merely dissipated in the press of irrelevant events. In this sense daily experience is meaningless and accidental. In art inhibition of tendency becomes meaningful because the relationship between the tendency and its necessary resolution is made explicit and apparent. Tendencies do not simply cease to exist: they are resolved, they conclude.[28]

Third, in life the factors which keep a tendency from reaching completion may be different in kind from those which activated the tendency in the first place. The stimulus activating a tendency may, for example, be a physical or psychic need of the organism, while the inhibiting factors may simply be a series of external circumstances which keep the organism from satisfying the need. This is the situation in the case of the habitual smoker who can find no cigarette. Or the situation may be reversed; that is, a tendency activated by an external stimulus may be inhibited by the psychic processes of the organism.

Furthermore, in everyday experience the resolutions of the tensions brought into play by inhibition may be irrelevant to the tendencies themselves. Tensions arising from psychic needs may be "worked off" in sheer physical activity which is without meaningful relation to the original stimulus or to the tendency itself.

In music, on the other hand, the same stimulus, the music, activates tendencies, inhibits them, and provides meaningful and relevant resolutions.

Tendency and Expectation in Music

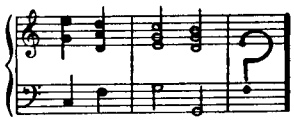
The assumption that the same basic psychological processes underlie all affective responses, whether the stimulus be musical or of some other kind, has been implicit in much musical theory and in the speculations of many aestheticians. But this does not in itself increase our understanding of the nature of musical experience and of the musical processes which form it. It does not explain the nature of the relationships which exist between the stimulus, the listener's perceptions and mental processes, and his responses. To do this it is necessary to demonstrate precisely how musical stimuli do, in fact, arouse and inhibit tendencies and thereby give rise to emotions.

What is meant by a tendency to respond? A "tendency" or, as MacCurdy uses the term, an "instinct" "is a pattern reaction that operates, or tends to operate, when activated, in an automatic way."[29] A pattern reaction consists of a set or series of regularly coincident mental or motor responses which, once brought

into play as part of the response to a given stimulus, follow a previously ordered course, unless inhibited or blocked in some way. The order established by a pattern reaction is both temporal and structural; that is, the series involves not only the relation of the parts of the total pattern to each other but also their timing. Thus a series may be disturbed either because the succession of the parts of the pattern is upset or because the timing of the series is upset or both.

The term "tendency," as used in this study, comprises all automatic response patterns, whether natural or learned. Since habit is "a mechanism of action, physiologically ingrained, which operates spontaneously and automatically,"[30] the term "tendency" also "includes habit reactions and, inevitably, acquired concepts and meanings."[31]

The tendency to respond may be either conscious or unconscious. If the pattern reaction runs its normal course to completion, then the whole process may be completely unconscious. Countless reaction patterns, of which the responding individual is unaware, are initiated and completed each hour. The more automatic behavior becomes, the less conscious it is. The tendency to respond becomes conscious where inhibition of some sort is present, when the normal course of the reaction pattern is disturbed or its final completion is inhibited. Such conscious and self-conscious tendencies are often thought of and referred to as "expectations."



In a broader sense all tendencies, even those which never reach the level of consciousness, are expectations. For since a tendency is a kind of chain reaction in which a present stimulus leads through a series of adjustments to a more or less specified consequent, the consequent is always implied in the tendency, once the tendency has been brought into play. Thus while our conscious minds do not actively expect a consequent unless the pattern reaction is disturbed, our habits and tendencies are expectant in the sense that each seeks out or "expects" the consequents relevant and appropriate to itself. Though he may never become aware of his expectations as he reaches in his pocket for a pack of cigarettes, the behavior of the habitual smoker shows that he does expect or, perhaps more accurately, his habits expect for him.

If tendencies are pattern reactions that are expectant in the broad sense, including unconscious as well as conscious anticipations, then it is not difficult to see how music is able to evoke tendencies. For it has been generally acknowledged that music arouses expectations, some conscious and others unconscious, which may or may not be directly and immediately satisfied.

> . . . the pleasure . . . arises from the perception of the artist's play with forms and conventions which are ingrained as *habits* of perception both in the artist and his audience. Without such habits . . . there would be no awareness whatever of the artist's fulfillment of and subtle departures from established forms. . . . But the pleasure which we derive from style is not an intellectual interest in detecting similarities and differences, but an immediate aesthetic delight in perception which results from the arousal and suspension or fulfillment of expectations which are the products of many previous encounters with works of art.[32]

Expectation, Suspense, and the Unexpected

Sometimes a very specific consequent is expected. In Western music of the eighteenth century, for example, we expect a specific chord, namely, the tonic (C major), to follow this sequence of harmonies (see example). Furthermore, the consequent chord is expected to arrive at a particular time, i.e., on the first beat of the next measure.

Of course, the consequent which is actually forthcoming, though it must be possible within the style, need not be the one which was specifically expected. Nor is it necessary that the consequent arrive at the expected time. It may arrive too soon or it may be delayed. But no matter which of these forms the consequent actually takes, the crucial point to be noted is that the ultimate and particular effect of the total pattern is clearly conditioned by the specificity of the original expectation.

At other times, expectation is more general; that is, though our expectations may be definite, in the sense of being marked, they are nonspecific, in that we are not sure precisely how they will be fulfilled. The antecedent stimulus situation may be such that several consequents may be almost equally probable. For instance, after a melodic fragment has been repeated several times, we begin to expect a change and also the completion of the fragment. A change is expected because we believe that the composer is not so illogical as to repeat the figure indefinitely and because we look forward to the completion of the incomplete figure. But precisely what the change will be or how the completion will be accomplished cannot perhaps be anticipated. The introductions to many movements written in the eighteenth or nineteenth centuries create expectation in this way, e.g., the opening measures of Beethoven's Ninth Symphony or the opening measures of the "March to the Gallows" from Berlioz's *Symphonie Fantastique.*

Expectation may also result because the stimulus situation is doubtful or ambiguous. If the musical patterns are less clear than expected, if there is confusion as to the relationship between melody and accompaniment, or if our expectations are continually mistaken or inhibited, then doubt and uncertainty as to the general significance, function, and outcome of the passage will result. As we have already seen, the mind rejects and reacts against such uncomfortable states and, if they are more than momentary, looks forward to and expects a return to the certainty of regularity and clarity. This is particularly striking in the responses made to works of art where, because of a firm belief in the purposeful-

ness and integrity of the artist, we expect that order will in the end triumph, and precision will replace ambiguity.

However, the manner in which clarification and order will be restored may not be predicted or envisaged. Expectation is not specific; the state is one of suspense. In fact, if doubt and uncertainty are strong enough, almost any resolution, within the realm of probability, which returns us to certainty will be acceptable, though no doubt some resolutions will, given the style, seem more natural than others.

The inclusion of suspense arising out of uncertainty may, at first sight, appear to be an extension and amplification of the concept of arrest and inhibition of a tendency. But when the matter is considered more carefully, it will be seen that every inhibition or delay creates uncertainty or suspense, if only briefly, because in the moment of delay we become aware of the possibility of alternative modes of continuation. The difference is one of scale and duration, not of kind. Both arouse uncertainties and anxieties as to coming events.

Suspense is essentially a product of ignorance as to the future course of events. This ignorance may arise either because the present course of events, though in a sense understandable in itself, presents several alternative and equally probable consequents or because the present course of events is itself so unusual and upsetting that, since it cannot be understood, no predictions as to the future can be made.

From the outset ignorance arouses strong mental tendencies toward clarification which are immediately affective. If ignorance persists in spite of all, then the individual is thrown into a state of doubt and uncertainty. He commences to sense his lack of control over the situation, has inability to act on the basis of the knowledge which he supposed that he possessed. In short, he begins to feel apprehensive, even fearful, though there is no object for his fear. Ignorance and its concomitant feelings of impotence breed apprehension and anxiety, even in music. But ignorance also gives rise to more sanguine feelings; for since the outcome cannot be envisaged, it may be pleasant. These feelings are themselves tendencies (the avoidance of painful apprehension and the expectation of a propitious conclusion) which become focused upon an expected resolution of the unpleasant stimulus situation.

The longer doubt and uncertainty persist, the greater the feeling of suspense will tend to be. The stimulus situation creating doubt and uncertainty must, of course, be progressively intensified if suspense is to be maintained or increased. For as we become accustomed to a given stimulus situation, even an unpleasant one, its effectiveness tends to diminish. Moreover, without a change in the stimulus situation in the direction of complication and uncertainty, those vital anticipatory feelings (that a break must come, that doubt and perplexity must give way to knowledge) which make us expect (both apprehensively and hopefully) would be lost.

The greater the buildup of suspense, of tension, the greater the emotional release upon resolution. This observation points up the fact that in aesthetic

experience emotional pattern must be considered not only in terms of tension itself but also in terms of the progression from tension to release. And the experience of suspense is aesthetically valueless unless it is followed by a release which is understandable in the given context.

Musical experiences of suspense are very similar to those experienced in real life. Both in life and in music the emotions thus arising have essentially the same stimulus situation: the situation of ignorance, the awareness of the individual's impotence and inability to act where the future course of events is unknown. Because these musical experiences are so very similar to those existing in the drama and in life itself, they are often felt to be particularly powerful and effective.

Musical suspense seems to have direct analogies in experience in general; it makes us feel something of the insignificance and powerlessness of man in the face of the inscrutable workings of destiny. The low, foreboding rumble of distant thunder on an oppressive summer afternoon, its growing intensity as it approaches, the crescendo of the gradually rising wind, the ominous darkening of the sky, all give rise to an emotional experience in which expectation is fraught with powerful uncertainty—the primordial and poignant uncertainty of human existence in the face of the inexorable forces of nature. With mixed feelings of hope and apprehension in the presence of the unknown, we anxiously await the breaking of the storm, the discovery of what unrelenting fate has decreed.

Similarly in music the state of suspense involves an awareness of the powerlessness of man in the face of the unknown.

What is expected in this state of suspense may not be specified, but this does not mean that any consequent is possible. Our expectations are inevitably circumscribed by the possibilities and probabilities of the style of the composition in question. The consequent must, given the circumstances, be possible within what Aiken has called "an ordering system of beliefs and attitudes."[33]

Although the consequent in any musical sequence must, in this sense, be possible, it may nevertheless be unexpected. But the unexpected should not be confused with the surprising. For when expectation is aroused, the unexpected is always considered to be a possibility, and, though it remains the less expected of several alternatives, it is not a complete surprise. Conditions of active expectation (especially general expectation and suspense) are not the most favorable to surprise. For the listener is on guard, anticipating a new and possibly unexpected consequent. Surprise is most intense where no special expectation is active, where, because there has been no inhibition of a tendency, continuity is expected.

As soon as the unexpected, or for that matter the surprising, is experienced, the listener attempts to fit it into the general system of beliefs relevant to the style of the work. This requires a very rapid re-evaluation of either the stimulus situation itself or its cause—the events antecedent to the stimulus. Or it may require a review of the whole system of beliefs that the listener supposed appropriate and relevant to the work. If this mental synthesis does not take place

immediately, three things may happen: (1) The mind may suspend judgment, so to speak, trusting that what follows will clarify the meaning of the unexpected consequent. (2) If no clarification takes place, the mind may reject the whole stimulus and irritation will set in.[34] (3) The unexpected consequent may be seen as a purposeful blunder. Whether the listener responds in the first or third manner will depend partly upon the character of the piece, its mood or designative content. The third response might well be made to music whose character was comic or satirical. Beckmesser's music in Wagner's *Die Meistersinger* would probably elicit this type of interpretive understanding.[35] In a piece whose character admitted no such purposeful blunders, the second response would probably be elicited.

Conscious and Unconscious Expectations

In the light of these observations it is clear that an expectation is not a blind, unthinking conditioned reflex. Expectation frequently involves a high order of mental activity. The fulfillment of a habit response, in art as well as in daily life, requires judgment and cognition both of the stimulus itself and of the situation in which it acts. The stimulus as a physical thing becomes a stimulus in the world of behavior only insofar as the mind of the perceiver is able to relate it, on the one hand, to the habit responses which the perceiver has developed and, on the other hand, to the particular stimulus situation. This is clear as soon as one considers that the same physical stimulus may call forth different tendencies in different stylistic contexts or in different situations within one and the same stylistic context. For example, a modal cadential progression will arouse one set of expectations in the musical style of the sixteenth century and quite another in the style of the nineteenth century. Likewise the same musical progression will evoke one set of expectations at the beginning of a piece and another at the end.

Expectation then is a product of the habit responses developed in connection with particular musical styles and of the modes of human perception, cognition, and response—the psychological laws of mental life.[36]

The mental activity involved in the perception of and response to music need not, however, be conscious. ". . . the intellectual satisfaction which the listener derives from continually following and anticipating the composer's intentions—now, to see his expectations fulfilled, and now, to see himself agreeably mistaken . . . this intellectual flux and reflux, this perpetual giving and receiving takes place unconsciously, and with the rapidity of lightning flashes"[37] So long as expectations are satisfied without delay, so long as tendencies are uninhibited, though intelligence is clearly and necessarily involved in the perception and understanding of the stimulus situation, the response will probably remain unconscious.

Mental activity tends to become conscious when reflection and deliberation are involved in the completion of the response pattern, that is, when automatic behavior is disturbed because a tendency has been inhibited. "Impulsion forever

boosted on its forward way would run its course thoughtless, and dead to emotion. . . . The only way it can become aware of its nature and its goal is by obstacles surmounted and means employed."[38]

But even when a habit response is inhibited, conscious awareness of the mental activity involved in the perception of and response to the stimulus situation is by no means inevitable. Intellectual experience (the conscious awareness of one's own expectations or, objectively, of the tendencies of the music), as distinguished from intellectual activity, is largely a product of the listener's own attitude toward his responses and hence toward the stimuli and mental activities which bring them into existence. That is to say, some listeners, whether because of training or natural psychological inclination, are disposed to rationalize their responses, to make experience self-conscious; others are not so disposed. If intellectual activity is allowed to remain unconscious, then the mental tensions and the deliberations involved when a tendency is inhibited are experienced as feeling or affect rather than as conscious cognition.

Having shown that music arouses tendencies and thus fulfils the conditions necessary for the arousal of affect and having demonstrated how this is accomplished, we can now state one of the basic hypotheses of this study. Namely: Affect or emotion-felt is aroused when an expectation—a tendency to respond—activated by the musical stimulus situation, is temporarily inhibited or permanently blocked.

As noted earlier, in musical experience the same stimulus, the music, activates tendencies, inhibits them, and provides meaningful and relevant resolutions for them. This is of particular importance from a methodological standpoint. For it means that granted listeners who have developed reaction patterns appropriate to the work in question, the structure of the affective response to a piece of music can be studied by examining the music itself.

Once those sound successions common to a culture, a style, or a particular work have been ascertained, then, if the customary succession is presented and completed without delay, it can be assumed that, since no tendency would have been inhibited, the listener would not respond in an affective way. If, on the other hand, the sound succession fails to follow its customary course, or if it involves obscurity or ambiguity, then it can be assumed that the listener's tendencies would be inhibited or otherwise upset and that the tensions arising in this process would be experienced as affect, provided that they were not rationalized as conscious intellectual experience.

In other words, the customary or expected progression of sounds can be considered as a norm, which from a stylistic point of view it is; and alteration in the expected progression can be considered as a deviation. Hence deviations can be regarded as emotional or affective stimuli.

The importance of this "objective" point of view of musical experience is clear. It means that once the norms of a style have been ascertained, the study and analysis of the affective content of a particular work in that style can be made

without continual and explicit reference to the responses of the listener or critic. That is, subjective content can be discussed objectively.[39]

The Meaning of Music

The Problem of Meaning in Music

The meaning of music has of late been the subject of much confused argument and controversy. The controversy has stemmed largely from disagreements as to what music communicates, while the confusion has resulted for the most part from a lack of clarity as to the nature and definition of meaning itself.

The debates as to what music communicates have centered around the question of whether music can designate, depict, or otherwise communicate referential concepts, images, experiences, and emotional states. This is the old argument between the absolutists and the referentialists.

Because it has not appeared problematical to them, the referentialists have not as a rule explicitly considered the problem of musical meaning. Musical meaning according to the referentialists lies in the relationship between a musical symbol or sign and the extramusical thing which it designates.

Since our concern in this study is not primarily with the referential meaning of music, suffice it to say that the disagreement between the referentialists and the absolutists is, as was pointed out at the beginning of this chapter, the result of a tendency toward philosophical monism rather than the result of any logical incompatibility. Both designative and nondesignative meanings arise out of musical experience, just as they do in other types of aesthetic experience.

The absolutists have contended that the meaning of music lies specifically, and some would assert exclusively, in the musical processes themselves. For them musical meaning is nondesignative. But in what sense these processes are meaningful, in what sense a succession or sequence of nonreferential musical stimuli can be said to give rise to meaning, they have been unable to state with either clarity or precision. They have also failed to relate musical meaning to other kinds of meaning—to meaning in general. This failure has led some critics to assert that musical meaning is a thing apart, different in some unexplained way from all other kinds of meaning. This is simply an evasion of the real issue. For it is obvious that if the term "meaning" is to have any signification at all as applied to music, then it must have the same signification as when applied to other kinds of experience.

Without reviewing all the untenable positions to which writers have tenaciously adhered, it seems fair to say that much of the confusion and uncertainty as to the nature of nonreferential musical meaning has resulted from two fallacies. On the one hand, there has been a tendency to locate meaning exclusively in one aspect of the communicative process; on the other hand, there has been a

propensity to regard all meanings arising in human communication as designative, as involving symbolism of some sort.

