2009	1	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 1 The origins and functions of music **1 The nature of music and its evolution**	Cross, fan	OUP	Inglés
2009	2	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 1 The origins and functions of music **2 Universals in music processing**	Stevens , Catherine Byron, Tim	OUP	Inglés
2009	3	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 1 The origins and functions of music **3 Music and meaning**	Cross, fan Tofbert, Elizabeth	OUP	Inglés
2009	4	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 1 The origins and functions of music **4 The social and personal functions of music in cross-cultural perspective**	Cfayton, Martin	OUP	Inglés
2009	5	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **5 The perception of pitch**	Stainsby, Thomas Cross, fan	OUP	Inglés
2009	6	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **6 Tonal cognition**	Bigand, Emmanuef Poulin-Charronnat, Bénédicte	OUP	Inglés
2009	7	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **7 The perception of musical timbre**	McAdams, Stephen L. Giordano, Bruno	OUP	Inglés
2009	8	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **8 Musical time**	Riess Jones, Mari	OUP	Inglés
2009	9	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **9 Components of melodic processing**	A. Schmuckfer, Mark	OUP	Inglés
2009	10	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 2 Music perception **10 Memory for music**	Snyder, Bob	OUP	Inglés
2009	11	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 3 Responses to music **11 Bodily responses to music**	A. Hodges, Donafd	OUP	Inglés
2009	12	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 3 Responses to music **12 Emotional responses to music**	N. Juslin, Patrik	OUP	Inglés
2009	13	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 3 Responses to music **13 The relationship between musical structure and perceived expression**	Gabrielsson, Alf	OUP	Inglés
2009	14	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 3 Responses to music **14 Aesthetics**	Huron, David	OUP	Inglés
2009	15	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 3 Responses to music **15 Musical preferences**	Lamont, Alexandra Greasley, Alinka	OUP	Inglés
2009	16	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 4 Music and the brain **16 The neurobiological basis of musical expectations**	J. Trainor , Laurel J. Zatorre, Robert	OUP	Inglés
2009	17	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 4 Music and the brain **17 Disorders of musical cognition**	Colectivo	OUP	Inglés
2009	18	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 4 Music and the brain **18 Music, musicians, and brain plasticity**	Schlaug, Gottfried	OUP	Inglés
2009	19	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 4 Music and the brain **19 Music and the brain: three links to language**	D. Patel, Aniruddh	OUP	Inglés
2009	20	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 5 Musical development **20 Prenatal development and the phylogeny and ontogeny of music**	Parncutt, Richard	OUP	Inglés
2009	21	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 5 Musical development **21 Music lessons from infants**	E. Trehub, Sandra	OUP	Inglés

2009	22	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 5 Musical development **22 Music in the school years**	Lamont, Alexandra	OUP	Inglés
2009	23	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 5 Musical development **23 The impact of music instruction on other skills**	H. Rauscher, Frances	OUP	Inglés
2009	24	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **24 Musical potential**	McPherson, Gary Hallam, Susan	OUP	Inglés
2009	25	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **25 Practising**	Jorgensen, Harald Hallam, Susan	OUP	Inglés
2009	26	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **26 Individuality in the learning of musical skills**	Gaunt, Helena Hallam, Susan	OUP	Inglés
2009	27	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **27 Motivation to learn**	Hallam, Susan	OUP	Inglés
2009	28	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **28 The role of the family in supporting learning**	Creech, Andrea	OUP	Inglés
2009	29	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 6 Learning musical skills **29 The role of the institution and teachers in supporting learning**	Welch, Graham Ockelford, Adam	OUP	Inglés
2009	30	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **30 Measurement and models of performance**	Windsor, W. Luke	OUP	Inglés
2009	31	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **31 Planning and performance**	Altenmuller, Eckart Schneider, Sabine	OUP	Inglés
2009	32	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **32 Sight-reading**	C. Lehmann, Andreas Kopiez, Reinhard	OUP	Inglés
2009	33	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **33 Performing from memory**	Colectivo	OUP	Inglés
2009	34	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **34 Movement and collaboration in musical performance**	W. Davidson, Jane	OUP	Inglés
2009	35	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **35 Emotion in music performance**	N. Juslin, Patrik	OUP	Inglés
2009	36	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 7 Musical performance **36 Optimizing physical and psychological health in performing musicians**	T. Kenny, Dianna Ackermann, Bronwen	OUP	Inglés
2009	37	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 8 Composition and improvisation **37 Making a mark: the psychology of composition**	Impett, Jonathan	OUP	Inglés
2009	38	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 8 Composition and improvisation **38 Musical improvisation**	Ashley, Richard	OUP	Inglés
2009	39	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 8 Composition and improvisation **39 Children as creative thinkers in music: focus on composition**	R. Webster, Peter	OUP	Inglés
2009	40	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **40 Choosing to hear music: motivation, process and effect**	Colectivo	OUP	Inglés
2009	41	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **41 Music in performance arts: film, theatre, and dance**	J. Cohen, Annabel	OUP	Inglés
2009	42	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **42 Peak experiences in music**	Colectivo	OUP	Inglés

2009	43	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **43 Musical identities**	Colectivo	OUP	Inglés
2009	44	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **44 The effects of music in community and educational settings**	Hallam, Susan MacDonald, Raymond	OUP	Inglés
2009	45	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 9 The role of music in everyday life **45 Music and consumer behaviour**	C. North, Adrian J. Hargreaves, David	OUP	Inglés
2009	46	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 10 Music therapy **46 Processes of music therapy: clinical and scientific rationales and models**	de l'Etoile, Shannon	OUP	Inglés
2009	47	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 10 Music therapy **47 Clinical practice in music therapy**	Hurt-Thaut, Corene	OUP	Inglés
2009	48	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 10 Music therapy **48 Research and evaluation in music therapy**	L. Wheeler, Barbara	OUP	Inglés
2009	49	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 10 Music therapy **49 Music therapy in medical and neurological rehabilitation settings**	Colectivo	OUP	Inglés
2009	50	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 11 Conceptual frameworks, research methods and future directions **50 Beyond music psychology**	Ockelford, Adam	OUP	Inglés
2009	51	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 11 Conceptual frameworks, research methods and future directions **51 History and research**	Thaut, Michael	OUP	Inglés
2009	52	**The Oxford Handbook of MUSIC PSYCHOLOGY** Part 11 Conceptual frameworks, research methods and future directions 52 Where now?	Colectivo	OUP	Inglés
2006	53	**Music, Motor Control and the Brain** Part 1: History **1. Historical increases in expert music performance skills: optimising instruments, playing techniques and training**	Lehmann, Andreas C.	OUP	Inglés
2006	54	Music, Motor Control and the Brain Part 2: Psychology **2. From cognition to action**	Jäncke, Lutz	OUP	
2006	55	Music, Motor Control and the Brain Part 2: Psychology **3. The nature of memory for music performance skills**	Palmer, Caroline	OUP	
2006	56	Music, Motor Control and the Brain Part 2: Psychology **4. Musical synchronization**	Repp, Bruno	OUP	
2006	57	Music, Motor Control and the Brain Part 3: Movement analysis **5. Hand movements and musical performance**	Jerde, Thomas E. Santello, Marco Soechting, John F.	OUP	
2006	58	Music, Motor Control and the Brain Part 3: Movement analysis **6. Movement analysis in pianists**	Jabusch, Hans-Christian	OUP	
2006	59	Music, Motor Control and the Brain Part 3: Movement analysis **7. Fingering and bowing in violinists**	Wiesendanger, Mario Baader, Andreas Kazennikov, Oleg	OUP	
2006	60	Music, Motor Control and the Brain PArt 3: Movement analysis **8. Movements and analysis of drumming**	Dahl, Sofia	OUP	
2006	61	Music, Motor Control and the Brain PArt 3: Movement analysis **5. Hand movements and musical performance**	Repp, Bruno	OUP	

2006	62	Music, Motor Control and the Brain Part 4: Representation in the Brain **9. Brain structures of musicians: executive functions and morphological implications**	Schlaug, Gottfried	OUP
2006	63	Music, Motor Control and the Brain Part 4: Representation in the Brain **10. The motor representation in pianists and string players**	Jäncke, Lutz	OUP
2006	64	Music, Motor Control and the Brain Part 4: Representation in the Brain **11. Brain activation during piano playing**	Bangert, Marc	OUP
2006	65	Music, Motor Control and the Brain Part 4: Representation in the Brain **12. Brain activation during string playing**	Nirkko, Arto Kristeva, Rumyana	OUP
2006	66	Music, Motor Control and the Brain Part 4: Representation in the Brain **13. 'Singing in the (b)rain': cerebral correlates of vocal music performance in humans**	Ackermann, Hermann Wildgruber, Dirk Riecker, Axel	OUP
2006	67	Music, Motor Control and the Brain Part 4: Representation in the Brain **14. Sensory-motor networks in singing and speaking: a comparative approach**	Gordon, Reyna Leigh Racette , Amelie Racette & Daniele Schon Schon, Daniele	OUP
2006	68	Music, Motor Control and the Brain Part 4: Representation in the Brain **15. Role of inhibition in motor control of finger functions**	Gerloff , Christian Hummel, Friedhelm	OUP
2006	69	Music, Motor Control and the Brain Part 5: Apollo's curse - the loss of motor control in musicians **16. The end of the song? Robert Schumann's focal dystonia**	Altenmüeller, Eckart	OUP
2006	70	Music, Motor Control and the Brain Part 5: Apollo's curse - the loss of motor control in musicians **17. Epidemiology, phenomenology and therapy of musician's cramp**	Jabusch, Hans-Christian Altenmüeller, Eckart	OUP
2006	71	Music, Motor Control and the Brain Part 5: Apollo's curse - the loss of motor control in musicians **18. The neurophysiology of focal hand dystonia in musicians**	Rosenkranz, Karin	OUP
2006	72	Music, Motor Control and the Brain Part 5: Apollo's curse - the loss of motor control in musicians **19. The development of focal dystonia in musicians as a consequence of maladaptive plasticity: implications for intervention**	Byl, Nancy Priori, Alberto	OUP
2006	73	Music, Motor Control and the Brain Part 5: Apollo's curse - the loss of motor control in musicians **20. Music performance anxiety**	Kesselring, Jurg	OUP
2006	74	**La interpretación musical** Primera parte: Conceptos y preconceptos **1. La interpretación a través de la historia**	Lawson, Colin	Alianza Música
2006	75	La interpretación musical Primera parte: Conceptos y preconceptos **2. La interpretación histórica y el intérprete moderno**	Walls, Peter	Alianza Música
2006	76	La interpretación musical Primera parte: Conceptos y preconceptos **3. Análisis y (¿o?) interpretación**	Rink, John	Alianza Música
2006	77	La interpretación musical Primera parte: Conceptos y preconceptos **4. Comprender la psicología de la interpretación**	Clarke, Eric	Alianza Música
2006	78	La interpretación musical Segunda parte: Aprender a interpretar **5. Sobre la enseñanza de la interpretación**	Ritterman, Janet	Alianza Música
2006	79	La interpretación musical Segunda parte: Aprender a interpretar **6. El desarrollo de la habilidad interpretativa**	Davidson, Jane	Alianza Música
2006	80	La interpretación musical Segunda parte: Aprender a interpretar **7. Preparándose para interpretar**	Reid, Stefan	Alianza Música

2006	81	La interpretación musical Segunda parte: Aprender a interpretar **8. La memorización de la música**	Williamon, Aaron	Alianza Música	
2006	82	La interpretación musical Tercera parte: Hacer música **9. De la partitura al sonido**	Hill, Peter	Alianza Música	
2006	83	La interpretación musical Tercera parte: Hacer música **10. El lenguaje del cuerpo durante la interpretación**	Davidson, Jane	Alianza Música	
2006	84	La interpretación musical Tercera parte: Hacer música **11. La interpretación en grupo**	Goodman, Elaine	Alianza Música	
2006	85	La interpretación musical Tercera parte: Hacer música **12. El miedo escénico**	Valentin, Elizabeth	Alianza Música	
2006	86	La interpretación musical Cuarta parte: Interpretar la interpretación. **Escuchar la interpretación**	Clarke, Eric	Alianza Música	
2006	87	La interpretación musical Cuarta parte: Interpretar la interpretación. **14. El legado de las grabaciones**	Johnson, Peter	Alianza Música	Español
2006	88	La interpretación musical **Cuarta parte: Interpretar la interpretación.** **15. La crítica de la interpretación musical**	Monelle, Raimond	Alianza Música	
2006	89	La interpretación musical Cuarta parte: Interpretar la interpretación. **16. Los intérpretes y la interpretación**	Dunsby, Jonathan	Alianza Música	
2005	90	**Exploring the musical mind** Cognitive processes The psychology of music reading **Structural cues within notation**	Sloboda, John	OUP	
2005	91	Exploring the musical mind Cognitive processes The psychology of music reading **The role of musical knowledge in reading**	Sloboda, John	OUP	
2005	92	Exploring the musical mind Cognitive processes The psychology of music reading **Teaching music reading**	Sloboda, John	OUP	
2005	93	Exploring the musical mind Cognitive processes Experimental studies of music reading: a review **Review of early reading research**	Sloboda, John	OUP	
2005	94	Exploring the musical mind Cognitive processes Experimental studies of music reading: a review **Experiments varying skill level and structure in text**	Sloboda, John	OUP	
2005	95	Exploring the musical mind Cognitive processes Experimental studies of music reading: a review **Expressive sight-reading**	Sloboda, John	OUP	
2005	96	Exploring the musical mind Cognitive processes The uses of space in music notation **Comparison of text and music notations**	Sloboda, John	OUP	
2005	97	Exploring the musical mind Cognitive processes The uses of space in music notation **Historical trends in notation development**	Sloboda, John	OUP	
2005	98	Exploring the musical mind Cognitive processes The uses of space in music notation **Conceptual issues in the design of notation**	Sloboda, John	OUP	

2005	99	Exploring the musical mind Cognitive processes The uses of space in music notation **Psychological issues in the design of notation**	Sloboda, John	OUP	
2005	100	Exploring the musical mind Cognitive processes Immediate recall of melodies **Problems of transcription from sung performance**	Sloboda, John	OUP	
2005	101	Exploring the musical mind Cognitive processes Immediate recall of melodies **Analysis of errors in sung recall**	Sloboda, John	OUP	
2005	102	Exploring the musical mind Cognitive processes Immediate recall of melodies **Memory representations for melodies**	Sloboda, John	OUP	
2005	103	Explorin the musical mind Cognitive processes Cognition and real music: the psychology of music comes of age **Nature of scientific paradigms**	Sloboda, John	OUP	Inglés
2005	104	Exploring the musical mind Cognitive processes Cognition and real music: the psychology of music comes of age **Is music psychology paradigmatic?**	Sloboda, John	OUP	
2005	105	Exploring the musical mind Cognitive processes Cognition and real music: the psychology of music comes of age **The contribution of Lerdahl and Jackendoff**	Sloboda, John	OUP	
2005	106	Exploring the musical mind Cognitive processes Psychological structures in music: core research 1980-1990 **Citation as a means of assessing significance of research**	Sloboda, John	OUP	
2005	107	Exploring the musical mind Cognitive processes Psychological structures in music: core research 1980-1990 **The contribution of Krumhansl**	Sloboda, John	OUP	
2005	108	Exploring the musical mind Cognitive processes Psychological structures in music: core research 1980-1990 **Establishing a sense of tonal centre**	Sloboda, John	OUP	
2005	109	Exploring the musical mind Cognitive processes Psychological structures in music: core research 1980-1990 **Hierarchies in tonal representation**	Sloboda, John	OUP	
2005	110	Exploring the musical mind Cognitive processes Review of Language, Music and Mind by Diana Raffman **The relationship of philosophy of music to psychology of music**	Sloboda, John	OUP	
2005	111	Exploring the musical mind Cognitive processes Review of Language, Music and Mind by Diana Raffman **Nuance and ineffability in music**	Sloboda, John	OUP	
2005	112	Exploring the musical mind Cognitive processes Review of Language, Music and Mind by Diana Raffman **Different ways in which music might be said to have 'meaning'**	Sloboda, John	OUP	
2005	113	Exploring the musical mind Cognitive processes Does music mean anything? **Is parsing sufficient for understanding in music?**	Sloboda, John	OUP	
2005	114	Exploring the musical mind Cognitive processes Does music mean anything? **Dynamic feelings as precursors of meaning**	Sloboda, John	OUP	

2005	115	Exploring the musical mind Cognitive processes Does music mean anything? ***Thrills* as proto-emotions concerns**	Sloboda, John	OUP
2005	116	Exploring the musical mind Emotion and motivation Music as a language **Musical phonology, syntax, and semantics**	Sloboda, John	OUP
2005	117	Exploring the musical mind Emotion and motivation Music as a language **Peak musical experiences in childhood**	Sloboda, John	OUP
2005	118	Exploring the musical mind Emotion and motivation Music as a language **Motivation for long-term commitment to music**	Sloboda, John	OUP
2005	119	Exploring the musical mind Emotion and motivation Music psychology and the composer **Different models for composer-psychologist dialogue**	Sloboda, John	OUP
2005	120	Exploring the musical mind Emotion and motivation Music psychology and the composer **Relationship of composition to functions of music**	Sloboda, John	OUP
2005	121	Exploring the musical mind Emotion and motivation Music psychology and the composer **Music as an aid to cognitive restructuring**	Sloboda, John	OUP
2005	122	Exploring the musical mind Music in the real world Everyday uses of music listening: a preliminary study **Music in public places**	Sloboda, John	OUP
2005	123	Exploring the musical mind Emotion and motivation Empirical studies of emotional response to music **Verbal responses within forced categories**	Sloboda, John	OUP
2005	124	Exploring the musical mind Emotion and motivation Empirical studies of emotional response to music **Extrinsic and intrinsic antecedents of musical emotion**	Sloboda, John	OUP
2005	125	Exploring the musical mind Emotion and motivation Emotional response to music: a review **Accounting for variation between and within people**	Sloboda, John	OUP
2005	126	Exploring the musical mind Emotion and motivation Emotional response to music: a review **Methods for measuring emotional response**	Sloboda, John	OUP
2005	127	Exploring the musical mind Emotion and motivation Emotional response to music: a review **How musical events elicit emotion**	Sloboda, John	OUP
2005	128	Exploring the musical mind Emotion and motivation Musical performance and emotion: issues and developments **Different expressive roles of performers**	Sloboda, John	OUP
2005	129	Exploring the musical mind Emotion and motivation Musical performance and emotion: issues and developments **Connection between music structure and expressive devices**	Sloboda, John	OUP
2005	130	Exploring the musical mind Emotion and motivation Musical performance and emotion: issues and developments **Evidence for deliberate planning of expressive communication**	Sloboda, John	OUP

2005	131	Exploring the musical mind Talent and skill development Musical expertise **Social and cultural relativity of musical expertise**	Sloboda, John	OUP
2005	132	Exploring the musical mind Talent and skill development Musical expertise **Musical skill acquisition in non-instructional settings**	Sloboda, John	OUP
2005	133	Exploring the musical mind Talent and skill development Musical expertise **Precursors of musical expertis**	Sloboda, John	OUP
2005	134	Exploring the musical mind Music in the real world The 'sound of music' versus the 'essence of music': dilemmas for music-emotionresearchers **Research which demonstrates the strong contribution of the individual to the n ature of the musical experience**	Sloboda, John	OUP
2005	135	Exploring the musical mind Talent and skill development Musical ability **Expressive playing in sight-reading as a strong test of ability**	Sloboda, John	OUP
2005	136	Exploring the musical mind Talent and skill development Musical ability **How to develop technical and expressive skill togethe**	Sloboda, John	OUP
2005	137	Exploring the musical mind Talent and skill development The acquisition of musical performance expertise: deconstructing the talent' account of individual differences in musical expressivit y **Is musical skill inherited?**	Sloboda, John	OUP
2005	138	Exploring the musical mind Talent and skill development The acquisition of musical performance expertise: deconstructing the talent' account of individual differences in musical expressivit y **The role of practice**	Sloboda, John	OUP
2005	139	Exploring the musical mind Talent and skill development The acquisition of musical performance expertise: deconstructing the talent' account of individual differences in musical expressivit y **Different learning mechanisms for technical and expressive skill**	Sloboda, John	OUP
2005	140	Exploring the musical mind Talent and skill development Are some children more gifted for music than others? **The role of early learning in skill development**	Sloboda, John	OUP
2005	141	Exploring the musical mind Talent and skill development Are some children more gifted for music than others? **Social support mechanisms for skill development**	Sloboda, John	OUP
2005	142	Exploring the musical mind Talent and skill development Are some children more gifted for music than others? **Motivational factors predicting success or dropout**	Sloboda, John	OUP
2005	143	Exploring the musical mind Music in the real world Everyday uses of music listening: a preliminary study **Importance of situation and volition in determining effects of music**	Sloboda, John	OUP
2005	144	Exploring the musical mind Music in the real world Everyday uses of music listening: a preliminary study **Free verbal descriptions of music's role in everyday life**	Sloboda, John	OUP

2005	145	Exploring the musical mind Music in the real world Music: where cognition and emotion meet **Mismatch between music's value to people and their level of musical skill**	Sloboda, John	OUP
2005	146	Exploring the musical mind Music in the real world Music: where cognition and emotion meet **Tracking everyday uses of music in real time**	Sloboda, John	OUP
2005	147	Exploring the musical mind Music in the real world Music: where cognition and emotion meet **Societal barriers to engagement with music**	Sloboda, John	OUP
2005	148	Exploring the musical mind Music in the real world Music and worship: a psychologist's perspective **Can music have assumed common effects within a defined situation?**	Sloboda, John	OUP
2005	149	Exploring the musical mind Music in the real world Music and worship: a psychologist's perspective **Parallels between different ways of listening to music and different aspects of w orship**	Sloboda, John	OUP
2005	150	Exploring the musical mind Music in the real world Music and worship: a psychologist's perspective **Ineffability as a core concept in both music and worship**	Sloboda, John	OUP
2005	151	Exploring the musical mind Music in the real world Emotion, functionality, and the everyday experience of music: where does music education fit? **Reasons why young adolescents give up instrumental engagement**	Sloboda, John	OUP
2005	152	Exploring the musical mind Music in the real world Emotion, functionality, and the everyday experience of music: where does music education fit? **Cultural trends associated with disengagement from formal music**	Sloboda, John	OUP
2005	153	Exploring the musical mind Music in the real world Emotion, functionality, and the everyday experience of music: where does music education fit? **Responses of the education system to cultural change**	Sloboda, John	OUP
2005	154	Exploring the musical mind Music in the real world The 'sound of music' versus the 'essence of music': dilemmas for music-emotion researchers **Cultural trends which deindividriate the musical experience**	Sloboda, John	OUP
2005	155	Exploring the musical mind Music in the real world The 'sound of music' versus the 'essence of music': dilemmas for music-emotion r esearchers **How science can be misused in the interests of cultural homogenization of the musical experience**	Sloboda, John	OUP
2005	156	Exploring the musical mind Music in the real world Assessing music psychology research: values, priorities, and outcomes **The social benefits of music psychology research psychology**	Sloboda, John	OUP
2005	157	Exploring the musical mind Music in the real world Assessing music psychology research: values, priorities, and outcomes **Differentiating the above from the social benefits of music**	Sloboda, John	OUP
2005	158	Exploring the musical mind Music in the real world Assessing music psychology research: values, priorities, and outcomes **Differing levels of engagement with social issues evident in research**	Sloboda, John	OUP

2005	159	Exploring the musical mind Emotion and motivation Empirical studies of emotional response to music **Free verbal emotional responses to music**	Sloboda, John	OUP	
2005	160	Exploring the musical mind Talent and skill development Musical ability **Cultural exposure as a primary source of basic ability**	Sloboda, John	OUP	
2004	161	**Musical Excelence** Strategies and techniques to enhance performance	Williamond, Aaron	OUP	Inglés
2004	162	Musical excellence Part I Prospects and limits **A guide to enhancing musical performance**	Williamon, Aaron	OUP	
2004	163	Musical excellence Part I Prospects and limits **General perspectives on achieving Musical excellence**	Chaffi, Roger Lemieux, Anthony F.	OUP	
2004	164	Musical excellence Part I Prospects and limits **Managing the physical demands of musical performance**	Wynn Parry, Christopher B.	OUP	
2004	165	Musical excellence Part I Prospects and limits **Measuring performance enhancement in music**	McPherson, Gary E. Schubert, Emery	OUP	
2004	166	Musical excellence Part II Practice strategies **Strategies for individual practice**	Jorgensen, Harald	OUP	
2004	167	Musical excellence Part II Practice strategies **Strategies for ensemble practice**	Davidson, Jane W. C. King, Elaine	OUP

The Oxford Handbook *of* MUSIC PSYCHOLOGY

OXFORD

The field of music psychology has grown dramatically in the past 20 years, to emerge as one of the mainstream topics within the brain sciences. However, until now, there has been no comprehensive international reference text in the field.

The *Oxford Handbook of Music Psychology* is a landmark text providing, for the first time ever in English, a comprehensive overview of the latest developments in this fast-growing area of research. With contributions from over 50 experts in the field, the range and depth of coverage is unequalled. All the chapters combine a solid review of the relevant literature with well-reasoned arguments and robust discussions of the major findings, as well as original insights and suggestions for future work.

Written by leading experts, the 52 chapters are divided into 11 parts covering both experimental and theoretical perspectives, each edited by an internationally recognized authority on the area.

The first 10 parts each present chapters that focus on specific areas of music psychology:

- the origins and functions of music
- music perception
- responses to music
- music and the brain
- musical development
- learning musical skills
- musical performance
- composition and improvisation
- the role of music in our everyday lives
- music therapy

In each part, expert authors critically review the literature, highlight current issues, and explore possibilities for the future.

The final part examines how, in recent years, the study of music psychology has broadened to include a range of other disciplines. It considers the way that the research has developed in relation to technological advances, fostering links across the field and providing an overview of the areas where the field needs further development in the future.

The *Oxford Handbook of Music Psychology* is the essential reference text for students and researchers across psychology and neuroscience interested in music.

PART 1

The origins and functions of music

Edited by Ian Cross

CHAPTER 1

The nature of music and its evolution

Ian Cross

The theory of evolution in musicological context

The idea that the theory of evolution has anything to offer to our understanding of music provokes strong reactions (both positive and negative) and has swung in and out of favour amongst those who have thought and written about music over the last hundred and fifty years. For the last few decades of the nineteenth century and the first few of the twentieth, the theory of evolution was of huge significance for music theorists, historians and anthropologists as a means of exploring and explaining musical change, musical difference and musical value. From around the 1940s to the beginning of the 1990s, the theory of evolution more or less vanished from musical and musicological discourse: the term 'evolution' tends to co-occur with musical terms only in the titles of books and articles such as 'The evolution of twelve-tone music', 'of Beethoven's late style'—and so on. However, from around the late 1980s, the theory of evolution began to re-emerge as a valid and prospectively valuable way of thinking about important aspects of music. This chapter will outline aspects of 'classical' evolutionary theory before delineating some of the factors that have led to the fall and rise in the fortunes of evolutionary theory as applied to music. It will give an outline of current conceptions of the relationships between music and evolutionary theory, and will conclude by exploring some of the implications for music psychology of evolutionary views of music.

Dictionary definitions of the term 'evolution' include 'the appearance of events in due succession', and 'the gradual development of something into a more complex or better form'. Only with the publication of Darwin's *Origin of Species* in 1859 did the meaning in terms of which 'evolution' is now most widely understood take clear shape: 'the theoretical process[es] by which all species develop from earlier forms of life'. 'Classical' evolutionary theory starts by noting that not all members of any given population of animals will be identical; there will be minor differences of form and capacity between individual members, and if those differences allow an individual to exploit its environment better than other individuals, they will increase the likelihood that the individual will survive and reproduce. If those differences can be inherited, all members of the population that bear them will be similarly advantaged by being better adapted to their environment, becoming prevalent in the population over time and leading to a change in its make up and perhaps to speciation, the emergence of new species (roughly speaking, a discrete population of animals that do not interbreed with other populations of animals). This process of variation, leading to differential levels of survival and reproduction, leading to speciation, can be termed 'natural selection'. Natural selection, together with sexual selection (evident in processes governing mate choice and hence affecting likelihood of reproduction) constituted the foundations of Darwin's theory of evolution, which was intended to provide an explanation

of the diversity of forms of life and their interrelationships without invoking any creative agency other than the workings of observable physical and biological processes.

The theory of evolution was developed to account for the natural world, but was almost immediately co-opted into theory and debate about human society. For many it appeared to offer a scientific basis on which to erect social theory, particularly insofar as it could be interpreted as giving support to ideas of scientifically grounded distinctions between human races, and of the progressive development of human societies. After all, it seemed to many influential thinkers that the processes of evolution constituted a means of explaining the continual refinement of a species' abilities. What could be more natural, in the Victorian age of progress, than to suppose that differences in degrees of ability between species—with human races interpretable as distinct species, or at least, as being analogous to species—conformed to universal principles that could be summarized in the theory of evolution? With these teleological trappings the theory of evolution came to serve as one of the key features of much writing about music at the beginning of the twentieth century. The 'progressivist' notion of evolution seemed to provide a systematic framework that could account not only for stylistic change and development in music across Western musical history, but also a means of qualifying music from non-Western societies as being more, or less, developed in their relationships to refined and hence 'highly evolved' Western musical practice (for an overview see Rehding 2000).

It should be noted that Darwin's own writings in *The expression of the emotions in man and animals*, and in *The descent of man* on music as an evolved human capacity played almost no role in any of the early twentieth-century musicological writings that espoused evolutionary perspectives. Darwin viewed the human capacity for music as a likely precursor of the capacity for language, having its origins in the vocal expression of emotion and as having had utility in processes of sexual selection (see Cross 2007). Moreover, he was somewhat agnostic concerning whether or not music of different cultures or races had greater or lesser value, but in any case did not agree with the proposition that racial difference corresponded to any difference in innate, human, musical capacity; in other words, humans, to Darwin, were a single species (see Chapters 7 and 19 of *The descent of man* [Darwin 2004]).

As the twentieth century progressed, consideration of origins in the study of music moved away from any exploration of music's relationship to biology to re-focus on the historical relationships between contemporary Western musical theory and practice, on Western musical history, or on music's relationships with abstract domains such as mathematics. For these strands of thought evolution was simply irrelevant to their interests, which were viewed as primarily musicological, concerned with the explication of the historical and ontological roots of Western music. Moreover, the repellent consequences of the racialist theorizing that teleogical interpretations of evolutionary theory had been called upon to sanction were all too evident in the aftermath of the Second World War.

In any case, within anthropology, an increasing tendency to focus on the cultural specificities of societies rather than on pancultural universalities or on any necessary concept of cultural progress diminished the apparent explanatory role of any biological foundation for culture and mind (see Shore 1996). By the middle of the twentieth century, exploration of music beyond the bounds of Western societies had come to concentrate on detailed ethnographic description and on attempts to understand the structures and functions of music in terms derived from the societies' own understandings of their music—in other words, in emic rather than etic terms. There is little evidence of evolutionary thinking as having had any significant impact on understanding music within societies or across cultures. Nevertheless, a vital feature of these ethnomusicological studies is the evidence they provide concerning the heterogeneity of music across different societies, a heterogeneity that problematizes the very notion of 'music' (see Chapter 4 this volume), and any evolutionary approach to understanding music requires at least an operational definition of what might constitute 'music'.

Evolutionary theory is first and foremost a theory about biology. It could be suggested that music has no existence that is independent of

the discourse that frames it: that 'music' is simply a discursive category with an identity that is dependent on its opposition to the other categories of discourse that we employ in the linguistic taxonomies that we have developed—largely in the west—to describe or talk about types of human behaviours. This is a view that seems at least implicit in much musicological thinking of the recent past (see e.g. Korsyn 2003, p. 187). However, most ethnomusicologists would subscribe to the view that there is something that can be described as 'musical' that is evident in the patterns of thought and behaviour of all known societies (see Chapters 2 and 4 this volume). If this is indeed the case, given that humans share a common biology as members of a single species, then whatever constitutes 'music' across cultures may reflect some general processes of thought and behaviour that should, in principle, be a proper focus of exploration in terms of evolutionary theory.

'Music' as an object of evolutionary exploration

Music varies from society to society to the extent that one culture's music may not be recognizable as music by members of another culture. This applies both to the structural features of the music and to the functions that it may fulfil. As Stevens and Byron show in Chapter 2 of this volume, the cognitive processing of music across human societies exhibits many common characteristics. Some of these processing commonalities map onto structural musical features, such as the use of discrete pitch levels, unequal-stepped scales, octave equivalence, low-integer frequency ratios, and periodic pulses. Moreover, features such as hierarchical organization and temporal structures that are shaped so as to modulate the expectancies of those engaged with the music, also appear to be generic in music across cultures. It may be that some features, particularly those concerned with the experience of fine-grained pitch structures and periodic temporal structures, should be considered as proper to music. Nevertheless, at least some of these common structural regularities may not be evident in particular instances otherwise identifiable as music (a paradigmatic, though controversial, case being Cage's *4'33'*), and at least some of the universal cognitive processes described in Chapter 2, such as the formation of hierarchical structures, and the implicit learning of expectancies, are operational in domains other than music. While arriving at an empirically grounded account of universal characteristics of musical processing and musical structure is essential in delineating what may constitute the foundations of music, it is not sufficient; it is also necessary to explore the extent to which there may be commonalities between people and across cultures in the ways in which music is manifested as social behaviour.

On the whole, ethnomusicologists have given surprisingly little consideration to the question of musical universals. Amongst the few significant exceptions are Bruno Nettl, Alan Merriam and John Blacking, who adopt somewhat different perspectives. Nettl (2005) takes a pragmatic approach, suggesting that etic (Western) and emic accounts should each feed in to determine what it is that ethnomusicologists should focus on as 'music'. Merriam (1964) suggests that 'music' can best be explored in terms of a tripartite model that embraces music as *sound* (what might conventionally be thought of as constituting music from a Western perspective), as *behaviour* (which embraces the musical—and 'non-musical'—acts of musicians, and the activities in which the production of music is embedded) and as *concept* (how people think about music in terms of its powers and its relations to other domains of human life). Blacking (1995), on the basis of his extensive fieldwork with the Venda peoples of southern Africa, and in particular, on his study of Venda children's music, claims that

> 'Music' is a primary modelling system of human thought and a part of the infrastructure of human life. 'Music'-making is a special kind of social action which can have important consequences for other kinds of social action.
>
> Blacking (1995, p. 223)

Blacking's claims appear to locate music as central to, and in some ways indissociable from, other domains of human behaviour. While the claim for music's centrality is not widely echoed

in the ethnomusicological literature, the conception of music as embedded in broader suites of behaviour is more general, as Bohlman puts it:

> expressive practices do not divide into those that produce music and those that produce something else, say ritual or dance. Music accumulates its identities ... from the ways in which it participates in other activities.
>
> Bohlman (2000, p. 293)

For those engaged in understanding music as it manifests itself across different cultures and historical times, 'music' appears to be protean, and its identification in any consistent manner seems particularly intractable. Certainly, music cannot be defined in the terms in which it is conventionally conceived of in contemporary Western societies, as a consumable commodity constituted of complexly patterned sound that is produced by a class of specialists and engaged with through listening for primarily hedonic reasons. In many, perhaps most, non-Western cultures it involves overt action and active group engagement, and is employed not only in caregiver–infant interaction, entertainment and courtship but also in ritual, particularly at times of significant life transitions (such as the passage from adolescence to adulthood, from season to season, or from life to death). More often than not, music is an integral part of a wider range of everyday activities. If a category of behaviours that can be termed 'music' has any generality across cultures, it seems that it can best be characterized as active, as founded in interaction, and as permeated by many other aspects of social life (see also Chapter 4 this volume).

Given that, in the ethnomusicological view, music and other human activities seem almost amalgamated, are there any features that would serve to distinguish 'music' as a discrete category of human thought and behaviour? At first sight, music seems to possess few characteristics that are not shared with other domains of behaviour, notably dance and language. Music involves patterned action in time, as does dance. Music appears communicative, complex, generative and representational, as does language. The concept of music is amalgamated with that of dance in many—perhaps the majority of—cultures. This fact, together with the stress on music as action in much of the ethnomusicological literature (see Chapter 2 this volume) suggests that it would be parsimonious to treat music and dance either as intrinsically related or simply as different manifestations of the same phenomenon.

Relationships between music and language are more difficult to disentangle, but perhaps the most significant factors that differentiate them are the types of structured interactions that they allow, and their contexts of use. Linguistic interactions are typically structured in time so as to coordinate the temporal succession of participants' contributions. Language possesses a generative complexity that allows for the production and reception of a potentially unlimited set of utterances: it is also directed towards the communication of representations of ideas, states of affairs, attitudes and affects that have relevance to their contexts of production and reception—language can signify or mean, unambiguously. While music seems to share some of these characteristics with language, at least two significant differences are apparent. Music may allow participants to act simultaneously rather than asynchronously as in language. In addition, music's meanings appear less stable and consensual than those of language (see Chapter 3 this volume).

Music's capacity to enable participants to act and to contribute to music-making simultaneously exploits the capacity of entrainment (Clayton *et al.* 2005). Entrainment here refers to the coordination in time of one participant's behaviours with those of another and involves the organization of the perception and behaviour of participants around temporal regularities that are inferred (generally non-consciously) from musical sounds and actions in the form of a periodic pulse or beat that is sensed by all participants (Clayton *et al.* 2005), being evidenced in continual processes of correction of errors by participants in alignment of action in both period and phase (see e.g. Repp 2001). Even engagement with music in apparently passive listening appears to rely on such entrainment processes, evidenced in periodic modulation of attentional load (see Chapter 8 this volume). It is notable that the capacity for entrainment may be unique to humans. While several species of cicadas and frogs do appear to

entrain, they do so in ways that appear different from those implicated in human entrainment and the issue of the origins of entrainment in the hominid or hominin lineage remains to be investigated (see Bispham 2006; Cross *et al.* 2008, in press).

Language has an indisputable efficacy in human interaction, in large part by virtue of its capacities to mean. It is often supposed that music's meanings can be reduced to the emotions it represents, expresses or elicits (see Juslin and Sloboda 2001) which suggests that meaning in music is a poor or natural cousin of meaning in language. However, while it is undoubtedly the case that music is valued for its affective powers in all societies, music's meanings extend beyond its affective value; as Tolbert (2001) notes, music's meanings are equally embodied, natural or affective, and artificial or symbolic. In general, however, meaning in music appears to be less susceptible to consensual determination than is meaning in language; music certainly bears meaning, but the meanings that it can bear are more impenetrable and susceptible to change according to the contexts in which they are experienced than are those of language. As Blacking (1995 p. 237) notes, 'Not only can the "same" patterns of sound have different meanings in different societies; they can also have different meanings within the same society because of different social contexts', an attribute of music characterizable as 'floating intentionality' (Cross 1999).