Since these difficulties can be best resolved in the light of a general definition of meaning, let us begin with such a definition: ". . . anything requires meaning if it is connected with, or indicates, or refers to, something beyond itself, so that its full nature points to and is revealed in that connection."[40]

Meaning is thus not a property of things. It cannot be located in the stimulus alone. The same stimulus may have many different meanings. To a geologist a large rock may indicate that at one time a glacier began to recede at a given spot; to a farmer the same rock may point to the necessity of having the field cleared for plowing; and to the sculptor the rock may indicate the possibility of artistic creation. A rock, a word, or motion in and of itself, merely as a stimulus, is meaningless.

Thus it is pointless to ask what the intrinsic meaning of a single tone or a series of tones is. Purely as physical existences they are meaningless. They become meaningful only insofar as they point to, indicate, or imply something beyond themselves.

Nor can meaning be located exclusively in the objects, events, or experiences which the stimulus indicates, refers to, or implies. The meaning of the rock is the product of the relationship between the stimulus and the thing it points to or indicates.

Though the perception of a relationship can only arise as the result of some individual's mental behavior, the relationship itself is not to be located in the mind of the perceiver. The meanings observed are not subjective. Thus the relationships existing between the tones themselves or those existing between the tones and the things they designate or connote, though a product of cultural experience, are real connections existing objectively in culture.[41] They are not arbitrary connections imposed by the capricious mind of the particular listener.

Meaning, then, is not in either the stimulus, or what it points to, or the observer. Rather it arises out of what both Cohen and Mead have called the "triadic" relationship between (1) an object or stimulus; (2) that to which the stimulus points—that which is its consequent; and (3) the conscious observer.

Discussions of the meaning of music have also been muddled by the failure to state explicitly what musical stimuli indicate or point to. A stimulus may indicate events or consequences which are different from itself in kind, as when a word designates or points to an object or action which is not itself a word. Or a stimulus may indicate or imply events or consequences which are of the same kind as the stimulus itself, as when a dim light on the eastern horizon heralds the coming of day. Here both the antecedent stimulus and the consequent event are natural phenomena. The former type of meaning may be called designative, the latter embodied.

Because most of the meanings which arise in human communication are of the designative type, employing linguistic signs or the iconic signs of the plastic

arts, numerous critics have failed to realize that this is not necessarily or exclusively the case. This mistake has led even avowed absolutists to allow designation to slip in through the secret door of semantic chicanery.[42]

But even more important than designative meaning is what we have called embodied meaning. From this point of view what a musical stimulus or a series of stimuli indicate and point to are not extramusical concepts and objects but other musical events which are about to happen. That is, one musical event (be it a tone, a phrase, or a whole section) has meaning because it points to and makes us expect another musical event. This is what music means from the viewpoint of the absolutist.

Music and Meaning

Embodied musical meaning is, in short, a product of expectation. If, on the basis of past experience, a present stimulus leads us to expect a more or less definite consequent musical event, then that stimulus has meaning.[43]

From this it follows that a stimulus or gesture which does not point to or arouse expectations of a subsequent musical event or consequent is meaningless. Because expectation is largely a product of stylistic experience, music in a style with which we are totally unfamiliar is meaningless.[44]

However, once the aesthetic attitude has been brought into play, very few gestures actually appear to be meaningless so long as the listener has some experience with the style of the work in question. For so long as a stimulus is possible within any known style, the listener will do his best to relate it to the style, to understand its meaning.

In and of themselves, for example, the opening chords of Beethoven's Third Symphony have no particular musical stylistic tendency. They establish no pattern of motion, arouse no tensions toward a particular fulfillment. Yet as part of the total aesthetic cultural act of attention they are meaningful. For since they are the first chords of a piece, we not only expect more music but our expectations are circumscribed by the limitations of the style which we believe the piece to be in and by the psychological demand for a more palpable pattern.

Thus the phrase "past experience," used in the definition of meaning given above, must be understood in a broad sense. It includes the immediate past of the particular stimulus or gesture, that which has already taken place in this particular work to condition the listener's opinion of the stimulus and hence his expectations as to the impending, consequent event. In the example given above, the past was silence. But this fact of the past is just as potent in conditioning expectation as a whole section of past events.[45] The phrase "past experience" also refers to the more remote, but ever present, past experience of similar musical stimuli and similar musical situations in other works. That is, it refers to those past experiences which constitute our sense and knowledge of style. The phrase also comprehends the dispositions and beliefs which the listener brings to the musical experience as well as the laws of mental behavior which govern his

organization of stimuli into patterns and the expectations aroused on the basis of those patterns.

The words "consequent musical event" must be understood to include: (1) those consequents which are envisaged or expected; (2) the events which do, in fact, follow the stimulus, whether they were the ones envisaged or not; and (3) the more distant ramifications or events which, because the total series of gestures is presumed to be causally connected, are considered as being the later consequences of the stimulus in question. Seen in this light, the meaning of the stimulus is not confined to or limited by the initial triadic relationship out of which it arises. As the later stages of the musical process establish new relationships with the stimulus, new meanings arise. These later meanings coexist in memory with the earlier ones and, combining with them, constitute the meaning of the work as a total experience.

In this development three stages of meaning may be distinguished.

"Hypothetical meanings" are those which arise during the act of expectation. Since what is envisaged is a product of the probability relationships which exist as part of style, and since these probability relationships always involve the possibility of alternative consequences, a given stimulus invariably gives rise to several alternative hypothetical meanings. One consequent may, of course, be so much more probable than any other that the listener, though aware of the possibility of less likely consequences, is really set and ready only for the most probable. In such a case hypothetical meaning is without ambiguity. In other cases several consequents may be almost equally probable, and, since the listener is in doubt as to which alternative will actually materialize, meaning is ambiguous, though not necessarily less forceful and marked.[46]

Though the consequent which is actually forthcoming must be possible within the style, it may or may not be one of those which was most probable. Or it may arrive only after a delay or a deceptive diversion through alternative consequences. But whether our expectations are confirmed or not, a new stage of meaning is reached when the consequent becomes actualized as a concrete musical event.

"Evident meanings" are those which are attributed to the antecedent gesture when the consequent becomes a physicopsychic fact and when the relationship between the antecedent and consequent is perceived. Since the consequent of a stimulus itself becomes a stimulus with consequents, evident meaning also includes the later stages of musical development which are presumed to be the products of a chain of causality. Thus in the following sequence, where a stimulus (S) leads to a consequent (C), which is also a stimulus that indicates and is actualized in further consequents,

$$S_1 \ldots\ldots C_1S_2 \ldots\ldots C_1S_3 \ldots\ldots \text{etc.}$$

evident meaning arises not only out of the relationship between S_1 and C_1 but also out of the relationships between S_1 and all subsequent consequences, insofar

as these are considered to issue from S_1. It is also important to realize that the motion $S_1 \ldots\ldots C_1$ may itself become a gesture that gives rise to envisaged and actual consequents and hence becomes a term or gesture on another level of triadic relationships. In other words, both evident and hypothetical meanings come into being and exist on several architectonic levels.

Evident meaning is colored and conditioned by hypothetical meaning. For the actual relationship between the gesture and its consequent is always considered in the light of the expected relationship. In a sense the listener even revises his opinion of the hypothetical meaning when the stimulus does not move to the expected consequent.

"Determinate meanings" are those meanings which arise out of the relationships existing between hypothetical meaning, evident meaning, and the later stages of the musical development. In other words, determinate meaning arises only after the experience of the work is timeless in memory, only when all the meanings which the stimulus has had in the particular experience are realized and their relationships to one another comprehended as fully as possible.

The Objectification of Meaning

A distinction must be drawn between the understanding of musical meaning which involves the awareness of the tendencies, resistances, tensions, and fulfilments embodied in a work and the self-conscious objectification of that meaning in the mind of the individual listener. The former may be said to involve a meaningful experience, the latter involves knowing what that meaning is, considering it as an objective thing in consciousness.

The operation of intelligence in listening to music need never become self-conscious. We are continually behaving in an intelligent way, comprehending meanings and acting upon our perceptions, cognitions, and evaluations without ever making the meanings themselves the objects of our scrutiny—without ever becoming self-conscious about what experience means. What Bertrand Russell says about understanding language also applies to the understanding of music: "Understanding language is . . . like understanding cricket: it is a matter of habits acquired in oneself and rightly presumed in others."[47]

Meanings become objectified only under conditions of self-consciousness and when reflection takes place. "One attains self-consciousness only as he takes, or finds himself stimulated to take, the attitude of the other."[48] Though training may make for a generally self-conscious attitude, one is stimulated to take the attitude of the other when the normal habits of response are disturbed in some way; when one is driven to ask one's self: What does this mean, what is the intention of this passage? Reflection is likewise brought into play where some tendency is delayed, some pattern of habitual behavior disturbed. So long as behavior is automatic and habitual there is no urge for it to become self-conscious, though it may become so. If meaning is to become objectified at all, it will as a rule become so when difficulties are encountered that make normal,

automatic behavior impossible. In other words, given a mind disposed toward objectification, meaning will become the focus of attention, an object of conscious consideration, when a tendency or habit reaction is delayed or inhibited.

Meaning and Affect

It thus appears that the same processes which were said to give rise to affect are now said to give rise to the objectification of embodied meaning.

But this is a dilemma only so long as the traditional dichotomy between reason and emotion and the parent polarity between mind and body are adopted. Once it is recognized that affective experience is just as dependent upon intelligent cognition as conscious intellection, that both involve perception, taking account of, envisaging, and so forth, then thinking and feeling need not be viewed as polar opposites but as different manifestations of a single psychological process.

There is no diametric opposition, no inseparable gulf, between the affective and the intellectual responses made to music. Though they are psychologically differentiated as responses, both depend upon the same perceptive processes, the same stylistic habits, the same modes of mental organization; and the same musical processes give rise to and shape both types of experience. Seen in this light, the formalist's conception of musical experience and the expressionist's conception of it appear as complementary rather than contradictory positions. They are considering not different processes but different ways of experiencing the same process.

Whether a piece of music gives rise to affective experience or to intellectual experience depends upon the disposition and training of the listener. To some minds the disembodied feeling of affective experience is uncanny and unpleasant and a process of rationalization is undertaken in which the musical processes are objectified as conscious meaning. Belief also probably plays an important role in determining the character of the response. Those who have been taught to believe that musical experience is primarily emotional and who are therefore disposed to respond affectively will probably do so. Those listeners who have learned to understand music in technical terms will tend to make musical processes an object of conscious consideration. This probably accounts for the fact that most trained critics and aestheticians favor the formalist position. Thus while the trained musician consciously waits for the expected resolution of a dominant seventh chord the untrained, but practiced, listener feels the delay as affect.

Music and Communication

Meanings and affects may, however, arise without communication taking place. Individual *A* observes another individual *B* wink and interprets the wink as a friendly gesture. It has meaning for *A* who observes it. But if the wink was not

intentional—if, for instance, *B* simply has a nervous tic—then no communication has taken place, for to *B* the act had no meaning. Communication, as Mead has pointed out, takes place only where the gesture made has the same meaning for the individual who makes it that it has for the individual who responds to it.[49]

It is this internalization of gestures, what Mead calls "taking the attitude of the other"[50] (the audience), which enables the creative artist, the composer, to communicate with listeners. It is because the composer is also a listener that he is able to control his inspiration with reference to the listener.[51] For instance, the composer knows how the listener will respond to a deceptive cadence and controls the later stages of the composition with reference to that supposed response. The performer too is continually "taking the attitude of the other"—of the listener. As Leopold Mozart puts it, the performer "must play everything in such a way that he will himself be moved by it."[52]

It is precisely because he is continually taking the attitude of the listener that the composer becomes aware and conscious of his own self, his ego, in the process of creation. In this process of differentiation between himself as composer and himself as audience, the composer becomes self-conscious and objective.[53]

But though the listener participates in the musical process, assuming the role which the composer envisaged for him, and though he must, in some sense, create his own experience, yet he need not take the attitude of the composer in order to do so. He need not ask: How will someone else respond to this stimulus? Nor is he obliged to objectify his own responses, to ask, How am I responding? Unlike the composer, the listener may and frequently does "lose himself in the music"; and, in following and responding to the sound gestures made by the composer, the listener may become oblivious of his own ego, which has literally become one with that of the music.

We must, then, be wary of easy and high-sounding statements to the effect that "we cannot understand a work of art without, to a certain degree, repeating and reconstructing the creative process by which it has come into being."[54] Certainly the listener must respond to the work of art as the artist intended, and the listener's experience of the work must be similar to that which the composer envisaged for him. But this is a different thing from experiencing the "creative process which brought it into being."

However, the listener may take the attitude of the composer. He may be self-conscious in the act of listening. Those trained in music, and perhaps those trained in the other arts as well, tend, because of the critical attitudes which they have developed in connection with their own artistic efforts, to become self-conscious and objective in all their aesthetic experiences. And it is no doubt partly for this reason that, as noted above, trained musicians tend to objectify meaning, to consider it as an object of conscious cognition.

Finally, and perhaps most important of all, this analysis of communication emphasizes the absolute necessity of a common universe of discourse in art. For without a set of gestures common to the social group, and without common

habit responses to those gestures, no communication whatsoever would be possible. Communication depends upon, presupposes, and arises out of the universe of discourse which in the aesthetics of music is called style.

13. J. T. MacCurdy, *The Psychology of Emotion* (New York: Harcourt, Brace & Co., 1925), p. 475.

14. For MacCurdy the term "instinct" includes learned habit responses.

15. Notice that this analysis makes apparent the great significance of Aiken's contention that our beliefs as to the nature of aesthetic experience lead to the suppression of overt responses; for such inhibiting of overt behavior tends to intensify the affective response.

16. F. Paulhan, *The Laws of Feeling*, trans. C. K. Ogden (New York: Harcourt, Brace & Co., 1930), p. 19.

17. *Ibid.*, p. 123.

18. The term affective or emotional "state" will henceforth be used to designate those aspects of emotional experience which have been given names and which are in one way or another fairly standardized in a broad sense.

19. See Robert S. Woodworth, "How Emotions Are Identified and Classified," in *Feelings and Emotions: The Wittenberg Symposium*, ed. M. L. Reymert (Worcester, Mass.: Clark University Press, 1928), p. 224.

20. Ernst Cassirer, *An Essay on Man: An Introduction to a Philosophy of Human Culture* (New York: Doubleday & Co., 1953), p. 190. This admirable statement like so many of its kind suffers at the end from an irritating vagueness in which an intangible "the

dynamic process of life itself" is substituted for a definite account of how and why the emotions of art are not comparable to any single state of emotion. It is for a solution to this problem that we are searching in the present discussion of emotional differentiation.

21. C. Landis, "Studies in Emotional Reactions: II, General Behavior and Facial Expression," *Journal of Comparative Psychology*, IV (1924), 496.

22. Donald O. Hebb, *The Organization of Behavior* (New York: John Wiley & Sons, 1952), p. 258.

23. *Ibid.*, p. 232.

24. This statement must be qualified by the reservation that insofar as it can designate or represent extramusical stimuli, music can be said to evoke such affective states as are normally connected with the situations represented.

25. It is also clear that since the world of emotions is not composed of a series of separate compartments, a given listener may feel that a purely musical emotion is comparable or analogous to affects experienced in real life.

26. The term "emotional expression" is misleading in that it implies that such behavior is the direct, necessary expression of affect.

27. Though not within the province of this study, it can, I believe, be shown that similar aspects of experience are involved in musical and other designation. Both, for example, utilize the generality of motion (fast or slow, continuous or interrupted, smooth or disjunct, intense or weak) in such designation. And musical designation, though probably in some respects natural, is, like designative behavior, in the last analysis a product of culture and learning rather than a product of nature.

28. See John Dewey, *Art as Experience* (New York: Minton, Balch & Co., 1934), pp. 35, 56.

29. MacCurdy, *op. cit.*, p. 556.

30. John Dewey, *Intelligence in the Modern World*, ed. J. Ratner ("Modern Library" [New York: Random House, 1939]), p. 733.

31. MacCurdy, *op. cit.*, p. 556.

32. Aiken, *op. cit.*, p. 313; also see Arthur D. Bissell, *The Role of Expectation in Music* (New Haven: Yale University Press, 1921), p. vii; and Hugo Riemann, *Catechism of Musical Aesthetics*, trans. H. Bewerung (London: Augener & Co., n.d.), p. 29.

33. Aiken, *op. cit.*, p. 305.

34. If this takes place, the listener may shift his attention to another aspect of the musical materials, or he may simply abandon the attempt to make sense of the music altogether.

35. Thus the designation of mood and character, whether accomplished in purely musical terms or with the aid of a program or text, is important not only for its own sake, as a source of enjoyment, but also because, as part of the stimulus situation, it is necessary for the proper understanding of the musical processes in progress.

36. Both these aspects of the process of expectation are discussed in later chapters of *Emotion and Meaning in Music*, where much of the preceding discussion is treated in more detail.

37. Eduard Hanslick, *The Beautiful in Music*, trans. E. Cohen (London: Novello, Ewer & Co., 1901), p. 135. The difficulty with this statement is that Hanslick confuses intellectual satisfaction with intellectual activity. For although intellectual activity, in the sense of mental awareness and cognition, may, as we shall see, be unconscious, intellectual satisfaction implies a self-conscious awareness of the activity taking place.

38. Dewey, *Art as Experience*, p. 59; also see *Intelligence in the Modern World*, pp. 755 ff. Robert Penn Warren writes to much the same effect: ". . . a poem, to be good, must earn itself. It is a motion toward a point of rest, but if it is not a resisted motion, it is a motion of no consequence" ("Pure and Impure Poetry," *Kenyon Review*, V [1943], 251).

39. It is clear that the terms "norm" and "deviation" are being used in a very broad and general sense. Deviation includes all delays and inhibitions which give rise to expectation within the context of the particular style in question.

40. Morris R. Cohen, *A Preface to Logic* (New York: Henry Holt & Co., 1944), p. 47.

41. See George H. Mead, *Mind, Self, and Society* (Chicago: University of Chicago Press, 1934), p. 76.

42. Thus Pratt, while maintaining that the ideas aroused in association with music "have little to do with the intrinsic nature of musical sound" (C. C. Pratt, "Music and Meaning," *Proceedings of the Music Teacher's National Association*, Series XXXVII [1942], p. 113), does contend that "music *sounds* the way emotions *feel*" (*Ibid.*, p. 117), a statement which seems to be a disguised form of referentialism.

Incidentally though Pratt's first statement is undoubtedly true, its implications are not. For while our associations may have nothing to do with the intrinsic nature of sound, whatever that may be, they do have something to do with our experience of sound.

43. The term "stimulus" as used here includes any tone or combination of tones which are marked off as a unitary event which is related to other musical events. It is, to use Mead's terminology, "a musical gesture." Or it is a "sound term." In this sense, a single tone, a phrase, or a whole composition may be considered to be a gesture, a stimulus, or a sound term. In other words, meaning must be considered as being architectonic as well as consecutive.

44. Of course, it may have designative meaning. The more difficult it is to grasp the embodied meaning of a work, the greater the tendency to search for designative meanings.

45. Notice, too, that the final tones of a piece, conditioned by all that has gone before, lead us to expect silence and that it is this expectation which makes them meaningful.

46. Note that hypothetical meanings as well as the other kinds of meaning are architectonic. If we are set to listen to a Haydn rondo, then the idea we have of Haydn rondos is, in a sense, the hypothetical meaning of that particular rondo; it is what we envisage and what points to the impinging stimulus.

47. Bertrand Russell, *Selected Papers* ("Modern Library," [New York: Random House, n.d.]), p. 358.

48. Mead, *op. cit.*, p. 194.

49. Mead, *op. cit.*, p. 42–75.

50. *Ibid.*, p. 47.

51. Of course, if the composer is developing a relatively new style, as many contemporary composers have tried to do, the imagined listener may correspond to no listener who actually exists. He is rather one whom the composer hopes to create as his style becomes part of the general style, part of the listening public's stock of habit responses.

52. Leopold Mozart, *Versuch einer gründlichen Violinschule*, quoted in *Source Readings in Music History*, ed. Oliver Strunk (New York: W. W. Norton & Co., Inc., 1950), p. 602.

53. Generally speaking this study is not concerned with the creative act but rather

with the experience which the art work brings into being. This aspect of the composer's creative life is discussed because it clearly concerns the problem of aesthetic experience. Obviously many other mental processes and attitudes which have not been touched upon are involved in the act of composition.

Music and Language: Parallels and Contrasts

RITA AIELLO

Introduction

The relationship between music and language has been addressed by musicians, philosophers, and scholars (Bernstein, 1976; Langer, 1956; see Winn, 1981, for a rich historical account on this topic). The musicologist Curt Sachs (1943) proposed that "music began with singing." Comparisons between music and language are prompted by the strong similarities between the two. Both have an inherent structure and evolve over a temporal continuum, both have a meaning for the listener, and are innate expressions of human capacities. In music and in language there is a phonetic, a syntactic, and a semantic level.

The research in psycholinguistics has influenced the research in the perception of music (Clarke, 1989; Lerdahl & Jackendoff, 1983; Sloboda, 1985). Psychologists have applied some of the experimental designs used to investigate the perception of language to research the perception of music (De Witt & Samuel, 1990; Locke & Kellar, 1973; Tan, Aiello, & Bever, 1985). Drawing on the psychological literature, this chapter discusses phonetic, syntactic, and semantic comparisons between language and music and urges that there be a greater emphasis on research in the emotional meaning of music.

Similarities Between Music and Language

Music and language are universal, innate expressions of human cognition and communication (Clarke, 1989b; McAdams, 1987; Sloboda, 1985). Their universality is evident in the fact that all cultures express themselves verbally and musically. Both are innate abilities that develop through personal interaction, as can be observed in the spontaneity with which children learn to act and interact musically and verbally from a very young age. But, specifically, how does the child acquire a language? In his book *Reflections on Language,* Noam Chomsky (1975) writes:

> [The child] quite effortlessly makes use of an intricate structure of specific rules and guiding principles to convey his thoughts and feelings to others, arousing in them novel ideas and subtle perception and judgments. . . . [I]t remains a distant goal to reconstruct and comprehend what the child has done intuitively and with minimal effort. Thus language is a mirror of the mind in a deep and significant sense. It is a product of human intelligence, created anew in each individual by operations that lie far beyond the reach of will or consciousness. (p. 4)

To learn a language, then, the child subconsciously abstracts the rules of the language structure and utilizes them to create his or her own novel sentences.

Children do not just repeat the sentences they hear, but create new sentences by applying the rules they have abstracted from their language. A similar proposal can be made for the way in which children learn and create music. Along these lines, music, too, can be viewed as "a mirror of the mind in a deep and significant sense." In order to learn and to create music, children abstract some of the rules of their musical culture and use them creatively. Just as they learn spontaneously the rules that allow them to originate an unlimited number of sentences, so they seem to learn the musical rules that allow them to create novel sequences in music. The musical growth of children occurs in stages that have been compared to stages of their cognitive and symbolic development (Gardner, 1973; Hargreaves, 1986; Serafine, 1980; see also Chapters 4 and 5 in this volume).

Although music and language vary across cultures, they share several significant cognitive characteristics (Clarke, 1989b; McAdams, 1987; Sloboda, 1985). Both evolve over time and involve a meaningful use of sound patterns. Throughout the world people use sound patterns to create words, motives, scales, ragas, and drones. The psychologist George Miller (1956) brilliantly showed that our capacity for segmenting and remembering verbal units is approximately seven items: "The magical number seven, plus or minus two;" as he called it. And to a great extent this limit also exists in music if we consider that the pentatonic scale (five pitches) and the diatonic scale (seven pitches) serve as the bases for most of the world's music. The finite length of words, of musical motives, and of verbal and musical phrases reflects our need to segment along the temporal continuum so that we may process most effectively the sounds we hear and create.

Music and language are both modes of communication, yet they have different goals. Generally speaking, while the primary aim of language is to communicate thought, one of the main goals of music is to heighten emotions and express them aesthetically. Music is born out of the need to express ourselves and to communicate aesthetically through the abstractness and the characteristics of sound.

Meter and rhythm are at the heart of music and poetry. Indeed, accents and stresses are the means used to define linguistic and musical patterns. In processing language and music as sensory data, we make use of many of the characteristics of sound—pitch, tone, and dynamics. Some Oriental languages offer striking evidence of the importance that pitch and tone can have, and we find that syllables may be pronounced with different pitch contours. For example, in the Peking dialect of the Chinese language, there are four tones: flat, rising, falling-rising, and falling. The same syllable has different meaning depending on the tone with which it is pronounced: *mā* (pronounced at the level tone) can mean "mother", *má* (rising tone) can mean "hemp", *mǎ* (falling-rising tone) can mean "horse," and *mà* (falling tone) can mean "scold" (Miller, 1981: 59). The dynamic level with which one speaks may be particularly revealing of one's emotions, and in some Western languages (e.g., Italian) the intonation alone of a sentence, not its grammatical structure, conveys whether it is a declarative sentence or a question.

The music of several African cultures shows a close bond between the pitches played by some instruments and the language itself. In west and central Africa, talking drums are used both as musical instruments and as speech surrogates. These instruments reproduce the intonation of words and the rhythms of spoken texts (Nketia, 1974). In the African languages of Kele and Mbane, each syllable possesses a fixed tone, which is high or low. The talking drum sends messages imitating the patterns of high and low that occur in the words (Carrington, 1969: 18). And the *masengo* and *endingidi* fiddles of Ethiopia and Uganda appear even to imitate vocal timbre (Wachsmann & Cooke, 1980).

Words and music are close neighbors physiologically and perceptually (Burrows, 1990). The link is so ingrained that some theories of the origin of music propose that music is a form of heightened speech (Bernstein, 1976; Revesz, 1953; Stacey, 1989). In 1974, Leonard Bernstein devoted the Norton lectures which he delivered at Harvard University to a comparison of the origins of music and language and to an exploration of the similarities in the ways in which we create and process them. These thought-provoking lectures have been recorded in the book *The Unanswered Question* (Bernstein, 1976), which borrows its title from a composition by Charles Ives. Seeking to answer the question "Whither music?" these lectures have influenced research on the similarities of music and language by both musicians and psychologists (Clarke, 1989b; Lerdahl & Jackendoff, 1983; Sloboda, 1985).

Bernstein proposed that, since sound is based on the harmonic series, it functions as a universal for all types of music. He compared the harmonic series to the monogenesis of language: just as languages can be traced to a common origin, so tones can be traced to the harmonic series. Moreover, Bernstein emphasized that the order in which the partials occur in the harmonic series is responsible for the fact that certain intervals, such of the octave, the fifth, and the minor third, are so prevalent the world over, and he compared this recurrence with that of certain syllables (e.g., *ma*) in many of the world's languages.

Many musicologists have mused over the origins of music. Curt Sachs proposed that music sprang from singing (1943: 21). Indeed, the presence and importance of singing in most of the world's cultures attest to the universal binding of music and speech. The word *melody* derives from the musical intonation of a cadenced phrase. As Stravinsky noted, "*melodia* in Greek, is the intonation of *melos*, which signifies a fragment, a part of a phrase" (1947: 42). The singing styles of *recitativo* and *sprechstimme*, for example, are particularly vivid examples of how speech and Western music can be fused.

Classical Greece gave special attention to the union of music and language. The Greeks used singing and instrumental accompaniments to heighten the significance of poetry and drama, a tradition that is at the core of opera. Not until the late Middle Ages did music emerge as an autonomous art form transcending the scope of language. In the splendid book *Unsuspected Eloquence: A History of the Relations Between Poetry and Music*, James Anderson Winn (1981) describes the birth of medieval polyphony:

> The fact that music could achieve actual simultaneity, that it could have vertical as well as horizontal events, was a revolutionary discovery. . . . In literature, one could claim that a line of poetry had four layers of meaning, but in music one could actually write four simultaneous parts . . . . Until this point in history, both the recitation of a poem and the singing or playing of a piece of music had reached the ear as a single series of sounds in time; now music had a new kind of interest, the accidental or contrived vertical combination of two or more pitches. (p. 89)

Until the late sixteenth century, a major role of instrumental accompaniments was to enhance the poignancy of the sung word and of dance. Given today's vast repertoire of instrumental music, it may be easy to forget when instrumental music began to acquire its own independence from the vocal line and to develop into an autonomous art form. Before then, instruments mostly accompanied or imitated dance and song. Igor Stravinsky (1947) in *Poetics of Music in the Form of Six Lessons* remarked: "Music of the kind that has meaning for us today is the youngest of all the arts, although its origin may be as old as man's" (p. 28).

Musical Phonology: Some Comparisons with Language Phonology

The linguist seeks to describe the structure of language just as the music theorist seeks to describe the structure of music. The psycholinguist and the psychomusicologist investigate in their respective domains the psychological processes by which language and music are created and understood. Psycholinguists study how language is created and processed according to three fundamental components: phonetics (the speech sounds of a language), syntax (the way in which words are put together to form phrases, clauses, or sentences), and semantics (the meanings of words). To understand a language, the listener must sufficiently process all three components of the language. Given the fundamental cognitive characteristics shared by music and language, a number of researchers investigating the perception of music have utilized some of the techniques that were developed to study the perception of language. In this section I will discuss two perceptual phenomena that occur in the perception of language and music at the phonetic level: categorical perception and phonemic restoration.

The phonetics of a language are the sound units that constitute the language itself. A phoneme is the smallest phonetic unit. It distinguishes one utterance from another and is roughly the same as a written letter of the alphabet (e.g., b, c, f). The words *bat* and *cat* and *fat* begin with three different phonemes, *b*, *c*, and *f*, but share others. The analysis of speech sounds into phonemes, as well as the division of phonemes into distinctive features, is critical for any analysis of speech perception.

How do we perceive a language at the phonetic level? Partly by categorizing

the sounds that we hear. Categorical perception is the way in which we categorize what we hear. Jusczyk (1986) explains: "Generally speaking, categorical perception is said to occur when the ability to discriminate among members of the same category is very poor, whereas the ability to discriminate among members of different categories is very good. As applied to speech sounds, categorical perception implies that discrimination of sounds from two different categories such as /b/ and /p/ should be relatively easy, but that the discrimination of two different tokens of /p/ from the same speaker should be almost nonexistent" (27-11).

This ability to categorize is strikingly similar to a musical phenomenon. Musicians categorize musical sounds more accurately than nonmusicians just as native speakers categorize speech sounds that are phonemic in their language more accurately than nonspeakers do (for a review of these latter data see Repp, 1984).

A musical note can roughly be compared to a phoneme (Bernstein, 1976; Sloboda, 1985). Locke and Kellar (1973) investigated the categorical perception of musicians and nonmusicians in detecting a difference between an A minor triad and an A major triad. They asked subjects to compare pairs of sine wave triads. The outer notes of the stimuli were always 440 Hz (A) and 659 Hz (E) while the middle note varied by 2, 4, 6, or 8 Hz, ranging from 523 Hz (C) to 554 Hz (C-sharp). It was found that the musicians discriminated better across category boundaries than the nonmusicians. They were more sensitive to the differences between the chords and were able to discriminate between the triads when the middle pitch varied by 4 Hz. In general, nonmusicians require a greater difference between the triads to perceive a change. The superiority of musicians in categorizing musical sounds has been proven using different types of musical stimuli (Wapnick, Bourassa, & Sampson, 1982; Zatorre & Halpern, 1979).

The perceptual phenomenon of phonemic restoration also occurs in both language and music; it describes the ability of listeners to use their previous knowledge to supply what is missing (Warren, 1970). De Witt and Samuel (1990) explain that if a phoneme occurring within a word is replaced with noise, listeners cannot indicate which phoneme has been distorted because their knowledge of the word supplies the missing information; therefore, they perceive having heard the intact word with nothing missing. Similarly, in the musical case, restoration occurs when listeners believe they have heard an auditory signal intact when in fact noise has replaced some of the notes.

De Witt and Samuel (1990: experiment 1) asked subjects to hear a series of familiar melodies and indicate whether a noise replaced or coincided with a musical pitch. The researchers found that the subjects' specific expectations about a particular musical sequence allowed them to notice disruptions to that sequence. The musical training of the listeners affected their perception of the stimuli as well: overall, musicians showed better discrimination performance than the less trained subjects. What one expects to hear influences the nature of what one hears. As De Witt and Samuel note, "musical restoration is an example

of a more general perceptual phenomenon in which prior knowledge and expectations lead to a filling in of a missing information" (p. 142). The perception of music is not simply a passive reception of tones but an active process. The occurrence of categorical perception and of restoration effects in speech and music demonstrates a certain level of commonality of processing across these two domains.

Musical Syntax: Some Comparisons with Language Syntax

Consciously or subconsciously, one listens to music according to some stylistic and perceptual laws. Music is composed and improvised according to a style, and even the musically untutored listeners acquire a musical syntax, a system of rules by which they make sense of music. Despite varying degrees of awareness, listeners understand the syntactic complexity of composition and the arguments of musical form (Spender, 1987: 502).

In music as in language, we are aware of the grammatical features of the stimulus. Experiments show that there are strong similarities in the way in which people perceive structure in music and in language. Deutsch (1981, 1982) asked musically trained subjects to recall sequences of 12 pitches by writing them down in musical notation. She found that the subjects' performance depended on the degree of structure in the stimuli. Sequences that were tonally structured were easier to write down than sequences that were not tonally structured. In addition, the placement of rests within the sequences also had an effect. The subjects' performance decreased when the rests were placed in locations that did not coincide with the tonal structure of the sequences.

A number of experiments have applied techniques that were developed to investigate the syntactical aspects of language perception to study the syntactical aspects of music perception. I will describe three categories of experiments that show that listeners are aware of the grammatical features of the stimuli, and whose results are rather similar in the language and the music domain: reading experiments, phrase boundary experiments, and experiments that consider the location of clicks within sequences.

Reading Experiments

A number of studies (Levin & Kaplan, 1970; Sloboda, 1974, 1977) have investigated the span (i.e., the number of words or notes) that readers take in ahead of time when reading language or sight-reading music. In language reading, experienced readers tend to take in material extending up to a phrase boundary, wait until the complete processing of that phrase, and then rapidly sweep to the next phrase boundary to take in the material of the next phrase. We tend to pause the longest after reading complete major grammatical units (Sloboda, 1985).

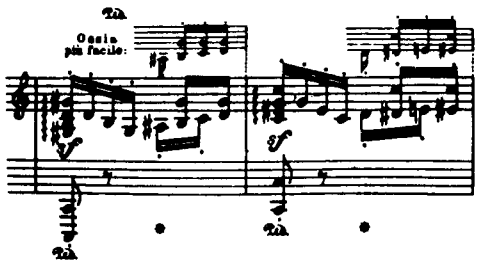

FIGURE 2.1. Brahms, Cappriccio, op. 76, no. 2, bars 76–78.