So music is differentiable from language in its exploitation of the human capacity to entrain, in the probable scope of its generativity and in ways in which it can mean. In some respects this comparison could appear to objectify music as an impoverished version of language. However, music and language coexist in all societies and fulfil different (though perhaps complementary) functions in those societies. While language is capable of expressing semantically decompos-able propositions that have unambiguous reference, music cannot. Nevertheless, there are numerous social situations in which unambiguous reference in communicative acts is not a desideratum as it may precipitate conflict in attitudes or actions. Music's exploitation of the human capacity for entrainment allows participants to experience a sense of 'shared intentionality', whilst under-specifying goals in ways that permit individuals to interact even while holding to personal meanings and goals that may actually be in conflict (Cross 2005). Music has a profoundly social efficacy (see Chapter 4 this volume), and it is possible to delineate music as a medium that is interactive, entraining, and that exhibits floating intentionality. Such a definition seems almost to exclude Western listening, which may often be passive and solitary rather than social. However, the object of listening—the music—can be conceived of as constituting a trace of human activity with which a listener may 'virtually' interact (see Clarke [2005] on 'subject-position' in music).

Music in recent evolutionary thought

In parallel with the development of broad conceptions of music, over the latter half of the twentieth century theories of evolution underwent a revolution, in part driven by developments in theoretical biology and by the rise of the science of genetics (see e.g. Maynard-Smith and Szathmáry 1995). Neo-Darwinian understandings of evolution elucidated the genetic mechanisms whereby organisms transmitted their characteristics from one generation to the next, as well as processes, in addition to natural and sexual selection, that could operate so as to shape an organism's fitness, or adaptedness, with respect to its environment. Processes of kin selection have been distinguished whereby genetic relatedness can be adduced to account for seemingly altruistic behaviours between members of social species as well as for the emergence of sterile animal castes (see e.g. Hölldobler and Wilson 1994). Processes of genetic drift have also been shown to be operational whereby random changes in the genetic make-up of a population come, over time, to lead to populations with quite different characteristics from the parent population (see Maynard Smith 1998). Other work has shown that processes of selection can *appear* to operate at the level of the group. Theories such as those proposed by Sober and Wilson (1998) support the notion of a role for relationships between

social environment and individual fitness in profoundly social species such as humans. In a social species, behaviours that contribute towards survival and reproductive success may be determined as much by relations between members of the species (and by individual capacities to manage such relations) as by relations between individuals and their physical environments. All these developments provided substantial foundations for postulating that complex individual and social behaviours such as language and music, as well as the mental processes that underlie those behaviours, could be explored and understood in terms of evolutionary theory.

By the beginning of the last decade of the twentieth century, evolutionary psychology was coalescing as an identifiable and significant strand of research within both psychology and evolutionary theory. At first little attention was paid to music, but in 1997 one of its main protagonists, Steven Pinker, produced an evolutionary treatment of music that relegated it to the status of evolutionary by product. In *How the mind works*, Pinker devotes ten pages of his final chapter to considering music, because, in his words, he wishes to consider a mental faculty which 'shows the clearest signs of not being' [an evolutionary adaptation] to set against examples of mental faculties that are self-evidently adaptive, such as language. Pinker starts from the premise that 'as far as biological cause and effect are concerned, music is useless' (p. 528), noting that music is variable in its complexity from culture to culture, that while all tend to enjoy listening to music only a small subset of the population are practitioners, and that music communicates nothing but formless emotion. Hence music shows clear signs of being a 'technology', a human capacity developed and exploited for its own sake and at best evolutionarily neutral, rather than an adaptation. He suggests that this technology developed to exploit capacities that had arisen for largely adaptive reasons, claiming that 'music is auditory cheesecake, an exquisite confection crafted to tickle the sensitive spots of at least six of our mental faculties' (p. 534). However, the significance of Pinker's discussion of music is severely diminished by the lack of fit between his ethnocentric conception of music and that outlined above. Pinker seems to subscribe to a thoroughly Westernized notion of music as a commodified set of complex sound patterns produced by the few and consumed by the many simply for pleasure, rather than as the complex and socially efficacious actions and structures that it is and has been both in the west and in other cultures, places and times.

Subsequently, another prominent evolutionary psychologist, Geoffrey Miller, presented an alternative evolutionary psychological account of music quite at variance with that of Pinker. For Miller, music constitutes a medium that is well-suited to demonstrate the 'protean', unpredictable and creative, properties of an individual, properties that are selectively advantageous and hence desirable in the determination of mate-choice. Music is well-suited to make manifest such properties as it combines 'ritualized rules of tonality, rhythmicity, melody and harmony and protean intentions and variations' (Miller 1997, p. 322). Hence protean individuals might well advertise their creative assets in musical display. Miller (in Wallin *et al.* 2000) seeks to support this argument by reference to a range of Western musical examples (including Jimi Hendrix) claiming that the sexual opportunities afforded by rock-star status are in line with the predictions of his theory. Although music is certainly used for courtship in most, if not all, societies, its roles are always more multifarious. Moreover, Miller's theory would predict that musical ability should exhibit, or at least should have exhibited, a significant sexual dimorphism. While this would be difficult to ascertain in our predecessor species, it is not the case with modern humans; while musical roles are often sexually differentiated, in most cultures musicality appears to be equally exhibited by both males and females. If anything, the manifestation of musicality that is perhaps most culturally widespread, in the form of the use of protomusical and musical forms of interaction between caregiver and infant, is primarily evidenced by females (see Dissanayake in Wallin *et al.* 2000). Moreover, as Fitch (2006) points out, the precocious capacities of human infants in music perception would suggest that musicality is a trait that is unlikely to have been sexually selected for, given that such traits tend to emerge only in sexual maturity in other species.

In contrast to the positions of both Miller and Pinker, the majority of recent evolutionary treatments of music have focused on its effects at the level of the group; music is viewed as having, and as having had, effects on inter-group and intra-group interaction, which are conceived of as having had evolutionary consequences. Hagen and Bryant (2003) propose that group musical displays allow groups to indicate to each other their cohesion and stability, affording groups which can engage successfully in such displays a means of deterring other, more fragmented, groups from attempting to compete for scarce resources. Merker (in Wallin *et al.* 2000) proposes a similar putative role for music as an indicator of coalition strength. Brown (2004) acknowledges music's prospective role in inter-group relations but emphasizes its functionality within groups. He develops the notion of music as efficacious at the level of the group, suggesting that music typically acts at to influence behaviours at the group level. He suggests that music acts to reinforce cooperative behaviour within the group by means of group ritual activities, promoting a sense of 'groupishness' that is likely to enhance prospects of group survival in addition to being effective in situations of inter-group conflict.

This focus on music's significance in promoting cooperative, within-group, behaviours, is mirrored by others. Kogan (1997) views music as significant in human evolution by virtue of its embeddedness in social interaction and its effect of the formation of group identity, as does Dunbar (2004), who suggests that its primary effect is in the consolidation of group bonds. Mithen's (2005) extensive treatment echoes Brown (in Wallin *et al.* 2000) in presenting a view of music and language as having common origins and in suggesting that music had an evolutionary efficacy in the formation of social bonds. Mithen concludes, however, that music is no more than an atavistic relic that may have been functional for earlier species of hominins but whose functions have come to be usurped by language—a view that contrasts significantly with that of most ethnomusicological evidence (see Chapter 4 this volume).

In a series of publications Cross (1999, 2005, 2008, in press) also subscribes to the notion that music has a bonding effect, but suggests in addition that music, by virtue of its polyvalent significances, can contribute positively to individual fitness within the group by facilitating communicative interactions that, were they to be conducted linguistically, might give rise to conflict, a view also presented in Morley (2002). Whilst proposing that music may have an impact on individual fitness outwith social contexts by virtue of its 'metaphorising' powers (Cross 1999), Cross notes that music's powers of entrainment, together with its 'floating intentionality', render it an extremely efficacious communicative medium in managing situations of social uncertainty (Cross 2008, in press, Cross and Woodruff 2008). Hence music can be regarded as possessing attributes that complement those of language, and it can be postulated that music and language are likely to have co-evolved as complementary aspects of the human communicative toolkit, differentiated only by the degree to which they are capable of specifying meaning unambiguously (see also Chapter 3 this volume).

Dissanayake (in Wallin *et al.* 2000) takes a rather more constrained notion of the 'group' that might have constituted the matrix for the evolution of human musicality; the mother–infant dyad. In alignment with the views of Trevarthen (1999), she views infant-directed speech (see Trehub 2003), the infant's responses, and the kinesthetically interactive context of mother–infant communication as forming protomusical behaviours that are oriented towards the (co-)regulation of emotion, as well as forming the basis for the infant's acquisition of prosodic, phonemic and social competence. In this her proposal is in line with that of Falk (2004), who suggests that complex, vocal and gestural mother–infant interactions of the type that can be categorized as motherese are an evolutionarily adaptive response to the emergence of bipedalism, at around the time of the chimp–hominin split (*c.* 5–7 million years ago).

Music and evolution—the evidence

These diverse evolutionary perspectives on music suggest that it can fruitfully be explored in terms of contemporary evolutionary theory.

The evidence would suggest that music has a significant role in human behaviour—that it is functional—and that it is distinguishable from other domains of human behaviour. The latter point suggests that music may have a distinct evolutionary track record, and its functionality implies that it may have been evolutionarily adaptive in the emergence of the human species (or at least, exaptive—that is, arising only as a consequence of the independent prior emergence of some adaptive capacity but having an impact on evolutionary fitness). This begs the questions of when might the capacities for music have arisen, and how they came to arise. In order to explore these issues we must turn to the archaeological evidence.

Music—and indeed, sound—in prehistory has received little attention in the archaeological literature. D'Errico *et al.* (2003) summarize much of what is known in the context of a re-evaluation of current archaeological approaches, particularly in the light of recent finds in southern Africa. They note that the earliest unequivocally musical artefact found to date is a bone pipe from Geissenklösterle in southern Germany, dating to *c.* 38 000 before the present (BP). A further sequence of bone pipes has been found at Isturitz in southern France (in contexts rich in parietal—cave—art), with dates ranging from 20 000 to 35 000 BP. The earliest of these dates more or less coincides with the arrival of modern humans in Europe and suggests that something like music was of high significance to those peoples. As D'Errico *et al.* (2003) comment, these artefacts are extremely sophisticated, exhibiting subtle design features that are analogous to those found in historic wind instruments; the time, effort and expertize devoted to their manufacture must have been considerable and suggests that music was likely to have been of considerable importance to a people who had just come to inhabit a new and potentially threatening environment. The use of musical artefacts will have been preceded by the expression of musical capacities by voice and body, and would appear likely to have an ancient provenance. The ubiquity of music in native American and Australian societies in forms that are not directly relatable to historic Eurasian or African musics strongly suggests that modern humans brought musicality with them out of Africa. If this is the case we must look to evidence that will enable us to identify the time-depth of the capacity for music, or perhaps of different subcapacities that make up human musicality, which means turning to the prehistoric human fossil record.

A brief account of stages in human evolution might be useful at this point. The hominin (human) lineage last shared a common ancestor with chimpanzees and bonobos some 5–7 million years ago (mya). The earliest unambiguous members of the hominin line are found in Africa: *Ardipithecus ramidus*, at between 7 and 4.5 mya, and a range of *australopithecine* species, from around 4.2 to 2.4 mya). Both lineages were morphologically much more similar to chimps than to modern humans (having similar-size brains at <400 cc), and can be inferred to have had lifeways that closely resembled chimps—other than, in the case of the australopiths, at least partial bipedalism. Subsequently, the homo line proper appears with *Homo habilis* (ca 2.4–1.6 mya) and *Homo ergaster* or *erectus* (ca 1.9–0.2 mya), the latter line having a body build similar to modern humans and possessing brains of at least double the size of the australopiths; both *habilis* and *ergaster* made stone (lithic) tools, the latter making objects of some sophistication. *Homo heidelbergensis* (despite the name a predominantly African species, from around 0.6 to about 0.1 mya) shows a considerable increase in brain size (to around 1200 cc), and evidence of complex lifeways, including the making of non-lithic artefacts such as wooden spears. This last species was the ancestor of both *Homo neanderthalensis*, a mainly northern, highly cold-adapted, species (ca 0.2–0.03 mya) and *Homo sapiens*, ourselves who appear first in Africa some 200 000 years ago.

The fossil record from which we are able to construct this lineage of species suggests strongly that musicality does not emerge as a full-blown capacity, but rather that subcomponents of that capacity emerge at different times and probably in response to different selection pressures. Australopiths had funnel-shaped chests (as do chimps), which do not permit sufficiently fine control over phonation to make the subtly differentiated vocal sounds that would be required of music. Only with *ergaster* does the barrel-shaped chest of modern humans arise

(Frayer and Nicolay in Wallin *et al.* 2000), hence only with this species can we postulate the emergence of a capacity for control of fine-grained vocalizations (see also Morley 2002). However, it is only with *heidelbergensis*, around 0.5 mya, that vocal and auditory capacities characteristic of modern humans can unambiguously be claimed to be in place (Martinez *et al.* 2004). By contrast, the dating of the emergence of a capacity for entrainment, which appears central in musical behaviour, is highly debatable. As mentioned above, it has been postulated that amongst extant species, a capacity for entrainment is specific to humans (Bispham 2006; Cross *et al.* 2008, in press). If this is so then the capacity to entrain must have arisen at some point in the hominin lineage over the last 5–7 million years, but at present we can be no more specific than that.

In view of the close link between music and social behaviour, the dating of the emergence of a capacity for complex sociality is also relevant to the question of music in human evolution. A variety of species, particularly primates, exhibit complex social behaviours, but as Foley (1995) notes, none appears to be as socially flexible and inventive as humans and, probably, our immediate ancestor species. Given the likely continuity in lifeways between chimpanzees and australopithecines, it seems that a complex capacity for sociality comparable to that of modern humans is unlikely to have predated *habilis* or *ergaster*. It is likely that only with the appearance of *heidelbergensis*, with a brain size in the (low) modern human range and some evidence for behavioural complexity of a different order from *ergaster*, that the modern human range of complex social behaviours began to emerge. However, it is only with the arrival of modern humans that we find clear evidence for symbolic behaviours (Henshilwood and Marean 2003), which has been taken to indicate that only with modern humans do we see the appearance of something that would be recognizable as language. Overall, a reasonable initial hypothesis appears to be that many of the capacities for music emerge independently at different times in hominin evolution, but only with modern humans are we likely to find an integrated capacity for music together with language, as suggested by several researchers (including Brown, Cross and Mithen). Whatever its precursors, it seems that modern musicality has very ancient roots.

Conclusions and directions for research

As should be evident, there is much about the relationships between human musicality and human evolution that remains unknown. If music is truly the product of distinct, and distinctly functional, human capacities, a better understanding of music in evolutionary terms should be of immense value in elucidating the significance and distinctness of music as cognitive process and as social behaviour. Much of what we know or infer is based on very sketchy evidence, and there is immense scope for empirical exploration.

As Stevens and Byron note in Chapter 3, most of the research on which our understanding of the universals of music processing is rooted in Western cultural practice and based on the responses of Western-encultured or formally trained participants. There is a pressing need to extend the scope of research on music cognition into non-Western musical domains. Similarly, ethnomusicological evidence, and the success of music as a therapeutic medium, suggests that music has profound efficacy in social context; research is urgently required that explores the cognitive and socially interactive correlates of that efficacy. Indeed, research into music as interactive behaviour in its own right is very much in its infancy. While a number of studies have explored musical interaction between formally trained western Musicians, and a few are beginning to investigate interaction amongst non-Western musicians (see Chapter 4 this volume and also Moran 2007), very little empirical research into either the generic foundations of musical interaction—though see Himberg (2006), or into musical interactions amongst encultured rather than formally trained participants, has been conducted.

One large-scale research programme that has aimed to identify key components of musicality in ways that might shed light on relationships between music and evolutionary process is that conducted by Peretz and her collaborators

(see e.g. Peretz 2006), which has systematically sought to explore the nature, distribution within the population, and recently, genetic provenance, of the condition known as 'amusia': the incapacity to process musical information coherently. It appears that this condition is associable with an inability to process fine-grained pitch structures and relationships and that it is independent of deficits in other domains such as language and hence proper only to music (though see Patel *et al.* 2008). However, as with other studies that seek to explore any identifiable genetic bases for musicality (see e.g. Drayna *et al.* 2001), the vast majority of research has been conducted in listening tests using Western-encultured participants and musical materials that conform to western common-practice musical principles. As the issues addressed in this chapter and in Chapters 2 and 4, should make clear, it is imperative for the cognitive sciences to engage with music in all its cultural diversity in order to begin adequately to understand the nature of human musicality.

Moreover, as noted above, we know very little about the extent to which aspects of human musicality may be shared with other species. We have very little concrete evidence concerning the cross-specific generality of many capacities that appear central to human musicality, such as the capacity to entrain, or to differentiate between complex sonic and gestural structures, or to use complexly patterned sound and gesture to mediate interactions. There are very substantial ethological literatures (dealing with, for example, inter-individual and social functions of birdsong, and sonic communication amongst primates), as well as a few studies of animal behaviours in the presence of music (for an overview see Rickard *et al.* 2005). However, these literatures and studies require to be explored and extended in the light of questions concerning possible continuities between the capacities of non-human animal species and human musicality that are raised by an evolutionary perspective on music.

Over the last few years there has been a significant increase in the amount of attention devoted to the relationships between music and evolutionary theory. This chapter can only provide a sketch of the field, but those interested to know more should certainly explore Darwin (1998) as well as the most significant publication in the field to date, the volume edited by Wallin *et al.* (2000). A more extended treatment of many of the issues raised in the present chapter is given in Cross (2007).

CHAPTER 2

Universals in music processing

Catherine Stevens and Tim Byron

Introduction and definitions

In this chapter we outline areas of musical processing that may be universal to humans. Music here refers to temporally structured human activities, social and individual, in the production and perception of sound organized in patterns that convey non-linguistic meaning. Music processing refers to the neural contribution in perception, cognition and production of music.

A universal in a domain of human activity such as music implies a static feature of a static environment. Not surprisingly, many ethnomusicologists have railed against a search for similarities at the expense of informative differences, and there is a logical problem with documenting definitive generalities rather than particular instances. The approach adopted here is to emphasize musical processing over content and discuss the psychological processes implicated in understanding and engaging in musical behaviour rather than the content of musical knowledge or action (cf. Harwood 1976; Meyer 1960). Our focus is on the principles by which the brain processes features of musical environments.

To call a process involved in the perception, cognition or production of music 'universal' does not necessarily mean that the process is found in all humans. When we refer to universality, we are using Nettl's (2005) concept of 'statistical universals'. Statistically universal music processing is universal to the great majority of adult humans and cultures. However, there may be statistical outliers—which may take the form of all participants in a particular culture (see Everett [2005] for a culture that may be a statistical outlier in the field of linguistics). Additionally, some people may belong to a different statistical population; for example, those who have been described as having congenital amusia or infants who, for example, lack higher-order cognitive processes not developed until later in life.

Experimental studies of music cognition tend to focus on psychophysical features of Western post-Renaissance tonal music, and samples of participants from a restricted range of countries and cultures. Additionally, most experiments treat music as a purely auditory event and assume implicitly that the use of music in other cultures is similar to the use of music in Western cultures. Both assumptions are inaccurate. Vocal and instrumental music is also visual, motoric and kinaesthetic. All of the arts—oral literature/song poetry, visual arts and performing arts—are integrated, for example, in Australian Aboriginal song (Ellis 1984).

The universal music processes discussed here are hypotheses that require investigation and falsification in as many and varied cultural contexts as possible. The discussion begins with processes of grouping and segmentation, then statistically universal features of musical environments, and finally more general-purpose psychological processes. We illustrate some processes drawing on examples of production of song from particular Australian Aboriginal cultures.

Perceptual principles of grouping and segmentation

The perceptual organization principles of grouping by proximity, similarity, common fate, good continuation, and figure-ground, which appear to operate in the early stages of music perception (Deutsch 1999; Handel 1984; Trehub and Hannon 2006) are candidates for universals in music processing. Perceptual organization of this kind can be demonstrated in very young animals; general grouping rules override learned knowledge about the shape of objects. For example, in visual perception, camouflage exploits this principle (Bregman 1990). Auditory grouping processes are thought to (a) organize acoustic information into music events (simultaneous grouping); (b) connect events into musical streams (sequential grouping); and (c) chunk event streams into musical units (segmentational grouping). These perceptual processes develop earlier than knowledge about the meaning of the events that have been grouped together (McAdams 1989). The suggestion is that these processes may be a basic property of the mammalian nervous system, and thus a likely contender for a universal in music processing.

At the level of sequential grouping, there are several processes which contribute to the perception of grouping. A sequence of tones is perceived as a group or stream when the pitch distance between temporally adjacent tones is small (pitch proximity); tones with distant pitches are segregated into separate streams (Bregman 1990). Whether events are perceived as a group or stream is also influenced by timbre similarity, grouping by temporal proximity, grouping by good continuation, and grouping by amplitude similarity (Deutsch 1999). At the level of segmentational grouping, we may have a universal preference for musical elements that are grouped correctly, though what is defined as correct grouping may be culture-dependent. Experiments investigating segmentation of Western tonal music in 6- and 4½-month-old infants have shown that infants prefer correctly segmented pieces with relatively long notes and downward pitch contours, over incorrectly segmented pieces (e.g. Krumhansl and Jusczyk 1990; see also Nan *et al.* 2006). Infants' correct segmentation of music may occur because music bears a structural resemblance to speech, which infants have learned through exposure, and/or because downward contours and extended durations naturally mark the end of all auditory signals (Thompson and Schellenberg 2006). Grouping principles could be investigated in broader musical contexts. However, that they work from the bottom up suggests that such processes are universal. Grouping likely aids encoding and storage in memory, enables an understanding of new material, and facilitates transmission to others.

The processing of melodic contour, the ups and downs in pitch of a melody, has the hallmarks of universality. It has been argued that efficient computational recognition of melodies uses melodic contour as chunks (Trehub 2000), and it appears that the rises and falls of a melody are part of the framework by which working memory processes melody. An ability to discriminate between short melodies on the basis of melodic contour is present in Western infants (e.g. Jusczyk and Krumhansl 1993) and adults (e.g. Dowling 1978), and may share cognitive resources with the processing of prosodic information (Patel *et al.* 1998). Ethnomusicologists have used different melodic contour shapes (for example, arch shapes) to categorize different kinds of melodies from a culture into different kinds of song (e.g. Kolinski 1970), and to compare cultures based on their use of different kinds of melodic contours (Lomax 1968). In an exploratory ethnomusicological study by Arom and Fürniss (1993) Aka Pygmy musicians were reported to be able to discriminate between melodies on the basis of melodic contour. As the processing of melodic contour appears to be present in Western infants and adults, and can be used to distinguish music by different cultures, insofar as melody is universal, it is likely that the processing of melodic contour in memory is universal.

Features of musical environments and perceptual and cognitive constraints

Most discussions of universals in music from a psychological perspective consider the limits

imposed by human perceptual and cognitive processes. The constraints that recur in the literature suggest consensus. However, results on which these accounts are based emanate, in the main, from psychophysical studies involving culturally narrow samples. Regarding pitch first and then time, patterns in musical environments related to human perceptual and cognitive limits that await further cross-cultural scrutiny include the following.

1 Perceptual fusion of harmonic spectra into pitches (Justus and Bharucha 2002).
2 The use of discrete pitch levels (Burns 1999).
3 The semitone as the smallest viable interval. As a semitone is six times larger than the smallest interval that most listeners are able to discriminate (McAdams 1989), human working memory and production limits rather than perceptual discrimination are likely to constrain retention of music constructed from finer-grained musical scales.
4 Musical scales with differently sized steps between consecutive tones. Unequal steps may confer a psychological advantage, allowing tones to have different functions within the scale, such as a reference tone (Balzano 1980).
5 The prevalence of small integer frequency ratios[1] possibly because of their efficiency in auditory perception, i.e., they facilitate encoding, retention of melodies, and enable detection of subtle violations (e.g. Schellenberg and Trehub 1996; but see Balzano 1982 for an alternative view). Such ratios apply not only to fundamental frequencies but also within spectra (Sethares 1998; Tenney 1988).
6 Tones and melodies that are separated by an octave being perceived as similar (Wright *et al.* 2000) although Carterette and Kendall (1999) note that the effect is subtle. The prevalence of octaves in the auditory environment is one possible explanation (Schwartz *et al.* 2003; Trainor 2006); a physiological basis is also debated (Burns 1999).
7 Perception of rhythmic groups of up to 5 seconds in duration—the approximate limit of auditory sensory memory (Darwin *et al.* 1972)—where inter-onset intervals are between 100 and 1500 ms; see Cowan (1984) for the limit exceeding 5 seconds.
8 A regular beat or periodic pulse that affords temporal coordination between performers and elicits a synchronized motor response from listeners (Drake and Bertrand 2001). Importantly, the concept and experience of beat may vary across cultures (Iyer 1998; Stobart and Cross 2000).
9 Small-integer ratios of durations being easier to process than more complex rhythms (Drake and Bertrand 2001). Regular rhythmic patterns may facilitate encoding and retention of gestural, spoken or sung material.

[1] However, Will (1997) gives an example of a cultural context within which frequency differences rather than ratios might constitute the basis for melodic prediction and perception.

Higher-order processes in music cognition

Hierarchical organization and relational processing

So far, we have listed perceptual features of music and bottom-up perceptual constraints relating to music. However, higher-level cognitive processes are also engaged in music cognition, composition, improvisation, and performance in diverse cultural settings. The hierarchical organization of music, and relational processes in music, are possible universal processes in music cognition (see also Chapter 6 this volume).

Music is generally complex, generative, multilayered and hierarchical (Bharucha *et al.* 2006) although exceptions to hierarchical organization include the cyclical structures of Balinese gamelan music (Tenzer 2006) and minimalist music (e.g., compositions by Steve Reich). In general, streams of sound are structured hierarchically within and across dimensions; such structure likely confers a processing advantage. Bharucha *et al.* divide hierarchical representations into tonal hierarchies and event hierarchies. Tonal hierarchies organize tones within a key into stable and unstable pitches; some tones are perceived as more stable, thus more important, than others. Event hierarchies extend

upward from smallest subdivisions of a beat, to beat level, then measure, phrase, period, and large-order forms.

Tonal hierarchies

Evidence of sensitivity to tonal hierarchies has also been established in Balinese music (Kessler *et al.* 1984), Scandinavian North Sami yoiks (Krumhansl *et al.* 2000), and Korean Court music (Nam 1998). These experiments sampled participants from within and outside those musical cultures. The basis of North Indian music, for example, is a set of melodic forms called the rāg that are built on a set of pitch scales called thāts. Tones within rāgs are organized hierarchically by importance, as in Western music. Castellano *et al.* (1984) demonstrated that both Indian and American students are sensitive to the hierarchical ordering of tones in rāgs.

Temporal hierarchies

The pulsation of some African musical styles is very different from the hierarchical concept of measure in Western classical music and the related concepts of metre, strong, and weak beats (Iyer 1998; Magill and Pressing 1997). Instead, this music is measured and is based on pulsations—a sequence of isochronous temporal units that can be realized as a beat. The beat is the analogue of the tactus of Western tonal music. In west African music, the main beat and its metric grouping are articulated in an indirect fashion—not with accentual reinforcement as in Western music, but with suggestion and complexity (Iyer 1998). The metre is encoded in the rhythm itself; it is unambiguous but culturally specific. Iyer provides examples of a standard bell pattern that would be heard phrased in three different ways by three different cultural groups.

Knowledge of temporal hierarchies is also attuned through experience. For example, Drake and Ben El Heni (2003) compared how Tunisian and French subjects synchronized tapping with music from those two contrasting musical cultures. Participants tapped more slowly and with more hierarchical levels with music of their own culture than with music of an unfamiliar musical culture. Musicians and non-musicians did not differ in a spontaneous synchronization task although musicians could synchronize with significantly more hierarchical levels.

Clayton (1997), examining tal, a concept in North Indian (Hindustani) music broadly equivalent to metre, finds similarities and differences between tal and metre. Tal is a temporal framework acting as a background for rhythmic design; it is a periodic and hierarchic temporal framework which involves the interaction of two or more streams of pulsation. Rhythm in Indian music is interpreted with respect to tal; musically untrained Indian listeners would infer tal much as musically untrained Western listeners infer metre. While the conception of metre in Western culture may not be a musical universal, the hierarchical organization of temporal information may be a musical universal.

Examples of hierarchical structure in Australian Aboriginal song

In Central Australia the song series or songline is the largest scale traditional musical form (Barwick 1989). A song series describes the Dreaming journey of one or more ancestral beings. A song performance consists of a number of song items, each of about 30 seconds duration, interspersed with periods of informal discussion. Central Australian songs are characterized by several exact repetitions of a fixed word string or text set to an unvarying rhythmic pattern. The textual and rhythmic components are regarded as two facets of the same structure (Barwick 1989). Each rhythmically articulated text relates to a different stage of the journey described in the associated myth. It is set to a melodic contour said by performers to be the same throughout the series and to embody the essence of the ancestral being whose journey through the country creating and naming present-day geographical features is celebrated in the series. For a performance to be classified as a 'song' it must correctly interlock all three elements—melody, rhythm and text (Ellis 1983). Unison group performance is the ideal and is made possible by inexperienced performers joining in when they have grasped the text words and the appropriate rhythm; they follow melodic cues given by the song leader who performs solo for the first few syllables of each item and who cues changes of pitch within the

melody slightly in advance of the group (Barwick 1989). The general melodic shape of the songs in the centre of Australia is, almost without exception, terraced (Ellis 1984); that is, a generally descending melodic line.

Performance involves the structuring of melodic contour according to various textual characteristics. Barwick (1989) argues that the melodic structure and rhythmic/textual structure are conceptually independent despite being performed in a song as an intermeshed sonic stream. Either element is able to be performed in isolation. Some evidence of this includes a) words to describe humming the sound of the Dreaming; b) rhythmically defined humming of verses in order to remember the words; c)wordless definitions of the melody; and d) instances of tapping out the rhythm of the words of a song (Barwick 1989). Thus memory for melody and rhythm is integrated but separable. Barwick describes hierarchical structures in both the melodic and rhythmic/textual dimension of central Australian song referring specifically to the *ngintaka* song series performed by Antakarinya, Yankunytjatjara and Pitjantjatjara people.

Melodic structure refers to the patterns of pitch relationships that recur in the different song items in a series, and the ways in which these recurring tonal patterns are organized into melodic sections, pitch areas, and main tones. In *ngintaka* songlines, there are three related forms of the basic melodic contour: a linear form, cyclical form, and a transposing cyclical form. Barwick describes and illustrates the hierarchical organization of the linear melodic form consisting of an introductory section, preliminary descent, main descent, and concluding section.

The rhythmic organization of the text of *ngintaka* is also hierarchical, reflecting organization of the pattern into text line pairs, text lines, rhythmic segments, and beating cells. The interdependence of melodic and temporal structures in *ngintaka* is reflected in the observation that the decision about which form of the melody to perform, its constitution in melodic sections, and tonal and durational realizations of the sections correlate with different properties of the text to be performed. The choice of linear, cyclical or transposing cyclical melodic form depends on rhythmic organization. Rhythm serves as a mnemonic device for recall of the extramusical information that is associated with a particular song text (Ellis 1984). Barwick (1989) examines the 'point of fit' in combining melodic and rhythmic/textual structures:

> although an item of singing need neither begin nor end at significant boundaries in the rhythmic/textual cyclical, there is always at least one internal point in the sung item at which the major rhythmic/textual and melodic boundaries coincide.
>
> Barwick (1989, p. 19)

This meticulous musicological and structural analysis of *ngintaka* points to the role of *hierarchy* as both an organizational and perceptual process:

> choices relating to the upper levels of the melodic hierarchy (melodic form and section composition), which correlate with structures at the upper levels of the rhythmic/textual hierarchy (overall style of beating accompaniment and repetition organization), have ramifications that extend down to the smaller level decisions about movement around main tones. Performance of the music therefore requires a constant shifting of attention from one level of the system to another.
>
> Barwick (1989, p. 26)

Cognitive processes related to hierarchical organization, grouping and segmentation, expectancy, and entrainment are evident in this example from Australian Aboriginal song.

Development of musical expectancies and abstract implicit knowledge

Musical expectancies

A piece of music in a familiar genre generates expectations based on implicit knowledge about common features of the genre; variations in how these expectations are met or violated are important in determining emotional and aesthetic response to music (Meyer 1956; Tillmann *et al.* 2000). In Western tonal music, musical expectancies are shaped by rhythmic or metric structure (Large and Jones 1999), tonal and harmonic structure (Schmuckler 1989) and

melodic structure (Cuddy and Lunney 1995). While it is unclear how broadly these principles apply cross-culturally, the tendency for large intervals to descend is evident in Australian Aboriginal music, Chinese folk songs, traditional Korean music, Ojibwa, Pondo, Venda, and Zulu songs (Huron 2006, although see Vos and Troost 1989), suggesting that melodic expectancies are important in emotional and aesthetic response to music in many cultures.

Differentiation of two kinds of expectations—schematic and veridical—solves a paradox of musical expectation (Bharucha 1994). A familiar piece of music contains no surprises—if the violation of expectations is aesthetically or emotionally important, a piece should become less aesthetically or emotionally interesting with each listen. This is not the case. Schematic expectations are automatic, culturally generic, and develop from assimilation of the music of a genre over years of experience. Veridical expectations refer to the actual next event in a familiar piece even though the event may be schematically unexpected. As schematic expectations are acquired from hearing many individual pieces the two kinds of expectancies will converge but, at times, will diverge, creating the continuing sense of violation in familiar pieces of music as described by Meyer (1956). The capacity to develop expectancies may be a universal process. Huron (2006) posits that implicit, statistical expectations are linked directly to emotional response, eliciting basic neurobiological responses. In his account, statistical learning (e.g., McMullen and Saffran 2004) underlies the development of musical expectations.

A small number of studies have examined expectations in music cross-culturally. Researchers have found listeners are sensitive to melodic expectancies in British folk songs, Webern Lieder, and Chinese pentatonic songs. On occasion, performance of American and Chinese participants has been compared and principles such as 'pitch proximity'—that a second pitch following a first pitch is likely to be close in pitch—and 'pitch reversal'—that listeners expect the direction of the melody to reverse—successfully predicted response patterns regardless of the musical style, or the formal music training, and cultural background of the participants (Schellenberg 1997).

Krumhansl (2000; Krumhansl *et al.* 2000) conducted investigations of an indigenous music of the Scandinavian peninsula, the North Sami yoiks, which are quite distinct from Western tonal music. These experiments used North Sami yoiks as stimuli, with participants including North Sami, Finnish music students who had studied yoiks, and North American musicians unfamiliar with yoiks. Results suggested that Western listeners were most influenced by Western schematic expectations, and that veridical expectations were strongest for Sami participants. However, statistical models of melodic expectancies, specifically melodic continuations, appear robust in explaining melodic expectancies in listeners of North Sami, Finnish or North American cultures. While these findings warrant investigation in other cultures, they nonetheless suggest that melodic expectations are universal, insofar as music is melodic.

Implicit knowledge of musical structures

Abstract, implicit knowledge of musical structures and conventions is acquired by infants and children through mere exposure to a particular musical environment (Bigand *et al.* 2003). Some people explicitly learn the musical theory of their culture, but most acquire implicit knowledge of musical structures and conventions through incidental exposure to the environment.

Implicit learning and Australian Aboriginal song

The process of learning via exposure is evident in descriptions of the performance of Australian Aboriginal song. For example, Barwick (2002) discusses the way rhythmic mode in *Church Lirrga* songs of Wadeye in the Northern Territory is brought into relief by the juxtaposition of contrasting songs: 'The pairing of items in different tempo bands is one of the main ways in which learners become aware of the importance of this dimension of performance' (p. 81). The pairing of slow and fast songs is commonly found in northern Central Australia and the Kimberleys (Barwick 2002). Barwick (1989) alludes to the complexity of dimensions,

relations and interrelations that are learned by an Aboriginal song leader:

> in addition to the mass of geographical and mythological detail to be mastered, leading a performance requires a high degree of sophisticated musical awareness, an awareness that is not taught directly, as in western educational practices, but is rather arrived at and internalized through repeated acts of performance.
>
> Barwick (1989, pp. 26–27)

Temporal expectancies, synchrony, and entrainment

Temporal entrainment is a domain-general mechanism and likely universal process in music perception and production (e.g., Clayton *et al.* 2005; Drake and Bertrand 2001; Fraisse 1982; see also Chapter 8 this volume). Entrainment occurs where two rhythmic processes interact with each other, eventually locking in to a common phase and/or periodicity. Such processes play a role in speech production (Goldstein *et al.* 2006) and models of joint action (e.g. Knoblich and Jordan 2003). Large and Jones (1999) argue that neural oscillators entrain to external events such as metres or rhythms. Because this entrainment process underlies temporal perception, periodic events (i.e., repeating rhythms, metre) facilitate the efficient allocation of limited attentional resources, and make synchronization activity (e.g., tapping along or musical activity) more accurate.

Non-periodic metres are common cross-culturally. 'Free rhythms' such as the Indian *alap* or the Turkish *taksim* are improvised and unmetred, while music with accelerating rhythms is found in Japanese Gagaku music and Tibetan monastic music (Huron 2006). The *aksak* metres (e.g., 3 + 2 + 2) of Bulgarian dances (Moelants 2006) and African rhythms are non-periodic. At first glance, non-periodic rhythms may be problematic for theories of entrainment. Jones argues that when there is no explicit pulse a listener might entrain to what they perceive as the median period length (Barnes and Jones 2000). Periodicity is not necessary for the formation of expectations, according to Huron (2006). Instead, listeners need to be experienced with the temporal structure of an event and some element of its temporal structure must be predictable. Regardless of whether accounts of entrainment or accounts of expectation are better at explaining the perception of temporal structure cross-culturally, some form of allocation of attentional resources based on the expectation of temporal information is likely to be universal.

Multimodal processes and integration

In many cultures, music and dance are inseparable. An analysis of the didjeridu-accompanied dance-song genre *Lirrga* from Wadeye in the Northern Territory of Australia, has shown that songs fall into named distinct tempo ranges which correlate with different metres in the vocal part resulting in rhythmic mode (Barwick 2002). The significance of rhythmic modes comes from their association with *dance* (Marett 2005). Thus, one universal process in music cognition might be movement perception and its development (Fraisse 1982; Friberg and Sundberg 1999).

Bharucha *et al.* (2006) have distinguished four primary facets of internal experiences of motion in music cognition: a fundamental sense of self-motion through space; perception of the motion of bodies, not necessarily one's own; movement elicited by abstract structures such as tonality; and a metaphorical, synaesthetic sense of motion. Movement in pitch, time, loudness, and timbre has been described as the interplay of tension and relaxation (Jackendoff and Lerdahl 2006). This metaphor of tension and relaxation may emerge as a universal quality in music cognition given further research cross-culturally.