In sight-reading music, experienced readers identify significant structural units and scan them differently, according to whether the music is homophonic or contrapuntal. Experienced sight readers do not read note-by-note but shape the music as they read it by emphasizing patterns, thus creating a meaningful interpretation. They create meaningful patterns by imposing performance markers onto the music they play. Although an experienced language reader reads a text roughly in the same way as an experienced musician sight-reads music, the proficiency of the musician is evident in one additional way: in the skill with which he or she eliminates some material from the score so that the sight-reading will be heard as being both technically proficient and musically coherent. It is very interesting that in sight-reading a score musicians tend to commit "proof-readers'" errors. Pianists fail to notice the errors that may be in a score and subconsciously correct them, possibly on the basis of their tacit knowledge of the stylistic norms of the music (Sloboda, 1985: 75)

In the second measure of Figure 2.1, most pianists will play the G as if it were written G-sharp. The fact that it is actually a G-natural will easily go unnoticed. It is the *inexperienced* pianist who, lacking the musical intuition, will tend to sight-read this passage as it is printed.

Phrase Boundary Experiments

We segment language and music in locations that reflect the grammatical structure of the stimuli. A phrase, whether it occurs in language or in music, is a psychological unit. Experiments indicate that, in both music and language processing, we tend to process more effectively material belonging to one phrase than material that integrates two phrases. Tan, Aiello, and Bever (1985) asked musicians and nonmusicians to listen to single-line melodies that used only equal-duration notes and that formed a two-phrase musical period. Using a psycholinguistic paradigm, the subjects were asked to recognize a two-note probe that either (1) occurred at the end of the first phrase, (2) straddled the phrase boundary, or (3) occurred at the beginning of the second phrase. All subjects, regardless of their musical training, perceived with greater difficulty the two-note probe that straddled the phrase boundary. The familiarity with the harmonic structure influenced the listener's perceptual organization of the melodies in

ways analogous to the perceptual organization of clauses or sentences. This result, however, was more accentuated for the musicians.

Click Experiments

Additional evidence of the syntactical similarities between language and music comes from studies that investigate the location of clicks (Fodor & Bever, 1965; Gregory, 1978). These experiments look at the perceived location of clicks and reveal the strategies that subjects use in processing the auditory material. Click experiments have shown that subjects use basically the same strategies in processing verbal and musical sequences because the grammatical structure of the stimuli guides the listeners' perception. In click experiments, a click is presented at one or more strategic locations while the subjects hear some verbal or musical material; the subjects' task is to indicate the syllables or notes that occurred simultaneously with the click (or clicks). Frequently listeners report the location of the clicks inaccurately. They believe they heard them at the end of phrases, regardless of the location where the clicks actually occurred. It is as if the clicks *migrated* toward the direction of the phrase boundary. This result illustrates that phrase boundaries are important in the perception of language and music.

Musical Grammars

The theories of language proposed by the linguist Noam Chomsky (1957) have been utilized by psychologists and musicians in making comparisons between the nature of music and language. Chomsky postulated that every possible sentence consists of two levels: a surface structure and a deep structure. The surface structure is closely related to the string of words that we hear or see, while the deep structure is closely related to the underlying meaning of the string of words. Let us consider an example. Although at the surface the sentences *John is easy to please* and *John is eager to please* differ in only one word, we understand that there is a substantial difference in their meaning. Indeed, they have different underlying deep structures. On the other hand, we understand that "the dog chased the cat" and "the cat was chased by the dog" are related in meaning (that is, have the same underlying deep structure) despite the dissimilarities in their surface structures.

Chomsky proposed that by applying various transformational rules to the deep structure—for example, *John* + *Love* + *Mary*—we can derive all the sentences that are related to this deep structure, such as *John loves Mary, John does not love Mary, Does John love Mary?* and so on. As I pointed out at the beginning of this chapter, we do not store the sentences that we would like to say but, rather, the rules that give rise to the sentences. If language were based exclusively on repeating what we heard, we could *only* repeat what we had heard before and say nothing new. Instead, we abstract the grammatical rules from the

previously heard sentences and use them to generate new sentences, thus expressing our own novel thoughts. And, in a general sense, the same can be said for music.

Leonard Bernstein (1976) was among the musicians seeking analogies between aspects of Chomskian theories and the structure of music (other interesting proposals have also been made by Lerdahl & Jackendoff, 1983; Sloboda, 1985; and Clarke, 1989b). Bernstein illustrated how a Chomskian transformational grammar could be compared, in some fashion, to the theories of music proposed by Heinrich Schenker (1935/1979). For Bernstein, Schenker's analyses trace what happens in a piece of music to a basic chordal structure, just as Chomskian transformational theories trace what we hear as the surface of language to the deep structure of language. In this vein, the melody (Schenker's *urline*) is equivalent to the surface structure of the language, and the harmonic structure (Schenker's *bassbrechung*) can be compared to the deep language structure.

One must keep in mind that while Schenker's musical analyses are based on long structures of music that can reflect as much as an entire piece (Schenker, 1969), Chomsky's theories of language are based on strings of words that are relatively short. Nevertheless, there is validity in the Chomsky-Schenker comparison because there is a relationship between the melody and the harmony that can be compared to the deep and the surface structure of language. But although this language-music analogy is attractive and stimulating, I believe that it fails to do justice to a major distinctive element between language grammar and music grammar: ambiguity. Ambiguity occurs rather seldom in language because language is based on communication (I will discuss ambiguity again later in this chapter with reference to the meaning of music). On the other hand, ambiguity is a major element of the grammar and aesthetics of music. Chomskian transformational theories of language explain that what is ambiguous in language is the result of two possible, but different, deep structures. For example, the sentence *they are visiting firemen* could be interpreted as *(they) ([are] [visiting firemen])* or *(they) [are visiting] [firemen])*.

In music, however, a specific harmonic progression can give rise to many melodies *and* the same melody can be harmonized by several different harmonies. Figures 2.2 and 2.3 present the Cantabile movement from Beethoven's Quartet, op. 18, no. 5, and two settings of the chorale "O Ewigkeit, du Donnerwort" by J. S. Bach which illustrate this last point.

Moreover, when listening to music there are many possible perceptions. Many elements occur simultaneously, and each musical element may have a specific syntax of its own. When listening to music we are subconsciously aware that there are *many* grammatical possibilities between the parts. The grammar of music allows for complexity and simultaneity. Overall, the syntax of music has much more latitude than that of language. Thus, in comparing the syntaxes of music and of language, we must remember that music is by far more flexible and ambiguous than language, almost regardless of style.

Let us look at an example where the syntactical ambiguity occurs because of

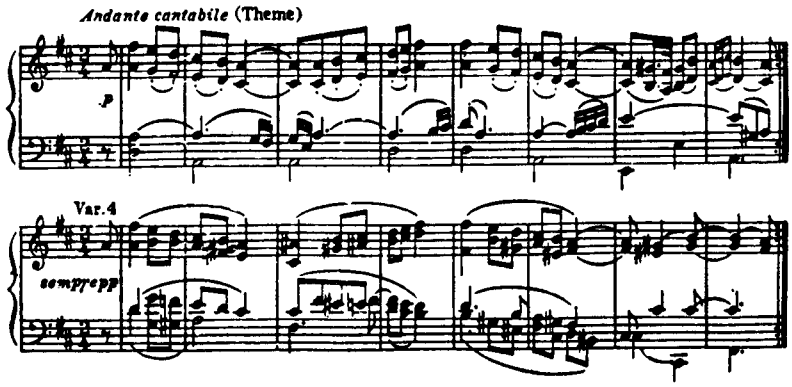

FIGURE 2.2. Beethoven, Andante Cantabile from Quartet, op. 18, no. 5, theme and variation 4.

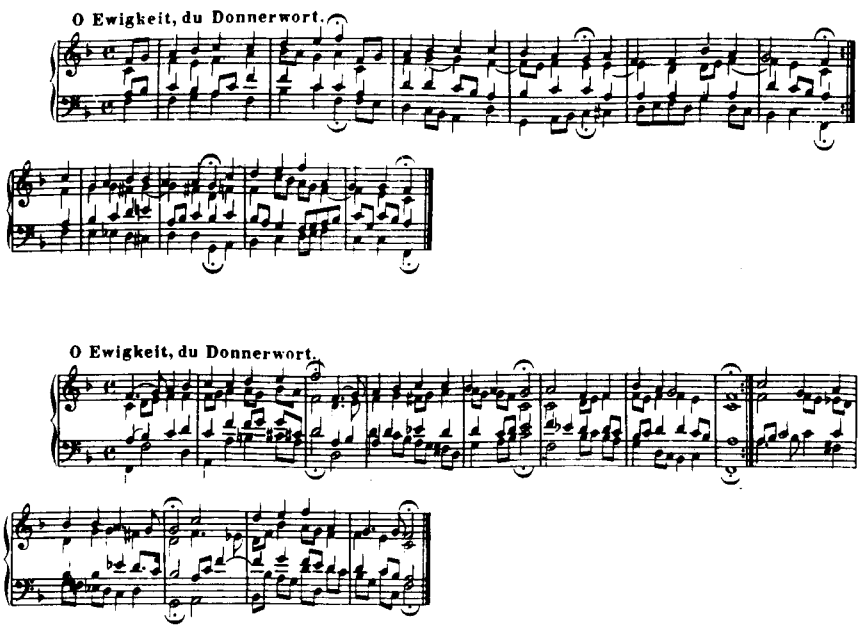

FIGURE 2.3. J. S. Bach, two settings of the chorale "O Ewigkeit, du Donnerwort."

the tonality of the piece: Chopin's Mazurka, op. 17, no. 4. What key is this mazurka in? We do not know until later in the piece when we finally realize that it is in the key of A minor. Clearly, in this case, it is the harmony that provides the element of ambiguity to the piece[1] (Figure 2.4).

In returning to Bernstein's analogy that the deep structure and the surface structure of language can be compared to the harmonic structure and the melody of music, I would like to propose that the deep structure of language be compared to a musical theme, and that the surface structure be compared to the musical variations that can be made with the theme. In this vein, by applying rhythmic, melodic, and harmonic transformations to the theme (the deep structure) the composer creates musical variations that reflect their original source but that, at the same time, have the freedom and the ambiguity which are characteristic of music.

For the psycholinguist, a grammar is a set of rules capable of generating an aspect of a structure of language. Grammars are collections of strategies for understanding and producing sentences. The developments in the psychology of music have influenced many researchers to write about musical grammars (Baroni, 1983; Roads, 1979). In recent years, grammars have been proposed for generating Swedish nursery songs (Lindblom & Sundberg, 1970), J. S. Bach's chorales (Baroni & Jacoboni, 1978), chord progressions in jazz (Steedman, 1984), and the setting of words to Gregorian chant (Chen, 1983), to mention only a few. And in *A Generative Theory of Tonal Music*, Lerdahl and Jackendoff (1983) combined principles of Chomskian transformational grammar and Schenkerian theory and proposed a theory of how listeners familiar with the tonal style listen to tonal music. This theory takes into account principles of: (1) grouping, (2) meter, (3) time-span reduction (a system that assigns the relative dominance of each surface event according to a tree structure), and (4) prolongation reduction (a system that describes the patterns of harmonic tension and relaxation). To date, however, only parts of this theory have found experimental support (Bigard, 1990; Deliège, 1987).

Although the proposal of musical grammars has been very instrumental in advancing research in the psychology of music as a whole, a psychology of music must be sensitive to features that are *unique* to music, because the application of psycholinguistic paradigms alone cannot answer the questions that are at the core of music itself (see also Clarke, 1989a, 1989b). A grammar prescribes an order, a set of rules; it does not guarantee an aesthetic reaction, it is not a prescription for it. Productive research in the psychology of music will need to address not only how the mind perceives the sounds, but the aesthetic and emotional meaning that the sounds give rise to.

Musically speaking, the style of a piece reflects its musical grammar. If the grammar of a musical composition is too taxing perceptually, will listeners relate well to the piece? David Smith and Jordan Witt (1989, see also Smith, 1987) tested how listeners react aesthetically to tonal and serial compositions. They asked subjects classified as "nonexperts who enjoyed classical music" to listen to

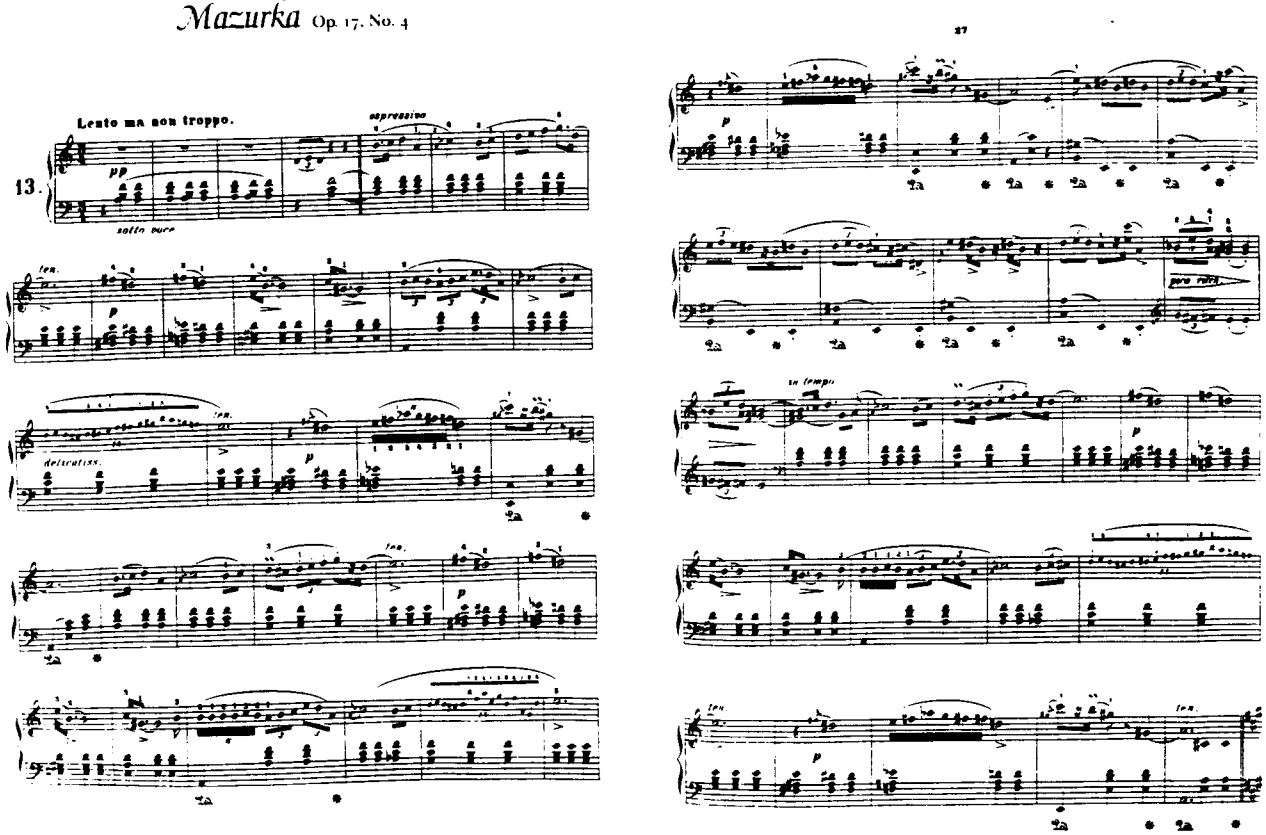

FIGURE 2.4. Chopin, Mazurka, op. 17, no. 4.

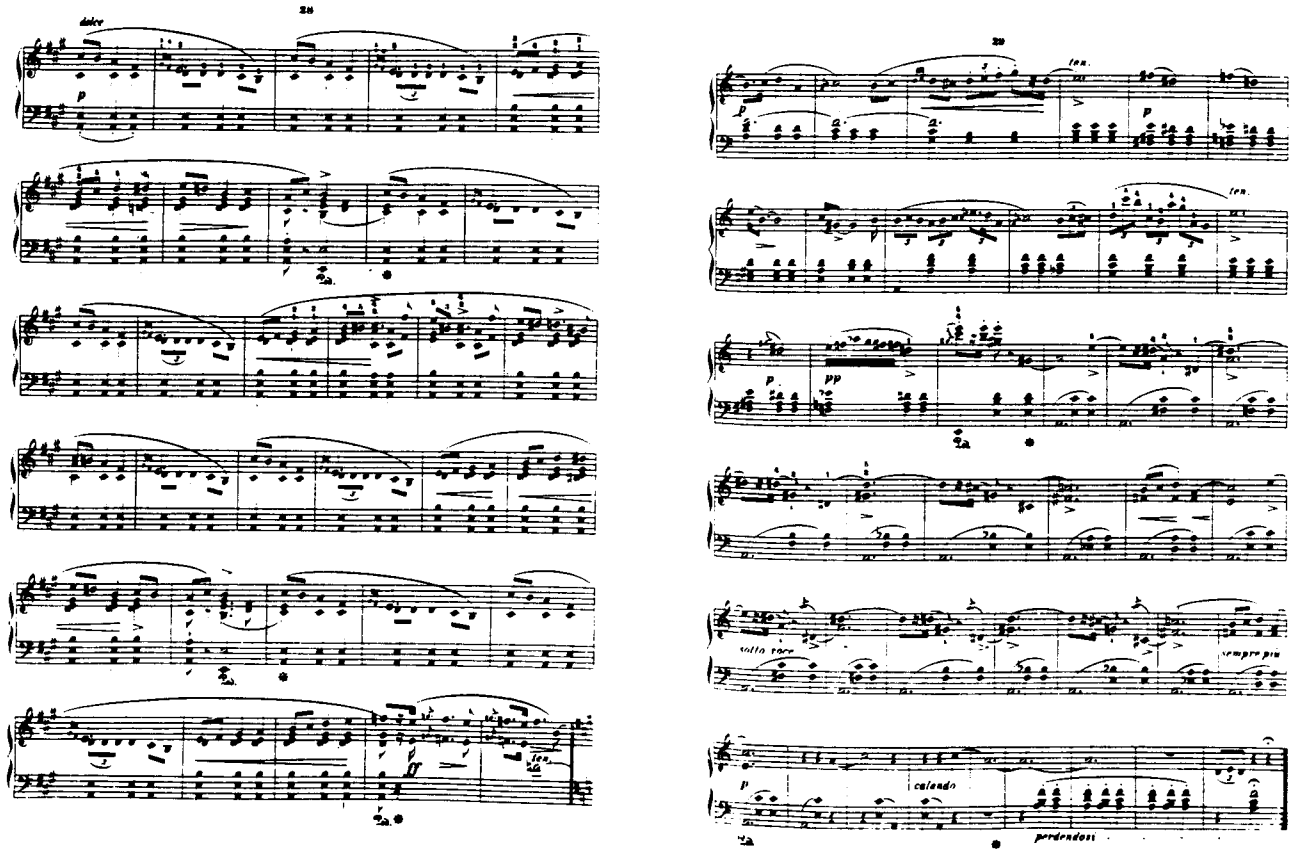

FIGURE 2.4 (*continued*)

brief excerpts from the beginning and the end of tonal and serial works by Schoenberg and Webern and to describe them using a set of 26 adjectives and a rating scale from 1 to 7. Thus, it became possible to draw an aesthetic profile of each musical excerpt. The results showed that listeners find serial music, with its atonality and rather unfamiliar grammar, to be less rich emotionally than tonal pieces written by the same composers. Smith and Witt, therefore, found that if the stylistic constraints of a piece are perceptually too demanding, listeners may not be able to understand the music and thus may not derive as much enjoyment from what they hear.

This is indeed the general reaction that many listeners will have, at least in the beginning. They will tend to perceive that the stylistic complexity of a serial piece is the result only of the composer's intellectualism. When that happens, the music loses its aesthetic and emotional message for many listeners. In this context, I am reminded of the remarks made by the writer Isaac Bashevis Singer on literature: "The very essence of literature is the war between emotion and intellect. When literature becomes too intellectual—when it begins to ignore the passions, the emotions—it becomes sterile, silly, and actually without any substance" (Page, *The New York Times*, July 26, 1991).

Listening to Music: Where Is the Meaning?

What is musical meaning? Specifically, how does the listener derive a meaning from music? Earlier I discussed some comparisons between language and music at the phonetic and the syntactical level. But, semantically, where is the musical meaning to be found? Is the semantic level of music to be found in the emotions that music elicits? To a great extent, *Yes*. But ultimately, *why* do we listen to music? To follow a grammar? To abide by a perceptual theory? Probably not. Most of us listen to music to partake of the emotional and aesthetic experience that music offers.

Unfortunately, there is a wide gap between the progress that has been made in understanding how music is perceived and what it means to listeners. A close link clearly exists between music cognition and the emotions that music elicits, but an evaluation of this link is yet to be researched thoroughly. Meaning, in all its complexity, most likely lies hidden in the emotional content of music, and all of us, consciously or not, perceive it.

Language is based on understanding the interaction of its phonetic, syntactic, and semantic levels. And while music conveys meanings, its semantic level is not as uniformly defined as that of language. Language is the means through which verbal information is shared, and at the level of literature and poetry, it becomes the art form through which we express ourselves verbally. Music is the art form that expresses feelings and meanings through the qualities of sounds and the relationships between sounds. In language, the specificity of the semantic component provides information. Indeed, verbal communication cannot take place

if the listener does not understand the semantic meaning. But in music this is not necessarily the case. Although the meaning of music is enhanced by our knowledge of musical styles and practices, musical meaning remains both pluralistic and personal.

To understand a language, the listener combines the sounds into words that have a semantic meaning and places them within an organized structure (i.e., a grammar). To understand music we combine sounds into motives, melodies, and phrases and listen with various degrees of awareness to many musical elements occurring simultaneously: rhythm, tonality, dynamics, interpretation, all within an overall structure that reflects stylistic influences. There is not one single, uniform meaning that can be attached to a musical composition by all listeners at all times with the same certainty as there is a semantic meaning in a language composition. Broadly speaking, the lack of a specific semantic component leaves the listeners quite free to select from the meanings created by the combinations of the musical elements, and to attach their own meanings to the musical composition as a whole. Because of the lack of a uniformly defined semantic meaning and the multiplicity of elements occurring in a musical piece, music has a plasticity and a richness that language does not.

Music contains a simultaneity of meanings and a plurality of meanings. The simultaneity of meanings exists because each musical element has its own line, its own importance, yet all contribute to an overall form and significance. In music many musical elements occur, simultaneously creating musical shapes and giving rise to musical meanings. The combination of the musical elements and the effect of the performer's interpretation create an exceptionally rich and complex stimulus.

Although our tone of voice and the dynamics of our speech influence very much the nuances of meaning that we wish to convey, communication through language is possible because of the specificity of the semantic level. For example, pronounce "good morning" placing a different emphasis each time on one of the two words. Now pronounce it using a variety of speech dynamics from a bitter, sarcastic comment to an affectionate greeting. Because music is not based on a unified semantic level, we become particularly sensitive to the specific combinations of the musical elements, the nuances, and the dynamics of each performance. Lewers (1980) writes: "If inflection and nuance *enhance* the effect of spoken language, in music they *create* the meaning of the notes. Unlike words, notes and rests do not point to ideas beyond themselves; their meaning lies precisely in the quality of the sounds and silences, so that the exact rendering of the notes, the nuances, the inflection, the intensity and energy with which notes are performed *become* their musical meaning" (p. 67). Indeed, a composition may take a particular meaning just because of the interpretation of a performer.

How many musical elements contribute to create a single measure of music? One of the principal reasons we can keep listening over and over again to a brief piece of music is because of the multiplicity of patterns that potentially we can attend to, and because of the potentially great number of meanings that listening

to music can offer us. The art of listening is the art of discovery, and it motivates us to listen again. Consciously or subconsciously, listeners realize that they could discover different degrees of saliency for specific elements in the music with every hearing. The simultaneity with which lines and elements occur in music is different from that of language; this influences the way in which we listen to music perceptually and influences the way in which we retrieve a meaning from music emotionally. When several people speak different words at the same time, they produce cacophony. But when they sing different words at the same time, it may result in immense beauty if the individual parts are coordinated harmonically, melodically, and rhythmically.

The knowledge of a musical style or tradition can be of great importance in relating the intent of the music. In listening to music, the meaning can be derived from (1) the intellectual appreciation of the musical elements, (2) the emotional, aesthetic reaction that results in the appreciation of the stylistic characteristics of the music (Meyer, 1956, see also Chapter 1 in this volume), and (3) the association of a piece with a specific event or place (what John Booth Davis called the "*Darling, they are playing our tune*" theory, 1978: 69). In the book *The Open Work*, Umberto Eco (1989) writes: "the form of the work of art gains its aesthetic validity precisely in proportion to the number of different perspectives from which it can be viewed and understood. These give it a wealth of different resonances and echoes without impairing its original essence" (p. 3).

In some way, then, listening to music is like looking into a prism: to appreciate its light, we view it from different angles since we may only observe the prism's light one way at a time. This does not deprive the prism of its multiplicity of splendors, but attests to our limitation in being able to focus on one side at a time. In this sense, we are always "correct" when we listen to music because there is no exclusive meaning that can be attributed to a piece. How many elements could we potentially focus on, and how many meanings could a musical composition potentially have?

Researchers have probed extensively into the relationship between music and semiotics, the philosophical theory that deals with the interpretation of signs and symbols. A number of writers have proposed that music, too, may be interpreted semiotically (Clarke, 1989b; Eco, 1979, 1989; Nattiez, 1990; Stefani, 1974). From this perspective, musical excerpts or entire musical compositions may be interpreted by listeners as signs having an explicit meaning because of their structure or their historical association. Umberto Eco (1979) explains:

> [M]usic presents, on the one hand, the problem of a semiotic system without a semantic level . . . on the other hand, however, there are musical signs . . . with an explicit denotative value (trumpet signals in the army) and there are . . . entire "texts" possessing pre-culturalized connotative value ("pastoral" or "thrilling music," etc.). In some historical eras music was conceived as conveying precise emotional and conceptual meanings, established by codes, or at least, "repertoires." (p. 11)

Information Theory

One reason people listen to music is that the listening confirms one's expectations. From this perspective, the listeners' awareness of the patterns of musical tensions and resolutions is what gives music its significance. The listeners' knowledge of the musical style allows them to partake of the tensions and resolutions of the music. As Meyer (1956, see also Chapter 1 in this volume) has proposed: "in music . . . the same stimulus, the music, activates tendencies, inhibits them and provides meaningful and relevant resolutions" (p. 23). In an insightful commentary on the first movement of Beethoven's Fifth Symphony, titled "Music, Mind and Meaning," Marvin Minsky (1981) asks: "Why do we like music? . . . everyone knows how it touches our emotions, but few think of how music touches other kinds of thoughts" (p. 28). He goes on to describe how listening to music engages the previously acquired personal knowledge of the listener. Specifically, Minsky asks: "Why do we like certain tunes? Because they have certain structural features. Because they resemble other tunes we like" (p. 34).

The views of Meyer and Minsky (see also Moles, 1968; Pinkerton, 1956; Youngblood, 1958) are rooted in information theory, the theory based on the mathematical probabilities of what will occur next in a chain of events. In brief, research in the applications of information theory to music examines the probabilities that a musical message will be understood by the listener considering the arousal, the satisfaction, and the frustration of the expectations of the listener. In music there are units (i.e., chords, isolated notes, etc.) that represent meaningful events. How can the listener predict what will happen in hearing the chain of musical events? And which specific predictions can the listener make? Events in music form patterns, and these occur especially at meaningful moments in the unfolding of the music (Coons & Kraehenbuehl, 1985; Kraehenbuehl & Coons, 1959; for a summary on information theory and music, see Bent, 1987). The listener, then, searches for a musical meaning by constantly interpreting what is occurring in the music. This view is consistent with research in the psychology of emotions as proposed by Mandler (1984).

In listening to music, the listener seeks an equilibrium: there must be a proportion of novelty within a background of predictability. So the meaning of music is based on the enigma: on the tension of hearing simultaneously the old and the new, in rejoicing in what we recognize, yet in being fascinated and intrigued by the new possibilities that the composer presents us. The theme from "Frère Jacques," as it appears in the beginning of the third movement of Mahler's First Symphony, is an example of how a familiar melody may present us with a completely different meaning because of the context in which it is heard, and

because of the way in which the composer has altered it. Here the French children's song is in a minor key, at a slower tempo than the usual one, and accompanied by the poignant ostinato of the timpani. Our emotions in recognizing the "Frere Jacques" theme are likely to reflect our ambiguity—on the one hand, recalling the way we heard it before and, on the other, wanting to embrace the way Mahler presents it now (Figure 2.5).

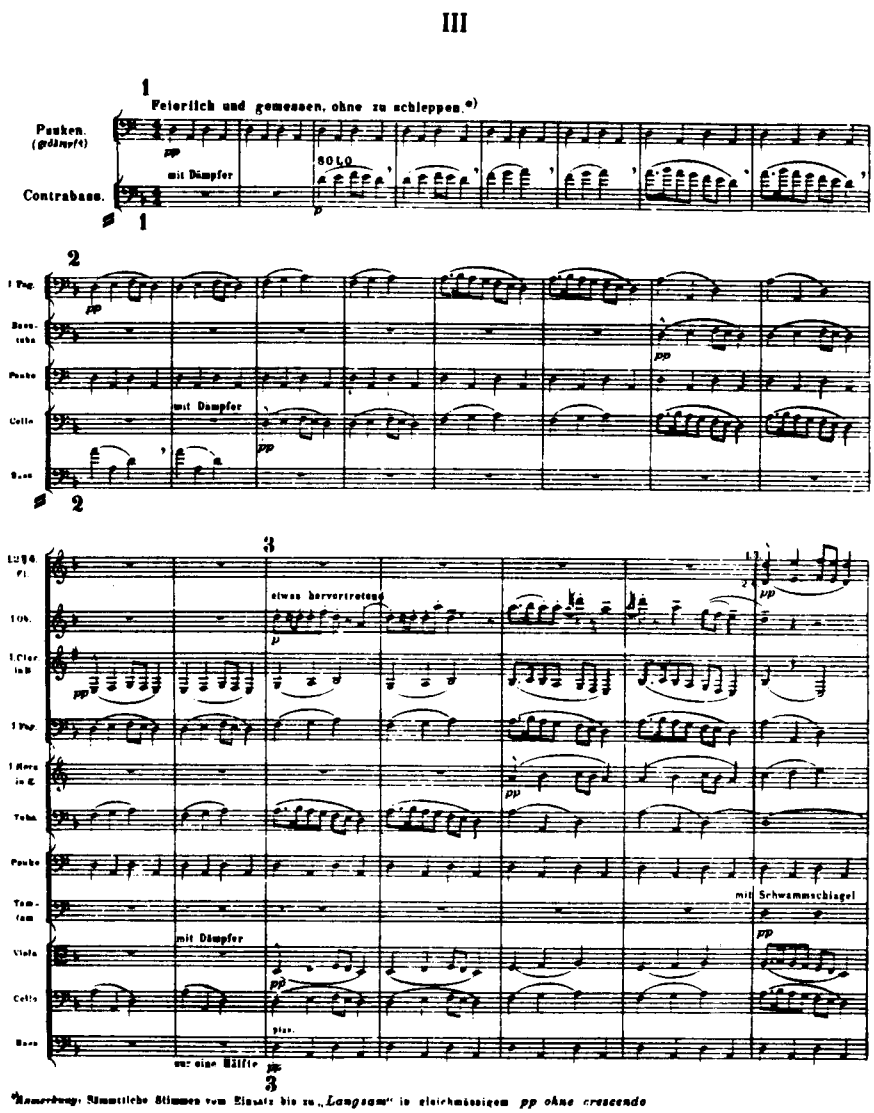

FIGURE 2.5. Mahler, Symphony No. 1, beginning of the third movement.

Experimental Research in the Meaning of Music

The scarcity of research in musical meaning must be attributed in part to the difficulties of the methods that would be needed to investigate this topic, the major one being caused by the fact that there is no uniform meaning in music for all listeners at all times, and that the meaning that the listeners derive from a piece of music may change over time. But, overall, when subjects are asked to assign a title or a descriptive adjective to musical excerpts, their responses do fall within broad clusters of agreement (Hevner, 1936; Wedin, 1972).

In the book *The Language of Music*, Deryck Cooke (1959) proposed that the intervals of the diatonic scale suggest different emotional qualities and described how some basic melodic tonal combinations give rise to specific emotions. Cooke based his theory on the music of the classic and romantic periods, focusing only on the tonal structure of recurring, brief, melodic motives, without taking into account the importance of their orchestration, tempo, rhythm, dynamics, and the broader musical context in which these motivic fragments occurred.

Recently, Sloboda (1991a, 1991b) has begun to investigate whether emotional reaction may be related to specific musical events. He asked listeners to fill out a questionnaire naming the particular pieces of music to which they could recall having experienced physical manifestations commonly associated with emotions. Sloboda found that there was much agreement in the subjects' responses, and that their emotional reactions could be linked to particular structural features of the musical score. Listeners attributed feelings associated with tears to passages containing appoggiaturas and melodic or harmonic sequences (such as the opening of Albinoni's Adagio for Strings), and they associated shivers with musical passages containing new or unprepared harmonies, or sudden shifts in tonality.

Many listeners emphasized how music promoted an intensification or a release of their existing emotions (Sloboda, 1991a). The comments of these listeners link pertinently with the words of the philosopher Susanne Langer. For Langer, musical structure logically resembles the dynamic pattern of human experience. In her book *Philosophy in a New Key* (1956), she writes: "Music is not the cause or the cure of feelings, but their logical expression. It is not usually derived from affects nor intended for them; but . . . it is about them" (p. 218). Thus Langer finds that music "is not self-expression. It is the expression of feelings" (p. 221).

Summary

Some analogies can be drawn between music and language, and a number of experiments have shown similarities between the perception of music and lan-

guage at the phonetic and syntactic levels. Unlike language, which is attached to semantic structure, music can truly be seen as a universal language in the sense that music has meaning for everyone who listens to it. This meaning is not static, but can change for each person with each listening as our focus shifts from melody to harmony to rhythm to form to the subtleties of the performer's interpretation.

NOTE

1. Bernstein (1976) also used this Chopin mazurka as an example of ambiguity, although his discussion had a different emphasis.