Music is an example of a perception–action cycle (Janata and Grafton 2003; Keller *et al.* 2007); that is, streams of sensory information forming the basis of goal-directed actions. Evidence of neural simulation and mirroring continues to accumulate—seeing *or* hearing an intentional *action* gives rise to neural activity that is comparable with that underlying *performance* of the action (Keysers *et al.* 2003). Studies of music perception and performance are likely to shed new light on universal processes that are the result of tightly coupled sensorimotor systems.

Conclusion

There is much to do to test assumptions of contemporary theories of music cognition and to identify unique features of musical environments and musical processing. More than 30 years ago, Harwood (1976) called for an emphasis in research on musical processes rather than musical content and suggested that looking at how people learn to listen to and play their community's music is more informative than studying what it is they listen to or play. Researchers will need to be creative in applying a range of appropriate methods to music processing in non-Western cultures; these range from initial ethological and ethnographic phases, to analysis of everyday, multimodal musical events, through to the design of experiments that test particular hypotheses. Clarke and Cook (2004) detail methods for this endeavour. As Cole (1996) notes, such studies will need to 'maintain the integrity of the real-life situations [they are] designed to investigate, be faithful to the larger social and cultural contexts from which the subjects come, and be consistent with ... participants' definitions' (p. 226). Interdisciplinary research that knits together the concerns and methods of the cognitive sciences with those of cultural anthropology, and that involves diverse materials, tasks, and cultural groups, is essential for explanatory and inclusive theories of music cognition, perception, and production.

CHAPTER 3

Music and meaning

Ian Cross and Elizabeth Tolbert

Introduction

What do we mean by 'meaning'? When we say that something has 'meaning', we are claiming that our original something points to, or is attached to, or can be used to infer the existence of, some other thing beyond itself. Some sort of relationship exists between our original entity or event and something beyond itself. Vernacularly, our original something has *significance*. Another simple way of putting it is that our original something *refers* to something else beyond itself. When we engage with music, we tend to feel that it has significance; it appears to mean something, even if that meaning is entirely personal to us. When we look at the ways in which music has been theorized and explored, the issue of musical meaning is often central, particularly when music is being explored in its social context (see Feld and Fox 1994). However, while music may have significance, by comparison with language it is very difficult to say what it is that music refers to, or indeed, whether music refers to anything else at all.

Contemporary methods of approaching the question of musical meaning have been shaped by a range of theories of meaning. Some theories hold that music is a species of art, which can only be understood as a phenomenon that is not susceptible to analysis in terms of general and formally expressible principles. Such theories tend to be predicated on the notion that recent and contemporary Western conceptions of music—in which music is produced by specialists for aural consumption by the many—are representative of music as a generic human phenomenon. Alternative views are found in literatures that aim to explore music as a social phenomenon (whether in Western or non-Western contexts), which tend to be pluralistic in the frameworks that they apply to articulate their understandings of meaning in music, drawing on semiotic, sociological and anthropological theories of meaning. Some influential theories that have emerged within analytical philosophy and that are prevalent in the study of linguistics seem to imply that meaning cannot properly be considered a property of music. In these theories meaning is held to be a property only of (formal) systems that are capable of embodying two types of meaning relation, *reference* and *sense* (see below), and that are thus capable of articulating complex propositions that are definable as true or false. The chapter will present an overview of theories of meaning that have been, and that may be, applicable to investigating music, particularly its cognitive dimensions.

Theories of meaning

Philosophers and logicians have devoted much attention to the problem of meaning—to analysing how it is that something means. In general, they have focused on meaning as it appears manifested through language. Their ideas, particularly in the form of theories of semantics, have tended to dominate conceptions of meaning within philosophy and within most sciences. Semantic theories generally aim to account for the relationships between the phenomena that constitute the objects of meaning and the expressions and sets of expressions that are used to articulate meanings.

One of the strongest influences on the development of recent and contemporary theories of the semantics of language has been the work of

Frege, who wrote at the end of the nineteenth century. Frege suggested that there are two necessary aspects of meaning that must be considered in any analysis; these he called *reference* and *sense*. Roughly speaking, the *reference* of a term is that which it denotes—that phenomenon in the world onto which it can be mapped. Its *sense* derives from the ways in which that original term relates to other terms that are interpretable as capable of bearing similar kinds of meanings. To give Frege's classic example, the expressions 'Morning Star' and 'Evening Star' have the same single reference—the planet Venus. But their senses differ in an obvious way, in that the sense of one is 'the star that appears in the morning', and that of the other 'the star that appears in the evening'. The senses of the two expressions arise by virtue of the meanings of the terms that are used to articulate them within the language system.

Hence in this view meaning is a consequence of the capacity of terms within a system to refer and at the same time be bounded by their relationships to other terms within a system of terms such as a formal logic (or a language when it is interpreted as having features that of the same type as those of a formal logic). These features enable terms within the system to be used to articulate propositions that may be evaluated as true or false—that have determinate *truth values*. Only in such systems can complex propositions be expressed and can their meaning be fully accounted for in terms of the elements that make up the complex propositions; only such systems have the capacity for *compositionality*, that of expressing semantically decomposable propositions. It has been suggested that only formal semantic theories founded on Frege's ideas, such as those of Montague or of Tarski, constitute 'genuine theories of meaning' (Scruton 1987). While these types of theories do not seem particularly pertinent to music (particularly in view of the difficulty that the ideas of reference, and of compositionality, pose for music), they are nonetheless highly relevant in that they have underpinned the development of theories of meaning throughout the twentieth century that has shaped much of the intellectual context in which any account of meaning in music has to be understood (for more detailed and technical considerations of Frege's ideas, see Grayling 2000, Vol. 1, Chapter 2; Vol. 2, Chapter 12).

A rather different approach to meaning that has been widely applied to music derives from the work of CS Peirce (see Hoopes 1991), who proposed that meaning could be understood in terms of systems of signs, which can be defined as *natural* or *conventional* and can stand in a variety of relationships to that which the sign represents—its meaning. A sign may point beyond itself by virtue of some formal resemblance between the sign and that which is represented, and thus be *iconic*; it may have meaning because of some necessary connection between itself and what it indicates (as in the case of smoke indicating fire) or by virtue of repeated co-occurence, the relationship between sign and its meaning thus being *indexical*; and it may mean by virtue of arbitrary convention, its meaning being rooted in the *symbolic* domain. While Peirce's *semiotic* ideas have largely been neglected or rejected by philosophers and semantic theorists, they have played a role in several influential theories of meaning in music (e.g. Nattiez 1990). Nevertheless, music does not easily map onto the natural–conventional distinction that lies at the root of Peirce's original theories. Music has tended to be viewed as having an ambiguous status somewhere between the natural and the conventional, limiting the explicitness with which the bases for its meanings can be articulated in semiotic terms.

It may seem that meaning is simply a mapping from a term to its referent (and vice versa). However, for Peirce, the source of meaning is in the mind; in his theory, 'All thought is in signs' (Peirce quoted in Violi 1999). The idea that consideration of mind is necessary to theories of meaning lies at the heart of contemporary cognitive science and is central in much contemporary philosophy of meaning and language. Mental states and processes are said to exhibit *intentionality* or aboutness (Dennett 1987, 1995); they represent, or point to, phenomena beyond themselves. The idea of intentionality can be applied to understand the ways in which language can be interpreted as bearing meaning, by taking into account the ways in which we employ language to articulate the aboutness of our mental states.

A more radical account which explicitly sets out to provide an alternative to the idea that meaning can only be correctly defined in relation to the abstract properties of formal systems is found in *experientialist* approaches, of which the most developed is that of Lakoff and Johnson (Johnson 1987; Lakoff 1987). In this view, meaning is a property of the relationships between mind and world; however, it is best understood as mediated not by the principles of formal logic but by the embodied nature of our experiences of being in the world. Meaning is motivated by kinesthetic-image schemas, which are (Lakoff 1987, p. 267) 'relatively simple structures that constantly recur in our everyday bodily experience', and which may take forms such as 'CONTAINERS, PATHS, LINKS etc.' These body-image schemas constitute the preconceptual bases for the formation and combination of concepts, grounding meaning in our bodily experience of the world. A somewhat different approach to an experientialist theory of meaning is proposed by Jackendoff (1987, 2002), although directed more explicitly towards making sense of language structure and use. Experientialist theories, in particular those of Lakoff and Johnson, have been applied to understanding the nature of meaning in music, as we shall see.

Ideas such as reference and sense, natural and conventional signs, and intentionality can help account for different aspects of the ways in which something may be interpreted as bearing meaning. Yet music seems to pose particular problems for these ways of approaching meaning. Usually, we cannot use music to refer to a state of affairs in the world in the ways in which we can use language. In at least this respect, music certainly does not seem capable of bearing the types of meaning borne by language, which would suggest that an analysis of musical meaning in terms of sense and reference is unfeasible. Musical meaning also fits ambiguously with any distinction between natural and conventional signs, and it is also unclear how the notion of intentionality might be applied to clarify the aboutness of the mental states that arise when we engage in music.

In order to elucidate the ways in which meaning in music can be, and has been, explored in ways that are relevant to music (and to the psychology of music), it is necessary to consider what are the kinds of things that can be the objects of meaning. Are they states of affairs in the material world or in possible worlds (for which see Johnson-Laird 1983, p. 172)? Are they states of affairs in some abstract yet immanent domain, such as the theorems of formal logic and their validity—their truth values—within some logical system (Tarski 1956)? Are they states of affairs in some abstract yet immanent domain that *cannot* be described within the theorems of formal logic, such as the domain of the aesthetic (Sibley 1959)? Are they mental phenomena such as the thoughts, beliefs and desires of individuals (Dennett 1987), or the preconceptual schemas proposed by Lakoff and Johnson? Or are they social phenomena, such as cultural groupings, institutions, contracts or shared understandings (Bourdieu 1990)? At different times, theories of meaning have postulated all these types of phenomena as being potential or actual objects of meaning, and in one way or another, all have been applied to understanding the question of meaning in music over the history of Western thought.

Meaning in music in the western intellectual tradition

For the classical Greek philosophical tradition, music presented two conflicting faces. On the one side, music—and music, for the Greeks, was melodic—moved the passions (for good or ill), and was a fundamentally human activity, affecting our emotions by being stirring and martial, or beautiful and enticing. Its purposes could thus be considered as aligned with those of the science of rhetoric, which aimed to bend human minds and actions to the purposes of the orator. On the other side, music, in the theories erected on the basis of the measurement of aspects of the sounds that comprised it, embodied the natural laws of number and could thus be viewed as reflecting abstract and immanent aspects of the universe such as the principles of natural order, or the workings of the divine (James 1993).

This dichotomous view of music persisted through the first millennium CE, gaining in complexity as it was refracted through the multiple

prisms of early Christian thought. Hence in the medieval world, music could be thought of as having meaning in at least two domains, the human and the divine. The tension between music as mirror of the heavenly world and music as mover of earthly passion was mediated by church doctrine and by the development of musical notations, through which polyphonic music that might be viewed as simply lascivious because of its sonorous beauty could alternatively be interpreted as reflecting the mathematical complexity of divine order (Sparshott and Goehr 2001).

By the later fifteenth century, music came to be seen in part as a foundationally human activity with its values and its meanings requiring to be expressed and interpreted in human rather than divine terms (Palisca 1985). Music's meanings were bound to the products and processes of human reason as well as to music's effects on human emotions, allowing for the possibility that music might express or bear types of meanings that were proper only to music as an art. By the later seventeenth and early eighteenth centuries, music's meanings had come to be largely theorized in terms of human passions or affects. Music's alignment with rhetoric was foregrounded (Sparshott 1998), as was the extent to which its forms mirrored those of the linguistic prosody, though the structures that music could articulate also became more important for their own sake. The values accorded to music and its meanings were largely those of rational pleasure, enjoyment founded on the exercise of reason; ostensibly rational principles (based in part on the development of the science of acoustics) were elaborated and adduced that were intended to account for the extent to which a piece of music had fulfilled its brief by expressing its meaning.

Through the eighteenth century the forms and the meanings of music changed radically. From being bound to the devices of rhetoric and hence to its purposes, music's forms became more and more intelligible in terms of theories of harmony, related to either, and sometimes to both, the findings of physical acoustics, and abstract principles of architectonic structure. Musical meaning thus no longer required any sort of justification by reference to the words that it could convey in song, or to the ways in which it conveyed those words (its 'prosody'); instrumental music came to be conceived of as equally capable of bearing meaning in its own right. However, the effects of music on human passions were not completely displaced from consideration; as Thomas (1995, p. 5) notes, most of the writing on music by the philosophers of the mid- to late-eighteenth century had as a 'governing assumption' the idea 'that music was a kind of language'. Hence by the late eighteenth century, the objects of the meanings of music could be conceived of as private, being in the mind, or as public and social.

The aesthetic perspective

Towards the end of the eighteenth century a new way of understanding meaning in music emerged, one which had its precursors in the notion that music should be valued for its beauty but which sought to detach music's meaning from its social value and to valorize its experience as art as an end in itself. It developed in tandem with the emergence of the notion of music as being autonomous, or as having value in its own right. The ideas that underpin this approach have come to constitute the prevalent means of addressing questions of music's value and significance within the Western intellectual tradition of the last two centuries or so.

This new approach was first crystallized in ideas that were developed by Hume and by Kant, in proposing that both art and natural beauty can give rise to aesthetic experiences that are exclusive in that they are bound to felt response (in being logically dependent on pleasure and liking) but that are not reducible to any specific set of principles (as they cannot be induced second-hand by verbal description). Kant proposed that aesthetic contemplation is distinguished by being fundamentally 'disinterested', or free from concern with desire or any other purposive attitude. In current approaches the notion of the aesthetic is bound up with the notion that there are phenomena that can only be described as 'art', and various attempts have been made to demarcate the qualities that art must have in order to be art (see e.g. Wollheim 1980). The identity of art has been variously proposed as lying in its capacity for representation, its structural qualities, or in its capacities for expression. In expression-based approaches, works of art are viewed as the loci for aesthetic

experience by virtue of encapsulating both emotional and rational qualities that may be more or less apparent to, or recuperable by, engaged audiences (see Davies 1994). In these theories, music's capacity to engender aesthetic experience does not rely on, and is not expressible in the same terms as, the capacity that language possesses of bearing meaning by expressing complex propositions that have determinable sense and reference (Dempster 1998).

Central to many expressivist analyses of musical meaning has been the idea that music's meaning is fundamentally emotional, though most of those who have sought to develop this approach have treated the relationship between music and emotion in ways that appear to have little connection with the scientific literature on music and affect. Two leading philosophers of music, Roger Scruton and Stephen Davies, both privilege the expressive dimensions of music in seeking to analyse its aesthetic qualities, though taking somewhat diverging paths. Davies (1994, 2003) proposes that a critical component of the aesthetic aspect of music is its engendering of an 'understanding response' in a listener, which requires the capacity to experience predictive coherence in the ongoing flow of a piece of music as heard. In addition to this aspect, music must be recognized as referring beyond itself in being expressive of emotion; music achieves this either by presenting the appearance of emotion (Davies 2003) or because we (1994, p. 277) 'experience the dynamic character of music as like the actions of a person'. The experience of music must involve both types of recognition to qualify as an appropriate aesthetic experience; only if both conditions are met will the music be understood, its 'meaning' grasped. Scruton (1987, 1997) suggests that music does not so much express emotion as embody it in a holistic way such that it is not possible to identify just which features of the music are directly responsible for this embodiment of emotion; he suggests that 'In responding to a piece of music we are being led through a series of gestures which gain their significance from the intimation of community' (1997, p. 357). However, for this aspect of meaning in music to be experienced, audiences must be capable of hearing the music *as* music. Thus for Scruton musical meaning is rooted in the metaphorical experience of movement and is situated in *a* musical culture which aligns the intuitive capacities of audiences, composers and performers.

In theories of musical meaning that are grounded in aesthetic considerations, 'meaning' appears to take quite a different form from that which it holds in the types of semantic theories that can be applied to language. Meaning is immanent as a condition of felt response that depends on the qualities of the music as the object of listening and on the cultural capacities of its audiences. The factors that motivate musical meaning might be expressive, or might have their roots in the structural properties of Western music (particularly in the harmonic domain) that can be analysed in terms of patterns of tension and resolution. Just these types of factors were identified as the proper locus of meaning in music by Hanslick in the nineteenth century, and cognitively oriented theories of music's meaning as rooted in its structural properties have been proposed by theorists such as Lerdahl (see e.g. Lerdahl 2003). Nevertheless, the majority of philosophical approaches to understanding meaning in music have differentiated musical meanings from 'everyday' meanings by binding music's significances solely to the aesthetic domain. As Cook (2001) points out, such approaches stand in stark opposition to those which aim to locate, and to understand, music and its meanings in the social contexts in which it arises. Theories of this latter type have emerged from sociological and ethnomusicological explorations of music; they are central to approaches that adopt anthropological perspectives on the investigation of relationships between musical sounds, practices and concepts (Merriam 1964) in non-Western and, increasingly, in Western cultural contexts, to understand meaning in music.

Meaning in music in social and cultural context

The idea that music's meanings are inseparable from the social and cultural situations and circumstances in which they arise has become widely accepted in musicological (e.g. Kramer 1995), sociological (e.g. Martin 1995) and ethnomusicological (e.g. Bohlman 2000) circles.

Here, the ideas that underpin much philosophical writing on music—that music constitutes an autonomous and primarily aesthetic domain—are called into question or outright rejected, whether on the basis that such ideas are grounded in ethnocentric assumptions as to what constitutes music, or on the grounds that such approaches cannot deal adequately with the historical and dynamic aspects of engagement with music.

The consensus surrounding the notion that music is explicable only as in its social context, evaporates when addressing the question of what *forms* these meanings may take. As Titon and Slobin (1996, p. 1) note, while 'Music is universal its meaning is not.' Across cultures there is a vast range of ways in which music may be experienced or interpreted as bearing meaning; music's meaning can be understood as foundationally aesthetic, personal or social, or in terms of combinations of any or all of these domains. Within such approaches, as Feld and Fox (1994) point out, it is difficult to disentangle specifically musical meanings from the meanings of the activities of which music is a part. For example, in writing of Venda children's music, Blacking (1967, p. 31) notes that 'Many songs add to the meaning of a social event; they crystallize and confirm certain norms of behaviour'; hence the meaning of musical activities may be thought of as complementary to the specific circumstances that incorporate the music.

From such perspectives, meaning in music is multifarious and cannot be understood solely as a consequence of music's aesthetic dimension. As Clayton (Chapter 4 this volume) indicates, music may fulfil a multiplicity of the functions in different societies; taking this into account, its meanings can be best interpreted as adverting to emic conceptions of social facts and circumstances. Hence Feld (1982) is able to present a compelling account of the music of the Kaluli of Papua New Guinea as displayed in the *gisalo* funerary ceremony, where the musical component of the ceremony possesses a structure, identity, and efficacy in mourning that are inextricably bound both to its sacred connotations (it employs a motif derived from the song of the *muni*, a local bird which is the central numinous entity in the main Kaluli myth of 'the boy who turned into a *muni* bird' and thus joined the departed spirits) and to its place in the ecology of the local environment. Hence the meaning of the music is complex and local, in that it can only be understood by addressing it in the context of the belief systems and cultural practices within which it has a role. In other cultural contexts music's meanings may be interpreted as oriented towards more mundane ends, as when Blacking notes of Venda children's music that 'Knowledge of the children's songs is a social asset and in some cases a social necessity for a child who wishes to be an accepted member of his own age group'(1967, p. 31). Here, music is interpreted as fulfilling an instrumental function in the formation of social groups, its meanings somehow bound up in the emergence, or the maintenance (cf. Slobin 1993), of individual and group identities as social facts.

In parallel with reconceptualizations of the idea of musical meaning emerging from anthropological perspectives are sociologically motivated theories that have sought to ground musical meanings in the social and historical contexts of music, particularly in Western culture. These theories have tended to conceive of music as social construct of which the meanings can only be elucidated by analysis of the processes and conditions that pertain to the contexts within which music is produced and received. Influentially adumbrated by Adorno (1976), subsequent accounts have frequently aimed to address issues of hegemony and resistance (Born and Hesmondalgh 2000), and have led to radical accounts of meaning in familiar works of the classical canon such as the work of McClary (1991) on questions of gender in music, as well as to critical and subjectivist accounts of meaning (Kramer 1995).

Meaning in music has been conceptualized variously by philosophers, musicians, anthropologists and sociologists. While the aesthetic view of music's meaning has been predominant for the last two centuries, other conceptions of the bases for meaning in music have emerged that locate these in the relationship between music and social factors and forces. Many of these theories have been explored in the context of cognitive theories of music although, as we shall see, certain views of musical meaning

present considerable obstacles to scientific theorization and investigation.

Theoretical and empirical approaches to meaning in the psychology of music

Most attempts to explore meaning empirically by way of music's aesthetic dimension have adopted a severely reduced notion of aesthetic engagement. As noted above, philosophical approaches view aesthetic judgement as dependent on, though not explicable solely in terms of, pleasure and liking; however, experimental approaches have tended to equate aesthetic judgement wholly with evaluative ratings of liking or pleasantness. The most influential theory in the field, that of Berlyne (1971), postulated an inverted U-shape function relating liking to stimulus complexity. Berlyne's theory has been empirically tested and found to account for aspects of the experience of music (North and Hargreaves 1995); however, other studies (Orr and Olsson 2005) have found no consistent relation between liking and complexity when factors such as musical style and level of musical expertize were taken into account.

There are fundamental difficulties in empirically exploring aesthetic experiences. In the first place, there is a lack of consensus as to the phenomenal and phenomenological correlates of aesthetic experience; do these inhere in the representative, the formal, or the expressive capacities of the artistic focus of aesthetic experience, or are they consequences of the capacities of the individual who has the experience? This lack of philosophical agreement is supplemented by the difficulties of implementing experimental designs that deal adequately with the issue of 'felt response' that is at the core of ideas of aesthetic experience. Perhaps some answers might be provided by neuroscientific approaches (see e.g. Blood and Zatorre [2001] in respect of intensely pleasurable responses to music), but even here what is being identified are not the phenomenological states that are the focus of philosophical aesthetics but neurophysiological states, albeit that these may have determinable correlates in behaviour and cognition.

Nevertheless, many recent accounts of aesthetic meaning in music tend to be rooted in the idea that music is expressive, particularly of the emotions. As is evident in the theories and empirical findings described in Chapter 35, most empirical approaches to emotion or affect in music explore the phenomenon within frameworks derived from cognitive and behavioural sciences. Emotions are viewed as dynamic mind–brain–body states that arise in response to the experience of environmental and social events (see e.g. Panksepp and Bernatzky 2002). From the perspective of the cognitive sciences, emotional responses to music tend to be viewed as belonging to subclasses of emotional responses in general rather than as being phenomenally in a category of their own (or even in a category together with responses to the expressivity of other art forms). Hence the types of meaning that psychological approaches understand as arising from emotional engagement with music do not appear to rest on the same types of premises as those that have been postulated by philosophers such as Davies or Scruton as pertinent to the workings of music's expressive powers.

While it might seem that psychological understandings of music's affective meaning should have precedence over the non-empirical ratiocinations of philosophers, it might instead be the case that philosophers have in fact identified good grounds for believing that music's expressivity cannot be understood simply by reference to general theories of emotional response. Indeed, the notion of 'disinterested pleasure' that is at the heart of Kant's conception of aesthetic engagement is one that seems almost to stand in opposition to the necessary interest that is implicit in psychological understandings of the experience of emotion. As yet, questions such as whether the affective states that music appears to elicit arise through empathic processes, as Davies (2001) suggests, or arise directly in response to objective properties of musical structures have not been the sustained focus of experimental investigation.

Affective dimensions of specifically musical meanings have, however, been explored fruitfully by empirical investigation from sociological and social–psychological perspectives. The work of DeNora (2000) suggests that

music can be meaningful in being employed by listeners to do 'emotional work' in regulating their emotions and moods in everyday life. DeNora's findings are reinforced by those of Sloboda *et al.* (2001), who employed an innovative approach (the Experience Sampling Method) to sample the nature and significance of the experience of music in day-to-day life. They found that music was particularly significant in social and individual contexts in which personal choice of music was available, and that the efficacy of music in regulating emotion and mood was greatest in such contexts. Intertwined with the empirical study of the individual and social functionality of music's affective dimensions are explorations of the ways in which music is used in the formation and maintenance of senses of self and of group. A wide range of research is reported in MacDonald *et al.* (2002) that indicates that perhaps the primary motivation for engaging with music in the contemporary Western world is to facilitate the transactions involved in formulating, presenting and affirming the multiple dimensions of individual and group identities.

A very different account of musical meaning seems to emerge from some recent neuroscientific research. In an intriguing experiment, Koelsch *et al.* (2004) found that similar types of brain responses were elicited when words that were semantically incongruous were presented following either linguistic or musical contexts (for the latter type of context, that words that were used had been rated as either congruous or incongruous in respect of the musical excerpts in a preceding experiment). This would seem to indicate that musical meanings were being experienced as directly relatable to the meanings of individual words; in their words (ibid., p. 302) 'music can, as language, determine physiological indices of semantic processing'. This finding suggests that musical meanings may indeed be of a similar type to those of language, in stark contrast to most philosophical accounts of musical meaning. However, in a subsequent experiment (Steinbeis and Koelsch 2008) they suggest that the results of the earlier experiment arose because of imagery or association elicited in response to the music rather than through any intrinsically semantic properties of music. In the latter experiment they find that the semantic unexpectedness of a sentence modulated the neural response to a simultaneously presented musical excerpt that contained an unexpected chord, but that the unexpectedness of the musical event had no effect on the processing of the sentence. They take this finding to indicate that tension–resolution patterns in harmony motivate cognitive and neural responses that are analogous with the contextual integration aspects of language processing, but do not call on representations of semantic knowledge. Hence they suggest that musical 'meaning' is best conceived of as being borne by the patterns of tension and resolution embodied in music, and is of a fundamentally different order from linguistic meaning.

This notion is somewhat problematized by research that applies the experientialist ideas of meaning developed by Johnson and Lakoff. Brower (2000) and Zbikowski (2002) present complex theories of the ways in which body-image schemas may be applied to understand the ways in which music may mean, illustrating their theories by reference to detailed analyses of structures in Western art music. They suggest that while the experience of musical meaning may well be mediated to patterns of tension and resolution, these patterns are themselves motivated by underlying body-image schemas that render the patterns coherent and comprehensible to listeners. Based on the results of a series of experiments and analyses, Larson (1998, 2002, 2004) has explored the extent to which experientialist ideas can account for listeners' experience of aspects of musical structure. Larson and Van Handel (2005) note that 'physical force schemas' appear to account well for listeners' judgements of musical pattern completion, supporting the idea that the types of musical meanings supposed to inhere in tension–relaxation structures in music are in fact grounded in experientialist schemas, a finding supported by subsequent experimental work by Martinez (2007).

Conclusions

One fact that becomes clear on surveying the literature on musical meaning is that there is no consensus as to how questions of musical

meaning should best be addressed; indeed, certain philosophical perspectives call into question the idea that music can be claimed to have meaning at all. However, the majority cross-disciplinary view is that music is imbued with meaning, whether music is conceived of as aesthetic object, cultural commodity or social process, yet each discipline tends to propagate ideas of musical meaning that tend to lack the robustness to survive outside its borders. Perhaps it is the case that musical meanings are multifarious and that there is no single approach that can claim precedence for its own conceptions of those meanings. This heterogeneity of solutions to the question of musical meaning poses problems for the psychological sciences; as we have seen, quite different depictions of musical meaning emerge from the theoretical and empirical literature surveyed above. Again, it could be suggested that this is an inevitable outcome of the diffuseness of the concept that is being investigated; nevertheless, the diversity of psychological approaches do exhibit some common themes, although it is evident that there are some conceptions of meaning in music that have not been addressed.

Musical meanings in non-Western contexts have remained largely unexplored from psychological perspectives. This is unsurprising, given the relative dearth of studies of music cognition in non-Western cultures compared to the number of studies conducted in Western contexts. Yet the issue of musical meaning can only properly be addressed by the cognitive sciences when the types of meanings highlighted in numerous ethnomusicological studies are made the foci of psychological exploration. In addition, most empirical approaches to meaning in music take as the object of their investigation the processes that are involved in music listening. While this view is consonant with the ideas of music expressed within most philosophical and many sociological approaches (a notable exception in the latter domain being the work of Finnegan [1989]), ethnomusicological research indicates that music might be better conceived of as a mode of interaction rather than as the object of auditory perception. The psychological sciences need to find means of addressing the study of the meanings that are inherent or emergent in processes of musical interaction, with a few studies beginning to indicate possible methods whereby this might be achieved (see e.g. Clayton 2007). Finally, the cognitive sciences of music will need to accommodate new approaches to meaning such as Millikan's (2004) 'teleosemantic' theory, which aims to account for meaning within an evolutionary framework (some theoretical groundwork in this area has been laid in Tolbert [2001] and in Cross and Woodruff [2008]).

The issue of musical meaning is unlikely to be accounted for by one generically applicable theory and is unlikely to be amenable to scientific exploration by any one method. This chapter has laid out some of the principal influences on the study of meaning in music and has suggested that some have had more impact on the scientific exploration of music's significance while others have been unduly neglected. Theoretical and empirical research into musical meaning is still at an early stage within the cognitive sciences; this chapter would suggest that it is important that multiple perspectives on meaning in music, particularly those emerging from the study of music in non-Western contexts, are taken fully into account in future explorations of musical meaning within the cognitive sciences.

CHAPTER 4

The social and personal functions of music in cross-cultural perspective

Martin Clayton

Introduction

In the grounds of an English country house, pop star Robbie Williams teases an audience of thousands before launching into his hit song 'Angels': the thousands sing along as one with his amplified voice, swaying from side to side in synchrony.[1] In the Peruvian Andes, weeks of silence are broken by a festival in which groups of men playing flutes or panpipes attempt to perform as one instrument, while fighting for the attention of the crowds in the town square of Conima (Turino 1993). In a healing ceremony held in Temiar village in Malaysia, a singing medium directs his voice into the back of a patient: he feels the spiritguide singing through him (Roseman 1991, pp. 80, 115). In a small concert hall in an industrial Bengali town, an audience member listens to a singer performing an evening raga and imagines an ideal landscape of gentle breeze, broad river and brilliant red sunset.[2]

Music's uses and contexts are so many and so various that the task of cataloguing its functions is daunting: how can we make sense of this diversity? These functions appear to range from the individual (music can affect the way we feel and the way we manage our lives)—to the social (it can facilitate the coordination of large numbers of people and help to forge a sense of group identity). I will argue that musical behaviour (within which category I include all kinds of listening as well as performance) also covers a vast middle ground in which relationships between self and other or between the individual and the collective are played out. This chapter surveys some of the extant literature on music's functions—referring to literature from ethnomusicology, anthropology, musicology, psychology, and sociology, and discussing a wide variety of musical contexts from around the world—and develops an argument emphasizing music's role in the management of relationships between self and other.

Approaches to the functions of music

Cross-cultural study of the functions of music reached a peak in the ethnomusicology of the 1950s and 1960s. The most concise and

[1] Robbie Williams, *What We Did Last Summer – Robbie Williams Live At Knebworth* (DVD, EMI, 2003). I would like to thank Laura Leante and Byron Dueck for their comments on a draft version of this chapter.

[2] This example is inspired by research Laura Leante, Tarun Kumar Nayak and I have been pursuing into audience attitudes and responses to raga performance.

comprehensive summary of this approach can be found in Merriam's *The Anthropology of Music* (1964), in which he distinguishes 'uses' from 'functions': '"Use" . . . refers to the situation in which music is employed in human action; "function" concerns the reasons for its employment and particularly the broader purpose which it serves' (p. 210). This distinction is a productive one for my purposes here. A catalogue of the uses of music would list innumerable categories—to lull babies to sleep, to court, to accompany dancing, worship, weddings, funerals, aerobics classes, spirit possession ceremonies, and so on. A discussion of functions should ask what purpose the music serves in these events.

Merriam enumerates no fewer than ten principal functions (pp. 219–227):

1 Emotional expression
2 Aesthetic enjoyment
3 Entertainment
4 Communication
5 Symbolic representation
6 Physical response
7 Enforcing conformity to social norms
8 Validation of social institutions and religious rituals
9 Contribution to the continuity and stability of culture, and
10 Contribution to the integration of society.

His list is a useful device on which to hang a compilation of numerous case studies, but should not be taken as a thoroughly worked-out taxonomy: 'aesthetic enjoyment' and 'entertainment' receive little attention, and can be read as a concession to those who would separate Western music out as a special category; their relationship to the more communicative, expressive and social functions Merriam lists is not examined. Merriam himself admits to finding 'communication' difficult to assess, while his functions 5, 7, 8, 9 and 10 could, as Nettl points out, perhaps be combined into 'the statement that music functions as the symbolic expression of the main values, patterns, or themes of a culture' (1983, p. 15). Attali's take on this was somewhat different, figuring music as 'prophetic' of social change (1985); more generally the issue of whether music *reflects* or *constitutes* a culture, or acts as a site for the *contestation* of cultural practice, has been a matter of debate.

Nettl also offers his own rating of the relative importance of Merriam's different functions in six very different cultures (1983, pp. 150–153). He uses the comparison to make the point that music has a range of different functions in his six chosen contexts, and that the balance between these functions varies cross-culturally. Another issue he raises is whether music has one overarching function or a multiplicity of overlapping functions, a question to which he devotes more thought. Although he has his own stab at the former—'The function of music in human society, what music ultimately does, is to control humanity's relationship to the supernatural, mediating between people and other beings, and to support the integrity of individual social groups' (p. 159)—he has at least as much sympathy for the 'many functions' argument. In this latter position we may find a parallel with Cross's more recent suggestion that music is effective precisely because of its ambiguity or 'floating intentionality', which enables it to 'serve as a medium for the maintenance of human social flexibility' (Cross 2005, p. 36). We might indeed argue that a single musical action can have multiple functions, and that it can perform these functions in different degrees for different participants. Two ethnomusicological examples will serve to reinforce this point. As Turino puts it in his study of Peruvian highland music:

> Music, dance, and drama are especially apt media for *simultaneously* articulating and uniting widely divergent and even conflicting images and meanings. The achachk'umu dancers, for example, represent figures of power who are at once local, sacred, foreign, positive, human, negative, divine, animal, serious, and comical through a performance that is both lightly entertaining and deeply meaningful . . . The complex imagery within Conimeño performing arts and festivals articulates—perhaps more accurately than other semiotic practices, such as everyday speech—the complexity and tensions of history and life itself.
>
> (p. 99, italics in original)

In her study of Prespa Albanian song, Sugarman refers this polysemy more explicitly to the topic of self and subjectivity:

> As a polysemic social practice, singing allows individuals to convey a range of messages that they might wish to make about themselves as social beings. Each rendition of each song thus serves as an embodied performance of *multiple aspects* of that performer's sense of self and of community.
>
> (1997, p. 3, italics added)

The comparative study of music's functions has received little attention in ethnomusicology since Nettl noted that 'the idea that we must find major, overriding functions for music seems to have come to a dead end' (1983, p. 150), although evolutionary, ethological and cognitive approaches have recently reopened the debate, and ethnomusicological literature continues to lend itself to cross-cultural schemes. This is demonstrated by ethologist Dissanayake in her list of 'Social functions served by ritual music', which I abbreviate here:

(D1) display of resources;

(D2) control and channelling of individual aggression;

(D3) facilitation of courtship;

(D4) establishment and maintenance of social identity through rites of passage;

(D5) relief from anxiety and psychological pain; and

(D6) promotion of group cooperation and prosperity.

The first three of these, she argues, can be traced back to the ritualization of animal behaviour, while the others, particularly (D4) and (D6) may be uniquely human (2006, pp. 43–49). These two categories, incidentally, are also the easiest to match with Merriam's list (functions 7–10): otherwise the different factors located by Dissanayake reflect a different disciplinary background more than they do any profound shift in the ethnomusicological research on which they draw.

Ethnomusicological studies have nonetheless made contributions that ought to influence discussions of music's functions. Amongst these are discussions of the role of music in inducing trance, possession and healing, and ecstatic listening (Rouget 1985; Roseman 1991; Friedson 1996; Racy 2003; Becker 2004); increasing awareness of the role of music in the negotiation of ideologies of gender and ethnicity (Koskoff 1989; Stokes 1994; Sugarman 1997; Moisala and Diamond 2000); and a greater focus on the use of music in maintaining and adapting cultural identity in migrant and diasporic cultures (Turino 1993; Shelemay 1998; Slobin 1993, 2003).

Durkheim's influence on ethnomusicology has also has been renewed in recent decades, his theories on the basis of religious thought in collective action inspiring reflections on music. As Durkheim wrote:

> [I]f collective life awakens religious thought on reaching a certain degree of intensity, it is because it brings about a state of effervescence which changes the conditions of psychic activity. Vital energies are over-excited, passions more active, sensations stronger.
>
> (1968, p. 422)

This idea of 'effervescence' or, as Stokes put it, 'the considerable surplus of affect [music-making and dance] generate in performance' (2008), offers a warning against defining music's functions too narrowly in terms of social efficacy. Durkheim suggested further that 'The life thus brought into being even enjoys so great an independence that it sometimes indulges in manifestations with no purpose or utility of any sort, for the mere pleasure of affirming itself' (p. 424). According to this view music is not limited to performing a function such as those on Merriam's and Dissanayake's lists: its power to arouse and excite becomes an end in itself. For some this might throw the whole issue of music's social 'function' into doubt, but it is important to separate motivation from effect here. The fact that participants may be motivated by the promise of a heightened state of arousal does not, for instance, preclude a musical event from influencing the way social relations are imagined: these effects may indeed be more profound if they are not brought to the surface and articulated.

Finally, while sociologists and social psychologists have discussed the deployment of musical resources in the realisation of individual identity

(see below), ethnomusicologists have stressed both the variety of concepts of 'self' cross-culturally and the social constitution of the individual. Roseman draws on the notion of the 'sociocentric self', 'an interactive self that doesn't quite end at the boundaries of the individual' (1991, p. 46). In the case of the Temiar, whose sense of self seems to conform to this model, 'the beauty of interconnectedness with community and nature is offset by concern for the integrity of self', which requires a 'code of ritualized behaviour' for its management. The individual is implicated in the social and the social in the personal, then, and music—however we define it—provides tools for managing these interrelationships.

Defining musical behaviour

By 'music' we refer to an aspect of *human behaviour*; the creation of *organized sound* is an important part of that behaviour, whether conceived as an aim itself or as a means to another end; and this behaviour is *distinguishable from everyday speech communication*.[3] To start talking about the definition of music at this point may seem an odd strategy: nonetheless, the question of music's functions is inseparably tied up with that of its definition, and therefore it is important to revisit definition in this discussion. If my statement is accepted as a working definition, where do the boundaries of 'musical' behaviour lie? Is the recitation of poetry an instance of music? Auctioneering? Hunting calls? Bell-ringing? Birdsong?