Perception: A Perspective from Music Theory

NICHOLAS COOK

Introduction

The study of the relationship between music theory and psychology can be traced to the work of Leonard Meyer (1956, see also Chapter 1 in this volume) and Christopher Longuet-Higgins (1976, 1978). It can also be traced to Marvin Minsky, a leading exponent of artificial intelligence, who in 1981 asked: "What might we discover if we were to study musical thinking? Have we the tools for such work?" And then went on to recommend that "music theory is not only about music, but about how people process it. To understand any art, we must look below its surface into the psychological details of its creation and absorption" (pp. 28–29).

The last decade has seen a blossoming of the research in the cognitive psychology of music (see Deutsch, 1982; Dowling & Harwood, 1986; Howell, Cross, & West, 1985; Jones & Holleran, 1992; Longuet-Higgins & Lisle, 1989; McAdams, 1987; Sloboda, 1985). Indeed, psychologists have become interested in music because the perception and cognition of music reflect mental structures. Their work has yielded models to test music theory empirically, and at the same time, some music theorists have placed musical analysis within a wide spectrum of knowledge that draws from linguistics and information theory (see Bent, 1987; and Lerdahl & Jackendoff, 1983).

Broadly speaking, musicians and music psychologists have a similar goal: to know how music is perceived and understood. The interest of music theorists and musicians is in understanding better the musical structure and musical interpretation of actual compositions; cognitive psychologists, on the other hand, have been more interested in researching mental theories of how specific musical events may be perceived. Their emphasis has been primarily to

investigate the perception of separate musical parameters rather than the musical experience.

In this chapter, Nicholas Cook acknowledges the growing interest in the psychology of music, but argues that cognitive psychology and music theory are two disciplines with essentially different and mutually incompatible aims. Cook challenges the notion that music theory ought to be considered a branch of psychology. He bases his position on the fact that psychological research has placed too much emphasis on the psychoacoustical parameters of music and has not addressed questions intrinsic to the meaning and the cultural value of music. Throughout this chapter, Cook points out that there are potential pitfalls in applying general psychological theories to music without taking into account what listeners actually hear, and why.

As an example of this research, Cook refers to *A Generative Theory of Tonal Music* by Lerdahl and Jackendoff (1983), which proposes that tonal music is based on a grammar. They suggest that in order to understand tonal music the listener needs to know its grammar. Since their book provides a model of the knowledge necessary to listen to tonal music, it is a contribution to both music theory and psychology. For Lerdahl and Jackendoff, the same grammatical principles of tonal music apply whether one listens to individual musical phrases or to entire tonal compositions.

Cook here argues with several aspects of Lerdahl and Jackendoff's theory and quotes experimental evidence demonstrating that people do not listen to music according to large-scale structures. In addition, Cook points out that studies on the recognition of intervals, chord progressions, and key centers are merely tests of ear training. They do not consider the significance of music. He laments: "[P]erceptual psychologists assume that music is made out of notes." Cook concludes by proposing that there be a more careful translation of the concepts from one discipline to the other.

Music and Psychology: A Mutual Regard?

There is no doubt that music theorists and perceptual psychologists have become better acquainted with one another's work in recent years. Journals have been set up, such as *Music Perception*, which welcome contributions from either camp. There have been conferences with titles such as "Music and Cognition" which are equally cross-disciplinary in thrust. And, as one might expect, there have been friendly and cooperative programs for cross-disciplinary research. David Clarke, a music theorist, recommends Schenkerian analysis to psychologists as a source of formal theories that may be transformed into empirically testable hypotheses (1989: 130). Carol Krumhansl, a psychologist, recommends empirical data to music theorists as an aid to framing theory in more psychologically relevant terms (1990a: 287). And Jay Dowling puts this picture of mutual cooperation into a nutshell: "Experiments provide tests of theories, and theories show experiments how to define phenomena" (1989: 249).

Of course, the relationship between music psychology and theory is not always so harmonious. One problem has been when musicians draw on perceptual data to justify their theoretical edifices. A classic example of this is the composer and theorist Milton Babbitt, who justified his theory of combinatorial serialism by saying that the system is built out of interval classes, and therefore anyone who can identify pitch classes can hear combinatorial structure (1962: 120). Another is the composer Karlheinz Stockhausen (1959), who justified his use of logarithmic relationships of duration on the grounds that logarithmic relationships are found in the perception of pitch, and that pitch is simply duration transferred to a higher level;[1] therefore, Stockhausen concluded, logarithmic duration structures are perceptually privileged. In each case, the argument—Eric Clarke (1989a: 11) calls it "sleight of hand"—works the same way. A perceptual principle that applies to one set of circumstances (identifying

an interval in an ear-training class in Babbitt's case, the logarithmic nature of pitch perception in Stockhausen's) is generalized to a quite different situation, without any consideration as to whether the generalization in fact has any perceptual validity. These are merely extreme and notorious examples of a quite general music-theoretical ploy, the purpose of which is essentially rhetorical: make an initial bow in the direction of the psychology of perception and then carry on with your theorizing regardless, but claiming the enduring benediction of psychology.

Psychologists of music have on occasion lost patience with theorists' cavalier attitudes toward perception. Vladimir Konečni and Heidi Gotlieb (hereafter referred to jointly as Konečni) carried out a number of tests in which well-known works from the classical canon—Bach's *Goldberg* Variations, Beethoven's sonatas—were played with their movements in the wrong order. College-level listeners showed no preference for the original ordering of the movements over the modified one (Konečni, 1984; Gotlieb & Konečni, 1985). Konečni then quoted a number of assertions by theorists to the effect that the movements *had* to be in the order the composer put them in because of considerations of higher unity. (It is worth pointing out that, as is often the case in psychological writings on music, the theoretical sources cited are not held in high regard by contemporary practitioners; genuine theories of intermovemental ordering, as opposed to the kind of old-fashioned pontificating Konečni cited, are in fact quite rare.) And from the contrast between what the theorists said and what the experiments showed, Konečni concluded sourly that "[a] greater degree of caution, moderation, and humility in the music critics' and theorists' often sweeping claims—mere speculations really—would be a welcome consequence of the type of research in the psychology of music that this article advocates" (Gotlieb & Konečni 1985: 98). Or to put it another way: let theorists submit their findings to the psychological tribunal.

Musicians have generally been less vocal in their complaints about music psychologists; they are inclined to mutter that psychologists do not understand music (or, as Eugene Narmour [1989: 97] puts it, "most music psychologists are not sufficiently well-trained to understand how hierarchical patterning emerges in music"), and leave it at that. One symptom of this is the tendency for psychologists to use test materials which are so musically impoverished that they do not really provide a context for *musical* perception at all. This has been widely criticized, and I am not going to repeat the arguments here.[2] There are other respects, too, in which psychological work can strike musicians as being unrealistic. And here a specific example may help.

The basic message of Rita Wolpert's article "Recognition of Melody, Harmonic Accompaniment, and Instrumentation: Musicians vs. Nonmusicians" (1990) is similar to Konečni's: untrained listeners do not listen to music in the same way that musicians do, and what matters to them is not the same as what matters to music theorists. Wolpert's starting point is that theorists view melody, harmony, and rhythm as the essential constituents of music, with instrumenta-

tion having a secondary function. (This is as much as to say that "Twinkle, Twinkle, Little Star" is "Twinkle, Twinkle, Little Star" regardless of whether it's played on a soprano saxophone, a sitar, or a sine wave generator.) The aim of Wolpert's research was to find out whether this corresponds to the perceptions of untrained listeners. She carried out a series of experiments, in the first of which trained and untrained subjects heard (1) a tune played on a given instrument (for instance, "Twinkle, Twinkle, Little Star" played on a celesta), then (2) the same tune played on another instrument ("Twinkle, Twinkle, Little Star" played on an oboe), and finally (3) a different tune played on the first instrument ("Hot Cross Buns" played on a celesta).[3] The subjects had to say whether (2) or (3) was "most like" (1). Whereas all the musicians chose (2)—that is, they chose the same tune on a different instrument—nearly half the nonmusicians chose (3)—that is, they chose the same instrument playing a different tune.

Wolpert then conducted two further experiments. In one of them, the same tunes were played as before, but this time they were played with simple harmonic accompaniments; the results were much the same as in the case of the melodies alone. In the other, listeners heard (1) a tune on a given instrument, (2) the same tune on a different instrument, and (3) the same tune on the original instrument, but now with the accompaniment transposed down a fifth, so that it was in a different key from the tune. This time 40 of the 42 nonmusicians chose (3); for them, the identity of the instrument outweighed any changes they noticed in the accompaniment. The musicians, on the other hand, continued to choose (2); for them, playing the accompaniment in the wrong key made a bigger difference than playing the music on a different instrument.

What does all this mean? According to Wolpert (pp. 103–4), it shows that

> Musicians and nonmusicians do not . . . listen by the same rules. Musicians consistently chose melody and correct harmonic accompaniment over instrumentation when matching an excerpt to a model, but nonmusicians did not do so. . . . This choice of instrumentation over correct harmonic accompaniment . . . has important ramifications. It suggests a profound overestimation of what it is that most listeners hear. . . . The implications of these findings are sobering. . . . Music educators may need to teach a new awareness of harmonic accompaniment and key relationships in a more systematic way than they are doing at present. Further, this research may lend empirical verification to what music therapists have long known: instrumentation is attended to and found of interest. . . . The need for empirical verification of what it is that untrained listeners actually attend to can and should inform music professionals.

But a musician might be inclined to retort that it shows nothing of the sort. What it shows is how different listeners respond to questions as to whether one musical extract is more or less like another. Wolpert anticipates objections regarding what she asked the subjects to do: "It was necessary to make the instructions vague, because it was important that the instructions not direct the subject's attention to any one aspect of the music, nor in any way make clear the musical

assumptions of the culture" (p. 102). But the result is that the two groups of listeners in Wolpert's tests may well have been engaged in different tasks.

To be a musician trained in the Western tradition means to operate within a language game organized around the concept of "things to play," with a "thing to play" being defined primarily in notational terms (that is, in terms of pitch and duration). You play "the same piece" in one key or another, in one style or another, on one instrument or another—and often to very different effect. When Western musicians, then, are asked whether "Twinkle, Twinkle, Little Star" played on a celesta is most like "Twinkle, Twinkle, Little Star" played on an oboe or "Hot Cross Buns" played on a celesta, they will generally choose "Twinkle, Twinkle, Little Star" played on an oboe because, for them, it is the same piece. This does not mean that they do not care whether the tune is played on a celesta or an oboe. It does not mean that they think other listeners do not care whether the tune is played on a celesta or an oboe. It does *not* mean that they are unaware that "instrumentation is attended to and found of interest." It just means that, when they reply to questions about what they have heard, they do so in terms of the language game of Western musicianship.[4]

But there is no corresponding language game to govern the responses of untrained listeners; that is part of what it means to say that they are untrained. Asking such listeners whether extract (1) is most like extract (2) or extract (3) is rather like asking them whether a melon is most like a banana or a football. It is a bit like both, only in different ways. In culinary and botanical terms, melons are much more like bananas than footballs. On the other hand, imagine an Englishman trying to order fruit in a Tunisian restaurant: "No, no, *not* a banana, what I want is like a *football!*" It is the situation that gives content to the comparison; posed in the abstract, the question whether a melon is more like a banana or a football is pretty meaningless and can be answered equally well either way. The same applies to Wolpert's tunes. Of the untrained listeners in the first two experiments, roughly half said that one excerpt was like another because it had the same tune, and roughly half said it was like another because it was played on the same instrument. In the third experiment, the untrained listeners may or may not have noticed that something had gone wrong with the accompaniment, but most of them said that one excerpt was like another when it had the same tune and was played on the same instrument. This all seems quite straightforward, and it is not an adequate basis for Wolpert's conclusion that "musicians and nonmusicians do not . . . listen by the same rules." In fact, it is not really an adequate basis for saying anything about how people listen to music.

What we have here, as often in psychological writings about music, is an attempt to give a purely psychological explanation for what are in part social phenomena. As I have tried to show, how people respond to psychologists' questions about music is largely a matter of language games, which are essentially social; how they listen to music (for instance, when there are no psychologists about) is quite a different matter. It is because Wolpert does not distinguish

between these two things that she arrives at an astonishing conclusion: "There is an immense gulf between the creative intent of the composer or improviser and the perception of the audience. Harmonic practice in classical music, as well as popular, rock, country, jazz, and middle of the road music, shares a similar traditional relationship between melody and harmonic accompaniment of which these listeners are unaware" (p. 104). According to Wolpert, then, even easy-listening music passes over the heads of its listeners; music educators please take note!

In saying this, Wolpert introduces an additional idea, again one that is frequently referred to in the music-psychological literature: the idea of the composer's intent being realized in perception. And this raises the question of how far music succeeds in communicating something from composer to listener.

Do People Hear Tonal Structure?

A good way to approach this question is by focusing on cases in which there is an apparent failure of communication between composer and listener. In his article "Cognitive Constraints on Compositional Systems" (1988a), Fred Lerdahl cites Pierre Boulez's *Le Marteau sans Maître* as an example of such a failure. As he says, *Le Marteau*, which was completed in 1954, was widely hailed as a masterpiece of postwar serialism, yet for years nobody could figure out just how the serial structure worked. Only recently has the code been cracked. But nobody hears the music differently because of this; the serial structure of *Le Marteau* is so complex and abstract that you cannot hear it, even if you make a special effort to. Here, then, we have a mismatch between the structure the composer puts into the piece and the mental representation of it that the listener forms; Boulez wrote a serial composition, but all that listeners hear is more or less pretty sounds. Lerdahl refers to this as a disjunction between "compositional grammar" and "listening grammar."

As Lerdahl's terminology makes clear, the idea that music involves the encoding and decoding of some kind of message—something that passes from the composer's brain to the listener's—is based on an analogy with language, and this analogy is central to the interaction between music theory and psychology with which this chapter is concerned. Lerdahl is the co-author, with Ray Jackendoff, of *A Generative Theory of Tonal Music*,[5] which might be described (not quite accurately) as a reformulation of established theoretical thinking on pitch and rhythm within the general framework of transformational grammar. This means that they are presenting insights drawn from Schenkerian analysis, Cooper and Meyer's rhythmic theory, and other sources as contributions toward "an explicit formal musical grammar that models the listener's connection between the presented musical surface of a piece and the structure he attributes to the piece" (1983: 3). In other words, Lerdahl and Jackendoff are saying that music theory is really a branch of psychology: "A piece of music is a mentally con-

structed entity, of which scores and performances are partial representations by which the piece is transmitted. . . . The central task of music theory should be to explicate this mentally produced organization" (p. 2).

Lerdahl and Jackendoff offer their theory to psychologists as a source of predictions regarding the perception of music (1984: 230)—predictions that can be subjected to empirical investigation, along the cooperative lines that I mentioned at the beginning of the chapter. Psychologists have responded to the challenge, and indeed a cursory survey of current writing in music psychology might suggest that *GTTM* is the dominant model in tonal music theory, almost to the exclusion of any other. (The picture is rather different in the music-theoretical literature, where Lerdahl and Jackendoff's work is widely admired, but people tend to stick to the established analytical methodologies or invent their own.) The first major experiment testing Lerdahl and Jackendoff's predictions was carried out by Irène Deliège (1987), who played both musicians and nonmusicians a series of short musical extracts ranging from Bach to Stravinsky. The listeners were supplied with simplified scores of the music, in which each melody note was represented by a dot; they had to draw vertical lines on these scores to show how the music fell into separate phrases or other segments. The subjects' responses were then compared with the segmentation predicted by *GTTM*. On the whole, there was a reasonable correspondence between the two; the theory worked better with musicians than nonmusicians, but Deliège comments that "musical training does not appear to induce the emergence of a grouping behavior radically different from the one used by the naïve listener" (1987: 344).

Now it is almost always possible to raise objections to psychological tests of musical listening, for the simple reason that listeners do not generally listen to music under test conditions, and there is therefore a problem as to how far the results of tests can be generalized to normal listening. (In this case, the question would be to what extent information about how people divide up dots on paper tells us about how people listen to music in the ordinary way.) If, however, we accept Deliège's conclusions—and they seem plausible enough—then how much of *GTTM* have we validated? The answer is: the initial segmentation of the musical surface, but not the larger hierarchical structure that Lerdahl and Jackendoff derive from the initial segmentation. From the standpoint of the music theorist, it is this hierarchical structure that lies at the heart of *GTTM*, because it shows how compositions can be coherent in a specifically *tonal* manner. We can clarify this by referring to the way in which Lerdahl has extended the original *GTTM* to cover atonal music. The essential part of his argument runs as follows (1989: 73–74):

> Given that two events connect, the more *stable* is the one that is more consonant or spatially closer to the (local) tonic; the more *salient* is the one that is in a strong metrical position, at a registral extreme, or more significant motivically. If one event turns out to be more stable and more salient, it unambiguously dominates the other. But if one event is more stable and the other is more salient, there is a

> conflict in the rules. In tonal music stability almost always overrides salience. One might say that the grammatical force of tonal pitch structures can be gauged by their ability to override surface salience. Atonal music may not have stability conditions, but it does project the relative salience of events. The absence of stability conditions makes salience cognitively all the more important. I argue that listeners organize atonal surfaces by means of it. As a result, atonal music collapses the distinction between salience and structural importance.

And a few pages later Lerdahl remarks that this "amounts to an acknowledgement that atonal music is not very grammatical" (p. 94).