In terms of the definition above the logical distinctions would be human vs non-human; organized sound vs noise; and music vs language. The first of these rules out birdsong—although Feld's analysis of the profound interconnectedness of bird calls, weeping and song in Kaluli culture in Papua New Guinea is a reminder that simple definitions are always challenged by the complexities of real life: non-human sounds are at least implicated in many conceptions of music (1990).

[3] This definition draws, of course, on Blacking's pithy 'humanly organized sound' (1973) and on Nettl's discussion of the issue (1983, pp. 15–25).

The distinction between music and noise lies not in the sound, but in the way human beings make use of it. A team of expert campanologists clearly make music; a bell accidentally sounding in the wind does not (even though the sound may be attractive); when Feld mixes his soundscape recordings into the 'compositions' of *The Time of Bells* (2004), he arguably nonetheless transforms non-musical sound into music.

To continue the same theme, a bell being struck to call people to a meal or meeting is probably not music—at least, not if heard merely as a signal that could have been replaced by a verbal instruction, just as a drum pattern *heard as a verbal message* is not for that listener music, but rather a form of language. Insofar as 'musical' sound can be substituted by words, it can be regarded as a form of language; conversely, almost all forms of vocalization can be said to have 'musical' qualities even when they are primarily linguistic in character. In each case, then, the boundaries of music can be seen to be less than clear cut.

For Rousseau both language and music originated together with the birth of human society (1998): the emergence of a single mode of vocal communication in the early stages of human development is echoed in more recent speculation (see the essays in Wallin *et al.* 2000), and child development studies suggest the same may be true ontogenetically. Vocal utterance is not the only source of musical behaviour, however. Just as important is a human tendency to rhythmic coordination and entrainment (Clayton *et al.* 2005). This can be observed in almost any kind of human activity—including walking and talking—but is particularly noticeable in forms of activity where rhythmic coordination makes physical work more efficient. Many examples of this can be found in the collaborative pounding of roots or grains, in which two or more people alternate strikes—a common activity in many parts of the world, and one which frequently incorporates a 'musical' dimension employing the sounds produced. In most kinds of musical behaviour, cross-culturally, these two elements (vocal utterance and coordinated action) are combined in some way—and if we regard most melodic instrumental music as a kind of extension of the voice (Cone 1974) then much if not

all music-making is founded on these two forms of behaviour.

Music as communicative medium

One thing that vocalization and coordinated action have in common is that both play a role in connecting individuals: they are both social. One of the ways in which speech and song may be distinguished, in fact, is in the kind of social relationships they presuppose. For Zuckerkandl, the fundamental distinction between speech and song is that speech involves communication from A to B, whereas song presupposes the merging of self and other into a social 'we':

> the tones—singing—essentially express not the individual but the group, more accurately, the individual in so far as he is a member of the group, still more accurately, the individual in so far as his relation to the others is not one of 'facing them' but of togetherness.
>
> (1973, p. 28)

As Miell, Macdonald and Hargreaves point out in their discussion of musical communication, transmission models have nonetheless predominated in music psychology. Their own model attempts 'to specify the main personal, musical and situational variables which give rise to a musical *performance*, [and similarly] to explain the *response* to music in a specific situation' (2005, p. 7): where the domains of performance and response meet they describe the 'spark' of communication (p. 18). In other fields authors have engaged similarly with the notion of 'transmission', whether considered to be from active performer to passive listener, or with active engagement on both sides of the equation. Nattiez's semiotic theory (1990) invokes three levels: instead of a unidirectional arrow from performer to listener, both relate to a 'neutral' middle level (located in the same place as Miell *et al.*'s 'spark' of communication). Feld plays down this neutral level and highlights the active and relational nature of meaning-making, allowing the listener greater autonomy in applying 'interpretive moves' (1994). Recent musicological writing has dealt with the ways in which music affords or contructs a 'subject position' for the listener, in effect constraining this act of interpretation while still allowing the listener some autonomy (Frith 1996, pp. 183ff; Cumming 2000; Dibben 2006). The ways in which real people deploy musical resources in managing their activities, identities and emotional states has been explored in music sociology, social psychology and ethnomusicology (Crafts *et al.* 1993; DeNora 2000; Hargreaves *et al.* 2002,), further elaborating the 'response' side of Miell *et al.*'s model. On the performance side of the equation, Swaine has argued that vocalization is a tool for an individual's emotional self-*regulation*,[4] with expression a secondary effect: the same could no doubt be said of much instrumental performance.

Transmission models clearly have explanatory power, especially when nuanced in the ways described above. No matter how good a fit they may be with some examples of musical behaviour, however, they are equally problematic in many others. I return to my example of Robbie Williams singing 'Angels': many in his audience know the song as well as the singer himself does; there is little, if any, new information to 'transmit'. In this case notions of interaction, intersubjectivity and encounter are surely more productive. If interaction is placed at the heart of our understanding of musical behaviour, the 'transmission' of information or affective states remains as a possibility but not a sine qua non.

Musical interaction can have other goals and other results, and these might include for instance—in the same or in other contexts—a loss or sublimation of ego or the promotion of fellow-feeling. Mithen argues for the evolutionary importance of collective music-making thus: 'Joint music-making served to facilitate cooperative behaviour by advertising one's willingness to cooperate, and by creating shared emotional states leading to "boundary loss"/"we-ness"/"coupling"/"in-group bias"' (218); in ethnomusicology Keil stresses the 'participation' found in many social musical events (1994), while Blacking favoured the term 'fellow feeling', both drawing on Durkheim (see above). Friedson, in his study of spirit healing among the Tumbuka people of Malawi, argues that in this context

[4] See Cross *et al.* 2009, in press.

music can lead to a state of communion or communitas—'a relational quality of full unmediated communication, even communion, between definite and determinate entities'—(Turner and Turner 1978, p. 250, cited in Friedson 1996, p. 125), of intersubjectivity and the annihilation of interpersonal distance.

The notion of 'encounter', too, has been deployed by ethnomusicologists: for Averill, music is an index of encounter (2003), while for Bohlman (2002) encounter is the key organizing concept in his history of 'world music'. Where the notions of communion, group solidarity and fellow-feeling can lead people to write exclusively of social unity, that of 'encounter' leaves space for conflict, for exclusion and for maintaining a sense of alterity, which also have a place in musical performance. Turino's example quoted in my first paragraph shows how group identity and inter-group conflict—albeit of a relatively benign kind—can go hand in hand. Another example of this can be found in Afro-Brazilian Congado ritual, in which individual groups playing simultaneously strive to maintain a tight intra-group rhythmic coordination which indexes their group solidarity, while resisting entrainment with other co-present groups for the same reason (Lucas 2002; Clayton *et al.* forthcoming).

All of these approaches complicate the idea of music as a medium of communication, if the notion of information transfer or transmission is taken as defining 'communication'. Finnegan presents a different view, however, building on Birdwhistell's much broader definition of 'communication' as the 'dynamic aspect of human interconnection' (1968, p. 27, cited in Finnegan 2002, p. 32): following Finnegan's line allows us to continue to address music and language as complementary modes of human communication. Whether music indexes communication, communion or encounter makes a difference, of course: music is either a way for A to transfer information to B; how A and B affirm their collective identity; or simply what happens when A meets B. In fact it can be any and all of these things, and this flexibility is part of the point. If 'communication' encompasses information transfer, communion and encounter of all sorts, then we can freely describe music as part of man's communicatory toolbox, asking how it relates to other related tools such as language and physical gesture.

My discussion above focused on the difficulty of defining boundaries such as those between music and language or between music and noise, but this does music something of a disservice: more positively, what defines music and what makes it a valuable analytical category cross-culturally? What would we lose if we argued the concept away? Ultimately, the phenomenon of people using organized sound in order to connect with each other—in ways which cannot be regarded simply as forms of language or information transfer, or completely explained in terms of verbal concepts—can be regarded as a single, generalizable idea, and a robust one no matter how ill-defined and porous its boundaries are.

Discussion: the functions of music

Music is not a single form of behaviour any more than it is a single kind of sonic product, but a composite of different forms of sound and behaviour. The behaviours we describe as 'musical' are founded principally on two distinct, yet interrelated phenomena: the human capacity for vocal utterance, and our innate tendency to mutually entrain our actions, especially those involving sound production and quasi-periodic behaviour. Neither of these factors can be reduced to the other, yet in practice most musical behaviour draws on both to varying degrees. Vocal utterance may also be considered as the origin of language, while music as coordinated action relates to other forms of group activity such as physical labour, marching and dance—the last of these frequently as inseparable from music as gesture is from speech. Musical behaviour generates humanly organized sound beyond the limits of normal speech communication: it is distinguishable from non-human sounds, from noise and from language, although each of these boundaries is inevitably fuzzy. In light of these discussions, I propose that musical behaviours tend to perform one or more of the following functions:

1 Regulation of an individual's emotional, cognitive or physiological state. Musical performance has physiological effects—singing

has implications for respiration and body posture, many instruments develop bimanual coordination skills, and so on. Given that physiological changes can influence emotional and cognitive states, it is not surprising that in many cultures musical behaviours are employed in the regulation of these states—involving mild effects such a temporary calming or excitation or more dramatic changes such as trance. Since music can be used in the regulation of emotional and cognitive states, again it is not surprising that performances are frequently taken as indexes of these states, and performers as expressing emotions. Music listening—whether in a live performance situation or to sound recordings—can be used in parallel ways as a tool for self-regulation (for example in managing mood), thanks to the role of mimesis and identification with the music's subjects (if the singer on the record is indicating an excited state, then to the extent that the listener sympathizes with the singer he or she may also become excited).

2 Mediation between self and other. Music has been used for centuries as a tool for interaction in instances where normal speech communication is found to be inadequate. Examples include the use of special forms of song or music to communicate with Gods, spirits or ancestors in ritual contexts. More mundane examples might include the use of song to communicate emotional states felt to be beyond the scope of everyday speech, or to communicate intimately with large numbers of people. Musicking can be both a powerful and an extremely flexible tool for modelling and mediating relations between self and other. These functions can be interpreted either as communication between the group and an external other (such as an ancestral spirit), or as a function of intragroup interaction. The 'other' could be the spirit or other entity felt to be singing through a performer (as in the case of the spirit guide described by Roseman above);[5] it could be another being (human, divinity or spirit) addressed in song; or it could be another entity constructed and represented through song. In the last sense musicologists have drawn attention to the multiplicity of voices created through a musical performance (Cone 1974), and to the role—in opera in particular—of the play of identity and alterity (Abbate 1991; McClary 1992, pp. 29–43).

3 Symbolic representation. Although music seems in some respects to display ambiguity in specifying its referents, it can also be extremely efficient as a semiotic medium. Just as gesture can indicate the direction and velocity of a movement, or the shape, size and spatial disposition of objects with more precision than does the speech it accompanies (McNeill 1992), and facial expression can indicate emotional states more economically than can language, so too musical sound and action can specify aspects both of affect and of movement more precisely than words. Conventional musical signs as deployed in cinema or advertising, moreover, can specify their referents with unmatched precision and economy (Tagg and Clarida 2003). This play of signs has a different emphasis to that in language, perhaps because musical signs tend to be concerned with identity and alterity, bodily motion, and relationships between self and other. If world music is an index of encounter, as Bohlman argues, this music of encounter in fact relies on a degree of ambiguity between the perception of 'self' and 'other' (Leante 2004). Music can clearly evoke issues of alterity and identity without articulating an unambiguous message on the subject.

4 Coordination of action. Human beings display a tendency to entrain their physical actions, either to each other or to an external sound reference (such as a musical performance or recording): the fact that entrainment occurs even when resisted (Clayton 2007; Clayton *et al.* forthcoming) indicates the pervasiveness of the phenomenon in human interactions. The use of music to facilitate coordinated action hardly needs demonstration: what is

[5] Similarly, I have elsewhere quoted Indian singer Veena Sahasrabuddhe's view that her main relationship is an identification with the raga she sings rather than with her audience (Clayton 2005, p. 373).

striking is that in many instances the urge to coordinate action is accompanied by a development of 'fellow feeling', with the emergence or strengthening of bonds of shared mood or emotional state, and in some cases shared ideologies. As Dueck has argued, musical performance not only entertains existing groups, it plays a key role in constituting publics (2007); numerous examples have been described in which music is deployed in order to maintain, revive and/or to create a sense of 'tradition', or to facilitate a sense of identity amongst particular social groups—for instance in diaspora.

There may be examples in which one of these functions outweighs each of the others to such a degree that we may identify it as the principal function of music in that instance. Perhaps, as Nettl suggests, the balance between functions varies between cultures (or indeed between genres, or even between different moments in a single performance). Possibly more common, however, are instances in which several of these functions operate simultaneously. For instance, a popular song such as Robbie Williams's 'Angels' might (1) originate in an urge towards the regulation of an emotional state; and (2) be used in an act of communication between singer and audience that could not have been accomplished by speech alone. It (3) represents a particular pattern of feeling dynamically and precisely, and points to numerous referents, from the singer's public persona to English culture at the end of the twentieth century. Its singing at large public concerts (4) elicits a coordination of both action (singing along, swaying bodies in time with the music) and emotion on a massive scale; and bringing the matter full circle, individuals partaking in this communal experience can be seen to deploy their listening experience and participation as a means of emotional regulation. In this way, this and many other forms of musical behaviour simultaneously perform several distinct yet interrelated functions. This example may also remind us of Durkheim's 'effervescence': it is not simply that multiple functions are performed simultaneously, rather the very intensity of experience provides a basis for its many effects and interpretations.

The four headings above are largely concerned with relations between the personal and the social—identity, alterity and mediation. Music is a tool for the discovery, manipulation and projection of individual identity; an individual's identity construction is however inherently social, implicating a variety of groups to which the individual feels he does or does not belong. Music is a tool for facilitating intimate interactions, and an index of such interactions: it therefore helps to bring social groups into being. Music is also a tool for constituting publics, for allowing social groups larger than the family, clan or village to create themselves and to include or exclude individuals. It can help to dissolve the boundary between self and other in a way speech generally does not; but music can also be deployed to reinforce boundaries and to distance or exclude. This is why it can be described as a flexible tool for managing relationships between self and other.

Like Merriam, I argue that underlying the bewildering variety of uses to which music is and has been put around the world we can define a finite set of global functions. My list is shorter and more synthetic than Merriam's, but this greater concision is offset by more emphasis on the idea that these functions can not be reduced to one: it is not simply that a particular writer, or the language itself, is incapable of specifying *the* function of music; rather, music frequently depends for its efficacy precisely on the indeterminacy of its 'true' or underlying function. We can say, nonetheless, that musical behaviour is deployed in the management of relations between self and other, and that it can and does perform this function at multiple levels simultaneously.

PART 2

Music perception

Edited by Ian Cross

CHAPTER 5

The perception of pitch

Thomas Stainsby and Ian Cross

Basic psychophysics of pitch perception

Pitch and frequency

While a musician may find a definition of pitch redundant, psychoacoustics—the scientific investigation of our perception of sound—nonetheless demands one. Although there is an intuitive understanding that pitch is related to frequency, it is important to understand that the two are not directly equatable. Pitch is a percept, measurable only by psychophysical investigation, and frequency is a physical quantity, which describes the periodic properties of a signal. Sounds that contain clearly measurable frequency content may not produce a clear or unambiguous sense of pitch, and the perceived pitch may also depend on other physical quantities such as intensity. The American National Standards Institute offers the following definition:

> Pitch [is] that attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high. Pitch depends primarily on the frequency content of the sound stimulus, but it also depends on the sound pressure and the waveform of the stimulus.
>
> ANSI (1994)

However, we require a more restricted definition for the present review. Frequencies below around 30 Hz and above around 5 kHz can lose their identities as *musical* pitches (Attneave and Olson 1971), while still sounding 'low' or 'high', respectively. Additionally, there is something more global about pitch than individual frequencies. Most sounds we hear are mixtures of components with many different simultaneous frequencies, yet our auditory system generally combines these into a single percept of one overall pitch. The mechanisms that group the individual frequency components into an overall pitch are also at work in processing combinations of notes arising from different instruments. Does the combined percept have a single overall sense of pitch, or perhaps a 'timbre' for that combination and instrumental voicing, or alternatively, is there a clear hierarchy with a given 'harmony' consisting of distinct individual pitches?

One solution is to offer definitions of pitch that require the ability to convey a musical melody (e.g. Attneave and Olson 1971; Burns and Viemeister 1976). A combination of this requirement and the ANSI definition meets an intuitive and informal definition that may satisfy most musicians, that 'pitch is the stuff that notes are made of'.

In this chapter's discussion of pitch, we begin with a brief introduction to the function of the auditory system. This considers what limitations there are on our ability to extract frequency information from the sounds reaching our ears, and provides an orientation for some of the mechanisms described in the later sections. A review is then offered of relevant psychoacoustic research—how do we construct a sense of pitch from the physical acoustic input? This leads to a consideration of higher auditory processing functions that include the mechanisms we use to interpret the complicated mixture of sounds around us and the relationships between pitch as it applies to music and how it is manifested in speech and language.

The only sound that has just one frequency component is termed a pure tone or sine tone,

having a quality like that of a tuning fork. Its frequency spectrum has energy at only a single frequency, and its temporal wave form has the shape of a sine function. Although single pure tones are rare in nature, the concept is useful when we consider that real-world complex sounds and mixtures of sounds are made up of the sum of multiple pure tones such as these, termed *frequency components* or *partials*. We can then understand the task of the auditory system as being that of detecting and decoding such mixtures of frequency components, and interpreting this information to make sense of the sound world or *auditory scene* around us (Bregman 1990).

Before describing the mechanics of frequency coding, which occurs primarily in the inner ear, it is necessary to consider briefly the physiology of the auditory system. The acoustic wave from the outside world is captured and filtered by the outer ear, consisting of the pinna (external ear) and the ear canal. This stage of acoustic processing helps amplify the sound and encode information about the direction of sound sources. Subsequently, the sound is transmitted through the middle ear to the inner ear, consisting of the labyrinth (not considered here) and the cochlea, a small fluid-filled coil containing the sensory mechanisms that transform (transduce) mechanical energy into the electrical signals that are processed in the brain. The middle ear, which consists of the eardrum and the auditory ossicles (the three smallest bones in the body), is primarily concerned with the task of matching the impedance of the external air (its resistance to the passage of sound energy) to that of the fluid inside the cochlea. This maximizes the amount of energy transmitted—around 95 per cent would be reflected otherwise. It is not until the sound reaches the inner ear that frequency analysis and coding takes place. The cochlea in the inner ear is situated in the temporal bone of the skull, and is divided along its length (approximately 35 mm) by the basilar membrane (BM). The actual sensory transducers, the hair cells, are aligned along this membrane, in one row of inner hair cells (IHCs)—about 3500 in total—and three or four rows of outer hair cells (OHCs)—about 12 000 in total. The incoming sound sets up a travelling wave of vibration along the basilar membrane (von Békésy 1947). The IHCs in the vicinity of points of significant BM displacement are stimulated by the movement of their stereocilia (tiny hair-like projections grouped in bundles at the top of each hair cell) in the cochlear fluid, which in turn send electrical signals along the auditory nerve fibres that connect with, or *synapse* onto, each IHC. The OHCs fulfil a somewhat different function, which is described below.

The primary method of frequency coding is offered by the structure of the basilar membrane, which varies in width, thickness and stiffness along its length. As a result, each point of the membrane has a unique resonant frequency, i.e. the frequency at which it vibrates most easily. The base of the cochlea (closest to the middle ear) responds maximally to high frequencies (up to around 20 kHz), while the opposite, apical, end responds maximally to low frequencies (down to around 20 Hz). The frequency for which a given place on the basilar membrane shows a maximum response is termed its *characteristic frequency*. This leads us to understanding the first method of coding frequency, termed *place coding* or *tonotopic coding*. For each location on the BM showing maximum response to a characteristic frequency, there are a number of hair cells in the vicinity that will be maximally stimulated. There are roughly 30 000 auditory neurons that synapse onto the 3500 or so IHCs. With tonotopic coding, frequency can be represented by which neurons have been stimulated (i.e. they trace back to a specific localized region of the basilar membrane). Note that because there is a small region of maximum displacement rather than a point source, neural activity is not signalled in a single auditory neuron's response, but in the distribution of the responses of a population of probably hundreds or over a thousand neurons, a pattern of activity that is termed the *neural excitation pattern*. It should be noted that this does not imply that only one frequency will excite a discrete population of neurons; the mapping between frequencies and neurones is many-to-many, with a group of neurons responding to a limited range or band of frequencies, which will vary with signal intensity.

We can see that there is thus a limit to the specificity of frequency information derived from place coding; BM output in response to a single input frequency appears more like the output of

a band-pass filter than the output of a sharply tuned system. This is enhanced by a second, active, tuning process, which is believed to be mediated by the OHCs in the vicinity of the peak of the travelling wave (Rhode 1971; Ruggero 1992; Robles and Ruggero 2001). These cells actively move and change shape in response to stimulation, thus increasing BM displacement, in turn causing greater stimulation of the IHCs. Because the action of the OHCs is quite localized, this spatially restricted amplification of travelling-wave displacement results in a sharpening of the excitation pattern around the characteristic frequency, and hence an improvement in frequency resolution.

Louder sounds generate a larger travelling wave, and hence a greater spread of excitation, than a quiet sound. Higher stimulus levels thus result in decreased frequency resolution, and increase the extent to which loud components 'mask' the quieter ones. This explains the loss of perceptible detail in sound mixtures at loud levels. The extent to which sounds mask each other in this way can be used to elucidate and quantify the concept of frequency selectivity (Fletcher 1940; Patterson 1976; Glasberg and Moore 1990), which can be defined as the ability to hear out the sinusoidal partials or components of a complex sound (Moore 2003). Sounds are said to fall within the same band-pass auditory filter when they are able to mask each other to a sufficient extent. Figure 5.1 shows how auditory filter bandwidth varies with centre frequency

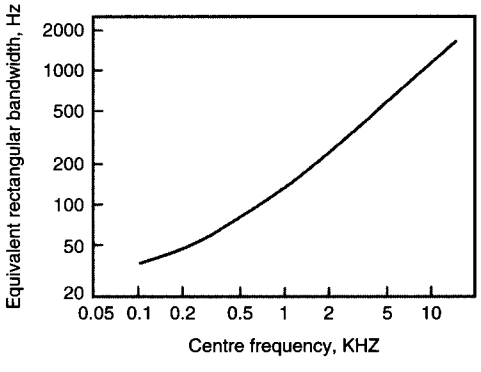

Fig. 5.1 Average auditory-filter width and the ERB scale (after Glasberg and Moore 1990). The solid line plots the calculated width of the auditory filter for a given centre frequency.

(Glasberg and Moore 1990; Moore 2003). For frequency components to be 'heard out' and processed independently from each other, they need to fall within the passbands of different auditory filters. Once the centre frequency of one auditory filter has been defined, the next adjacent auditory filter needs be a certain distance along the basilar membrane to achieve the requisite independence of frequency selectivity. This is the logic behind the equivalent rectangular bandwidth (ERB) frequency scale (Glasberg and Moore 1990), which can be used to measure frequency in the perceptually relevant scale of auditory-filter bandwidth. Measured in this way, human hearing can be said to cover a range of a little fewer than 40 ERBs. Multiple frequencies falling within the same auditory filter cannot be resolved or processed independently, and only their combined effect is available to the auditory system.

The tonotopic organization and place frequency coding established in the cochlea are maintained up through higher centres in the auditory neural pathways. Progressively less is known about the nature of auditory processing and the function of particular structures as the auditory pathway ascends. A comprehensive review of the neurophysiology of pitch is provided in the chapter by Winter in Plack *et al.* (2005).

The second type of frequency coding, *temporal coding*, is achieved by an analysis of the behaviour of neural firings over time. That is, once the initial place coding of frequency has been achieved from the overall number of firings in a given population of neurons, further frequency information can be extracted from analysis of the period between successive spikes (more-or-less simultaneous bursts of energy produced by a group of neurones). However, such temporal information is only available for the coding of frequencies below approximately 5 kHz. Two factors contribute to this limitation on the frequencies that can be encoded by neural temporal coding. The first is the refractory period of an individual neuron. Once it has fired, a neuron is unable to fire again until it is metabolically 'recharged', which limits its firing to a maximum rate of 1 kHz. However, because stimulus frequency is being coded by populations of fibres, timing information averaged

across multiple neurons can still code frequencies up to 5 kHz. At this point the second limiting factor is reached, that of the breakdown of phase locking (Rose *et al.* 1967; Palmer and Russell 1986). Phase locking is required for the information obtained from the timing of neural spikes to have any meaningful relationship to the stimulus frequency. The term refers to the ability of a neurone to fire at a predictable time point—phase—in the stimulus waveform cycle—e.g. at the maximum downward displacement of the basilar membrane's vibration. Once a neuron can no longer fire at a consistent phase of the stimulus, its response is random and hence noisy. Above 5 kHz, the stimulation period simply becomes too short for any neurons to fire at a predictable phase.

We can thus see that temporal coding should provide robust and reliable frequency information for lower frequencies. By contrast, all coding of frequencies above 5 kHz can only be achieved by place coding. Both types of coding are available over a good portion of the audible frequency range, meaning that the mechanisms of pitch perception can employ both types of frequency information in the majority of instances.

It is relatively straightforward to understand how the auditory system can derive pitch from pure tones. For such stimuli, the pitch is unambiguously related to the frequency. Place and temporal cues are fully congruent for these tones, which is not always the case for more complex stimuli. For these reasons, the pitch of any type of stimulus is often quantified by using the frequency of a pure tone that is subjectively matched to the complex tone as having the same pitch.

The relative contribution of place and temporal frequency coding to the perception of pitch for pure tones has been investigated by examining frequency discrimination data from different task types. This shows that place resolution is more or less constant across the usable frequency range, while for lower frequencies, temporal coding offers superior performance to that achievable from place coding alone (Sek and Moore 1995), yielding frequency discrimination thresholds of *c.* 3–4 Hz at 1 kHz. This observation is supported by the results of Attneave and Olson (1971), who found that while listeners could still detect changes in frequency above 5 kHz, the sense of pitch deteriorated to the point where melodies ceased to be recognizable. Musical practice is consistent with this in that C8, the highest note on a piano and the highest note of an orchestral instrument (the piccolo), has a fundamental frequency of 4176 Hz. Taken together, these facts suggest that temporal-frequency information is necessary for a sense of musical pitch.

The pitch of pure tones is not exclusively determined by frequency however. While an early study by Stevens (1935) found quite large interactions of pitch and level, subsequent studies (e.g. Terhardt 1974; Verschuure and van Meeteren 1975) have found similar but smaller effects. In summary, the pitch of pure tones above around 4000 Hz rises with an increase in level, while it falls with an increase in level for frequencies below about 2000 Hz. The magnitude of the effect in these ranges can be up to 5 per cent, but is less than 1 per cent for intermediate frequencies, and the magnitude and pattern of results is highly variable between individuals. The pitch of pure tones is also affected by duration. Moore (1973) showed that performance on frequency discrimination gets much better at all frequencies as tone duration increases. There is a sharp deterioration in performance for all durations at higher frequencies, where only place-frequency information is available.

Pitch of complex tones

The pitch of pure tones is a special case, in that it is not of primary importance to consider information across multiple auditory filters or channels. Sufficient temporal and place information can be obtained by attending primarily to only the single filter centred on the signal frequency (though at high levels there is increased spread of excitation to adjacent channels). However, the vast majority of sounds are complex, consisting of multiple frequency components across a number of channels, and it is in such circumstances that one of the most interesting aspects of pitch perception is manifested—the ability to derive an overall unitary percept from a mixture of frequency information. This skill is essential for the appreciation of

music, given that a typical instrument will produce dozens of partials, yet we can assign a single pitch to this, and hence experience melody and harmony. In fact, an argument for the evolution of pitch perception is that it aids the segregation and identification of sound sources, such as the human voice, by helping to group related partials together, and in so doing assists us in interpreting the surrounding auditory scene (see chapter by Darwin, in Plack *et al.* 2005). While many complex sounds have harmonic spectra, ie. their partials have frequencies that are integer multiples of a common fundamental frequency, pitch can also be derived from stimuli that have inharmonic components (Schouten *et al.* 1962) or that contain only broadband noise in their spectra (Cramer and Huggins 1958; Burns and Viemeister 1976). There are also examples of pitches that arise from the input of different stimuli to each ear (Cramer and Huggins 1958; Houtsma 1972; Klein and Hartmann 1981).

A variety of models have been put forward over the years to explain how the auditory system derives a sense of pitch from such a range of stimuli. Related to the duality of place and temporal coding of frequency, pitch perception models tend to be divided into the *pattern matching* and *temporal* families (for overviews of these models see Houtsma 1995, see also the chapter by de Cheveigné in Plack *et al.* 2005). These models principally differ in the relative importance of frequency components that are resolved or unresolved by the auditory system. As described earlier, a component is said to be resolved if its place and temporal frequency information can be interpreted independently of any other components. Figure 5.2 (after Plack and Oxenham 2005) offers an illustration of the relationship between stimulus frequency spectrum, peripheral filtering, and the resultant excitation pattern and BM vibration. A range of studies (Plomp 1964; Plomp and Mimpen 1968; Moore and Ohgushi 1993) suggest that subjects are able to 'hear out' only the first five to eight components of a harmonic complex tone; these studies offer psychoacoustic evidence that beyond these harmonic numbers, the components remain unresolved by the auditory periphery.

The most common sounds we hear in music, such as sustained notes on strings, woodwinds, brass, most keyboard instruments, and sung vowels, have harmonic spectra similar to the one shown in Figure 5.2 (although of course the relative amplitudes of the spectral components differ between instruments). Given that the pitch of such sounds usually corresponds to the fundamental frequency, it might be tempting to assume that the pitch is simply determined by this lowest frequency component. However, the phenomenon of the 'missing fundamental, robustly demonstrated by Schouten (1938), indicates that this is not the case. When higher harmonic components are present but not the fundamental, the pitch may remain the same as if the fundamental were physically present. In the example shown in Figure 5.2, imagine if the lowest component present were at 200 Hz, and all the other multiples of 100 Hz, i.e. 300 Hz, 400 Hz, 500 Hz, etc., remained. The pitch heard would still be 100 Hz, not 200 Hz. Schouten termed the pitch derived from the higher (non-fundamental) components the *residue pitch*, and it has also been called *periodicity pitch, virtual pitch*, or *low pitch* in the literature. Somehow, the global pattern of frequencies physically present is interpreted to create a pitch at a frequency that may not be physically present, and this effect is not a consequence of the existence of combination tones (Licklider 1956). Both pattern-matching and temporal models have been proposed as underlying the sensation of a unitary pitch experienced in respect of a complex tone.

The preceding discussion has considered the case in which a single sense of pitch is derived from simple or complex stimuli. However, much musical practice relies on the ability of the listener to perceive the relationship between simultaneous pitches. A fundamental aspect of this is the perception of consonance and dissonance. While musically trained listeners may have a specific concept of which intervals are more consonant than others, this assessment is heavily influenced by instruction in a particular musical culture. Of particular interest is the fact that even naive listeners have an intuitive sense of consonance as being the degree to which simultaneous notes sound pleasant, harmonious, or euphonious. This unlearned sense of consonance has been termed 'tonal consonance' by Plomp and Levelt (1965). They found that

when simultaneously presented pure tones had very similar frequencies, a high degree of consonance was observed. However, dissonance increased rapidly as frequency difference was increased, reaching a maximum at around 25 per cent of the auditory-filter bandwidth. Further increases in frequency resulted in a progressive increase in consonance until a maximum was reached and maintained once the critical bandwidth was exceeded. Thus, sensory dissonance is related to the amount of interference between two tones within the same auditory filter. This same mechanism can account for the degree of consonance perceived when complex tones are

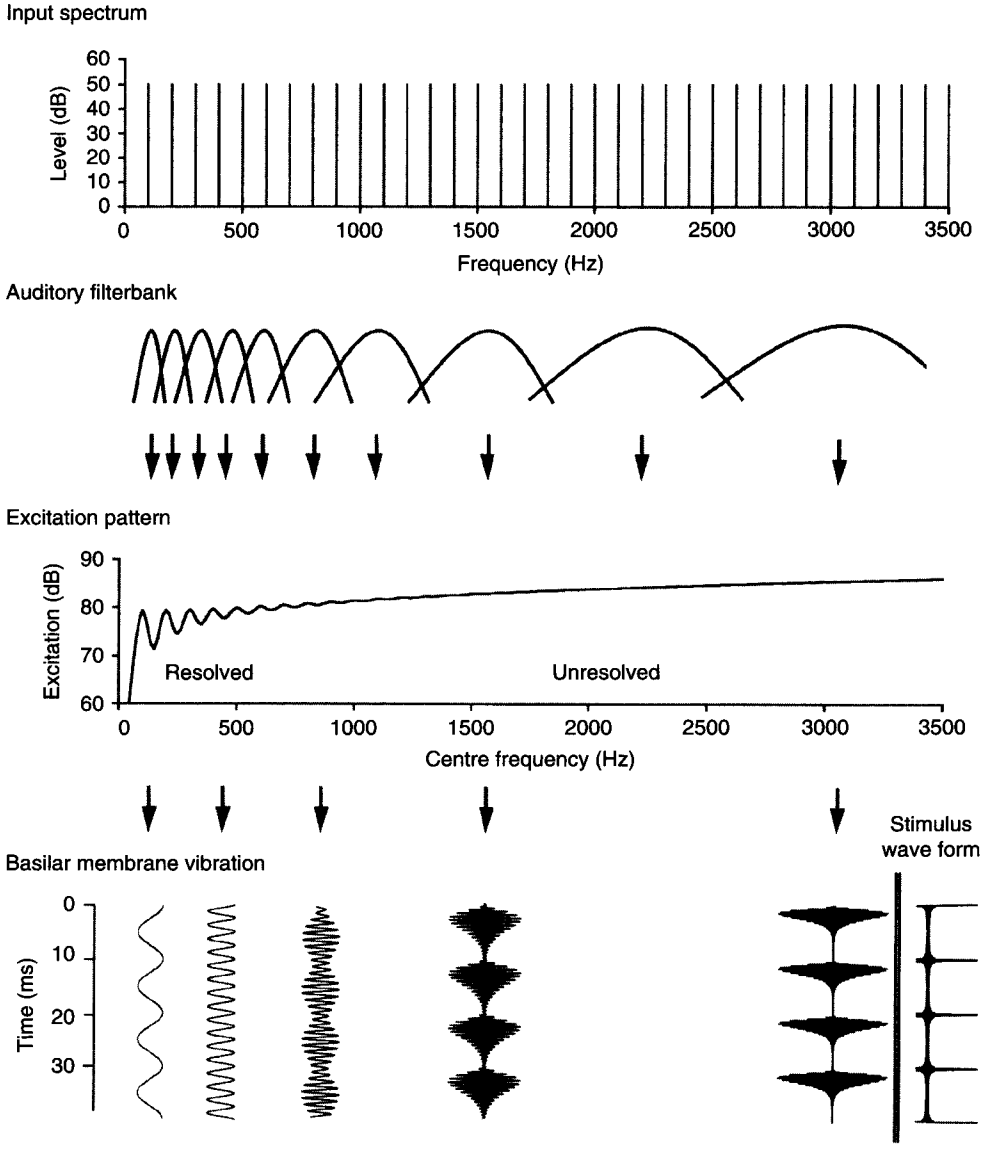

Fig. 5.2 A schematic illustration of the relationship between a harmonic complex stimulus, its analysis by the auditory filterbank, and the resulting excitation pattern and basilar membrane vibration (from Plack 2005).

when simultaneously presented pure tones had very similar frequencies, a high degree of consonance was observed. However, dissonance increased rapidly as frequency difference was increased, reaching a maximum at around 25 per cent of the auditory-filter bandwidth. Further increases in frequency resulted in a progressive increase in consonance until a maximum was reached and maintained once the critical bandwidth was exceeded. Thus, sensory dissonance is related to the amount of interference between two tones within the same auditory filter. This same mechanism can account for the degree of consonance perceived when complex tones are

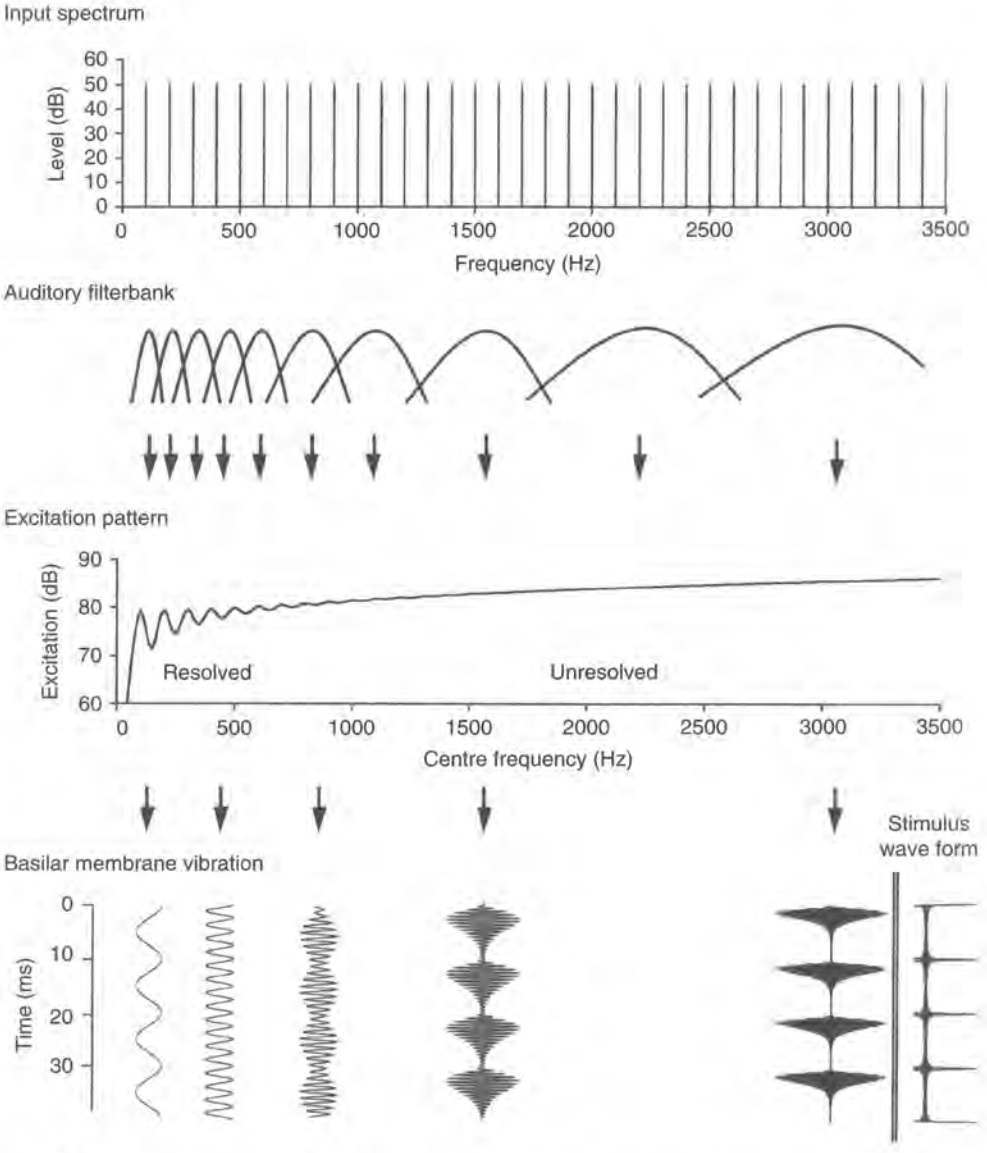

Fig. 5.2 A schematic illustration of the relationship between a harmonic complex stimulus, its analysis by the auditory filterbank, and the resulting excitation pattern and basilar membrane vibration (from Plack 2005).

presented simultaneously. Unlike the results seen with pure tones however, complex tones do not plateau at a level of maximum consonance once the critical bandwidth is exceeded. Rather, there are peaks in consonance when the fundamental frequencies possess simple integer ratios, e.g. 2:1 (octave), 2:3 (fifth), 3:4 (fourth), etc., as a consequence of the interactions between the individual partials of each tone complex. Dissonance is dependent on the roughness or interference of partials in various auditory filters, even if these are considerably above the filter centred on the fundamental frequency.