Several psychologists have carried out tests showing how this kind of salience influences segmentation. Deliège's (1987) experiments, mentioned above, document the role of such attributes as timbre, register, and dynamics on segmentation. Again, in an experiment where listeners were asked to match musical excerpts with middle-ground reductions, Serafine, Glassman, and Overbeeke found that "metric accent is a major determiner of the structural importance given to tones" (1989: 405). And in tests where musically trained listeners had to rate the strength of boundaries between segments in Mozart's Fantasie in C minor (K. 475), Eric Clarke and Carol Krumhansl found that segmentation was based on such salience-related criteria as change of texture, change of dynamics, and change of register; moreover, they found that these same criteria operated on different levels of structure, from the musical surface to higher-level grouping involving durations of 30–50 seconds (1990: 248–9).

But there is a problem. All these tests were based on tonal music—music, that is, in which criteria based on salience should (according to Lerdahl's theory) have been overridden by criteria based on stability. This emerges with particular clarity from Clarke and Krumhansl's experiments, which compared responses to the Mozart Fantasie with responses to a highly atonal piece: Stockhausen's *Klavierstück IX*. Listeners (and remember these were musically trained listeners) used very much the same criteria in segmenting the Stockhausen piece as the Mozart; in fact, the tables in which Clarke and Krumhansl summarize these criteria for the two pieces are strikingly similar (pp. 227, 243). As the authors comment, there are only two differences between them: "the greater emphasis on pauses and silences as grouping factors in the *Klavierstück* than in the Fantasie, which is a direct result of the more continuous nature of the music in the Mozart, and the greater importance of repetition as a boundary indicator in the Stockhausen" (p. 249). What is strikingly absent from the criteria adopted in the Mozart is any sign of specifically *tonal* features, such as modulations, cadence points, or tonal closure (the return of a tonal excursion to the chord or key with which it began). The conclusion seems inescapable: if people (musically trained people) listen to tonal and atonal music in much the same way, and if atonal music is not very grammatical, then tonal music cannot be very grammatical either.

A few years ago, I carried out a series of tests designed to address the perception of tonal closure in a more direct manner. The significance of tonal closure is that it represents the basic principle of virtually all theories of tonal music—not

just Lerdahl and Jackendoff's, but Meyer's, Schenker's, and Schoenberg's. (It is a much more important principle for music theorists than the issue of intermovemental ordering that Gotlieb and Konečni were dealing with.) Put rather too simply, the theory works like this. Tonal compositions begin and end in the same key; that is, a sonata or a symphony is in G major or F-sharp minor, even though it may well contain movements in other keys. Similarly, an individual movement will be in a given key, even though it will probably contain passages in other keys. The idea is that the "home" key, or tonic, represents a point of stability; excursions to other keys represent an increase of tension, which is resolved by the return to the tonic. So the typical sonata movement, which begins on the tonic, moves to the dominant and passes through a series of other keys before returning to the tonic, represents an archlike increase and decrease of tension. The theory, then, purports to explain the practice of tonal composers in terms of the psychological effects that their music has on listeners.

As an illustration of this, consider the third of Liszt's *Fünf kleine Klavierstücke* (Figure 3.1).[6] Bars 1–16 are in F-sharp major, with no more than slight inflections toward the dominant (bars 6–7) and subdominant (bar 11); at the beginning of bar 16 there is a cadence on a diminished seventh, which can be understood as standing for V_7 of F-sharp. Liszt could easily have continued in F-sharp major, for instance by repeating the opening. But he does not do this. Instead, the music shifts unexpectedly into A major. (The voice-leading in the bass—the D of bar 16 falling to C-sharp—means that, although the A major is unexpected, it is not incoherent.) However, the sense of an F-sharp major tonic does not entirely disappear during the A major episode; the B major chord over a C-sharp bass at bar 22, which functions as a modified V_7 of F-sharp and leads to the final tonic, creates a sense of homecoming. The return to F-sharp resolves the tension created by the move to A, and the piece concludes with a satisfying finality. That, at any rate, is the received theoretical wisdom regarding this kind of tonal structure, and similar patterns are found—and explained along the same lines—in much more extended pieces than this *Kleines Klavierstück*.

The question is: do listeners actually respond to this large-scale tonal closure? A simple way to answer this is to play listeners two versions of the piece: the original, as shown in Figure 3.1, and a recomposed version in which the music does not end in the same key as it began in. Figure 3.2 shows such a recomposed version, following on from bar 14 of Figure 3.1; here the music continues, perfectly logically, in F-sharp major. This means that it ends in a rather hard-to-decipher D-sharp major. There is no tonal closure. Tonal theory, then, predicts that the recomposed version of the music will end inconclusively, without creating the satisfying sense of completion engendered by Liszt's version. It might, in fact, lead one to expect a less rich aesthetic experience. My tests, in which the subjects were music students, did not confirm these theoretical predictions.[7] In the case of this particular piece, there was a slight, and not statistically significant, preference for the original version over the recomposed one. In the case of other test pieces there were slight, and not statistically significant, preferences for

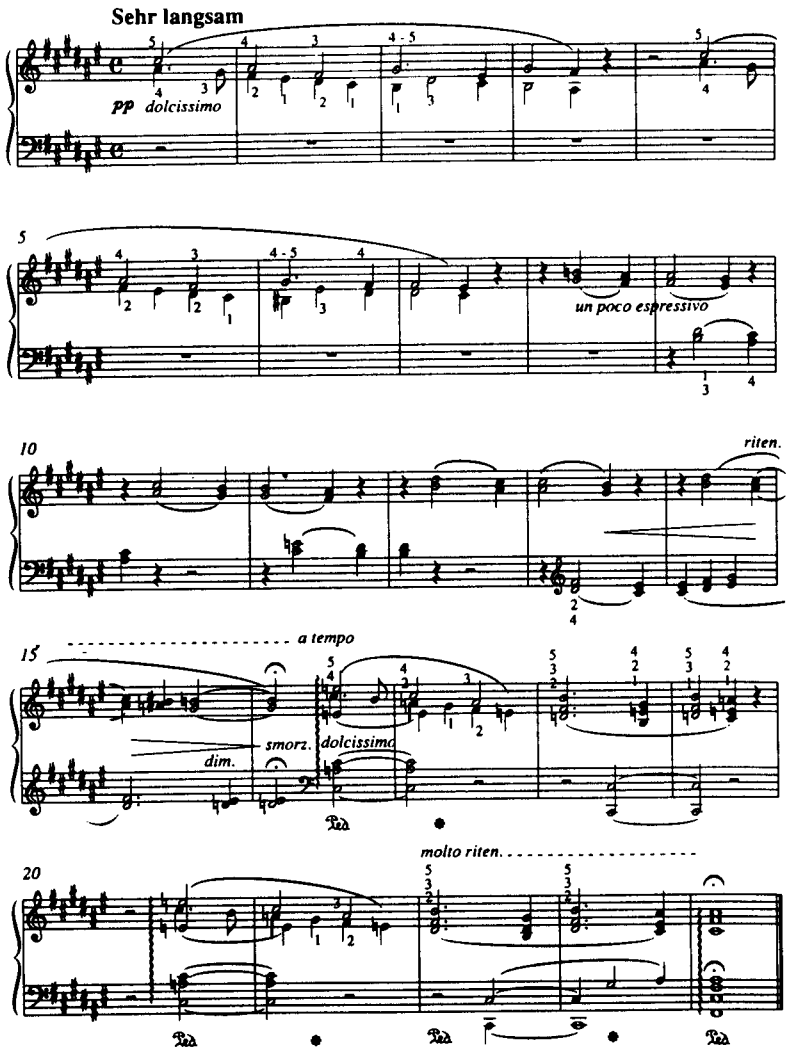

FIGURE 3.1. Liszt, *Kleines Klavierstück* no. 3.

the recomposed version over the original one. Only in the case of the two shortest pieces was there a significant correlation of tonal closure and listener preference, and even here preferences were partly the result of ordering effects (listeners tended to prefer whichever version they heard second over the one they heard first). To eliminate the effects of ordering, I carried out further tests. The listeners were divided into groups, each of which heard the two shortest pieces, but with the original and recomposed versions in a different order. This time only the very shortest piece yielded a significant correlation between tonal closure and listener response.

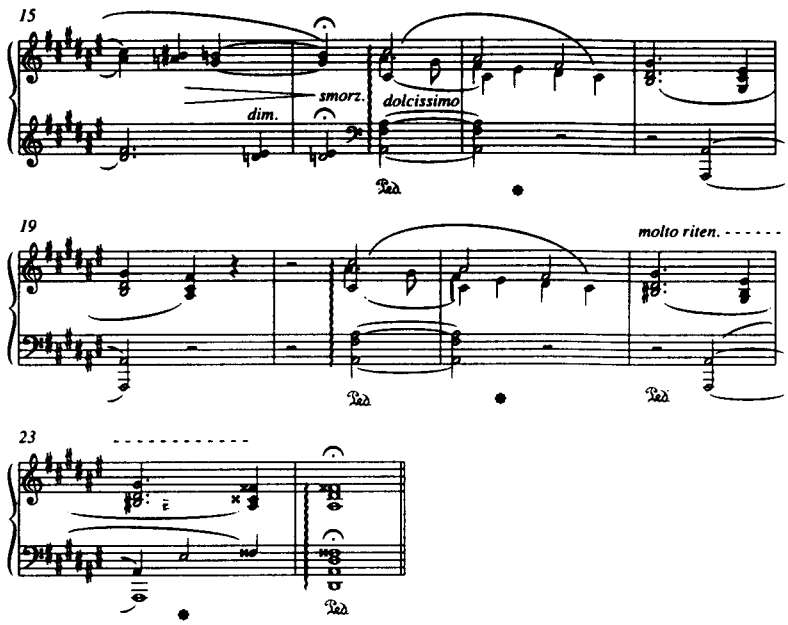

FIGURE 3.2. Liszt, *Kleines Klavierstück* no. 3, bars 15–24 (modified).

The shortest piece of music in these tests was about 30 seconds long,[8] while the next shortest was about 55 seconds. So the tests indicate that tonal closure only has a direct effect on listeners (even musically trained listeners) when the time scale involved is well under a minute. This means that, in perceptual terms, an extended composition cannot have the tonal unity that a single phrase has. Such a conclusion must be disturbing to anybody who expects tonal theory to be psychologically valid, in the sense of correctly predicting the effect of music on listeners. After all, the basic explanatory thrust of theories such as Schenker's or Lerdahl and Jackendoff's is that large-scale musical structures are to be explained along the same lines as small-scale structures. That is what it means to have a hierarchical theory of music; that is what it means to explain music by analogy with the hierarchical structures of transformational grammar.

Burton Rosner and Leonard Meyer have criticized the analogy between musical and linguistic hierarchies from just this point of view; their analysis is so penetrating that it is worth quoting in full (1986: 37).

> Analysts such as Schenker . . . and Lerdahl and Jackendoff . . . may well produce hierarchical diagrams of quite long musical passages. But if "higher" events exert increasingly tenuous perceptual influences, the psychological force of the outputs from such analytical machinery will dwindle quickly, whatever may be their value for the theory of music. In this regard, we must point out a fundamental difference between the tree structures used in linguistics and those presented by music theorists like Lerdahl and Jackendoff. The top node of a grammatical tree is an immediately observed datum: a sentence or an utterance. It represents

> some incident, occurring over time, which can be entered completely and rapidly into memory. The associated tree decomposes that uppermost node into parts at several lower levels of a strict hierarchy. The lowest nodes in music-theoretic tree structures, however, represent a datum: an actual stretch of music. Quite often, only fragments of it are held faithfully in memory. The lower nodes in the tree are not decompositions of higher ones. Instead, higher nodes are *selections* from among lower ones. We therefore cannot believe that the increasingly higher nodes, which represent ever more rarified selections, form the core of music perception.

Rosner and Meyer are saying that while the top node of a grammatical tree corresponds to something that is actually said or heard, the musical equivalent has a purely theoretical existence. A related observation—or maybe it is just another way of saying the same thing—is that, whereas the analysis of language converges on semantic content (Chomsky's "deep structure"), the analysis of music does not converge on anything; the "deepest" level of Schenkerian structure, the *Ursatz*, is simply an abstraction. It means nothing at all.

Psychology of Music or Psychology of Ear Training?

One of the major problems in applying models drawn from linguistics to music theory, then, has to do with the significance to be attached to different levels of structure. Another set of problems can be focused around a further concept borrowed from the study of language: pragmatics. Now pragmatics comes in two flavors. What we could call the "mild" flavor means "studying the use of a language as distinct from, but complementary to, the language itself seen as a formal system" (Leech, 1983: x). Or to put it another way, pragmatics deals with what grammar leaves out; to say this is to define pragmatics in terms of grammar. We can focus what is at issue here around Chomsky's well-known distinction between "competence" and "performance." By "competence," Chomsky means the grammatical knowledge that a competent language user has internalized; as the use of the word "internalize" shows, this is considered to be a mental construct. "Performance," on the other hand, refers to the way in which this knowledge is used in actual situations. If theories of competence deal exclusively with perfect, well-formed sentences, theories of performance deal also with interruptions, syntactic breakdowns, failures of comprehension, and the goals that people have in using language in specific contexts (the last of these being the subject matter of pragmatics more narrowly defined). And it is an axiom of formal linguistics that issues of performance cannot be properly understood except on the basis of a theory of competence: as Eytan Agmon puts it, using a different terminology, "one cannot answer the question 'how' before having answered the question 'what'" (1990: 298).

This principle has been transferred intact into linguistically orientated music theory. Lerdahl and Jackendoff state it thus: "In our view it would be fruitless to

theorize about mental processing before understanding the organization to which the processing leads" (1983: 4). But there are distinct problems in applying the idea of competence to music. The classic definition of a grammar is a finite set of rules that will generate all, and only, well-formed sentences in a given language; as I said, competence means having internalized such a grammar. Now it is not at all obvious how a clear distinction is to be drawn between musical structures that are well formed and those that are not. To be sure, there are some styles so constrained that one can always say with assurance that this note is right whereas that note is wrong: species counterpoint is one. But then species counterpoint is a pedagogical construct, a demonstration of rules; Palestrina notoriously did things that counterpoint textbooks don't allow. Again, imagine misprints in a Schubert song: some would be obviously wrong (that *can't* be an F-sharp!), but others would be merely questionable (Schumann might write that F-sharp, but surely not Schubert?). To cope with the last case we would need to hypothesize a grammar for Schubert that is different from a grammar for Schumann. And obviously, the process could continue until we had different grammars for early Schubert and late Schubert, for songs and symphonies, for heroic songs and sentimental ones, and so on.

As Eric Clarke (1989b) has said, there are many factors that militate against the usefulness of explaining music in terms of strict grammars: the ways in which composers consciously mix musical styles, the coexistence of different musical styles within a single cultural community, the rate at which style change occurs in music. He explains these things in terms of the different functions served by language and music (p. 19):

> Natural language is essential to the cohesion and survival of human social organization, and hence must make use of structural constraints (grammar) which, by remaining relatively unchanging, ensure successful communication. By contrast, music in European art culture, although serving as an important cultural indicator, does not bear the same functional responsibility, and thus has less need for long-lasting structural constraints. Each piece can make use of a substantial number of principles that are specific only to that work, and which are consequently inexplicable (or at best explicable only at a very general level) in terms of a broad and general structural theory.

Music, in other words, is much more fluid than language. Before you start a conversation, you know what the grammar is going to be; in music, you can never be sure of the grammar until you have heard the piece.

Alan Marsden (1989) has outlined a model of musical listening based on the idea of discovery learning. This model suggests that, as somebody listens to music, certain parsing rules (the kind of rules that *GTTM* is based on) are dynamically strengthened or weakened, according to how well they fit the music. Moreover, the model allows for new rules to be derived. What Marsden is suggesting, then, is that listening to music involves creating a grammar to fit the piece being heard. But to say this is, in effect, to abandon the idea of grammar

altogether, at least as it is understood in formal linguistics. For it means that a musical grammar is essentially a collection of strategies for understanding music.[9] In other words, it means that the distinction between competence and performance cannot be sustained as applied to music. So it comes as no surprise that Lerdahl and Jackendoff fail to sustain it in their own work. As Uwe Seifert has pointed out (1991), *GTTM* is not really a theory of competence at all. It is a model of the way in which a structural description may be derived from a musical surface. It is an input-output mechanism. That is, it is a theory of performance, though an incomplete one.

We started with what I called the "mild" flavor of pragmatics. But by now we have advanced to the "strong" flavor, which maintains that the whole idea of a formal grammar (and therefore the distinction between performance and competence) is a theoretical artifact, an illegitimate abstraction from the real-world phenomenon of language. Roy Harris (1980, 1981) is a leading proponent of this position, and he argues that formal linguistics is a pseudoscience that has come into being by adopting the principles of traditional grammar (which mainly means Latin grammar), and then claiming what traditional grammarians never claimed, that these principles have some kind of psychological validity. In other words, pedagogical principles (for traditional grammar was a system of teaching) have been reinterpreted as psychological ones. Harris sees the competence/performance distinction as playing a crucial role in this transition, because it means that while grammatical rules are asserted to be "in the brain," it is impossible to prove or disprove their existence; it is only the *use* of these rules, that is to say performance, that can be subjected to psychological investigation. If experiments cast doubt on any given model of language, that need not affect the issue of competence; it can always be said that, by its nature, performance is determined by all sorts of factors, and the model under investigation has failed to make proper allowance for these (1981: 109). In this way the linguist's claim to be talking about psychological realities is secured against all possible counterevidence from psychologists.

I am going to argue that there has been a corresponding, if less thoroughgoing, transformation of music theory (which again is in essence a system of teaching) into a theory of perception. Perhaps the best way to approach this is to look at a key issue in Harris's account of the transformation of traditional grammar into formal linguistics and see how it applies to music. This is the issue of *scriptism*.