Higher-order processing and organization of pitch

When we experience pitch in music we do not experience single pitches, or arbitrary collections of individual pitches; we experience pitch *patterns*. We can conceptualize such pitch patterns in terms of the vertical dimension producing harmony, while the horizontal dimension produces melody. As Attneave and Olson (1971) put it, musical pitch is a morphophoric—pattern-bearing—medium. In general, the processes outlined above constrain but do not determine the types of patterns that we experience in musical pitch. In order to understand the experience of musical pitch we must take into account processes that operate on, and are in part driven by, the acoustic musical signal, *and* also processes that are mediated by central (largely cortical) mechanisms that have arisen through processes of development and learning. In other words, the perception of musical pitch relies on both bottom-up processes (driven by the musical signal) and top-down processes (arising from our evolutionary history and from individual, culturally situated, learning). The following section will focus on these top-down processes.

Grouping principles, stream formation and auditory scene analysis

The facility to extract musical patterns from the rich mixture of auditory information that reaches our ears has been termed *auditory scene analysis* by Albert Bregman (Bregman 1990). Although Bregman developed much of his work in terms of the processing of all kinds of auditory stimuli (as evolutionary processes would have shaped us for optimally analysing all events around us), we can take music as a special case in which musical notes are the auditory events of interest. There are two ways in which auditory scene analysis, or auditory grouping, can function. In the case of a solo unaccompanied melody, there is the grouping process whereby we link the successive isolated notes to form one percept of contour. The same processes also allow us to disentangle the mixture of overlapping elements that occurs when multiple sounds are present. This ability to assign some elements to one inferred perceptual auditory source or 'stream', and others to a different stream, has been termed *auditory streaming*. Applied to the vertical dimension, we describe the grouping and parsing of elements that overlap in time as *simultaneous streaming*. It is this process that leads to the perception of harmony, when some frequency components are parsed into different simultaneous notes. The grouping and parsing of temporally non-overlapping notes, termed *sequential streaming*, is what gives rise to a perception of counterpoint. An extensive consideration of how these processes can be shown to generate the commonly accepted rules of harmony and voice-leading in Western music is provided by Huron (2001).

The principle of proximity states that notes are likely to be integrated into the same stream when they are close together in frequency or time. Most melodic writing conforms to a preference for movement by step or small intervals, an adherence to register, and minimal use of rests within a phrase. If other voices or parts are present, the same principles help prevent the notes of one voice being confused with those of others. Where larger melodic leaps do occur, it is very rare for the voice with the large leap to cross over the pitch of an adjacent voice. In the case of unaccompanied melodies, similar principles ensure the internal coherence of a single stream. The breakdown of such coherence, termed *stream segregation*, has been exploited by composers in the use of the technique of *compound melody* or *pseudo-polyphony*, whereby a single instrumental part can produce the percept

of multiple simultaneous streams (a technique popular in much Baroque music: see the works for solo violin or cello by JS Bach). Such examples demonstrate that proximity in the frequency domain is not an independent determinant of streaming, however, as there is a strong interaction with the rate of note presentation. The illusion of multiple interleaved melodies breaks down when the tempo is slowed down sufficiently. Both Miller and Heise (1950) and van Noorden (1975) found that below a minimum pitch proximity of around one semitone, tone sequences were always perceived as integrated, independent of the rate of presentation up to a note inter-onset time of around 500 ms, beyond which larger pitch differences could lead to an integrated percept at these slower rates. The critical pitch difference was termed the *trill threshold* or the *fission boundary* in the two studies, respectively. Van Noorden also identified the *temporal coherence boundary*, which is the pitch difference above which stream segregation is always heard. Between the fission boundary and the temporal coherence boundary, there is a range of ambiguity where tone sequences can be perceived as either integrated or segregated, depending on context and the individual listener.

Two more principles derived from the Gestalt tradition that are relevant to stream formation in the auditory context are those of *common fate* and *good continuation*. These apply both at the level of discrete notes and of spectral components from sounds that may or not be overlapping in time. The principal of common fate groups events that have synchronous features. The principle of good continuation (Bregman and Dannenbring 1973) would lead listeners to group notes together that form a coherent line, and a logical melody. This would work in conjunction with the preference for linear, stepwise or small-interval motion described above.

A further strong streaming or grouping principle in the auditory domain is that of harmonicity. This is the tendency to group together frequency components that all consist of integer multiples of the same fundamental frequency (Moore *et al.* 1985). As many of the sound sources we commonly encounter are harmonic, e.g. sounds deriving from vibrating strings and air columns, it is a very useful cue for grouping components from the same source. The influence of this phenomenon on contrapuntal writing and harmonic voice leading can be seen in the generally accepted practice of avoiding 'parallel fifths and octaves' between voices—such perfect consonances would be instances where all the resolved spectral components of both voices would be harmonically related, and hence an excessive degree or spectral fusion or grouping would result, leading to a loss of independence of the musical voices.

The broad principle of grouping by similarity does not rely on relatedness by pitch; it could work against a particular tendency of a pitch relationship to integrate or segregate a tone sequence. Examples of non-pitch similarity that influence streaming include timbre and temporal fine structure (Roberts *et al.* 2002; Stainsby *et al.* 2004a), level (Stainsby *et al.* 2004b), temporal envelope and apparent spatial location (Hartmann and Johnson 1991). In fact, Moore and Gockel (2002) argue that grouping by similarity can be so strong, that any perceptually salient acoustic attribute can induce streaming. Thus, the final effect of whether integration or segregation is perceived will be the result of the interaction of a number of, possibly competing, factors and the particular sensitivities of the individual listener.

Pitch in music, music-specific processes and constraints

It is evident that pitch is a continuous percept, which can take any value over a range of more than eight octaves. However, this is not the way musical traditions across many cultures use pitch. Instead, pitch is broken up into discrete piece-wise constant steps or quanta—the degrees of a scale. In Western music, the most common scales are the diatonic modes and the chromatic scale, while other musical cultures have their own individual scale systems, such as the *ragas* of North Indian music, *slendro* and *pelog* scales of Balinese gamelan music, or the *dastgah* of Persian music (Sadie 2001). The fact that musical traditions have adopted scales with discrete steps despite the fact that the most primary of all instruments, the human voice, is not bound by them, suggests that there is a perceptual requirement for such stepwise structuring of pitch. We can perceive frequency differences

that are much smaller than the semitone by which we are bound in Western tonal music (Sek and Moore 1995). Many Arabic scales routinely use quarter-tone steps, yet this does not mean music is composed that uses a 24-step equal-interval scale (Burns 1999). Instead, it uses unequal step sizes, some smaller than the semitone and others larger, so that there are still approximately seven steps to the octave (similar to the Western seven-step diatonic modes). A plausible justification for this is the limited information-handling capacity of the human listener. Across a variety of sensory modes, continua are routinely divided into approximately seven categories (Miller 1956). Humans are intuitively good at having a meaningful 'feel' and reference for approximately seven degrees of a quantity, but errors increase markedly beyond this. The use of musical scales with discrete steps can thus be seen as a method of ensuring the robustness of melodies within a musical tradition.

Linked to the use of discrete steps for a sensory continuum is the phenomenon of *categorical perception*. This refers to the ability to assign the same label to a whole group of broadly similar yet still different stimuli, and the related step-like jump in assignment to the next available label as soon as a stimulus crosses a category boundary. The phenomenon was first described in the perception of speech sounds (Liberman *et al.* 1967), but has since also been demonstrated for non-speech sounds (Locke and Kellar 1973; Miller *et al.* 1976) and for musical pitches (Burns and Ward 1978). A musical example is the tendency to group a range of disparate tunings, some flat and some sharp, to the same note, such as a 'c', while with just a little increase in pitch, a note abruptly changes from being a 'sharp c natural' to being a 'flat c sharp'.

It can readily be seen why a categorical mode of perception is necessary in speech communication, to accommodate the whole range of acoustically diverse sounds that come from different speakers of differing age, sex, and accent. It is plausible that similar forces have shaped the selection of the dominant scales in general musical practice. For example, although Harry Partch (Sadie 2001) developed a whole range of instruments with 43-tone temperament, and Schoenberg advocated the equality of 12 equally tempered semitones, diatonic melodies still dominate the common musical experience in Western performance practice. Admittedly however, there is also a mass of cultural and sociological factors that weigh on any purely perceptually driven evolution of musical fitness and acceptability in these cases.

If it is almost universal for music to be quantized into scale steps, the question arises as to what selects the particular intervals used. Nearly all the examples cited so far use intervals of non-equal size, so it is clear that we do not simply divide the octave neatly into seven equally tempered steps, as may at first appear a mathematically neat solution. The most plausible explanations are that melodic step sizes are selected for intervals that would work well in harmony with other voices, and that unequal step sizes enable listeners clearly to identify and differentiate between serial pattern structures. Harmonic intervals are preferred that maximize consonance, as discussed earlier (Plomp and Levelt 1965), and thus notes that would form such consonant intervals are preferred as scale degrees (Houtsma 1995). In the melodic domain, Trehub *et al.* (1999) showed that infants and adults showed a performance advantage in detecting mistunings in unequal-step scale melodies compared to those presented in equal-step scales.

It is interesting to note how pitch is generally used quite differently in music and language. Speech exhibits a variable pitch contour, with fundamental frequencies ranging over an octave (Fitzsimons *et al.* 2001). Variation in fundamental frequency shapes a phrase and gives clear emphasis to certain words. Meaning can be altered by placement of pitch accent, and whether an utterance is a statement or a question can be cued by the presence or absence of a rising pitch contour at the end of a sentence. This pragmatic function is probably the limit of pitch's contribution to many languages, particularly most European ones (Crystal 1969). However, pitch has explicit lexical significance in tonal languages, such as those found in South East Asia. As an example, Mandarin uses four tones, which when placed on the same combination of consonants and vowels, create words with totally different meanings. This is clearly a specific, categorical and semantic use of pitch,

which goes beyond an auxiliary role of emphasis or clarification. Note however that the four tones of Mandarin are not equatable with four tones of a musical scale. They are categorized as much by contour as by absolute pitch height. The fact that these tones are not arranged in scale steps highlights an important difference between the uses of pitch in music and language. There is still something approximate about pitch in language—there are very broad perceptual categories for pitch and there would need to be a gross difference in pitch before a tone boundary in a tonal language were crossed. Similarly, for the role of intonation and emphasis in European languages, the actual deviation in fundamental frequency contour could be scaled significantly without a change in meaning; it is the shape of the contour that is most significant. Both of these factors clearly do not apply to music in the same way. Sensitivity to tuning is quite precise in music, as only a small deviation from a target pitch is required for a musical performance to be judged as being out of tune. Additionally, melodies cease to be identifiable when the interval range is significantly expanded or compressed (Moore and Rosen 1979). In summary, the use of pitch in music differs from that in speech by articulating complex, set patterns of contour, encoded by the robust categories of scale steps.

Summary and conclusion

This chapter began with description of the basic physiology and psychophysics that enable pitch to be derived from the acoustic stimulus reaching our ears. The fundamental means of coding frequency in the neural pathways of the auditory system are the dual systems of place coding and temporal coding. While a fairly straightforward relationship can be seen between the physical quantity of frequency and the perceptual quantity of pitch in the case of pure tones, the case is more complicated and can remain ambiguous in the case of complex tones. The auditory system can analyse a range of information from many frequency components to arrive at a unitary percept of overall pitch. The argument was presented that this is an essential skill as part of the process of auditory scene analysis, whereby perceptual representations of distinct sound sources in our environment, so-called auditory streams, can be produced. The processes of auditory scene analysis and auditory streaming were further elucidated by a consideration of other grouping mechanisms such as common onset times, common fate, proximity and similarity. While on one level these processes group the spectral components of individual notes together, on a higher level they also group successive notes together to form melodies and counterpoint.

Finally, a consideration was presented of the different ways pitch is used in music and language. Music relies on the use of discrete, ordered sets of pitches called musical scales. The use of a finite set of discrete steps was argued to facilitate musical memory, melodic recognizability and robustness for transmission. By contrast, pitch in language can be seen to function in two main ways. In non-tonal languages, pitch contour is of primary importance, giving emphasis and inflexion, and distinguishing between a statement and a question. In tonal languages, tones differentiate lexical meaning, and as such absolute frequency values are more fundamental than in non-tonal languages. However, the use of tones in the former still differs significantly from that in music, as the categorical boundaries are significantly broader than in musical scales, and there is not the same use of specifically defined, intervallic steps along a musical scale.

CHAPTER 6

Tonal cognition

Emmanuel Bigand and Bénédicte Poulin-Charronnat

THE term *tonal music* can be applied to a large variety of musical styles in the West. This includes that of the four periods (Baroque, Classical, Romantic, and Modern) into which Western art-music is commonly divided, as well as other musical styles from popular traditions such as jazz, rock-pop music, reggae, and salsa. Pieces from these musical styles sound so different that it can be difficult to realize that they share some of the same features. The most basic is that they rest on a single set of 12 pitch classes, referred to as the chromatic scale, *c, c#/db, d, d#/eb, e, f, f#/gb, g, g#/ab, a, a#/bb, b.*[1] These 12 notes are recycled every octave leading to a large number of musical tones. However, the number of pitch classes (12) remains low, (see Chapter 5 this volume for more detailed information about the difference between *pitch height* and *pitch chroma*). This set of pitch classes is organized in subsets of seven tones referred to as diatonic scales. The fact that so many styles in West rest on a low number of pitch classes organized in small subsets of seven notes highlights the combinatory nature of Western music. The purpose of this chapter is to focus on this combinatory aspect. What type of organization in the tonal pitch structure allows producing so many different styles, and so many different pieces inside each style?

In order to address this issue, we start by considering the theoretical distinction between 'tonal' and 'event hierarchies'. The main features of tonal hierarchies are then summarized and we consider how these hierarchies may be parsimoniously represented. The influence of tonal hierarchies on music perception is then reviewed. To conclude this chapter, we briefly consider how tonal hierarchies contribute, along with other musical parameters, to the definition of an event hierarchy specific to a given piece.

[1] For convenience, musical notes will be represented by lower case letters in italics and chords by upper case letters.

Tonal and event hierarchies in Western music

A critical feature of Western music is its hierarchical organization (Lerdahl and Jackendoff 1983; Meyer 1973; Schenker 1935). This is not to say that all structures in Western music are of hierarchical nature. Associative relations (between thematic cells, for example) also contribute to musical structure. However, the possibility of organizing musical events in a hierarchy of structural importance has deep implications for the listeners. A simple way to understand the concept of hierarchy is to consider that musical events are not all of equal importance: some are structurally important, while others are primarily ornamental. Ornamental events have aesthetic and expressive qualities but they do not contribute to the structure of the piece per se. Removing the ornamental notes does not alter the perceptual identity of a melody, while removing structural tones would modify the melody greatly (Dibben 1994; Mélen and Deliège 1995). If musical events were strictly of equal importance, pieces would sound like monotonous strings of sounds. By contrast, the presence of a hierarchy confers dynamic qualities on musical pieces that have powerful psychological implications: ornamental events seem to 'go towards' events of structural importance, which in turn tend to 'go towards' events

hierarchically more important, and so on across the extent of a piece.

Like linguistic discourses, music is a time-oriented structure that progresses from a beginning to an end. If the music stops at some point before the end, most listeners will realize that it has been irregularly interrupted (Bigand 1993; Palmer and Kruhmansl 1987). In a related vein, playing a piece backwards would strongly alter its perceptual identity because the dynamic relationships between tones would be reversed. Let us consider the set of tones *b-c-d#-e-f#-g*. This set of tones is perceived as a melody in the key of C major when played forwards but as a melody in B major when played backwards (Bharucha 1984). In the former case, the tones *b*, *d#*, and *f#* are perceived as ornamental tones anchored on the structurally important tones of the C major chord (*c-e-g*). Playing the tune backwards reverses the relationships between musical events, and the tones *g*, *e*, and *c* are now perceived as ornamental tones anchored to the structurally more important tones of the B major chord (*f#-d#-b*). This change in perceptual organization may be metaphorically compared with the change in meaning that occurs when a sentence is read in a retrograde way (the boy calls the girl *versus* the girl calls the boy). In the first sentence, *the boy* is anchored to the verb *calls*. In the second sentence, *the girl* is anchored to that verb. In language, the main aspect of syntactic computation is to understand 'who is doing what to who'. Similarly, the core aspect of tonal cognition is to perceive 'which tones anchor which tones'. Solving such a problem reminds us of syntactic computation, because musical events can be deeply anchored to the overall structure of the piece: a given tone can be anchored to another one, which may be, in turn, anchored to another one, and so on. Organizing the pitch events of a piece into a single coherent structure, in such a way that the pitch events are heard in a hierarchy of relative importance, is the most fundamental aspect of tonal cognition for Western music (Lerdahl and Jackendoff 1983).

Where do hierarchies between events come from? Two types of hierarchies have been distinguished in music cognition (see Bharucha 1984; Krumhansl 1990; Lerdahl 1989). The term 'tonal hierarchy' was used to designate an atemporal schema of pitch regularities, specific to Western music, which is stored in long-term memory (see Chapter 2 this volume). It embodies the hierarchical relations that accrue to an entire tonal system beyond instantiation in any particular piece. It is atemporal in that it represents more or less permanent knowledge about the musical system rather than a response to a specific sequence of events. Tonal hierarchies thus designate the regularities in pitch that prevail for all styles of tonal music. By contrast an 'event hierarchy' is a hierarchy of specific pitch–time events inferred from the ongoing temporal sequence of musical events. In the next sections, we will focus on tonal hierarchies however, in conclusion, we will briefly consider how tonal hierarchies influence event hierarchies.

Tonal hierarchies: intra-key hierarchies and inter-key distances

The main aspects of tonal hierarchies can be summarized in the following way. From a set of 12 pitches, several subsets of seven pitches are defined, each defining a musical key. A musical key is defined in reference to a specific tone which is called the tonic tone and that gives its name to the key. Since there are 12 tones, there are 12 possible tonics. In Western music, some subsets of tones form major keys. Others form minor keys. For example, the C major key is made of the following tones: *c-d-e-f-g-a-b*. The C minor harmonic key is made of the tones, *c-d-e♭-f-g-a♭-b*. In both cases, the pitch *c* is the tonic. Major and minor correspond to two different scales of pitch intervals. For example, the set of pitch intervals separating the tones of the C major key is tone-tone-semitone-tone-tone-tone-semitone. This set defines a scale that is constant for all major keys. In a minor harmonic key, the scale is different: tone-semitone-tone-tone-semitone-one tone and a half-semitone. Applying these major and minor scales to each tone of the chromatic scale defines 24 major and minor keys.

The critical aspect of the tonal pitch system relates to the organization of pitches within keys (referred to as intra-key hierarchies), and to the organization that exists between the 24 major and minor keys (referred to as inter-key distances). Kruhmansl and collaborators (see Krumhansl

1990, for a complete account) have investigated intra-key hierarchies with a 'probe tone' method, which consists of playing a test tone (the probe) after a musical context in a given key. Participants have to evaluate on a seven-point scale how the probe tone fits with the context. The 12 tones of the chromatic scale are presented as probe tones. It was found that all the probe tones did not received the same ratings of 'goodness of fit'. In major key contexts, the highest rating was given to the tonic note (the tone *c* in C major), followed by the fifth degree of the scale (*g*), and then the third degree (*e*), the fourth (*f*) and the remaining tones of the key (*d-a-b*). The tones that do not belong to the key (the 'non-diatonic tones'), received the lowest ratings. This set of values defined the C major key profile (Figure 6.1, top). The reader could easily obtain the profiles of all the other keys by translating these profiles to all the remaining tonics. As illustrated by Figure 6.1 (bottom), the ratings found when minor keys were used as context differed in an interesting way; the tonic remains the tone that fits the best with the key context, but then comes the third scale degree (*e♭*), followed by the fifth and the sixth scale degrees (g and *a♭*, respectively). The other diatonic tones received lower ratings, and the non-diatonic tones, the lowest. The minor key profile remains the same for all other minor keys but it has to be translated towards the tonic of the given key context. Important tones in these key

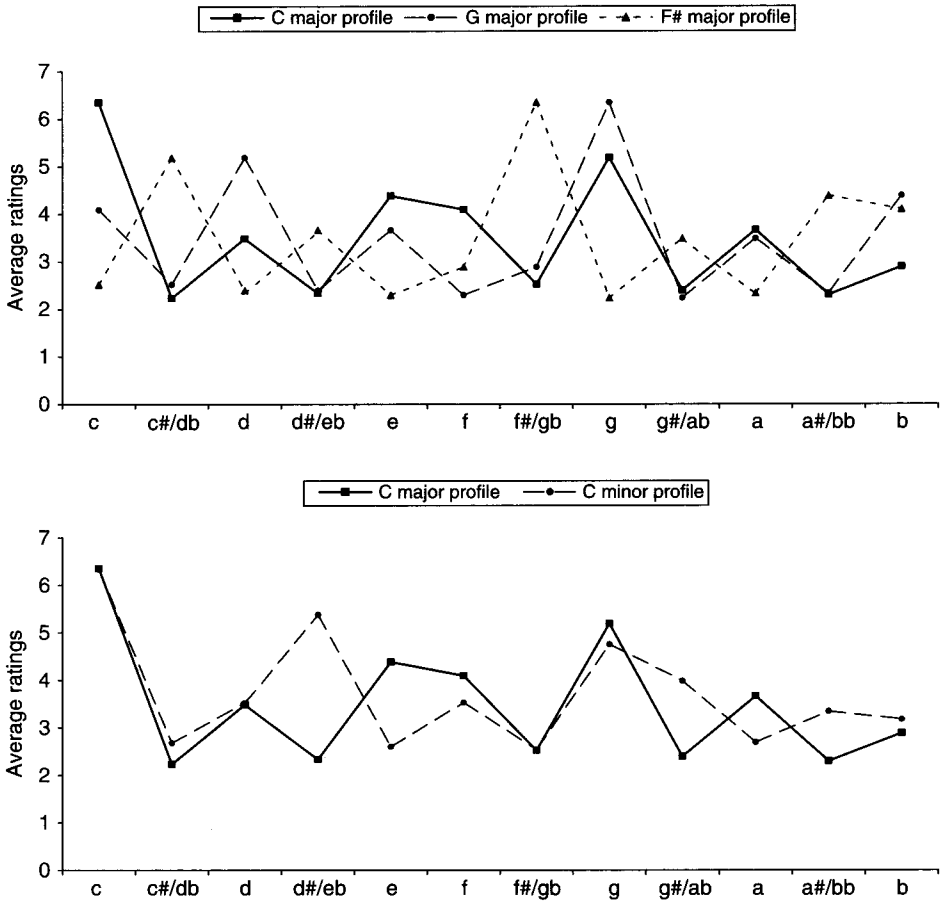

Fig. 6.1 Key profiles in the keys of C, G and F# major (top) and in the key of C major and C minor (bottom), after Krumhansl (1990).

profiles act as cognitive reference points that anchor all other events. In Western tonal music, the tonic is thus the most important cognitive reference point that anchors all the other tones (Schenker 1935).

Within a key, tones may be grouped to define larger musical units called chords. A chord is the simultaneous or sequential sounding of, at least, three different tones.[2] The three basic component tones of a perfect major or minor chord (also called a triad) are separated by one scale degree. For example, the C major triad is made of the tones *c-e-g*. The E minor triad is made of the tone *e-g-b*. The first interval defines the third of the chord. In a major chord, the third corresponds to a pitch interval of 4 semitones (*c-e*). In a minor chord, the third is made of a pitch interval of three semitones (*c-e♭*). The second interval defines the fifth of the chord. Since there are seven tones per scale, there are seven chords in each key, some being major, others minor, and others diminished.[3] Over all the keys, there are 12 major, 12 minor, and 12 diminished chords. Chords are important events for Western music: they define harmonic frames from which thematic units derive. Vincent d'Indy (1900) metaphorically compared the themes of a musical piece to the actions of a drama, and the relationships between chords to the places where the actions occurred. This points up the fact that the relationships between chords (i.e., the harmony) are of considerable importance in defining the structure of a given piece.

In Western music, the relationships between chords are also of a hierarchical nature; some chords are structurally more important than others. Using the probe tone method, Krumhansl *et al.* (1982) investigated the hierarchies between chords. Goodness of fit ratings varied significantly with the chords: in major key context, chords build on the first scale degree (referred to as the tonic chord) received the highest ratings, followed by the chords build on the fourth and fifth scale degrees (respectively referred to as subdominant and dominant chords). The other chords received lower ratings. Among all the major chords, those that did not belong to the key context received the lowest ratings. In other words, a harmonic hierarchy was found between chords.

The last main aspect of tonal hierarchies relies on the distance between the 12 major and 12 minor keys. Some keys share more tones and chords than others. For example, the key of C and G major share 6 tones and 4 chords, while the key of C major shares only 3 tones and no chord with the key of E major. These relationships are reflected on the chromatic circle of fifths (C-G-D-A-E-B-F#/G♭-C#/D♭- G#/A♭-D#/E♭-A#/B♭-F). The higher the number of steps between two keys, the fewer the common tones and chords shared by the keys. Major keys share also tones and chords with minor keys. For example, C major and A minor share six tones and three chords. The number of tones and chords shared by keys contributes to define musical distances between the keys, with keys sharing numerous tones and chords being closer than others.

From a psychological point of view, the musical distances between keys is more complex that this simple computation. Krumhansl (1990) demonstrated that the perceptual distance between keys is expressed by the correlation that exists between the hierarchical profiles of the keys: the higher the correlation, the closer the keys. This finding suggests that keys are not only related because they share several tones, but also because hierarchically important tones in one key continue to be of importance in others. The hierarchical organization of tones and chords thus changes less between two related keys than between two distant ones. For example, the keys of C major and C minor are musically related although they do not share many tones and chords (four tones, and no chord). However, in both keys, the notes *c* and *g* act as the two most important reference points which anchor the other tones. In a similar way, the key of C major is close to its relative minor key (i.e., A minor). Indeed, the tones *c* and *e* that are hierarchically important in the former key continue to act as referential points in the latter. As a consequence, every major key (C, for example) is close to two minor keys (its parallel and relative minor keys; C

[2] The sounding of two sounds defines an interval, not a chord. More complex chords contained additional tones. For example, the famous dominant seventh chord is made of the tones *c-e-g-b♭* in the F major key, and chords containing two or three ornamental tones are frequent in jazz and bossa nova (as in the major ninth chord *c-e-g-b-d*, or the minor ninth chord *d-f-a-c-e*).

[3] The C major key is made of the following chords: C major (*c-e-g*), D minor (*d-f-a*), E minor (*e-g-b*), F major (*f-a-c*), G major (*g-b-d*), A minor (*a-c-e*), and B diminished (*b-d-f*).

and A minor) and two major keys (those that are separated by one step on the circle of fifths: G and F major). Every major key is also indirectly close to the relative minor keys of the major keys that surround it (C major is close to E minor which is the relative minor of G major). The 12 major and 12 minor keys thus define a complex net of musical relationships (Figure 6.2, bottom).

Moving from one key to another results in a mental reorganization of the hierarchical values of tones and chords. This reorganization is as strong as the new key is distant from the previous one. These changes in cognitive reference points are experienced in an expressive way by listeners. Moreover, the expressive quality of a modulation (i.e., a change in key) is held to depend upon the distances between the two keys: the farther away the keys, the stronger the cognitive reorganization of reference points, and the stronger the expressive effect. As the 12 major and 12 minor keys define a complex net of keys, an almost infinite number of ways exists to modulate from one key to another and to express different feelings for/in listeners.

Two models of tonal hierarchies

Notes, chords, and keys define three levels of entwined structures that allow Western composers to invent an infinite number of expressive musical pieces. An important issue for cognitive psychology is to capture in a single parsimonious model the creative power of such a musical system. In the present section, we will consider two models of Western pitch structures that derive from different scientific backgrounds.

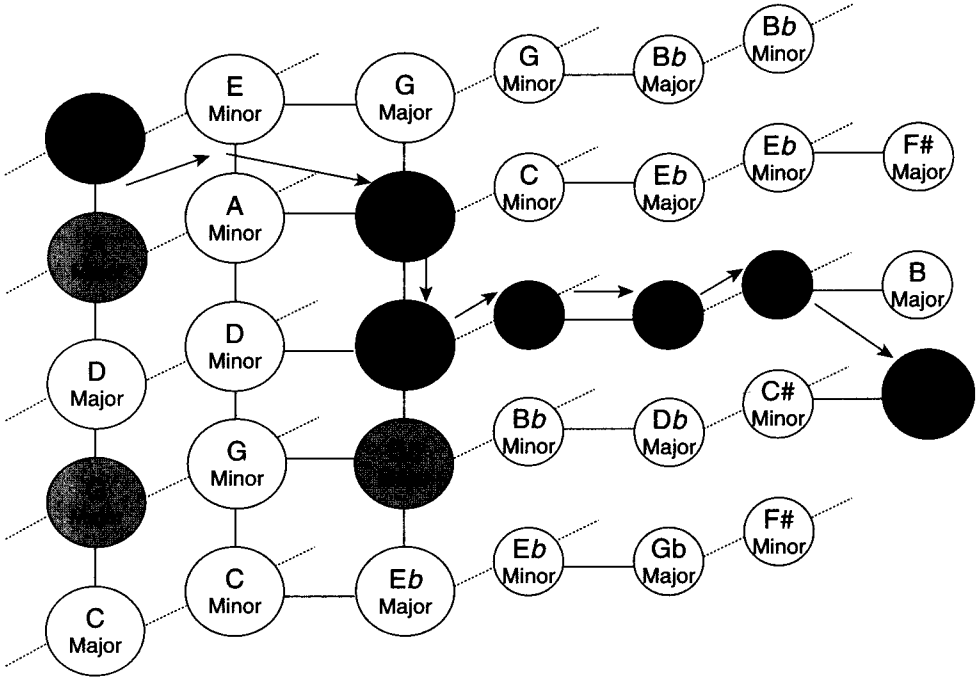

Fig. 6.2 Pitch class level (top) and regional level (bottom) of Lerdahl's tonal pitch space theory. The arrow illustrates the journey through pitch space of Chopin's E major prelude (adapted from Lerdahl 1991).

The Tonal Pitch Space Theory (TPST), initially described by Lerdahl (1988) and further developed in Lerdahl (1991, 1996, 2001) rests on a long tradition of representing the structure of Western music as a multidimensional space (Longuet-Higgins 1978; Krumhansl 1990; Shepard 1982). In such an approach, tonal hierarchies are represented in a space so that the distances between tones and chords from the instantiated tonic correspond to their relative hierarchical importance: the smaller the distances from the tonic, the stronger the importance. Lerdahl's TPST provides a formal means of quantifying the tonal distances maintained between any two events belonging to any key. Tonal hierarchy is represented in three embedded levels, the first two (pitch class and chordal level) representing the intra-key hierarchy, while the third (regional level) represents the distance between keys. The pitch class level expresses the relationships between the 12 pitch classes. It contains five sublevels corresponding to the chromatic level (1), the diatonic level (2), the triadic level (3), the fifth level (4) and the tonic level (5) (Figure 6.2, top). This basic space expresses Krumhansl and Kessler (1982)'s key profiles of Figure 6.1. In a given context (say, a C major chord in C major), the tonic tone (*c*) will be represented at all five levels. The dominant and the mediant tones (*g* and *e*) will be represented up to levels four and three, respectively. The diatonic tones are represented at level two and non-diatonic tones are represented at level one only. The level at which a given pitch class is represented thus expresses its importance in the tonal hierarchies of the key context. Hierarchies between pitch classes change as a function of context. For example, a C major chord in G major will produce a single change in pitch class (the f# will be now represented at level 2 and the f at level 1). The core idea of TPST is to quantify the tonal stability of each event (i.e., its place in the tonal hierarchy) by computing the number of changes in pitch classes it introduces in the context.

Let us consider the second level of the model, which involves the hierarchies between chords within a given key. The hierarchical values of the chords depend upon their distance to the tonic. This distance is measured in the model by the number of steps that separates the chords on the diatonic circle of fifths (C-G-D-A-E-B-F) and the number of changes in pitch class created by the second chord. In C major, the G major chord stands one step apart from the C major chord on this circle, and it creates four changes in pitch classes by reference to the C major chord. As a consequence, its distance to the tonic chord equals five. Similarly, the tonal pitch space distance of the subdominant chord (F) is five, but the distance of the other chords, hierarchically less important, is higher (e.g., eight for the supertonic chord D minor). These distances express the local changes in hierarchies between tones that prevail when music moves from one chord to another. These changes are experienced by listeners as musical tensions (when the distance increases), or as musical relaxations (when the distance decreases) (Bigand *et al.* 1996). The set of distances traveled through pitch space by a musical sequence thus captures the dynamic quality of the sequence.

The two previous levels would suffice to account for intra-key hierarchies. The third level (regional level) deals with the distances between the 24 keys. The model accounts for key distances by measuring the number of changes in hierarchies between tones and chords consecutive to a shift towards a new key. Not surprisingly, the TPST computes small distances between keys that are one step apart on the chromatic circle of fifths (C, G, and F, for example, which have a distance of 7) and between keys that are related according to parallel and relative minor/major relations (C and C minor, C and A minor). The greatest distance computed by the TPST (30) is found between a given key and its augmented fourth key (C and F# major keys). The distance between two chords belonging to different keys depends upon the way the two chords are interpreted. Given that chords may belong to different keys, this distance can be reduced when the two chords are interpreted as chords of closely related keys. For example, the distance between a C major chord and a C# minor chord equals 30 if the latter chord is analysed as the tonic chord of the C# minor key. The same distance equals 23 if the C# minor chord is analyzed as a member of the E major key. By default, the model would compute the shortest distance. Figure 6.2 (bottom) illustrates how the 24 keys may be organized in a two-dimensional space. Circle of fifth relationships are represented on the vertical axis, and

parallel/relative minor/major relationships are represented on the horizontal axis. Modulating to G, F, E, or C minor from the C major key would result in smaller movements than modulating to a musically less related key (e.g., A♭).

Lerdahl suggests that listening to music corresponds to a journey through pitch space. The arrows of Figure 6.2 illustrate a journey provided by the Chopin prelude in E major. The first part of the prelude remains in E major, with local movements from one chord to another. The second part introduces an intense journey from E to the A♭ major and a fast return to the main key of E. There seems no doubt that the expressive quality of this prelude comes from the velocity at which this journey from E to A♭ occurs during the second phrase (Bigand 2003). The TPST is a musical model of tonal hierarchies that has both theoretical and empirical roots, and that has received support from several empirical studies (Bigand and Parncutt 1999; Bigand *et al.* 1996; Krumhansl 1996; Lerdahl and Krumhansl 2007; Smith and Cuddy 2003; Vega 2003). The TPST is helpful in investigating challenging assumptions about tonal cognition and it has a number of psychological implications (see Bigand 2003). However, it may be viewed as a rather ad hoc complex model, difficult to implement in an automatic way in an artificial system, and of which the architecture is too abstract, as it stands, to correspond point by point to real cognitive processes.

An alternative account of tonal hierarchies that has roots in cognitive psychology and computational sciences has been proposed by Bharucha (1987). Following McClelland and Rumelhart's interactive model of lexical access (McClelland and Rumelhart 1981; Rumelhart and McClelland 1982), Bharucha defines a three-layer interactive model that links tones, chords, and keys. In this model, tone units are connected to all major and minor chords to which they belong (Figure 6.3a). These chords are, in turn, linked to each of the major key units to which they belong. An important musical limitation of the model is that only major and minor triads are represented, and that the model does not contain minor keys. However, the model captures interesting features of tonal hierarchies. For example, when a given triad is sounded (say the tones *c-e-g*), the activated tone units send activation towards all the chord units to which they are connected (Figure 6.3b). At the second iteration, these chord units propagate activation towards the keys to which they are related, and backward to the tones they are connected to (Figure 6.3c). As a consequence, tone units that were not in the stimulus start to be activated. For example, the tone *a* receives some activation from the F and A major chords and the A minor chord that were stimulated by the tones *c* and *e*. At the third iteration, these new activations of the tones propagate towards the chord level. At the same time the activation of the key level spreads backward to the chord units (Figure 6.3d). Since the C major key was active, all the chords of the C major key now start to be stimulated. During the next iterations, all of these activations spread backward and forward up to a point of equilibrium where spreading activation is so small that it does not change the overall state of the network. The interesting point is that this model of MUSical ACTivation (MUSACT) nicely expresses tonal hierarchies. For example, after a C major triad, the most activated chord units correspond to the tonic chord (C), the dominant and subdominant chords (G and F). The activations decrease progressively as long as chords are musically distant from the C major chords. The pattern of activation found for the key units also reflects the inter-key distances. For example, after a perfect cadence in the C major key, the C major key unit is the most activated unit, and this activation decreases as a function of the musical distances from the C major key.