Harris defines scriptism (a word of his own coinage) as "the assumption that writing is a more ideal form of linguistic representation than speech" (1980: 6). Modern linguists vociferously disassociate themselves from any such idea, insisting that speech is primary and that the written word is not to be understood as anything other than a representation of the spoken word. But Harris argues persuasively that, in reality, linguists analyze speech on the model of writing. They regard *Mary had a little lamb* as a linguistic unit that can be articulated in two different ways (depending on whether it is a reply to *What did Mary have?* or

Who had a little lamb?), rather than as two basic linguistic units that happen to be written the same. They regard words as basic linguistic units, and as late as the 1950s were defining them by reference to "potential pauses" in speech—clearly on the model of the space on either side of the written word. They regard phonemes as linguistic units that happen to correspond rather closely to letters, and as late as the 1970s were trying to analyze speech into fixed sound units corresponding to phonemes (1981: 57). Linguistics, as Harris puts it, is cryptoscriptist.

What about music theory? Again, we have the vociferous insistence that the proper object of study is the sound of music, not the written score. Except in a few special instances (say a study of music preserved in an imperfectly understood notation), no music theorist would care—or dare—to say that she was interested in the score as anything other than a representation of the sound, the listener's experience of the sound, or both. In other words, music theorists *use* scores, but they do not *study* scores—they study the music. Or at least that is the claim. But, in fact, it is obvious that the claim is not always true. Consider a set-theoretical analysis of a piece of atonal piano music, say Schoenberg's *Sechs Kleine Klavierstücke*, op. 19, no. 3. Set theory[10] deals with the relationships between the individual notes you can see in the score. Of course, you hear the notes when you listen to the music. Or do you? Well, you hear a succession of composite sounds which, if you have a good musical training, you may be able to distinguish into their component pitches. But then again, you may not; there is no law saying that, in order to do an analysis of atonal piano music, you have to be able to "hear out" each note of the music. Of course, you might hear each note in the sense that if a wrong note was played, or if a note was left out or added, you would recognize that something was wrong. But then again, you might not; in practice it would probably depend on what the note in question was. In other words, there is, to put it mildly, a nonlinear relationship between the notes in the score and what people hear when they listen to a performance of it. Set theory takes no account of this.

At least, in the case of atonal piano pieces, the note is actually there, in the sense that either the pianist plays it or he doesn't. But there is a lot of music in which even this is doubtful proposition. An opera singer sings a rapid scale: does she actually sing every note? Is there a clear transition between each note and the next, or does one slide into the other? If so, how do you tell where one note stops and the next one starts? Or is there just a rather uneven glissando? Is the only way of answering these questions to record the sound and slow it down or print out a time/frequency graph of it? But if you have to do this to decide what notes are there, can you really say they are there in a *musical* sense? Problems of this sort become particularly pressing in the case of the florid singing characteristic of many Asian cultures. Robert Gjerdingen (1988) recently published a computer analysis of extracts, a few seconds long, from recordings made by the South Indian singer Gayathri Kassebaum. As he explains, Kassebaum's voice is constantly in motion; traditional melograms (the ethnomusicologist's word for com-

bined time/frequency and time/intensity graphs) reveal a bewildering multiplicity of events. Yet comparison between Kassebaum's different recordings of this passage, and between Kassebaum's recordings and students' imitations of her singing, reveals a much smaller number of events that remain invariant between the different performances. It is presumably these that are the notes—that is, if there *are* notes in Kassebaum's singing.

Gjerdingen offers a transcription of the passage into Western notation based, not on traditional melograms, but on graphs of the combined rates of change in frequency and intensity; these graphs throw the invariant events into relief. But he observes that such graphs can provide no more than a "good foundation" for transcription, because any musical notation involves cultural values (pp. 59–60):

> When we move from the analysis of curves, functions, and rates of change to a discussion of notes or particular rhythms, we are moving towards the consideration of cultural units of meaning, not simply pitches and intensities. Sensitivity is required when different cultures have differing ideas about the nature of such units.

Another way to put this is that the notes are not "in" the recording of Kassebaum's singing. Rather, they are constructed *out* of it through appropriate (or inappropriate) interpretation. And this is also true of Western music. There are no notes "in" the opera singer's rapid scale; if we interpret what we hear as a scale, a series of notes, and not as a rather uneven glissando, that is because in most operatic styles we expect scales rather than glissandos. (If she were singing music by Ligeti, we might hear the glissando.) Again, music students often have difficulty when they are asked to write down the inner lines of four-part chorale settings, which is part of the traditional music curriculum. It's not that they hear the lines but can't write them down; it's that they can't hear them. Later, when they have learned more harmony, they find that they can hear the inner lines quite easily. This is because they now know how to "compose" possible inner lines, so to speak, and compare these with what they hear. In other words, they have learned how to *create* notes and lines in what was previously a composite, undifferentiated mass of sound. Untrained listeners, of course, cannot do this. For them, there are no notes in the inner lines. Or rather, there are no inner lines—just, at most, inner parts.

If music theorists really wanted to analyze how music sounds, and only how it sounds, they would put away their scores and forget all about notes. Some phenomenologically minded theorists have tried to do just this. The trouble is that they almost invariably end up creating scores of their own. The only difference is that their scores tend to be relatively impoverished representations of the music, so the analytical results are generally unsatisfying from a musical point of view. This is not really surprising. In the first place, music theorists can no more forget about notes than linguists can forget about letters; they are part of our mental equipment. In the second place, any music theorist who achieves the impossible and forgets about notes "risks being left with a shapeless mass which

he does not know what to make of" (Harris, 1980: 17). Harris is talking about language, but what he says applies with no less force to music. For all music has its source in mental representations based either on notation or on kinesthetic imagery derived from singing or playing musical instruments; to compose is to manipulate images (Cook, 1990: Chapters 2, 4). It stands to reason, then, that the kind of full and satisfying comprehension of music at which the theorist aims is unlikely to be attained, except on the basis of a representation as richly determinate as that in terms of which the music was conceived. For this reason, there is nothing wrong in principle with the theorist who carries out a set-theoretical analysis of notes that he could not pick out from the musical sound. And in any case, he may well end up hearing them. It is often claimed that one of the benefits of music theory is that it enables people to hear music better. In fact, you might say that the main point of analyzing music is to enable us to respond to the excess of music over sound. I shall come back to this later.

This kind of defense against charges of scriptism is not available to psychologists, whose studies of musical perception are meant to be descriptive rather than prescriptive (that is, we expect them to tell us how people hear music, not how they might best hear it). And even a cursory examination of the music-psychological literature will show that such charges are warranted. The general picture that emerges is that, as Eric Clarke puts it, listeners "accumulate and integrate individual notes of a performance . . . into successively more abstract and global representations" (1989a: 4); we have studies of how listeners distinguish the voices of polyphonic music, discriminate intervals, follow chord progressions, and judge key centers. Now people can do all these things, at least within certain constraints. They are trained to do these things if they become music students. (They have to be trained, because otherwise they can't do them.) Such training—called ear training, aural training, or aural analysis—creates the interface between musical sound and the theoretical knowledge in terms of which musicians create, notate, and reproduce music. So we have a lot of psychological studies of ear training. The trouble is that they are not called studies of ear training. They are called studies of musical listening. And as such they are thoroughly unsatisfactory, because they begin with the premise that people hear music in terms of music-theoretical categories. They assume what music theory assumes; that music is made out of notes. This is scriptism with a vengeance. I am tempted to improve on Harris's coinage and call it *theorism*.

Theory of Music or Theory of Mind?

Perhaps the most revealing example of theorism is tonal hierarchy theory. This theory, most conspicuously represented by the work of Carol Krumhansl, can be traced to two sources: one theoretical, and the other psychological. The theoretical source is a tradition of representing key relationships in topological terms that originated in eighteenth-century Germany, the best-known example being

the "chart of the regions" in Schoenberg's *Structural Functions of Harmony* (Figure 3.3). Schoenberg's chart shows a two-dimensional space with minor thirds on one axis and perfect fifths on the other, and its purpose is to indicate how closely different tonal regions are related to one another. For instance, the chart shows the distance from C major to F-sharp major as being much greater than the distance from C major to G major. What this means is that, in writing music in the tonal style, it is not easy to make the relationship between C major and F-sharp major sound coherent; modulating from C to F-sharp major requires a lot more care, if it is to be done convincingly, than modulating from C to G major. The purpose of the chart, then, is pedagogical. *Structural Functions of Harmony* is a textbook.

The psychological source of tonal hierarchy theory is a methodological one: the probe tone technique, introduced by Krumhansl and Roger Shepard in 1979. The purpose of this technique is to find out how the perception of individual pitches is affected by the context in which they are situated. Usually the contexts provided in experiments of this sort are very simple: subjects may hear a rising major scale, or 16 notes selected more or less at random from a given diatonic set. (Some recent work has involved more extensive contexts.) After listeners have heard these materials, they are played a final note—this is the probe tone—and asked how well this final note follows from the others "in a musical sense" (Krumhansl, 1983: 35). Such tests are carried out using a range of probe tones (usually all the notes of the chromatic set). The results are analyzed statistically, and this yields a profile showing how well each of the different probe tones has been judged to fit in that particular context; this is what Krumhansl calls a tonal hierarchy. For instance, you find that the tonic and fifth are judged to fit better than other notes in a diatonic major context. Moreover, you can compare the profiles of different diatonic sets; it turns out that, as you might expect, C major and G major are much more similar than C and F-sharp major. Krumhansl and her co-workers take this to be a measure of the distance between different keys, and if you express the results of such comparisons topologically, you end up with a chart that is essentially identical to Schoenberg's "chart of the regions."[11] So these experiments may be said to demonstrate the psychological reality of Schoenberg's topological representation of key relationships.

Krumhansl's work has come in for a good deal of criticism, some of it

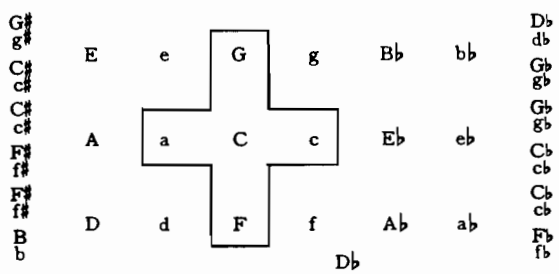

FIGURE 3.3. "Chart of the regions" from Schoenberg, 1969.

acrimonious. One of the main complaints is the one I leveled at Wolpert's experiments: the task required of the subjects is too vague. Just what does it mean to ask how well the probe tone fits "in a musical sense"? In *what* musical sense? One of Krumhansl's experiments highlights the complexities of the response situation: in probe tone tests based on serial contexts, listeners inexperienced in serial music produced profiles similar to those found in tonal music, whereas experienced listeners produced exactly the opposite profiles. Krumhansl and her associates suggest that this was because the experienced listeners adopted "a strategy, whether conscious or not, of relating the serial contexts to tonal hierarchies of major and minor keys, and simply reversing the ordering of the ratings" (Krumhansl, Sandell, & Sergeant, 1987: 73–74). In this case, since the responses were fairly consistent within each group of subjects, it can't have been too hard to see that they were adopting different strategies. In other cases, however, the divergences between response strategies might be much harder to spot. David Butler, who has been foremost among Krumhansl's critics, writes of a particular experiment that "the rating of any probe tone following the contextual series of chords might have signaled one listener's judgment of melodic continuation at the same time that it recorded another listener's judgment that the probe tone represented a well- or ill-fitting extrapolation of the roots of the chords in the contextual pattern" (1990: 329). Adding such divergent ratings together would make little sense, because the listeners are not engaged in the same task. Each is judging how well the probe tone fits, but in a *different* musical sense.[12]

Krumhansl responds to such objections by pointing out that there is considerable consistency in the results obtained by means of the probe tone technique; "Different listeners exhibit similar patterns of responses, and the same individual tends to produce the same or nearly the same response on different occasions when the identical musical stimulus is presented" (1990a: 11). Butler, however, has another explanation for this consistency: the test materials in these experiments have been consistently weighted toward the tones that end up with the highest ratings in the profiles. In other words, listeners have generally said that the tonic and the fifth fit best in a major-scale context because there have generally been more tonics and fifths in the test materials than other scale degrees; the resulting profile is "a stimulus artifact . . . rather than a reflection of mental representations of pitch relations" (1989: 230). Now this is at first sight a very damaging claim. Krumhansl, however, agrees that her tests do indeed show that "humans . . . are highly sensitive to information about frequency of occurrence" (1990b: 315). And she refers to comparative tests of Western and Indian listeners who heard materials taken from North Indian ragas. Although the Western listeners had no experience of Indian music, they produced profiles very similar to those of the Indian listeners, all of whom were trained in Indian music. Krumhansl's (1990a: 262–63) explanation of this result is that the Western listeners must have registered

> the relative salience or emphasis given the various tones in the musical contexts. In this case, this strategy produced style-appropriate tonal hierarchies. Thus, it could be used to achieve a sense of tonal organization that, when refined and solidified through experience, would serve as the basis for appreciating and remembering more complex and subtle structural features. For the Indian listeners, the high correlations between the probe tone ratings and the tone durations reflect the convergence between the surface emphasis given the various tones and the underlying tonal organization of the rāgs.

And in her response to Butler, she cites some statistical measures of the relative frequency of occurrence of different scale degrees in different works by composers like Mozart, Schubert, and Schumann, showing how these note frequencies correspond closely to the profiles for major and minor keys yielded by probe tone studies (1990b: 316, also in 1990a: 68).

By this stage in the argument it is becoming less and less clear what the probe tone studies are actually telling us. How can the same results for Western and Indian listeners in Krumhansl's experiment tell us different things in each case—that Western listeners are responding to surface features, while Indian listeners are responding to the convergence between surface features and underlying tonal organization? If perceived tonal hierarchies are a function of the frequency of occurrence of different notes, chords, or keys, then won't any probe tone experiment yield profiles that simply reflect the test materials and so cannot be generalized to any other musical context? But it isn't this simple; sometimes the attributes of the test materials and the results of probe tone experiments don't go hand in hand. For instance, tests using Balinese materials yielded different results for Western and Balinese listeners (Krumhansl, 1990a: 266–68). Krumhansl explains this in terms of the different knowledge of musical style with which the two groups of listeners approached the task. Her basic assumption is that probe tone tests reveal stable, long-term knowledge that listeners use in processing musical sounds. In an overview of her work written in 1983, she described it as "an initial attempt to understand the kinds of internal representations and processes involved in listening to tonal music. The results provide a quantitative, structural description of the kinds of knowledge listeners have about fundamental aspects of tonal organization" (1983: 59). And she referred to the tonal hierarchy as "the fundamental underlying feature of tonal music, one that is generative of interkey relations" (p. 56). The word "generative" says it all; tonal hierarchy theory was to provide something like a competence theory for tonal music. Krumhansl began her 1983 overview with a reference to Chomsky.

Since then, however, it has become increasingly evident that the static nature of tonal hierarchy theory drastically limits its explanatory scope. In Butler's words, "it is necessarily based on a rigid, time-independent conception of musical consonance in which the tonic is always considered most consonant and most stable, the dominant is next-most consonant and next-most stable, and so on" (1989: 223). But key identification, to take one of the things Krumhansl has tried

to explain in terms of tonal hierarchies, is clearly time-dependent. Whether a given passage projects a specific tonic, say C, does not simply depend on the notes in the passage: it depends on their ordering (which is to say, on their harmonic implications, contour, and so forth). A recent experimental study of key identification grew out of "a class in the psychology of music in which the . . . author had programmed a computer to sound out the notes of a diatonic scale in random succession and, after a minute or so of this continuous stream of notes, asked the class of musically highly educated listeners to hum what they thought was the major-mode tonic. To his (and the class's) surprise, the result was a cacophony" (West and Fryer, 1990: 254). The ensuing experiment, based on a version of the probe tone method in which subjects were asked "to judge the suitability of the probe tone *as a tonic*" (p. 255, my italics), confirmed the impression: responses depend on the order in which the notes are presented. This means that tonal hierarchy theory can capture, at best, only part of the phenomenon of key identification.

In her 1990 response to Butler (who for years has been arguing that key identification is time-dependent), Krumhansl takes an accommodating line over the question of key identification, suggesting that tonal hierarchies constitute just one of several relevant factors (1990b: 317). And her characterization of the general scope of tonal hierarchy theory is also more modest than it was in 1983: "tonal contexts (even simple, schematic ones) evoke listeners' knowledge about how musical entities, such as tones, chords, and keys, are generally used in the style. These abstract pitch relations provide a background that facilitates understanding the organization of a particular piece" (pp. 313–14). As a matter of fact, Lerdahl has recently incorporated tonal hierarchy theory within *GTTM* in a way that is very much in line with this. In the original version of *GTTM*, there were informally stated "stability conditions" favoring certain structural interpretations over others. (The basic idea was that connections are more likely between elements that are tonally close to one another.) In his article "Tonal Pitch Space" (1988b), however, Lerdahl presents a more formal model of these stability conditions; this is, in essence, an amplified and generalized version of Schoenberg's "chart of the regions."[13] And he invokes Krumhansl's experiments as showing the psychological reality of the model. He doesn't express a view as to exactly what the model represents; as a theorist (rather than a psychologist) he doesn't need to. He is using tonal hierarchy theory as a rule of thumb, and you can do this without knowing whether it reflects listeners' long-term knowledge of a given style, or their responses to note distributions in a given passage, or, for that matter, some other factor such as tonal consonance.