In this model the knowledge of tonal hierarchy is expressed by the pattern of activation that spreads automatically towards tone, chord, and key units. Closely related events lead to a highly correlated pattern of activation, distant events, to negative correlations. In a given context, the amount of activation found for each unit (tones or chords) represents their hierarchical importance in the context. MUSACT thus captures features of tonal hierarchies that are strongly similar to those accounted for by Lerdahl's TPST, but with a completely different architecture. In MUSACT, the tonal hierarchies are represented in a distributed way by the weights of the connections that link tones to major and minor chord units, and chord units to key units. The specific values of these weights were defined ad hoc in the pioneer work by Bharucha (1987),

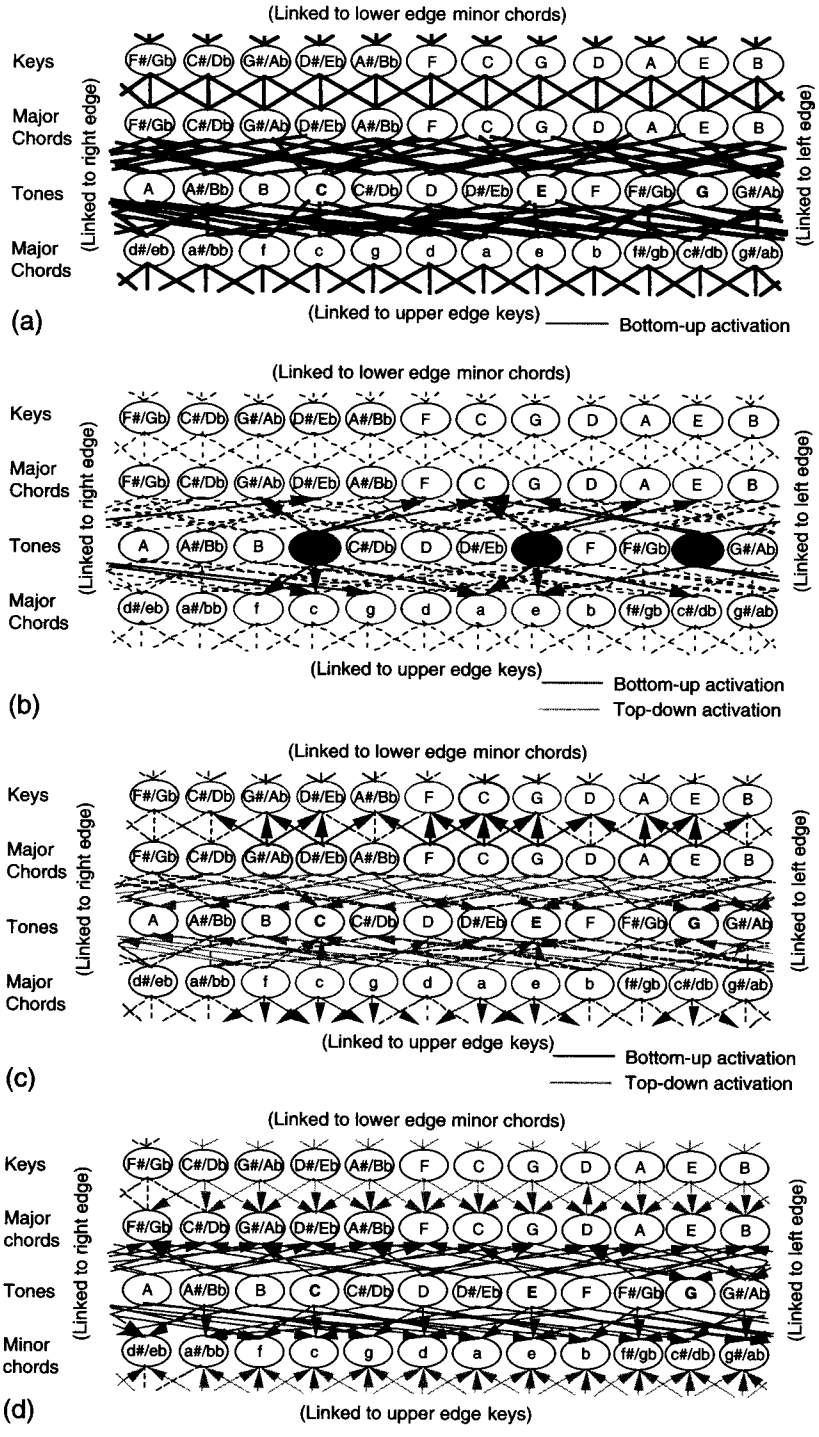

Fig. 6.3 Bharucha's MUSACT model. (a) When three tones are sounding, activation spread from tones to chord units (b), and then from chord to key and tone units (c), and from key units to chord and from tone to chord units (d) and so on up to equilibrium. See also colour plate section.

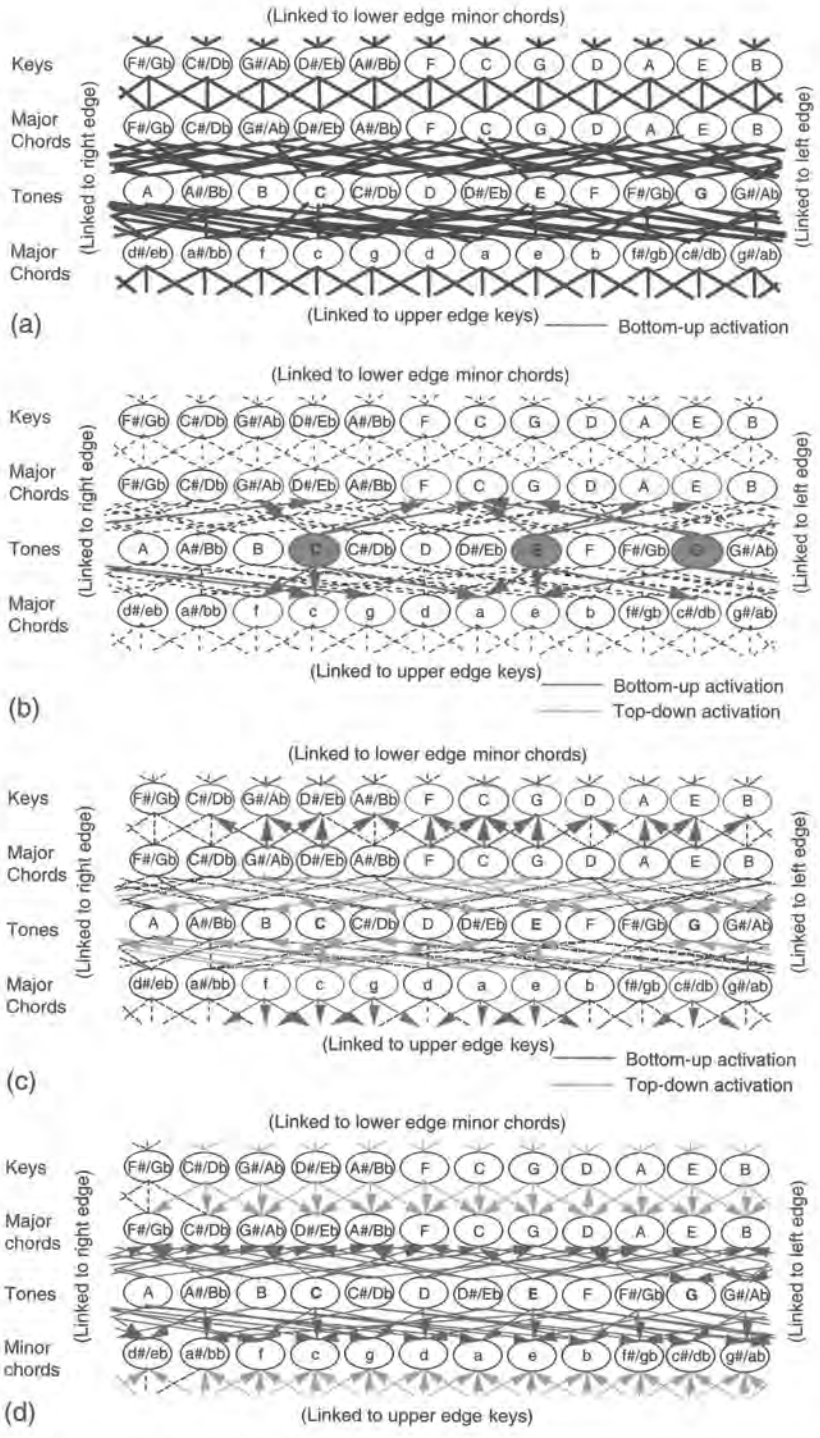

Fig. 6.3 Bharucha's MUSACT model. (a) When three tones are sounding, activation spread from tones to chord units (b), and then from chord to key and tone units (c), and from key units to chord and from tone to chord units (d) and so on up to equilibrium. See also colour plate section.

but it has been demonstrated that these weights may arise from a learning process that occurs automatically when the neural network is exposed to Western music (Tillmann *et al.* 2000).

Influences of tonal hierarchies on Western music perception

Much evidence has been collected demonstrating the influence of tonal hierarchies on music perception. For example, Francès (1958) required musicians to detect mistuned notes in piano pieces. This mistuning was performed in different ways. In one condition, some musical notes were mistuned in such a way that the pitch interval between the mistuned notes and those that anchored them was reduced. For example, the leading note (*b* in C major) which is hierarchically weakly important is generally anchored by the tonic note (*c* in C major). Francès mistuned the leading tone by increasing its fundamental frequency (F0) so that the pitch interval between the leading tone and the tonic was reduced. In the other experimental condition, this mistuning was performed in the opposite way. When played without a musical context, participants easily perceived both types of mistuning. Placed in a musical context, only the second type of mistuning (which conflicted with musical anchoring) was perceived. This outcome shows that the perceptual ability to perceive the shift of the F0 of a musical note is modulated by top-down processes that integrate the note into tonal hierarchies. More generally, performers such as violinists or cellists constantly adjust the fundamental frequency of the tones in order to make as clear as possible the way in which these tones are anchored by the hierarchically important tones of the context. This expressive intonation, which is entirely related to the tonal hierarchy, considerably increases a listener's comprehension of the musical discourse.[4]

Tonal hierarchies also influence the perception of melodic contour. Several experiments demonstrate that discriminating a small change in a contour is more difficult when the standard and the comparison melodies are in distant, rather than close, keys (Dowling 1986). Several experiments run by Krumhansl and collaborators (see Krumhansl 1990) demonstrate the influence of tonal hierarchy on the perceptual distance of tones and chords and on their memorization. This influence can be summarized in terms of three contextual principles. The perceptual distance between two events (tones or chords) increases when these events are of hierarchical importance (contextual distance). The perceptual identity of two instances of a given event increases with its hierarchical importance (contextual identity). Two occurrences of the chord C would sound more similar if they occurred in a C major key context rather than in a distant key context (say, in an F# key context). Finally, the perceptual distance of two events depends on their sequential occurrence: the distance decreases when the hierarchically strong important event occurs after the other one (i.e., anchoring principle). It increases in the other case (contextual asymmetry). Krumhansl and collaborators demonstrate that these principles account for confusion errors in memory. For example, it is easier to detect that two occurrences of a seven chord sequence are identical when these chords belong to a single key (diatonic sequence; 69.3 per cent) than when they belong to different keys (55 per cent), illustrating the principle of contextual identity. When the second occurrence of the sequence contains a different chord, it is easier to detect the difference when the chord is changed for a chord belonging to another key than when it remains in the same key (86 per cent *versus* 56.9 per cent). This illustrates the principle of contextual distance. Finally, when the initial sequence is diatonic and the comparison sequence contains a non-diatonic chord, the change is easier to detect (86.8 per cent) than when the first sequence contains a non-diatonic chord that is replaced in the second sequence by a diatonic chord (61.3 per cent). This illustrates the principle of contextual asymmetry.

The influence of tonal hierarchy on the memorization of melody may be very impressive. In one experiment (Bigand 1997), participants were required to listen several times to a target melody

[4] The reader would find a remarkable demonstration of such expressive intonation in Casals' performances of the cello suite by Bach.

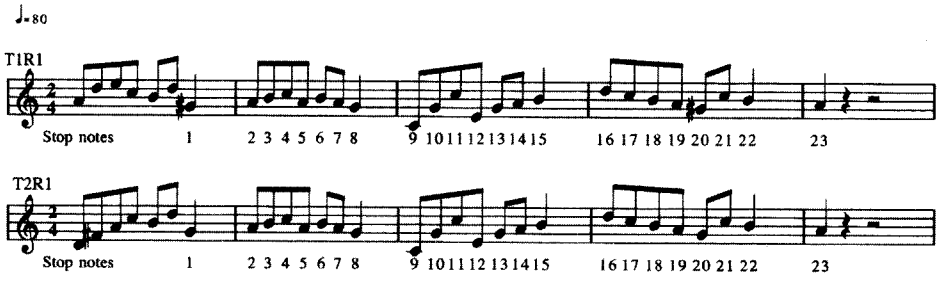

Fig. 6.4 Examples of standard and comparison melodies used in Bigand (1997).

such as the melody in A minor represented in Figure 6.4 (top). Participants were then presented with new melodies and were asked to evaluate how many pitches had been changed in comparison to the standard. Figure 6.4 (bottom) displays one of the comparison melodies used. As can be seen, it contains most of the tones of the standard. Only a few tones have been changed in order to instill the key of G major at the beginning of the melody. This new key context was assumed to modify the hierarchical weights of the melodic tones. Indeed, the *a* is no longer a tonic tone in this comparison melody, but a weakly important supertonic tone. The reader is invited to use the key profiles of Figure 6.1 to understand how much the hierarchical weights of the tones have been changed in the comparison melody. Not surprisingly, the participants (musically trained and untrained listeners) evaluate that about 66 per cent of the tones have been changed in the comparison melody, that is to say, much more than what has actually been done.

The influence of tonal hierarchies has been reported in several other studies in which participants were asked to evaluate the degree of completion or the degree of musical stability experienced at different points of a musical sequence. Ratings of completion or musical stability were higher when the music stopped on hierarchically important events (Bigand 1993, 1997; Palmer and Krumhansl 1987). A similar result was found for chord sequences (Bigand and Parncutt 1999; Bigand *et al.* 1996). In recent studies, a continuous measure of musical stability has been used, and data were found to correlate significantly with tonal hierarchy (Krumhansl 1996; Lerdahl and Krumhansl 2007). Other studies have investigated the influence of tonal hierarchies on the speed at which some musical features are processed. In Bharucha and Stoeckig's (1986) chord priming experiments, the participants were required to decide accurately but as fast as possible whether a target chord was in tune or out of tune. For the purpose of the experiment one component tone of the chord was slightly mistuned in half of the trials. The target chord was preceded by a chord prime. The critical point of the study was to assess whether the processing of the sensory consonance of the target chord would be modulated by the harmonic relationship of the two chords. The authors provided evidence that consonant target chords were more accurately and more quickly identified as consonant when they were preceded by a related prime (e.g., C and G chords) than by an unrelated prime (e.g., C and F# chords). An opposite finding was found for dissonant targets. Bharucha and Stoeckig argued that a given context primes the processing of chords that are musically related in the context, a finding which is reminiscent of semantic priming effects reported in language (McNamara 2005). Further experiments attempted to demonstrate that this priming effect in music occurs at a cognitive level and does not result from the overlap in harmonic spectra of both chords (Bharucha and Stoeckig 1987; Tekman and Bharucha 1998).

The influence of tonal hierarchies on perceptual expectancy in long musical contexts has also been investigated with the priming paradigm (Bigand and Poulin-Charronnat 2006, for a review). In our experiments, participants were presented with chord sequences (of 8 or 14 chords depending on the studies) that ended on

a target chord. The target acted either as a tonic or as a subdominant chord depending upon the context. The chord preceding the target was always kept constant, except when the local and global harmonic contexts surrounding the target were simultaneously manipulated (Tillmann *et al.* 1998). In most of the studies, participants were required to indicate as quickly and as accurately as possible whether the target chord was consonant or dissonant. Dissonant targets contained a supplementary tone, a half tone above or below a triadic tone. In more recent studies, target chords were played with two different timbres which participants had to identify as fast and accurately as possible (Tillmann and Lebrun-Guillaud 2006). Processing the sensory consonance of the target or its harmonic spectra was always faster and easier when the target acted as a hierarchically important tonic chord. This effect is extremely robust since it has been replicated for relatively long chord sequences organized at three hierarchical levels (Bigand *et al.* 1999), for normal and scrambled musical sequences (Tillmann and Bigand 2001), for chord sequences that have extremely poor voice leading (Poulin-Charronnat *et al.* 2005a), and even when sensory priming was manipulated in order to favour the subdominant target (Bigand *et al.* 2003). Harmonic priming was also found to be stronger than repetition priming (Bigand *et al.* 2005), and to modulate the processing of linguistic information in sung music (Bigand *et al.* 2001; Poulin-Charronnat *et al.* 2005). Finally, it was observed for musically trained and untrained listeners (Bigand and Poulin-Charronnat 2006, for a review), as well as with young children (Schellenberg *et al.* 2005). This large set of consistent data highlights the strength of tonal hierarchies on the formation of musical expectancies.

It is likely that tonal hierarchies influence several other aspects of music perception. In one recent study, we investigated how the tonal hierarchy influences emotional responses to music (Filipic and Bigand 2003). Participants were required to decide as fast and as accurately as possible whether two musical sequences expressed the same or different emotion. Musical sequences that were qualified as either sad or serene in Peretz *et al.*'s (1998) studies were used and the participants were informed that all stimuli fall into one of these two emotional categories. In half of the trials, the musical pieces were in the same keys. In the other half they were in distant keys. We found that emotional responses were faster and more accurate when both pieces were in the same key. This finding suggests that interpreting the tones in a tonal key context is a prerequisite for the recognition of the emotional value of the stimuli.

From tonal hierarchies to event hierarchies

The critical importance of the tonal hierarchy is to contribute to instilling an event hierarchy specific to a given piece. As formalized in Lerdahl and Jackendoff's Generative Theory of Tonal Music (1983), the tonal hierarchy provides the stability conditions that need to be integrated into rhythmic parameters (notably) in order to define the structural importance of each tone of the piece. The structural importance of a musical event thus depends upon its place in

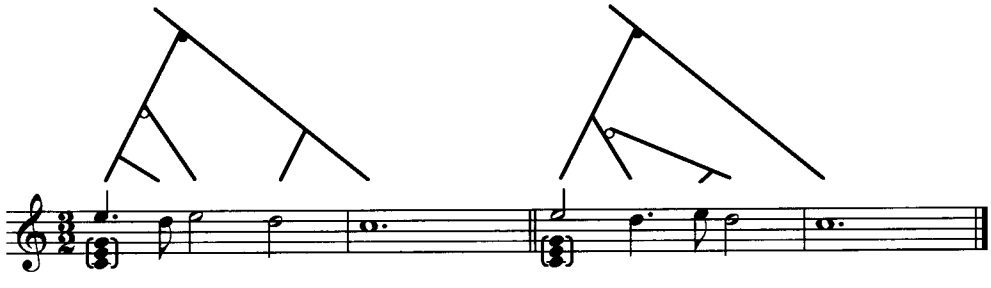

Fig. 6.5 Influence of tonal hierarchies and rhythm on event hierarchies. Inspired by Lerdahl and Jackendoff (1983) with the help of the first author.

tonal hierarchy and the rhythmic context in which it appears. A tonic note of a given melody would not always act as a structurally important tone. Depending upon the group of tones in which it appears as well as its duration and its metrical position, a tonic note may act as an ornamental event in the event hierarchy. Modifying the rhythm of a set of tones is enough to change the event hierarchy as expressed in the following example (Figure 6.5). The *e*, which is an important tone in the C major key context, may act as an important anchoring tone in some rhythmic contexts (Figure 6.5 left) but not in others (Figure 6.5 right). This point is most crucial as it means that the tonal hierarchy is considerably modulated by numerous other musical parameters such as rhythm, loudness, and timbre. These parameters are adjusted by the composer and the performer in numerous ways, leading to a quasi infinite number of possible event hierarchies. The combination of tonal and event hierarchies creates a great unity in a quasi-infinite variety of Western musical pieces.

CHAPTER 7

The perception of musical timbre[1]

Stephen McAdams and Bruno L. Giordano

TIMBRE is a misleadingly simple and vague word encompassing a very complex set of auditory attributes, as well as a plethora of psychological and musical issues. It covers many parameters of perception that are not accounted for by pitch, loudness, spatial position, duration, and various environmental characteristics such as room reverberation. This leaves a wealth of possibilities that have been explored over the last 40 years or so. We now understand timbre to have two broad characteristics that contribute to the perception of music: (1) it is a multifarious set of abstract sensory attributes, some of which are continuously varying (e.g. attack sharpness, brightness, nasality, richness), others of which are discrete or categorical (e.g., the 'blatt' at the beginning of a sforzando trombone sound or the pinched offset of a harpsichord sound), and (2) it is one of the primary perceptual vehicles for the recognition, identification, and tracking over time of a sound source (singer's voice, clarinet, set of carillon bells), and thus involves the absolute categorization of a sound (Hajda *et al.* 1997; McAdams 1993; Risset and Wessel 1999). The psychological approach to timbre has also included work on the musical implications of timbre as a set of form-bearing dimensions in music (McAdams 1989).

Timbre as a multidimensional set of auditory attributes

One of the main approaches to timbre perception attempts to characterize quantitatively the ways in which sounds are perceived to differ. Early research on the perceptual nature of timbre focused on preconceived aspects such as the relative weights of different frequencies present in a given sound, or its 'sound color' (Slawson 1985). A voice singing a constant middle C while varying the vowel being sung, or a brass player holding a given note while varying the embouchure and mouth cavity shape would both vary the shape of the sound spectrum, which represents the level of each sound partial as a function of its frequency (cf. McAdams *et al.* 2004b). Helmholtz (1885/1954) invented some rather ingenious resonating devices for controlling spectral shape to explore these aspects of timbre. However, the real advances in understanding the perceptual representation of timbre had to wait for the development of multidimensional data analysis techniques in the 1960s and signal processing techniques in the 1970s. Plomp (1970) and Wessel (1973) first applied these to timbre perception.

Timbre space

Multidimensional scaling makes no preconceptions about the physical or perceptual structure of timbre. Listeners simply rate on a scale varying from very similar to very dissimilar all pairs from a given set of sounds. The sounds are usually equalized in terms of pitch, loudness, and duration so that only the timbre varies in order to focus listeners' attention on this attribute. The dissimilarity ratings are then fit to a distance model in which sounds with similar timbres are close together and those with dissimilar

[1] This chapter is an updated version of two previous summaries of musical timbre research (McAdams, 1999, 2003).

timbres are far apart. The graphic representation is called a 'timbre space'. The basic model is expressed in terms of continuous dimensions that are shared among the timbres, the underlying assumption being that all listeners use the same perceptual dimensions to compare the timbres. More complex models also include dimensions or features that are specific to individual timbres (called 'specificities') and different perceptual weights accorded to the dimensions and specificities by individual listeners or classes of listeners (Grey 1977; McAdams *et al.* 1995). Such techniques have been applied to synthetic sounds (Miller and Carterette 1975; Plomp 1970), resynthesized or simulated instrument sounds (Grey 1977; Krumhansl 1989; McAdams *et al.* 1995; Wessel 1979), recorded instrument sounds (Iverson and Krumhansl 1993; Lakatos 2000), and even dyads of recorded instrument sounds (Kendall and Carterette 1991).

Specificities are often found for complex acoustic and synthesized sounds. They are considered to represent the presence of a unique feature that distinguishes a sound from all others in a given context. For example, in a set of brass, woodwind, and string sounds, a harpsichord has a feature shared with no other sound: the return of the hopper which creates a slight 'thump' and quickly damps the sound at the end. This might appear as a strong specificity in the distance model (Krumhansl 1989; McAdams *et al.* 1995).

The models integrate individual and class differences as weighting factors on the different dimensions and the set of specificities. Some listeners pay more attention to spectral properties and ignore temporal aspects, whereas others have the inverse pattern. Such variability may reflect either differences in sensory processing or in listening and rating strategies. Interestingly, no study to date has demonstrated that such individual differences have anything to do with musical experience or training (McAdams *et al.* 1995). It may be that because timbre perception is so closely allied with the ability to recognize sound sources in everyday life, everybody is an expert to some degree.

Acoustic correlates of timbral dimensions

In many studies, independent acoustic correlates have been determined for the continuous dimensions by correlating the position along the perceptual dimension with a unidimensional acoustic parameter extracted from the sounds (e.g. Grey and Gordon 1978; Krimphoff *et al.* 1994). The most ubiquitous correlates derived from musical instrument sounds include spectral centroid (representing the relative weights of high and low frequencies and corresponding to timbral brightness: an oboe has a higher spectral centroid than a French horn), the logarithm of the attack time (distinguishing continuant instruments that are blown or bowed from impulsive instruments that are struck or plucked), spectral flux (the degree of evolution of the spectral shape over a tone's duration which is high for brass and lower for single reeds), and spectral irregularity (the degree of jaggedness of the spectral shape, which is high for clarinet and vibraphone and low for trumpet). A confirmatory study employing dissimilarity ratings on purely synthetic sounds in which the exact nature of the stimulus dimensions could be controlled was performed by Caclin *et al.* (2005). These authors confirmed the perception of stimulus dimensions related to spectral centroid, attack time and spectral irregularity, but did not confirm spectral flux.

The combination of a quantitative model of perceptual relations among timbres and the psychophysical explanation of the parameters of the model is an important step in gaining predictive control of timbre in several domains such as sound analysis and synthesis and intelligent search in sound databases (Peeters *et al.* 2000). Such representations are only useful to the extent that they are: (a) generalizable beyond the set of sounds actually studied, (b) robust with respect to changes in musical context, and (c) generalizable to other kinds of listening tasks than those used to construct the model. To the degree that a representation has these properties, it may be considered as an accurate account of musical timbre, characterized by an important feature of a scientific model, the ability to predict new empirical phenomena.

Timbre space models have been useful in predicting listeners' perception in situations beyond those specifically measured in the experiments, which suggests that they do in fact capture important aspects of timbre representation. Consistent with the predictions of a timbre

model, Grey and Gordon (1978) found that by exchanging the spectral envelopes on pairs of sounds that differed primarily along the spectral dimension, these sounds switched positions in the space. Timbre space has also been useful in predicting the perception of intervals between timbres, as well as stream segregation based on timbre-related acoustic cues (see below).

Effects of pitch change on timbre relations

Marozeau and colleagues (2003) have shown that timbre spaces for recorded musical instrument tones are similar at different pitches (B3, C#4, B♭4). Listeners are also able to ignore pitch differences within an octave when asked to compare only the timbres of the tones. When the pitch variation is greater than an octave, interactions between the two attributes occur. Marozeau and de Cheveigné (2007) varied the brightness of a set of synthesized sounds, while also varying the pitch over a range of 18 semitones. They found that differences in pitch affected timbre relations in two ways:

1 Pitch shows up in the timbre space representation as a dimension orthogonal to the timbre dimensions (indicating simply that listeners were no longer ignoring the pitch difference), and
2 Pitch differences systematically affect the timbre dimension related to spectral centroid.

These results suggest a close relation between timbral brightness and pitch height. This link would be consistent with underlying neural representations that share common attributes, such as a tonotopic organization.

Timbre as a vehicle for source identity

The second approach to timbre concerns its role in the recognition of the identity of a musical instrument or, in general, of a sound-generating event. One reasonable hypothesis is that the sensory dimensions that compose timbre serve as indicators used in the categorization, recognition, and identification of sound events and sound sources (McAdams 1993; Handel 1995).

Research on musical instrument identification is relevant to this issue. Saldanha and Corso (1964) studied identification of isolated musical instrument sounds from the Western orchestra played with and without vibrato. They were interested in the relative importance of onset and offset transients, spectral envelope of the sustain portion of the sound, and vibrato. Identification of isolated sounds is surprisingly poor for some instruments. When attacks and decays were excised, identification decreased markedly for some instruments, particularly for the attack portion in sounds without vibrato. However, when vibrato was present, the effect of cutting the attack was less, identification being better. These results suggest that important information for instrument identification is present in the attack portion, but that in the absence of this information, additional information is still available in the sustain portion (although it is more important for some instruments than others), particularly when vibrato is present. The vibrato may increase our ability to extract information relative to the resonance structure of the instrument (McAdams and Rodet 1988).

Giordano (2005) analysed previously published data on the identification and dissimilarity ratings of musical tones. The goal of this study was to ascertain the extent to which tones generated with large differences in the mechanisms for sound production were recovered in the perceptual data. Across all identification studies, listeners frequently confused tones generated by musical instruments with a similar physical structure (e.g., clarinets and saxophones, both single-reed instruments), and seldom confused tones generated by very different physical systems (e.g., the trumpet, a lip-reed instrument, and the bassoon, a double-reed instrument). Consistently, the vast majority of previously published timbre spaces revealed that tones generated with similar resonating structures (e.g., string instruments vs wind instruments) or with similar excitation mechanisms (e.g., impulsive excitation as in piano tones vs sustained excitation as in flute tones) occupied the same region in the space. These results suggest that listeners can reliably identify large differences in the mechanisms of tone production, focusing on the timbre attributes used to evaluate the dissimilarity of musical sounds.

Several investigations on the perception of everyday sounds extend the concept of timbre

beyond the musical context (see McAdams 1993; Handel 1995; Lutfi 2008 for reviews). Among them, studies on impact sounds provide information on the timbre attributes useful to the perception of the properties of percussion instruments: bar geometry (Lakatos *et al.* 1997), bar material (McAdams *et al.* 2004a), plate material (Giordano and McAdams 2006), and mallet hardness (Freed 1990). The timbral factors relevant to perceptual judgements vary with the task at hand. Spectral factors are primary for the perception of the geometry (Lakatos *et al.* 1997). Spectrotemporal factors (e.g., the rate of temporal change of the spectral centroid and of loudness) dominate the perception of the material of struck objects (McAdams *et al.* 2004a, Giordano and McAdams 2006) and of mallets (Freed 1990).

The perception of an instrument's identity in spite of variations in pitch may be related to timbral invariance, those aspects of timbre that remain constant with change in pitch and loudness. Handel and Erickson (2001) found that musically untrained listeners are able to recognize two sounds produced at different pitches as coming from the same instrument or voice only within a pitch range of about an octave. Steele and Williams (2006) found that musically trained listeners could perform this task at about 80 per cent correct even with pitch differences on the order of 2.5 octaves. These results suggest that there are limits to timbral invariance across pitch, but that they depend on musical training.

Its role in source identification and categorization is perhaps the more neglected aspect of timbre, and brings with it advantages and disadvantages for the use of timbre as a form-bearing dimension in music (McAdams 1989). One of the advantages is that categorization and identification of a sound source may bring into play perceptual knowledge (acquired by listeners implicitly through experience in the everyday world and in musical situations) that helps them track a given voice or instrument in a complex musical texture. Listeners do this easily and some research has shown that timbral factors may make an important contribution in voice tracking (Culling and Darwin 1993; Gregory 1994), which is particularly important in polyphonic settings.

The disadvantages may arise in situations in which the composer seeks to create melodies across instrumental timbres, e.g., the *Klangfarbenmelodien* of Schoenberg (1911/1978). Our predisposition to identify the sound source and follow it through time would impede a more relative perception in which the timbral differences were perceived as a movement through timbre space rather than as a simple change of sound source. For cases in which such timbral compositions work, the composers have often taken special precautions to create a musical situation that draws the listener more into a relative than into an absolute mode of perceiving.

Timbral intervals

If timbral interval perception can be demonstrated, it opens the door to musical operations on timbre sequences that are commonly used on pitch sequences (Slawson 1985). Another interest of this exploration is that it extends the use of the timbre space as a perceptual model beyond the dissimilarity paradigm.

Ehresman and Wessel (1978; Wessel 1979) took a first step forward in this direction, developing a task in which listeners were asked to make judgements on the similarity of intervals formed between pairs of timbres. The basic idea was that timbre intervals may have properties similar to pitch intervals; that is, a pitch interval is a relation along a well-ordered dimension that retains a degree of invariance under certain kinds of transformation, such as translation along the dimension, or what musicians call 'transposition'. What does transposition mean in a multidimensional space? A timbre interval can be considered as a vector in space connecting two timbres. It has a specific length (the distance between the timbres) and a specific orientation. Together these two properties define the amount of change along each dimension of the space that is needed to move from one timbre to another. If we assume these dimensions to be continuous and linear from a perceptual point of view, then pairs of timbres characterized by the same vector relation should have the same relative perceptual relation and thus embody the same timbre interval. Transposition thus consists of translating the vector anywhere else in the space as long as its length and orientation are preserved.

Ehresman and Wessel tested this hypothesis using a task in which listeners had to compare

two timbral intervals (e.g. A–B vs C–D) and rank various timbre D's according to how well they fulfilled the analogy: timbre A is to timbre B as timbre C is to timbre D. They essentially found that the closer timbre D was to the ideal point defined by the vector model in timbre space (i.e. the ideal C–D vector was a simple translation of the A–B vector), the higher the ranking.

McAdams and Cunibile (1992) subsequently tested the vector model using the 3D space from Krumhansl (1989) (ignoring the specificities). Five sets of timbres at different places in timbre space were chosen for each comparison to test for the generality of the results. Both electroacoustic composers and non-musicians were tested to see if musical training and experience had any effect. All listeners found the task rather difficult to do, which is not surprising given that even professional composers have had almost no experience with music that uses timbre intervals in a systematic way. The main result is encouraging in that globally the data support the vector model, although this support was much stronger for composers than for non-musicians. However, when one examines in detail the five different versions of each comparison type, it is clear that not all timbre comparisons go in the direction of the model predictions.

One confounding factor is that the specificities on some timbres in this set were ignored. These, quite to the contrary, would necessarily distort the vectors that were used to choose the timbres, because the specificities are like an additional dimension for each timbre. As such, certain timbre intervals correspond well to what is predicted because specificities are absent or low in value, whereas others would be seriously distorted and thus not perceived as similar to other intervals due to moderate or high specificity values. What this line of reasoning suggests is that the use of timbre intervals as an integral part of a musical discourse runs the risk of being very difficult to achieve with very complex and idiosyncratic sound sources, because they will in all probability have specificities of some kind or another. The use of timbre intervals may, in the long run, be limited to synthesized sounds or blended sounds created through the combination of several instruments.

Timbre and musical grouping

An important way in which timbre can contribute to the organization of musical structure is related to the fact that listeners tend to connect perceptually sound events that arise from the same sound source. In general, a given source will produce sounds that are relatively similar in pitch, loudness, timbre and spatial position from one event to the next (cf. Bregman 1990; McAdams and Bregman 1979 for reviews). The perceptual connection of successive sound events into a coherent 'message' through time is referred to as auditory stream integration, and the separation of events into distinct messages is called auditory stream segregation (Bregman and Campbell 1971). One guiding principle that seems to operate in the formation of auditory streams is the following: successive events that are relatively similar in their spectrotemporal properties (i.e. in their timbres) may have arisen from the same source and should be grouped together; individual sources do not tend to change their acoustic properties suddenly and repeatedly from one event to the next. Early demonstrations of auditory streaming on the basis of timbre (Wessel 1979) suggest a link between the timbre–space representation and the tendency for auditory streaming on the basis of the spectral differences that were created (McAdams and Bregman 1979). Early researchers were convinced that it was primarily the spectral aspects of timbre (such as spectral centroid) that were responsible for auditory streaming and that temporal aspects (such as attack time) had little effect (Hartmann and Johnson 1991).

Recently the picture has changed significantly and several studies indicate an important role for both spectral and temporal attributes of timbre in auditory stream segregation (Moore and Gockel 2002). Iverson (1995) used sequences alternating between two recorded instrument tones with the same pitch and loudness and asked listeners to judge the degree of segregation. Multidimensional scaling of the segregation judgments treated as a measure of dissimilarity was performed to determine which acoustic attributes contributed to the impression of auditory stream segregation. A comparison with previous timbre–space work using the

same sounds (Iverson and Krumhansl 1993) showed that both static acoustic cues (such as spectral centroid) and dynamic acoustic cues (such as attack time and spectral flux) were implicated in segregation. Other results consistent with this study have also been reported (Bey and McAdams 2003; Singh and Bregman 1997).

All of these results are important for auditory stream segregation theory on the one hand, because they show that several of a source's acoustic properties are taken into account when forming auditory streams. On the other hand, they are important for music-making (whether it be with computer or acoustic instruments), because they show that many aspects of timbre strongly affect the basic organization of the musical surface into streams. Different orchestrations of a given pitch sequence can completely change what is heard as melody and rhythm, as has been demonstrated by Wessel (1979). Timbre is also an important component in the perception of musical groupings, whether they are at the level of sequences of notes distinguished by changes in timbre (Deliège 1987) or of larger-scale musical sections delimited by marked changes in orchestration and timbral texture (Deliège 1989).

Timbre as a structuring force in music perception

Timbre perception is at the heart of orchestration, a realm of musical practice that has received relatively little experimental study. Instrumental combinations can give rise to new timbres if the sounds are perceived as blended, and timbre can play a role in creating and releasing musical tension.

Timbral blend

The creation of new timbres through orchestration necessarily depends on the degree to which the constituent sound sources fuse together or blend to create the newly emerged sound (Brant 1971; Erickson 1975). Sandell (1995) has proposed that there are three classes of perceptual goals in combining instruments:

1 timbral heterogeneity in which one seeks to keep the instruments perceptually distinct,
2 timbral augmentation in which one instrument embellishes another one that perceptually dominates the combination, and
3 timbral emergence in which a new sound results that is identified as none of its constituents.

Blend appears to depend on a number of acoustic factors such as onset synchrony of the constituent sounds and others that are more directly related to timbre, such as the similarity of the attacks, the difference in the spectral centroids, and the overall centroid of the combination.

Role of timbre in building and release of musical tension

Timbre can also contribute to larger-scale musical form and in particular to the sense of movement between tension and relaxation. This movement has been considered by many music theorists as one of the primary bases for the perception of larger-scale form in music. It has traditionally been tied to harmony in Western music and plays an important role in Lerdahl and Jackendoff's (1983)*A generative theory of tonal music*. Experimental work on the role of harmony in the perception of musical tension and relaxation (or inversely, in the sense of tension that accompanies a moment at which the music must continue and the sense of relaxation that accompanies the completion of the musical phrase) has suggested that auditory roughness is an important component of perceived tension (Bigand *et al.* 1996). Roughness is an elementary timbral attribute based on the sensation of rapid fluctuations in the amplitude envelope. It can be generated by proximal frequency components that beat with one another. Dissonant intervals tend to have more such beating than consonant intervals. As such, a fairly direct relation between sensory dissonance and roughness has been demonstrated (cf. Parncutt 1989; Plomp 1976 for reviews).

As a first step toward understanding how this operates in music, Paraskeva and McAdams (1997) measured the inflection of musical tension and relaxation due to timbral change. Listeners were asked to make judgments on a 7-point scale concerning the perceived degree of completion of the music at several points at

which the music stopped. What results is a completion profile, which can be used to infer musical tension by equating completion with release and lack of completion with tension. Two pieces were tested: a fragment from the Ricercar from the *Musical Offering* for six voices by Bach (tonal) and the first movement of the *Six Pieces for Orchestra* by Webern (non-tonal). Each piece was played in an orchestral version (the Webern instrumentation was used for the Bach), and a direct transcription of this orchestral version for piano on a digital sampler. There were significant differences between the piano and orchestral versions, indicating a significant effect of timbre change on perceived musical tension. However, when they were significantly different, the orchestral version was always more relaxed than the piano version.

The hypothesis advanced by Paraskeva and McAdams (1997) for this effect was that the higher relaxation of the orchestral version might have been due to processes involved in auditory stream formation and the dependence of perceived roughness on the results of such processes (Wright and Bregman 1987). Roughness, or any other auditory attribute of a single sound event, is computed after auditory organization processes have grouped the bits of acoustic information together. Piano sounds have a rather sharp attack. If several notes occur at the same time in the score and are played with a piano sound, they will be quite synchronous. Because they all start at the same time and have similar amplitude envelopes, they will tend to be fused together and the computed roughness will result from the interactions of all the frequency components of all the notes.

The situation may be quite different for the orchestral version for two reasons. The first is that the same timing is used for piano and orchestra versions. In the latter, many instruments are used that have slow attacks whereas others have faster attacks. There could then be a great deal of asynchrony between the instruments in terms of perceived attack time (Gordon 1987). In addition, because the timbres of these instruments are often quite different, several different voices with different timbres arrive momentarily at a given vertical sonority, but the verticality is not perceived because the listener would more likely continue to track individual instruments horizontally. So the attack asynchrony and the decomposition of verticalities into horizontalities would concur to reduce the degree of perceptual fusion. Reduced fusion would mean greater segregation. Thus the roughness in the orchestral version would be computed on each individually grouped auditory event rather than on the whole sound mass. These individual roughnesses in the orchestral version would most likely be much less than that of the piano version. So once again, timbral composition can have a very tight interaction with auditory stream formation processes.

Conclusion

Musical timbre is a combination of continuous perceptual dimensions and discrete features to which listeners are differentially sensitive. The continuous dimensions often have quantifiable acoustic correlates. The timbre–space representation is a powerful psychological model that allows predictions to be made about timbre perception in situations beyond those used to derive the model in the first place. Timbre intervals, for example, can be conceived as vectors within the space of common dimensions. Timbre space also makes at least qualitative predictions about the magnitude of timbre differences that will provoke auditory stream segregation.

Timbre can play a role in larger-scale movements of tension and relaxation and thus contribute to the expression inherent in musical form. Under conditions of high blend among instruments composing a vertical sonority, timbral roughness is a major component of musical tension. However, it strongly depends on the way auditory grouping processes have parsed the incoming acoustic information into events and streams.

CHAPTER 8

Musical time

Mari Riess Jones

THIS chapter presents perspectives on perception of metre and rhythm, with a focus on dynamic attending theory (DAT). Three major sections address, respectively, metre perception, rhythm perception, and the role of time markers.

Metre perception

Intuitively, metre perception refers to a listener's sensitivity to musical timing regularities, evident when 'keeping time' by tapping in synchrony with musical tones. Sometimes tones are clearly accented and contribute to *metric hierarchies*, as suggested in Figure 8.1(a). Here, an idealized hierarchy features accents that are increasingly stronger (i.e. more salient; thicker bars) on non-adjacent tones separated by increasingly longer time spans. Metric hierarchies comprise overlapping (i.e., *embedded*) time spans; they can be distinguished from time spans between successive tones (i.e., *serial spans*). Whereas metric spans reflect temporal embeddings (Figure 8.1(a)), serial spans invite rhythmic grouping (Figure 8.1(b)). Conventional wisdom holds that metre and rhythm are distinct time structures, engaging different perceptual processes. In this chapter I question this dichotomy.

Let's begin with metre perception. First, we should differentiate metric information in a visual score from that which meets a listener's ears. A typical (Western) score spells out two hierarchical time spans: a measure and its subdivisions. Thus, a notated 4/4 metric signature defines the measure as a time level evenly subdivided into

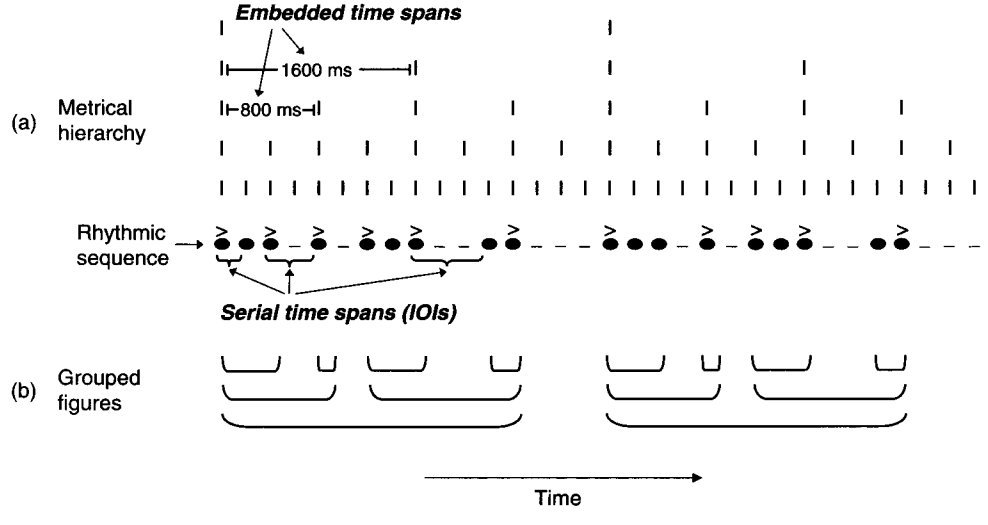

Fig. 8.1 Metric hierarchy, with embedding time spans (a); and rhythmic groups with serial (IOIs) time spans (b).

four quarter notes (a 4:1 embedded time ratio, Figure 8.1(a)), whereas a triple (3/4) metre implies a subdivision of three (a 3:1 ratio).

Yet, given an unfamiliar melody, a listener often does not 'know' its designated metre; people don't have scored bar lines in their heads. To understand metre perception in sound patterns, we must consider that listeners may infer several metric time levels. From this, challenging issues arise. For instance, listeners may selectively internalize aspects of a metric hierarchy by engaging a series of internal *beats* at one or more time levels. Stronger beats might be felt at points in a sound pattern where multiple objective accents align. Further, if an internal beat pattern persists, then beats are also felt at times where no objective accents exist, i.e., 'subjective accents'. Also, different listeners may focus upon different internal beat patterns as a referent level (tactus). In short, to understand metre perception, we must discover factors in sound patterns and in listeners that bias people to hear a pattern's time structure in a particular way.

Contemporary research on musical time began with classic work of Fraisse (1963), who focused on rhythmic groupings. He proposed that listeners rely on favoured *serial* time ratios to segment groups. Preferred ratios approximated 1:1 for within-group time spans and 2:1 for between-group serial time ratios. However, metric issues entered the picture when Povel (1981) showed that metrical context modulates listeners preferences for 2:1 serial time ratios. Next, I describe theory and research surrounding two current psychological theories of metre perception, an encoding theory and a dynamic attending theory (DAT).

An encoding theory

Povel and Essens (1985) proposed that metre perception is governed by an internal clock. Metrical sequences, containing regular accents, readily induce a 'good' clock and lead to efficient encoding of serial time intervals, whereas non-metrical sequences, with irregular accents, do not. Examples of metrical and non-metrical monotone sequences, involving various inter-onset time intervals (IOIs), appear in Figures 8.1 and 8.2. Grouping accents (>) putatively occur on:

1 isolated tones;
2 the second tone of a two-tone group; and
3 initial and final tones in groups of three or more tones (Povel and Okkerman 1981).

This clock model has two stages. The first stage entails matching accents with internal clock ticks (i.e., beats). The best clock maximizes accent isochrony via minimizing mismatches (clock violations). Strong metric patterns (patterns 1 and 2, Figure 8.2), have accents (>) that coincide entirely with ticks (●) of the best clock,

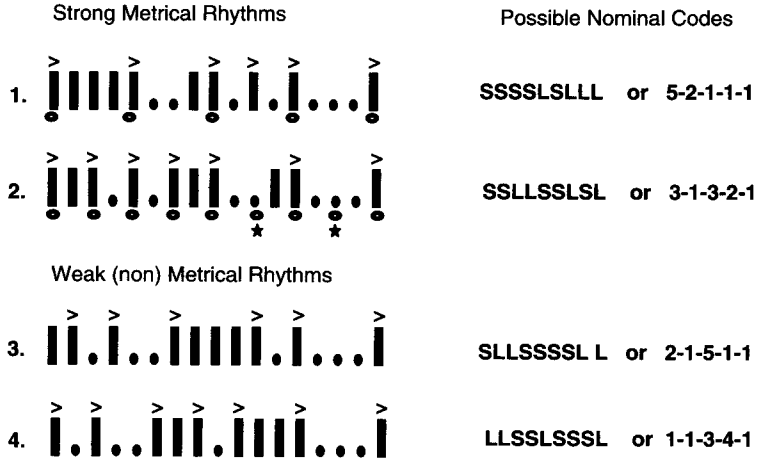

Fig. 8.2 Four patterns from Povel and Essens (1985). Grouping accents are >; clock ticks are ●; negative clock evidence, s, is *.

namely the clock with fewest violations, i.e., least counter-evidence, C, where:

$$C = W \cdot s + u \quad (1)$$

The W (W > 1.0) weights the number of clock ticks falling on a silence, s (*stars* in Figure 8.2) and u is the number of ticks on unaccented elements. Thus, for pattern 1, $s = 0$ and $u = 0$ whereas for pattern 2, $s = 2$ and $u = 0$. For both patterns, C is low reflecting strong metrical patterns.

The second stage features symbolic memory codes which are more economical for metric than for non-metric patterns. For non-metric patterns, codes reflect grouping properties (cf. Figure 8.2). Thus, although the non-metric pattern 3 lacks a good clock fit, its five groups produce nominal codes of Short or Long IOIs, or symbols of group sizes: 2–1–5–1–1. These codes reflect nominal segmentations, not interval time relationships. Others propose different coding strategies (e.g. Lerdahl and Jackendoff 1983; Temperley 2001).

Evidence for metric encoding

Povel and Essens required people to reproduce many metric and non-metric sequences. Consistent with clock model predictions, best temporal accuracy occurred with metrical sequences. Since 1985, this model has stimulated much research on metric encoding. However, conflicting reports surround its implications that highly metrical patterns elicit better temporal acuity (Handel 1992; Ross and Houtsma 1994; Handel 1998). Hebert and Cuddy (2002) found that both a metric frame (metrical sequences) and the presence of a rhythmic figure (non-metrical sequences) benefit time-change detection.

Much research on synchronized tapping appeals to motor control theory (see Repp 2005 for review). However, few (e.g. Palmer and Pfordresher 2003) consider metre perception. Some empirical examinations of synchronized and reproduction tapping do directly address clock model assumptions (e.g. McAuley and Semple 1999; Patel *et al.* 2005). McAuley and Semple questioned whether clock induction depends only on negative, i.e., counter-evidence (i.e., ticks at unaccented times). They formulated alternative versions of Equation 1, creating a positive evidence model (P), weighting clock ticks coinciding with accents; and a hybrid model (H), weighting both positive and negative evidence. Musicians and non-musicians tapped to metrical sequences, indexed by C, P, and H. The Hybrid model best predicted musicians' behaviour, whereas Povel's C index best predicted non-musicians' performance. Thus, non-musicians appear to be affected by clock violations, consistent with Povel and Essens model, whereas musicians draw strength from confirmations as well as clock violations.

Patel *et al.* (2005) found that tapping to isochronous patterns at a fixed beat period of 800 ms was less variable with isochronous subdivisions of this period than with non-isochronous (rhythmic) ones. Although consistent with clock predictions, other findings involving subdivisions by 2 or 4 were more difficult for the clock model. These data converge with others (Essens 1986) to suggest that listeners rely on relationships among multiple time levels. Indeed, even very young children appear to use multiple time levels to differentiate duple from triple metre categories (Phillips-Silver and Trainor 2005; Trehub and Hannon 2006; Bergeson and Trehub 2006), although reports of children's preference for duple metre (2:1 ratios) (Drake 1993) were not confirmed.

Dynamic attending theory and the metric binding hypothesis

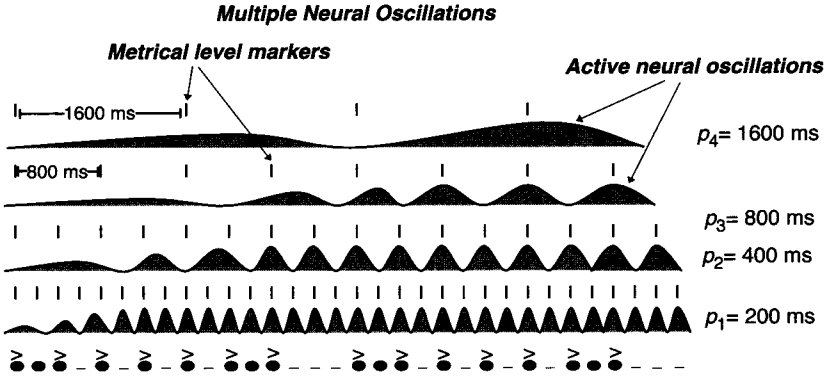
Dynamic attending theory (DAT) addresses 'in-the-moment' expectancies in listening. Its relevance to metre perception is discussed in this section, where I propose a new hypothesis: the *metric binding hypothesis*.

Entrainment is a biological process that realizes adaptive synchrony of *internal* attending oscillations with an *external* event. Different event timescales correspond to marked (i.e., accented) metric levels (Figures 8.1, 8.3). Time spans within a metric level can elicit a corresponding neural oscillation, which has a persisting internal periodicity (Pi), manifest as a *temporal expectancy*. It 'tunes into' recurrent time spans at a given level by adjusting its phase in response to temporal *expectancy violations* (ϕ) at that level.

Various DAT models share four assumptions (Large 1994; McAuley 1995; Large and Kolen 1995;

Large and Jones 1999). First, neural oscillations are *self-sustaining;* they persist over time, extrapolating the induced beat. Second, an oscillator's intrinsic period exhibits *stability;* a perturbation from an ill-timed tone only briefly disrupts a stable oscillation, which returns to its intrinsic period. Third, entraining oscillations exhibit *adaptivity*, the flip side of stability; an oscillator responds appropriately to event-generated expectancy violations by adjusting phase and period. Fourth, *multiple related oscillations* are activated by multiple time levels within metric and rhythmic events.

The metric binding hypothesis expands these assumptions. It adds learning principles to address training and enculturation that contribute to listeners' familiarity with metric categories. It holds: *whenever two or more neural oscillations are simultaneously active, over time their internal entrainments lead to binding and formation of a metric cluster.* A metric cluster comprises sets of co-occurring oscillations with interrelationships that persist due to acquired internal bindings. Entrainments among internal oscillations promote binding, which strengthens as a function of:



1 Duration of co-occurring oscillatory activity.

2 Phase coincidences, and,

3 Resonance (i.e., relatedness) among oscillator periods.

Figure 8.3 illustrates how metric clusters form. As a rhythmic pattern unfolds, it successively activates neural oscillations with periods (Pi) matching each of the lower-level IOIs. Initially recurrent IOIs, in this case, elicit an oscillation with a period of 200 ms, which is strongly coupled to these IOIs. However, this rhythm subsequently awakens oscillations with periods of 400 and 800 ms due to serial IOIs that follow. Oscillations of periods 400 and 800 ms find added support mainly from higher event time spans between non-adjacent tones. This analysis shows how rhythm and metre co-constrain oscillation activities. Once active, co-occurring internal oscillations mutually entrain.

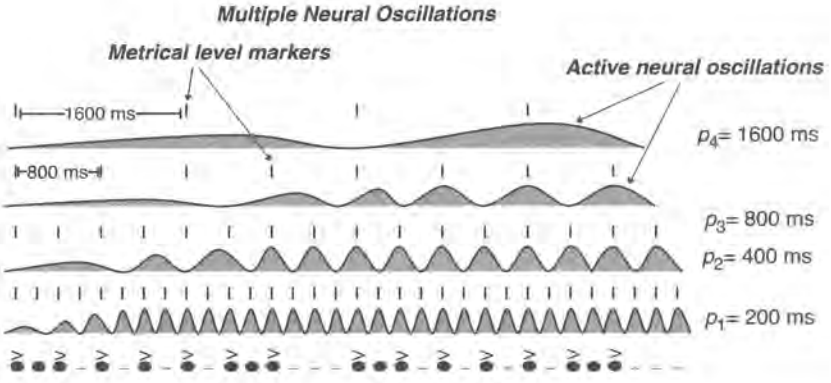
I propose that, over time, internal entrainment leads to cluster binding and the formation of a persisting metric form (here duple metre). This is a mechanism for bootstrapping learning based on pattern relationships. It is constrained by binding principles such that learning is facilitated not only by longer total times of oscillator co-activity (e.g., Hebbian learning), but also by strong resonance and phase relations among active oscillations. The metric binding

Multiple simultaneously-active oscillations *bind* as a function of: 1. Duration of simultaneous activity 2. Intrinsic period ratios (*pi/pj*)3. Coincidence of pulse peaks

Fig. 8.3 Multiple metric levels entrain corresponding neural oscillations. Rhythm (serial IOIs) also activates oscillations. This figure illustrates metric binding hypothesis principles.

Large and Jones 1999). First, neural oscillations are *self-sustaining;* they persist over time, extrapolating the induced beat. Second, an oscillator's intrinsic period exhibits *stability;* a perturbation from an ill-timed tone only briefly disrupts a stable oscillation, which returns to its intrinsic period. Third, entraining oscillations exhibit *adaptivity*, the flip side of stability; an oscillator responds appropriately to event-generated expectancy violations by adjusting phase and period. Fourth, *multiple related oscillations* are activated by multiple time levels within metric and rhythmic events.

The metric binding hypothesis expands these assumptions. It adds learning principles to address training and enculturation that contribute to listeners' familiarity with metric categories. It holds: *whenever two or more neural oscillations are simultaneously active, over time their internal entrainments lead to binding and formation of a metric cluster*. A metric cluster comprises sets of co-occurring oscillations with interrelationships that persist due to acquired internal bindings. Entrainments among internal oscillations promote binding, which strengthens as a function of:



1 Duration of co-occurring oscillatory activity.

2 Phase coincidences, and,

3 Resonance (i.e., relatedness) among oscillator periods.

Figure 8.3 illustrates how metric clusters form. As a rhythmic pattern unfolds, it successively activates neural oscillations with periods (Pi) matching each of the lower-level IOIs. Initially recurrent IOIs, in this case, elicit an oscillation with a period of 200 ms, which is strongly coupled to these IOIs. However, this rhythm subsequently awakens oscillations with periods of 400 and 800 ms due to serial IOIs that follow. Oscillations of periods 400 and 800 ms find added support mainly from higher event time spans between non-adjacent tones. This analysis shows how rhythm and metre co-constrain oscillation activities. Once active, co-occurring internal oscillations mutually entrain.

I propose that, over time, internal entrainment leads to cluster binding and the formation of a persisting metric form (here duple metre). This is a mechanism for bootstrapping learning based on pattern relationships. It is constrained by binding principles such that learning is facilitated not only by longer total times of oscillator co-activity (e.g., Hebbian learning), but also by strong resonance and phase relations among active oscillations. The metric binding

Multiple simultaneously-active oscillations *bind* as a function of: 1. Duration of simultaneous activity 2. Intrinsic period ratios (***pi/pj***)3. Coincidence of pulse peaks

Fig. 8.3 Multiple metric levels entrain corresponding neural oscillations. Rhythm (serial IOIs) also activates oscillations. This figure illustrates metric binding hypothesis principles.

hypothesis implies that: 'Oscillators that align together, bind together.'

Once acquired, metric clusters grant trained listeners attentional flexibility to activate oscillators for unmarked metric levels (Palmer and Krumhansl 1990) and to flexibly shift focal attending to different marked levels. In fact, Jones and Boltz (1989) proposed two attending modes, future-oriented and analytic attending, to reflect focal attending to higher and lower time levels, respectively.

Specialized entrainment models

Several DAT models formalize oscillator behaviours for different tasks; typically, a single oscillation exhibits three components: period; pulse, and phase. Some tasks rely on a single oscillation model, others on multiple oscillations.

The simplest oscillator model appears in Figure 8.4 entraining to an isochronous event (Large and Jones 1999). This single oscillation carries a concentration of attending energy, an attentional pulse. With rhythmically simple events, an oscillator's 'tuning' is reflected in a steady narrowing of an attentional pulse about an expected phase point: $\phi = 0$. This entails continuous phase adjustments to minimize differences between momentarily expected phases and observed tone onsets. The goal is an attractor, defined by phase coincidence (synchrony), of expected and observed time points. Once attuned, an entrained oscillation persists to extrapolate beats (attentional pulses), each beat realizing an anticipated region in time (insert).

Metre perception is described with more complex models; at least two oscillations, entraining at different metric levels, are necessary (see Figure 8.3) (Large and Jones 1999; Large and Palmer 2002). Moreover, these oscillations can interact. To illustrate, consider pattern 2 (Figure 8.2). This rhythm differs from the rhythm of Figure 8.3 in containing lower order IOIs that elicit oscillations with periods: 200, 400, 600, 800 ms. That is, three oscillator periods (200, 400, 800 ms) nest neatly with higher metric levels (400, 800 ms, 1600 ms), but one does not (600 ms). Nevertheless, the metric binding hypothesis assumes internal entrainments

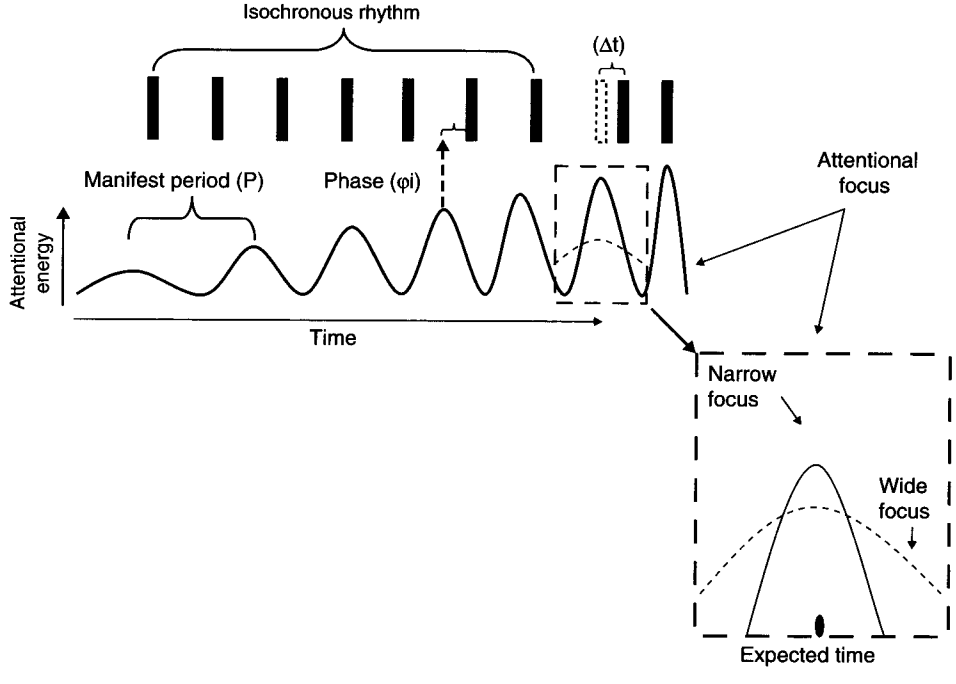


Fig. 8.4 A single oscillator entrains to an isochronous rhythm. Basic components are period, pulse (insert) and phase.

hypothesis implies that: 'Oscillators that align together, bind together.'

Once acquired, metric clusters grant trained listeners attentional flexibility to activate oscillators for unmarked metric levels (Palmer and Krumhansl 1990) and to flexibly shift focal attending to different marked levels. In fact, Jones and Boltz (1989) proposed two attending modes, future-oriented and analytic attending, to reflect focal attending to higher and lower time levels, respectively.

Specialized entrainment models

Several DAT models formalize oscillator behaviours for different tasks; typically, a single oscillation exhibits three components: period; pulse, and phase. Some tasks rely on a single oscillation model, others on multiple oscillations.

The simplest oscillator model appears in Figure 8.4 entraining to an isochronous event (Large and Jones 1999). This single oscillation carries a concentration of attending energy, an attentional pulse. With rhythmically simple events, an oscillator's 'tuning' is reflected in a steady narrowing of an attentional pulse about an expected phase point: $\phi = 0$. This entails continuous phase adjustments to minimize differences between momentarily expected phases and observed tone onsets. The goal is an attractor, defined by phase coincidence (synchrony), of expected and observed time points. Once attuned, an entrained oscillation persists to extrapolate beats (attentional pulses), each beat realizing an anticipated region in time (insert).

Metre perception is described with more complex models; at least two oscillations, entraining at different metric levels, are necessary (see Figure 8.3) (Large and Jones 1999; Large and Palmer 2002). Moreover, these oscillations can interact. To illustrate, consider pattern 2 (Figure 8.2). This rhythm differs from the rhythm of Figure 8.3 in containing lower order IOIs that elicit oscillations with periods: 200, 400, 600, 800 ms. That is, three oscillator periods (200, 400, 800 ms) nest neatly with higher metric levels (400, 800 ms, 1600 ms), but one does not (600 ms). Nevertheless, the metric binding hypothesis assumes internal entrainments

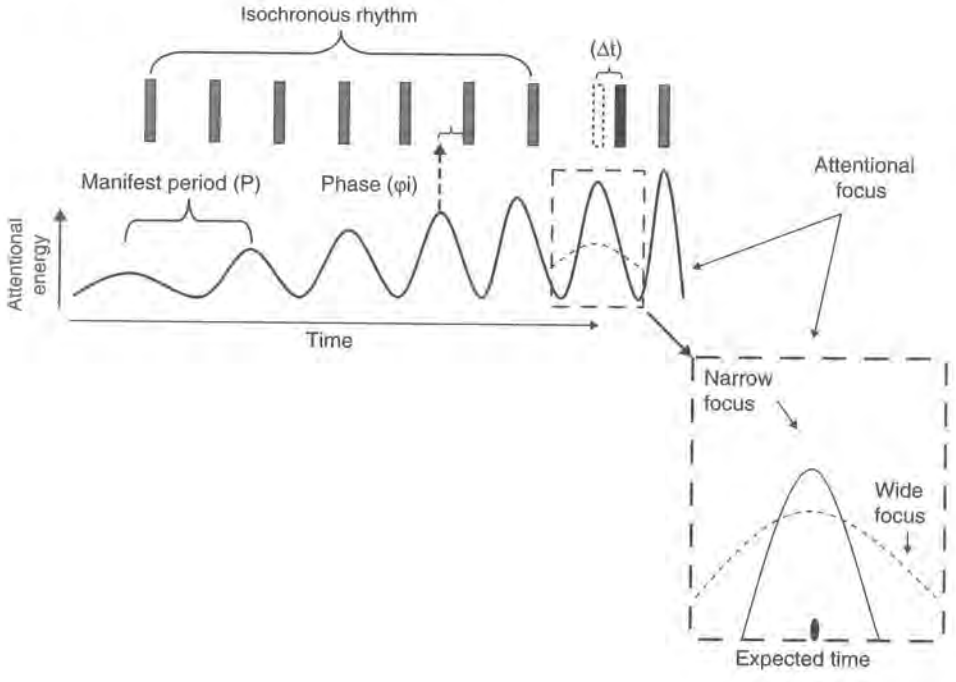

Fig. 8.4 A single oscillator entrains to an isochronous rhythm. Basic components are period, pulse (insert) and phase.

among active oscillations lead to common metric percepts for different rhythms. Binding among oscillations depends not only on the duration of joint oscillator activities, but also on resonance relations among these oscillations, namely period and phase relationships. Thus, for pattern 2, although the oscillator with an ill-fitting period (e.g., 600 ms), is initially active, it dies out due to poor resonance. The winning metric cluster for pattern 2 turns out to be identical to the metric cluster for the different rhythm of Figure 8.3. This analysis predicts that the 600 ms IOI (pattern 2, Figure 8.2) will be perceptually distorted to 'fit' the duple metre frame common to both rhythms. More generally, metric binding in multi-oscillator systems explains how various rhythmic instances are perceived as members of a common metric category.

The mathematics of multi-oscillator systems is complex. Nevertheless, resonance properties require some mention. When two oscillations are active, their periods form embedding ratios (e.g., 1:1, 2:1, 3:1, 1:2, 2:3; 3:2 etc.) that gauge overall stability of their interaction. Embedding ratios specify resonance states (i.e., attractors) that have different degrees of stability; this, in turn, predicts differential lasting qualities of metric clusters (Large and Kolen 1995; cf. London 2004). For instance, clusters based on duple metre ratios are predicted to be more stable than those based on complex ratios.

Finally, it is common to distinguish metre perception from rhythm perception, in that it reflects an acquired skill, whereas rhythm perception is attributed to innate Gestalt principles (Bregman 1990; Handel 1989). DAT does not incorporate this dichotomy. Rather, dynamical properties offer biological springboards that differentially constrain the learning of metric versus rhythmic time structures. DAT implies that unlearned biological responses (neural oscillations) are fundamental to time perception, whether metric or rhythmic. These biological dispositions (oscillatory entrainments) initially facilitate attending to event structure via activated oscillations. Next, stability differences among simultaneously active oscillations lead to differential learning of metric patterns versus non-metric and rhythmic patterns given the metric binding hypothesis.

Evidence for DAT

Evidence associated with various entrainment models of metre perception derives from both behavioral and biological sources.

Behavioural assessments of DAT

Experimental research often concerns responses to timing of metrically regular and irregular contexts. The most rigorous tests involve threshold judgements of timing and categorical time judgements (see Jones 2004 for a review).

Single oscillator entrainment models predict that lower-order serial IOIs of monotone rhythms are important, a finding confirmed by Demany and Semal (2002). These models also correctly predict that, in judging time intervals, listeners will distort unexpected time intervals to fit with a contextually expected beat span (Barnes and Jones 2000). Other entrainment models, which involve biologically preferred periods (McAuley 1995), also find support McAuley *et al.* (2006). Two oscillator entrainment models, used to describe metre perception, assume that one oscillation entrains to a higher metric level, marked by more salient accents, while another oscillation, with a shorter period, entrains to embedded event time spans, marked by less salient accents. Such a model was shown to correctly predict that greater metric regularity (within and between trials) enhances temporal acuity (Jones and Yee 1997; Large and Jones 1999).

Acuity thresholds are affected by tempo. London (2004) argued that such acuity limits affect metre identification, biasing listeners toward particular metres at certain tempi. Effectively, a perceived tactus corresponds to a lower metrical level in relatively slow patterns but a higher one in faster patterns (Handel and Oshinsky 1981; Parncutt 1994; Duke 1989).

McAuley *et al.* (2006) found that the limits of tempo perception (e.g. Weber's Law) depend upon entrainment constraints expressed by *entrainment regions.* An entrainment region is a range of tempi, surrounding a preferred event rate, that corresponds to good entrainment. Both the location and width of these regions were found to shift with age: children were shown to prefer narrow entrainment regions, surrounding a fast event rate (active oscillations with brief periods), whereas elderly listeners had

broader entrainment regions centered on slower events (active oscillations with longer periods). Thus, perceived metre may modulate not only with tempo but also with age. Also see Drake and Botte (1993), Miller and McAuley (2005), Jones and McAuley (2005), and Parncutt (1994).

Biological assessments of DAT

Neurophysiological findings buttress entrainment theory (see Zanto *et al.* 2006). Consistent with DAT, electroencephalography (EEG) reveals neural oscillations that synchronize to periodic auditory stimuli in the musical range, i.e. 2 Hz (Will and Berg 2007).

Using event-related potentials (ERPs), Brochard *et al.* (2003) were the first to verify the presence of subjective accents, i.e., internalized beat patterns (Fraisse 1963; Woodrow 1932). They found ERP activity in the parietal cortex of non-musicians that reflected duple metre expectancies (see also Besson and Faita 1995; Janata 2001). Often ERP signal frequencies (0–10 Hz) reveal relatively long latency brain responses (e.g., P300), which may reflect a synthesis of higher frequency oscillations (Makeig *et al.* 2004). Indeed, fronto-cortical ERP recordings revealed two kinds of high frequency activities (Snyder and Large 2005):

1 An induced periodic response, in the Beta/Gamma range (20–30Hz), prior to onsets of metrically expected tones;

2 A phase-locked evoked Gamma (30–60 Hz) response following tone onsets.

These findings confirm DAT distinctions between expectancies (oscillator period) and expectancy violations (phase corrections) (Janata 2001; Zanto *et al.* 2005).

A common question is: 'Are internal oscillations purely event driven?' (Iverson *et al.* 2006). Both behavioural and neurophysiological studies suggest the answer is 'No'. Combined manipulations of event structure with task and instructions (imagery, attentional set) suggest that event structure plays a role in facilitating or inhibiting listeners' compliance with instructions (Palmer and Krumhansl 1990; Klein and Jones 1996; Janata and Grafton 2003; Snyder and Large 2005; Iverson *et al.* 2006). Clearly, people rely upon both guided imagination and event structure to shape metric expectancies.

Rhythm

Rhythm is a serial figure based on an arrangement of discrete time intervals. It contrasts with metre, which is based upon embedded time intervals. In this section, I outline current limits on our understanding of rhythm perception.

Theoretical background

Many contemporary approaches to rhythm perception assume that it is psychologically distinct from metre perception (Figure 8.1(b) versus Figure 8.1(a)). Rhythm perception is assumed to depend upon temporal grouping principles, given by Gestalt rules of proximity, similarity, continuity, etc. In turn, Gestalt theory holds that rhythm perception is innate, based upon an automatic, primitive, universal process that is governed by hard-wired, domain-free, grouping principles. Thus, rhythm perception is considered inherently different from metre perception, which is viewed as an acquired skill, reflecting domain-specific musical rules.

The classic dichotomy of rhythm and metre perception is appealing for several reasons. First, it captures an experiential difference between serial (rhythmic) and embedded (metric) time structures. Second, reliance on Gestalt principles leads to coarse coding of serial time spans which correctly captures listeners' often fuzzy percepts of rhythmic time spans. By this account, the rhythmic figure of 400–200–200 ms invites lax encoding of proximal tones as 'groups', segmented by non-proximal tones (i.e., groups of 1 versus 3 tones; cf. Figure 8.2). Nominal codes of time intervals as either short (proximal) or long (non-proximal) yield a coarse rhythmic code, such as long–short–short for this figure. Third, nominal codes often accurately predict perceptual confusions among rhythms. For instance, the 400–200–200 ms figure has the same nominal code (long–short–short) as 500–100–200 ms, leading to observed confusions of such rhythms. In sum, Gestalt rules are intuitively compelling and coarse temporal groupings, nominally encoded, offer explanatory value.

In spite of the appeal of Gestalt theory, a rhythmic/metre dichotomy cloaks pitfalls. First, because Gestalt principles are hard-wired, this approach denies that listeners may blend innate

with acquired responses to time structures. For instance, the two confusable rhythms (above) may be eventually differentiated as listeners acquire sensitivity to different temporal nesting properties. Second, by denying a role for learning, this approach discourages research on this topic. Indeed, Gestalt rules are often mistaken for final explanations when they are simply useful descriptions of phenomena that require explanation. Third, this dichotomy renders it difficult or impossible to address rhythmic priming of metre and vice versa.

DAT assumes that learning builds upon innate oscillatory brain activities. It offers a potential for explaining both metre and rhythm perception based on entrainment constraints associated with their respective time properties. Perceptual learning (i.e. the metric binding hypothesis) depends upon entrainments of innate oscillations elicited by an event's time spans. Although multiple time spans occur in both metric and non-metric rhythms (cf. Figure 8.1), they promote different learning paths. Relationships among saliently marked embedded time spans are typically orderly and aligned to highlight consistent ratio time relationships in metric patterns, whereas in rhythmic figures, time spans from grouping accents can offer unruly, misaligned, embeddings (especially in non-metric patterns) that obscure higher level temporal regularities. Because of this, metric patterns promote quicker binding of oscillators across embedded time levels than do rhythmic patterns. Rhythmic figures that lack consistent higher-order time spans cannot support effective entrainment of higher level oscillators; instead, loosely connected oscillations among IOI resolve to group segmentations. It follows that DAT can address rhythmic priming of metre and vice versa (Desain and Honing 2003). Nevertheless, despite its potential no DAT task model has formalized these ideas to rigorously explain serial segmentation in rhythmic patterns. In this regard DAT and Gestalt approaches share incomplete explanations of rhythm perception.

Empirical evidence on rhythm perception

Listeners can distinguish among theoretically confusable rhythms if timing differences are sufficiently large (Hebert and Cuddy 2002) or if patterns occur repeatedly (Handel 1992). Although poorly understood, listeners do learn to differentiate confusable rhythms having similar Gestalt grouping codes.

An important difference between DAT and Gestalt accounts is the latter's emphasis on nominal coding of rhythmic time spans. By contrast, DAT features roles for both interval (tempo) and ratio (metre/rhythm) time relationships. Critically, even in brief rhythmic sequences, listeners are sensitive to rhythmic categories with special serial time ratios (e.g., 1:1, 2:1) (e.g., Desain and Honing 2003). Using only two time intervals, incremental lengthening of the first interval (relative to the second) between serial ratios of 1:1 and 2:1 (and vice versa) revealed preferences for the simpler anchoring ratios, consistent with Fraisse's ideas. Not to be overlooked is research showing metric priming of such rhythms (Povel 1981; Clarke 1987; ten Hoopen *et al.* 2006)

Related findings accompany a *time-shrinking* phenomenon (Nakajima *et al.* 1992; Sasaki *et al.* 2002; Nakajima *et al.* 2004). Using brief two-interval patterns, Nakijima and his colleagues find that when a long time interval follows a short one, listeners underestimate it, revealing a gravitation to a preferred serial time ratio of 1:1. However, reversal of the two intervals fails to elicit time expansion. Generally, research on time distortions suggests that perception of rhythmic figures is influenced by stability of certain serial time ratios: 1:1, 2:1, 1:2. Interestingly, brain activities, measured by functional magnetic resonance imaging (fMRI), also appear to depend upon the simpler time ratios produced by listeners (i.e., stable anchoring ratios) and not stimulus ratios (Sakai *et al.* 1999).

Marking time and accent salience

All time patterns exist because *accents* mark constituent time spans. Accents 'call attention' to onsets of time spans. In this section I focus upon the neglected issue of *accent salience* (for different perspectives, see Krumhansl 2000; Clarke 1999).

Theoretical background

The dichotomy of rhythm and metre perception holds implications for understanding accents as time markers. Sometimes accents are drawn into this dichotomy through the assumption that codes for metre and rhythm are processed independently and/or stored in respectively separate modules. Thus, metric versus rhythmic accents may be distinguished by linking them, respectively, with different physical dimensions (e.g., time, intensity, pitch etc.). For instance, in some views metre is considered to be marked by intensity accents whereas rhythm is marked by duration accents. A related hypothesis holds that rhythm and metre percepts are not only dichotomous, but that both are independent of melodic features, e.g., pitch accents.

Complicating discussions of independence versus dependence of metre, rhythm and melody is the practice of differentiating musical accents a priori by dimensionality alone, e.g., as intensity, time, or pitch accents. This practice raises certain dilemmas. Consider this: if an accent effectively 'calls' attention to a point in time, then logically accents *cannot* be solely defined by their dimensions. Rather, accents must be contextually defined because they only occur in serial contexts. An accent gains its power as a *serial change*, regardless of dimension. A large relative intensity change in a musical sequence is more attention-getting, i.e., more salient, than a small one. Thus, to compare accents of different types (i.e., dimensions) as effective markers of metre, it is important to equate them for salience.

Dynamic attending theory assumes that accents arise from local serial changes (Jones 1987). This broadens the definition of phenomenal accents of Lerdahl and Jackendoff (1983). Operationally, the salience of an accented tone increases with the:

1 Magnitude of its local serial change along a dimension of variation;
2 Number of simultaneous accents on it (i.e., all else equal, two co-occurring serial changes are stronger than one);
3 Surrounding variability (melodic, rhythmic, etc.) in global serial context (Ellis and Jones in press).

In DAT, various accent types mark time spans of both rhythm and metre. Further, if the perceptual impact of an accent, i.e. its salience, turns on the magnitude of a local serial change, then different accent types (pitch, time, etc.) can have equivalent salience. This idea is formalized in the concept of joint accent structure (JAS) (Jones 1987). A JAS reflects a temporal collaboration of different (salient) accent types that

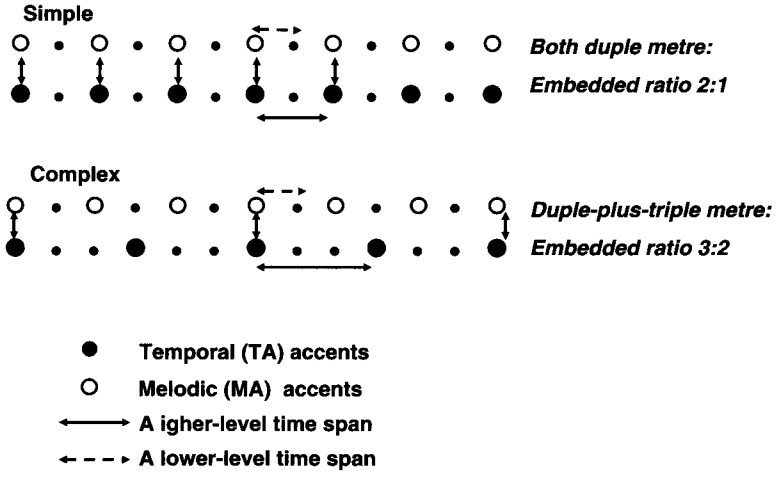

Fig. 8.5 Upper JAS example: aligned melodic (MA) and duration accents (TA) lead to a duple metre JAS pattern. Lower: misaligned accent sequences form a polyrhythmic JAS-based duple (MA) and triple (TA) patterns.

outline a common, higher order, time structure. As shown in Figure 8.5, structural interdependence of melodic (pitch change) and rhythmic (duration changes) accents is inherent in that a metric structure emerges from time spans marked by both melodic and rhythmic accents. One configuration reflects a simple combination of melodic accent and rhythmic accent sequences (duple metre embedding ratios of 2:1) where both melodic (MA) and temporal (TA) accents align; in the other, a more complex JAS combination results in misaligned accents (polyrhythmic ratios of 3:2). According to a metric binding hypothesis, the former is the more stable due to its resonance properties. Nevertheless, as experimental compositions, both JAS patterns reflect interdependence of melodic, rhythmic and metric structures.

Experimental evidence on marking time

Experimental evidence offers mixed support for hypotheses about perception of musical events containing melodic and temporal accents. Some favours a hypothesis that melody, rhythm and metre are perceived independently, whereas other evidence favours a perceptual dependency hypothesis. Such issues remain unresolved.

Research which relies upon established compositions is consistent with the idea that melody and metre are perceptually independent. For instance, listeners' inferred beats indicate a reliance on rhythmic (duration) over melodic accents (Snyder and Krumhansl 2001; Hannon *et al.* 2004). Hence, Huron and Royal (1996) question the effectiveness of melodic accents for marking metre. Yet evidence for this conclusion remains inconclusive. In part, this is because the salience of various accents is unknown, and in part it is because such correlational evidence precludes causal inferences. Furthermore, other evidence, based on experimental compositions, favours the alternative view. In these, melodic (pitch) and rhythmic (temporal) accents together appeared to determine listeners' sense of metre (Boltz and Jones 1986; Pfordresher 2003).

A resolution of this issue depends upon insuring comparable salience across accent types. For example, in specified musical contexts we must gauge whether a three semitone pitch leap (melodic accent) is equal in salience to lengthening tone duration by 5 per cent or by 15 per cent (rhythm accents). Overall variability of surrounding melodic and rhythmic contexts must also be controlled.

A few studies have controlled accent salience. Windsor (1993) calibrated intensity accents, and confirmed that larger serial changes in intensity yielded clearer metric identifications. Ellis and Jones (in press) used melodic (MA) and temporal (TA) accents of calibrated equivalence in various sequences to create nine different JAS patterns; to appear in Figure 8.5 (i.e., 2:1 duple; 3:2 polyrhythm). Different JAS conditions combined duple and triple accent patterns in aligned (e.g., duple for TA and MA) and misaligned (e.g., duple TA and triple MA) ways. Listeners rated the metric clarity of all patterns. Results appear in Figure 8.6. In JAS patterns with aligned MAs and TAs, time spans should activate multiple aligned oscillations (for duple or triple metre), and thus here DAT correctly predicts stable metric clusters and high metric clarity. By contrast, in misaligned JAS patterns, with irregular high-level time spans, DAT correctly predicts lower clarity.

These findings reveal the importance of calibrating accent salience. Melodic and rhythmic accents, of comparable salience, lead to JAS

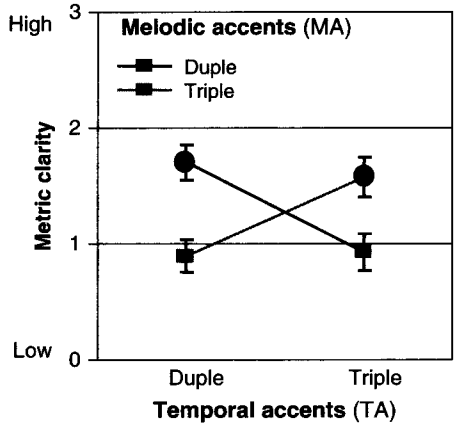

Fig. 8.6 Metric clarity ratings of average listeners. Melodic (MAs, dark lines) and temporal (TAs, light lines) accent patterns are either aligned (e.g., circles) or mis-aligned (squares) (Ellis and Jones in press).

outline a common, higher order, time structure. As shown in Figure 8.5, structural interdependence of melodic (pitch change) and rhythmic (duration changes) accents is inherent in that a metric structure emerges from time spans marked by both melodic and rhythmic accents. One configuration reflects a simple combination of melodic accent and rhythmic accent sequences (duple metre embedding ratios of 2:1) where both melodic (MA) and temporal (TA) accents align; in the other, a more complex JAS combination results in misaligned accents (polyrhythmic ratios of 3:2). According to a metric binding hypothesis, the former is the more stable due to its resonance properties. Nevertheless, as experimental compositions, both JAS patterns reflect interdependence of melodic, rhythmic and metric structures.

patterns of different complexity when combined with embedding ratios of 2:1 versus 3:2. Listeners' ratings of these patterns supports the hypothesis that percepts of melody, rhythm and metre are not independent.

Summary

This chapter selectively reviews psychological research on perception of metre and rhythm. Its focus is upon the dynamics of attending to patterns in time. It considers how event timing, as outlined by salient accents in metre, rhythm, and even melodic structures, may guide attending in time, bootstrap learning, and influence time perception.

CHAPTER 9

Components of melodic processing

Mark A. Schmuckler

Introduction

Melody is the most ubiquitous form of musical structure with which listeners come into contact on a daily basis. Mirroring the prevalence and importance of melody, research in music cognition has focused extensively on the processes involved in perceiving and remembering melodic structure. Despite these years of study, however, our understanding of pitch structure in melody can be described simply, with respect to the two components of tonality and pitch contour. Although the importance of these two components has been recognized over the years, it is only recently that workable models of these components have been proposed. This chapter describes such models of tonality and melodic contour, and discusses the role of these components in listeners' perceptions of and memory for melody.

Components of melodic processing

Melody is, with little doubt, the most ubiquitous form of musical structure with which people come into contact on a daily basis. Everywhere in our environment we are exposed to melody, from the songs we hear on the radio to the tunes we hum to ourselves. Additionally, melody is arguably the first clearly musical structure to which infants are exposed, through the prevalence of parental singing (e.g. Nakata and Trehub 2004, Rock *et al.* 1999; Shenfield *et al.* 2003). Finally, although cultures throughout the world vary in their respective musical structures, virtually all contain some form of melody (Eerola *et al.* 2006; Unyk *et al.* 1992).

Given its central role in music, it is no surprise that investigations of melody have occupied a similarly privileged position in music cognition. Such research has taken a variety of forms, ranging from explorations of how melodies are formed (i.e., what principles underlie the grouping of individual notes into a single perceptual object such as melody), to investigations of how melodies are themselves perceived (e.g., what does a listener truly experience upon hearing a melody) to how melodies are perceived in relation to one another (e.g., melodic categorization or similarity) to how melodies are remembered. Interestingly, although research on such questions has been extensive and insightful, there has been little explicit integration across these topics. Along these lines, one can ask whether there are any fundamental principles or organizational structures that function across these diverse aspects of melodic processing.

Fortunately, a close look at the literature on melodic processing implicates the operation of two basic organizational structures. Specifically, there is strong evidence for two fundamental components of melodic processing—a melody's tonal structure, and its melodic contour. Throughout a wealth of empirical findings these two components have time and again shown themselves to play a principal role in listeners' melodic processing, with tonality and contour continually influencing listeners' perceptions of

and responses to melodies, as well as their subsequent memory for these melodies.

Recognition of the importance of tonality and contour in melody perception is not a new insight (e.g. Dowling 1978). In a classic paper, Dowling (1978) identified just these two components as critical in melodic processing, positing that melodic memory, and by implication melodic perception, is driven by a melody's tonality and contour. Over the years Dowling and others have continually demonstrated the importance of these components in melodic processing, employing a wide array of perceptual encoding, similarity, and memory paradigms.

Although our understanding of melodic processing has grown substantially since Dowling's (1978) original insights, nothing has yet arisen that would undermine the proposed fundamental role played by these two components. As such, tonality and contour are still considered to be the two primary characteristics of listeners' perceptions of melody (e.g. Krumhansl 2000; Schmuckler 2004). One way in which our knowledge has advanced, however, is in the establishment of models for formalizing the structure of these components. Such models allow for an explicit characterization of these parameters, and thus enable the generation of specific predictions for melodic processing based on the structure highlighted by these models.

Models of tonality and contour

Models of tonality

The impact of musical tonality, or the hierarchical organization of the chromatic set around a single reference pitch, on the processing of musical passages is one of the most thoroughly studied research topics in music cognition. Approached from musicological (e.g. Lerdahl 2001; Temperley 2001, 2007), psychological (e.g. Krumhansl 1990a, 2000), and neuroscientific perspectives (e.g. Janata *et al.* 2002; Koelsch and Siebel 2005), our knowledge of the impact of tonal structure on musical processing is immense.

In keeping with this focus, there have been a large number of models proposed to account for the psychological organization of tonality (Krumhansl and Kessler 1982; Shepard 1982; Tillman *et al.* 2000), as well as explaining how listeners apprehend tonality in the first place. With reference to this latter goal, models describing the process of key-finding can be roughly divided into two categories (Huron and Parncutt 1993; Schmuckler and Tomovski 2005; Temperley and Marvin 2008)—those that posit the use of structural–functional information in key determination, and those that employ an event distribution strategy to key-finding.

The structural–functional models that have been proposed are diverse (e.g. Abe and Hoshino 1990; Brown 1988; Brown and Butler 1981; Butler 1990; Butler and Brown 1994; Holtzman 1977; Longuet-Higgins and Steedman 1971; Matsunaga and Abe 2005; Yoshino and Abe 2004), although all share an underlying assumption that there are particular local features or components of musical patterns that signal or indicate a specific musical key. Of these structural models, the most well-known are the approaches proposed by David Butler and Helen Brown (Brown 1988; Brown and Butler 1981; Butler 1990; Butler and Brown 1984, 1994) and by Jun-ichi Abe and colleagues (Matsunaga and Abe 2005; Yoshino and Abe 2004). Although a full review of these approaches cannot be considered here, Brown and Butler's 'intervallic rivalry theory' assumes that it is the presence of the rare intervals of the diatonic set (the minor seconds and the tritone), along with an additional disambiguating tone, that indicate the to-be-perceived tonality. Similarly, Abe and colleagues have posited that key-finding arises due to attempts to interpret the tones of a melodic pattern as members of a given diatonic set, and specifically the tonic triad (Abe and Hoshino 1990; Abe and Okada 2004; Matsunaga and Abe 2005; Yoshino and Abe 2004). Thus, both approaches explicitly look for certain structural and/or functional relations within musical events, and use the occurrence of these events to establish a key.

An alternative to this approach are distributional models of key-finding. Probably the best-known such model was proposed by Krumhansl and Schmuckler (1986a; see Krumhansl 1990a), who suggested that key-finding could be accomplished by matching the relative durations of the chromatic set in a piece of music with the hierarchies of perceived tonality stability of the

chromatic set with reference to the 12 major and 12 minor tonalities (Krumhansl and Kessler 1982). Although numerous refinements to this model have been proposed (Huron and Parncutt 1993; Smith and Schmuckler 2004; Temperley 1999, 2001, 2002, 2007; Toiviainen and Krumhansl 2003), the basic premise of this approach has remained invariant.

Both models have, over the years, garnered an impressive degree of empirical support. Multiple studies have demonstrated the importance of certain structural relations in key-finding (Brown 1988; Brown and Butler 1981; Brown *et al.* 1994). In Brown and Butler (1981), for instance, listeners' key judgements in response to melodic trichords accorded well with the predictions of the rare interval hypothesis, with tonal judgements more consistent for trichords containing rare interval information than trichords in which the interval information was consistent with multiple keys. Similarly, multiple studies have demonstrated the importance of distributional information in key-finding (e.g., Schmuckler and Tomovski 2005; Toiviainen and Krumhansl 2003). Schmuckler and Tomovski (2005), for example, found that this model predicted listeners' tonal percepts for a range of materials, including very short initial excerpts of Bach and Chopin preludes, increasingly longer segments of Chopin preludes, and an entire Chopin prelude. In all of these cases, this approach modelled tonal percepts in terms of sensitivity to picking up the intended key of the passage, as well as in predicting errors in key-finding.

The simultaneous success of these different models raises the question of the relation between these approaches. Typically, these models have been viewed as fundamentally inconsistent with one another (Butler 1989; Krumhansl 1990b), although there have surprisingly been no attempts to explicitly compare these approaches. In one exception, reported by Schmuckler and Tomovski (2000), four variants of short musical excerpts were created that systematically manipulated the rare interval and distributional information available in these passages. Samples of these variants appear in Figure 9.1, and presents a series of passages in which distributional and rare interval information imply the same key (variant A), distributional but not rare interval information is specific to a given key (variant B), and distributional and rare interval information implicate different keys (variants C and D).

Using a probe tone and a tonic finding procedure, listeners' tonal percepts in response to these variants were assessed. Figure 9.2 summarizes the results from these studies, presenting the correlation between the averaged probe tone ratings and the C and G major tonal hierarchies and the percentage tonic choices for the target keys of C and G major (all data were ultimately transposed to these keys) for the variants. One clear finding is that tonal percepts matched the note distributions of the passages, a result seen most easily in variants C and D in which ratings and tonic choices aligned with predictions based on note distributions. There was, however, a subtle influence of rare interval information on tonal percepts. Specifically, Figure 9.2 also reveals a systematic weakening of tonal percepts when the two cues do not coincide. Thus, variant A, in which both sets of information indicated the same key, produced the strongest tonal percepts, followed by variant B, in which rare interval information was ambiguous, and finally variants C and D, in which the two sets of information diverged. Clearly the two types of information support each other in tonal perception.

Subsequent analyses support the idea that distributional and rare interval information converge in their tonal implications. For both processes to operate in musical contexts not built solely on the diatonic scale, it must be that the pattern of interval occurrences characterizing the diatonic set also represents the interval frequency of real musical contexts. In keeping with this idea, Table 9.1 presents an interval count for the four variants of the stimulus passages of this study, and reveals that the diatonic interval vector closely matches the interval content of these musical passages. Moreover, in a simulation study, 50 40-note melodies were randomly generated using note frequencies that either matched the tonal hierarchy, or were randomly organized (see Smith and Schmuckler 2004). Table 9.1 also presents the interval counts from this simulation, and demonstrates that randomly generated melodies containing note distributions similar to that found in tonal music also produce interval sets matching the

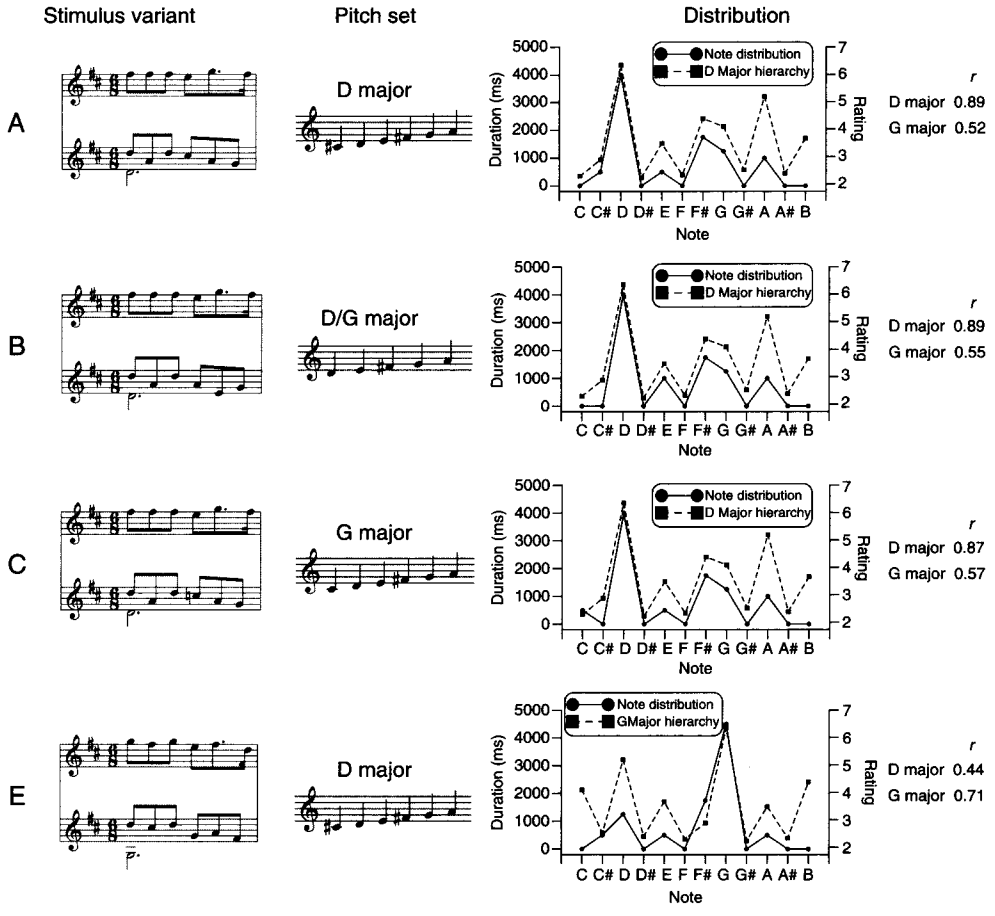

Fig. 9.1 Sample stimuli from Schmuckler and Tomovski (2000). The four variants correspond to passages in which both the pitch set and the note duration distribution strongly indicate the same key (variant A), the note distribution but not the pitch set indicates a single key (variant B), and the pitch set and note distributions indicate different keys (variants C and D).

diatonic interval vector. Together, these findings suggest that distributional and structural–functional approaches are really part of the same process, and that a complete description of tonality and key-finding will require both global distributional properties, along with more localized, structural–functional information, an idea that has been recognized by other researchers (Temperley and Marvin 2008).

Models of contour

In contrast to tonality, models of melodic contour have received less attention over the years. Of the contour models that do exist, it is also (roughly) possible to divide them into two categories, the first based on local parameters of contour and the second on global contour information. In the first group are models focusing on the individual interval content of contour (Friedmann 1985, 1987; Marvin 1991, 1995; Marvin and Laprade 1987; Morris 1993; Quinn 1999), whereas the second group consists of procedures for characterizing the rises and falls within the contour, primarily through the use of time series analyes (Eerola and Bregman 2007; Eerola *et al.* 2001, 2006; Schmuckler 1999).

Again, both types of models have generated supporting experimental results. Quinn (1999),

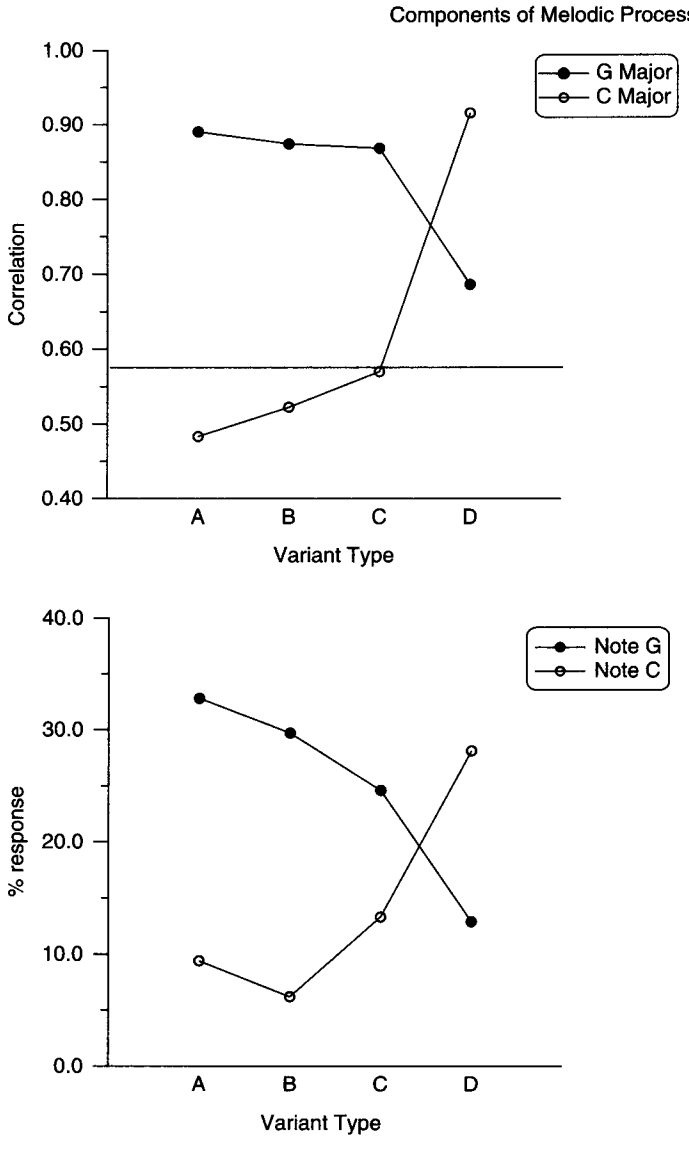

Fig. 9.2 Results from the two experiments of Schmuckler and Tomovski (2000). The top figure graphs the correlation between the averaged probe tone ratings and the tonal hierarchies for the target keys of G and C major across the four stimulus variants. The bottom figure graphs the percentage of times the notes G and C were chosen as the tonic tone, as a function of the four stimulus variants.

for instance, demonstrated that the perceived similarity of pairs of short melodies was predictable from comparability in the rise/fall relation between adjacent notes, and from non-adjacent notes separated by a single tone. Schmuckler (1999), in contrast, demonstrated that perceived contour similarity for pairs of melodies was predictable from the degree of overlap of the cyclic information of these contours, as quantified by a Fourier analysis of the contour code.

Table 9.1 The interval content of the diatonic set (Brown and Butler 1981), the stimulus variants of Schmuckler and Tomovski (2000), and of the simulation study using hierarchical and random organizations of pitch information (Smith and Schmuckler 2004). The final column shows the correlation between the interval vector of the diatonic set and the remaining interval vectors

Source	Interval vector						Correlation
	m2	M2	m3	M3	P4	TT	
Diatonic set	2	5	4	3	6	1	–
Variant A	212	352	303	301	534	58	$r(4) = 0.95^{**}$
Variant B	140	378	325	253	521	0	$r(4) = 0.99^{**}$
Variant C	145	341	328	297	508	36	$r(4) = 0.96^{**}$
Variant D	195	296	244	281	567	57	$r(4) = 0.90^{**}$
Hierarchical	98.1	131.9	120.4	114.7	170.0	43.0	$r(4) = 0.95^{**}$
Random	137.6	128.7	137.7	111.4	114.2	50.1	$r(4) = 0.52$

** $p<.01$

Subsequent work (Schmuckler (2004 submitted) extended these findings to rhythmically complex melodies, using both direct and indirect similarity measures. Together, these findings suggest that melodic contour can be reliably characterized by both the individual interval relations within the contour as well as by more global contour parameters, although it is critical to recognize that these two approaches are not mutually exclusive. Schmuckler (2004) has hypothesized that the former approaches might be most applicable to short melodic contours, whereas the latter approach could be more powerful when applied to longer melodies.

Tonality and contour in melody perception

One advantage to the availability of tonal and contour models is that they provide a means for predicting aspects of melodic processing such as the perceptual organization of melodic form and melodic memory. The remainder of this chapter focuses on the role of contour and tonality in these aspects of melodic processing.

Tonality and contour in perceptual organization

Given the interest in tonality and contour, it is surprising that research on the role of these factors in the perceptual organization of melodies per se has been relatively neglected over the years. Of the two, research on perceptual organization has looked more at the role of contour, and has (not surprisingly) found that this factor influences perceptual organization. Probably the most obvious aspect of perceptual organization in which contour has been examined is in stream segregation (Bregman 1990, 2005; Miller and Heise 1950; Van Noorden 1975). Unfortunately, a thorough review of this research is outside the purview of this chapter (see Bregman 1990, 2005; Carlyon 2004; Snyder and Alain 2007, for reviews). Even a cursory look at this topic, however, demonstrates that of the myriad of factors underlying stream segregation, one of the most important involves pitch proximity, and more critically in the current context, that the contour of pitch changes can drive stream segregation. For instance, Bregman and Dannenbring (1973) demonstrated that frequency glides, or tones with a continuous pitch contour, were grouped together into a single auditory stream, as opposed to discrete tones varying in pitch that grouped into separate streams; similar arguments have been advanced for pitch contour in the grouping of speech sounds (Darwin and Bethell-Fox 1977; Remez *et al.*1994).

Two well-known auditory perception illusions—Deutsch's (1975) scale illusion (Butler 1979; Deutsch 1975; Radvanysky *et al.* 1992), and the continuity illusion (Grossberg *et al.* 2004; Miller and Lickliter 1950; Tougas and Bregman 1990)—provide another example of contour influencing perceptual organization. In the scale

illusion, listeners hear simultaneously sounded ascending and descending diatonic scales, with the tones of these scales alternated between the ears. Rather than hearing this pattern organized based on source localization (by ear) or as a prototypical musical pattern (the diatonic scale), listeners hear two simple melodies, the first consisting of an ascending and descending line and the second consisting of a descending and ascending line. In the continuity illusion, a sound of long duration that is interrupted by a sound of short duration is heard as continuing through the noise. However, when the continuous information involves a set of competing glides, listeners sometimes hear a pair of bouncing pitch glides, comparable to the percept in the scale illusion (Grossberg *et al.* 2004; Tougas and Bregman 1990).

In both cases, these percepts are typically ascribed to perceptual organization by pitch proximity, and possibly good continuation. An alternative, however, is that listeners are hearing two simple melodic contours, ones that, according to the Fourier analysis model, contain a large amount of power in the fewest number of cyclic frequency components. This observation suggests that the role of contour in perceptual organization might be more quantitatively predictable, with simplicity of the amplitude spectrum driving a specific organization. If true, this would provide an interesting formalization of the Gestalt law of *prägnanz* (Koffka 1935), or the idea that good patterns have few alternatives (Garner 1970).

Somewhat surprisingly, there are few studies demonstrating an explicit role for tonality on perceptual organization. One line of work related to this question involves research on the perception of polytonality (Krumhansl and Schmuckler 1986b; Thompson and Mor 1992). Krumhansl and Schmuckler (1986b), for instance, examined tonal percepts in Stravinsky's *Petroushka* (which instantiates the two tonal centres of C and F# major) using both selective and divided attention tasks, and demonstrated that listeners were unable to form two independent tonal percepts. Instead, percepts of this passage were a complex amalgamation of the two tonalities, similar in structure to a music-theoretic proposal by Van den Toorn (1983) based on the octatonic collection. Thompson and Mor (1992), in contrast, did find that listeners perceived both keys of bitonal passages by Dubois and Milhaud, with the weights of these tonalities consistent with their relative importance in the musical score. Irrespective of an explanation for these divergent findings (which likely lies in the specifics of the musical contexts employed), this work does imply (indirectly) that tonal information can be a means of perceptually organizing melodic passages.

In a more explicit look at the role of tonality on perceptual organization, Dowling *et al.* (1987) had listeners identify nursery rhymes in which the melody notes were interspersed with distractor tones varying in their pitch overlap, temporal organization, and tonality, with the target. Interestingly, although pitch overlap and temporal organization influenced target identification, the tonal relation between target and distractors did not impact performance. In contrast, Bigand *et al.* (2000) had listeners attend to one of two French nursery rhythms, presented an octave apart, with these melodies played in the same key, a related key, or a distant key. These authors observed that varying tonal relations had no effect on detection of changes to the melodies (hits), although increasing tonal distance did lead to increased false alarms. Together, this work presents a mixed pattern, with some results consistent with the notion that tonality influences the perceptual organization of melodies, whereas other results indicated no such effect.

Recently, Vuvan and Schmuckler (2007) have further explored this question, employing the interleaved melody task of Bey and McAdams (2002) in which listeners hear a target melody followed by a pair of interleaved melodies, and must determine whether one of the interleaved melodies was the same as the target melody. In this study, the interleaved melodies varied in their average pitch spread (6, 9, 12, and 15 semitones), their inter-onset interval between sequential tones (80, 100, 120, and 140 msec), and in their tonalities (same, related, and unrelated; see Figure 9.3 for sample stimuli).

Figure 9.4 shows the averaged d' and bias scores for same/different judgment as a function of pitch spread and tonality (inter-onset interval had no effect in this study). Analyses of discrimination scores revealed a surprising pattern of

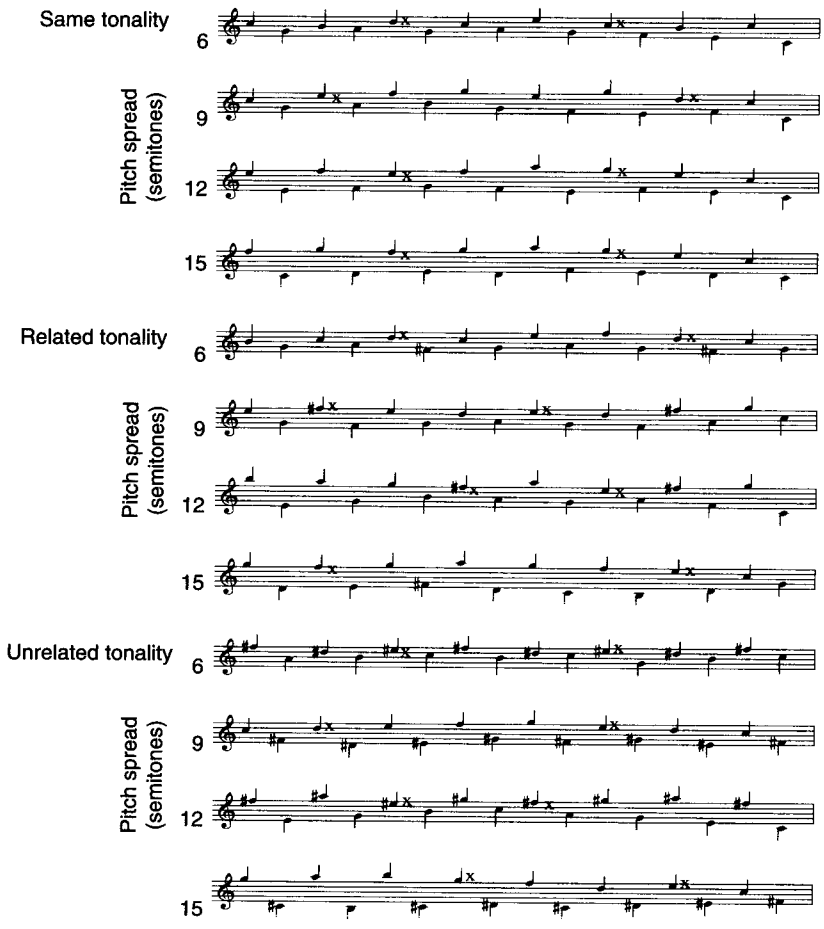

Fig. 9.3 Sample stimuli from Vuvan and Schmuckler (2007). The two interleaved comparison melodies could be in either the same key (e.g., C and C major), a related key (e.g., C and G major), or an unrelated key (e.g., C and F# major), and could be separated by an average of 6, 9, 12, or 15 semitones. The location and pitch of the changed notes in the target melody is notated by an 'X' adjacent to the note in the musical staff.

decreasing discrimination with increasing pitch spread, although this effect was likely due to a drop in performance at the largest pitch spread. More importantly, analyses of discrimination and bias revealed the worst performance for interleaved melodies having unrelated tonalities, followed by melodies with related tonalities, and finally by melodies with the same tonality. Although counterintuitive, this finding does converge with Krumhansl and Schmuckler (1986b) and Bigand *et al.* (2000), who both observed that divergent tonalities negatively impacted the formation of independent streams.

Tonality and contour in musical memory

Probably the most central arena in which tonality and contour have been recognized as critical factors in melodic processing involves memory for music. Unfortunately, a comprehensive review of work on this question cannot be presented here. Nevertheless, it is instructive to discuss, even if only superficially, some of the evidence demonstrating the importance of these factors in memory for music.

Research on the role of melodic contour in musical memory has a long history in music

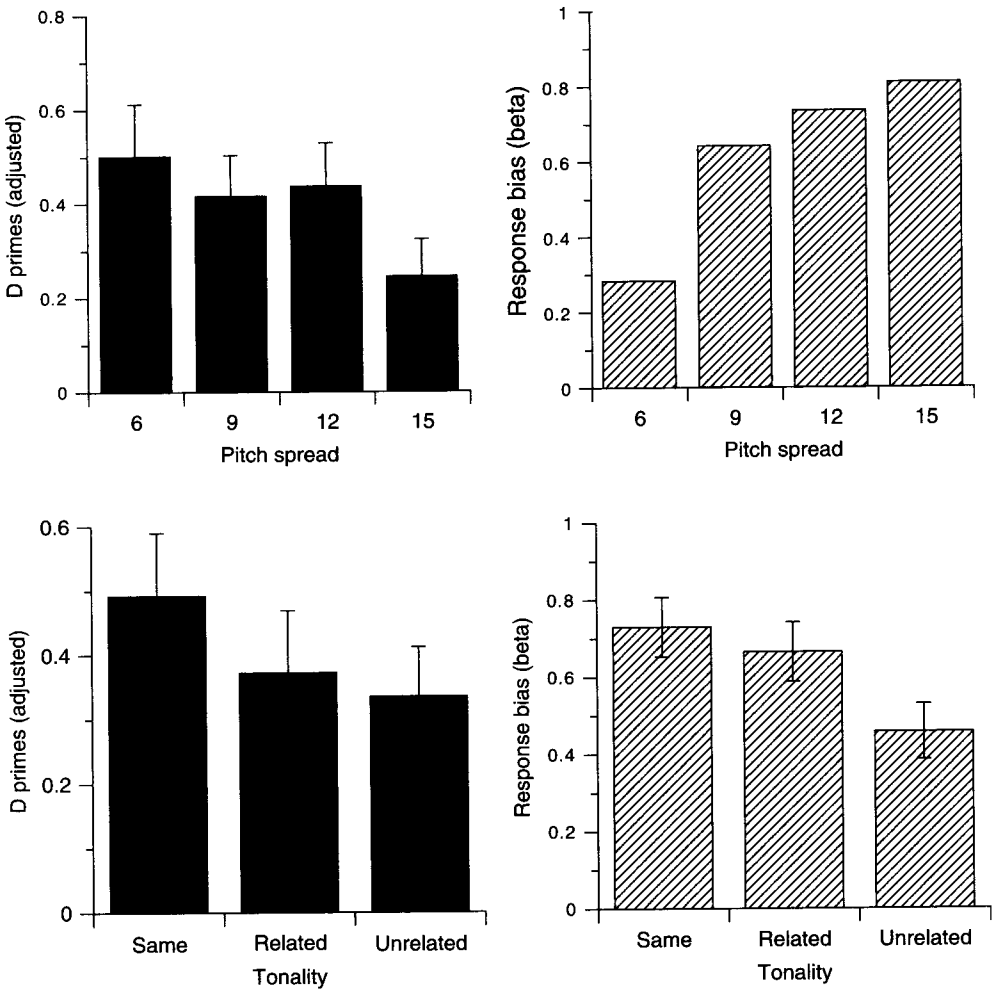

Fig. 9.4 D' and bias for same/different target-comparison judgements as a function of pitch spread (top) and tonality (bottom) in Vuvan and Schmuckler (2007).

cognition. In early classic work on this topic, Dowling and colleagues (Dowling 1971, 1972; Dowling and Fujitani 1971) demonstrated that listeners' short-term melodic memory was dramatically influenced by the melody's contour, with the ability to distinguish between a standard melody and a comparison melody transposed to a different starting pitch more difficult when the melodies shared a comparable melodic contour. Similarly, Dowling and Hollombe (1977) found that recognition of octave-scrambled familiar melodies (hence melodies available in long-term memory) was significantly enhanced when these melodies retained their original melodic contour, relative to versions that violated this contour. These findings, and others like them, demonstrate that short-term melody recognition is strongly influenced by contour information (Croonen and Kop 1989; Cuddy *et al.* 1981; DeWitt and Crowder 1986; Dowling 1991; Dyson and Watkins 1984; Freedman 1999; Idson and Massaro 1978; Massaro *et al.* 1980; Watkins 1985).

There are, however, important limitations to the use of contour in melody recognition. Edworthy (1982, 1985), for instance, demonstrated that

contour information becomes less precise in memory as melody length increases, a finding attributed to the growth of tonal information in memory. Moreover, multiple studies have demonstrated that contour information dominates memory following short delays, but decreases in potency after longer delays (Dowling 1991; Dowling *et al.* 1995). Dowling (1991), for instance, found that listeners frequently confused same contour, tonal melodies after short delays (e.g., 11 s) but not after long delays (e.g., 39 s). Most importantly, and as summarized by Dowling (1994), it is clear that although contour is crucial for melodic memory, it does not function independently, but rather, it is integrated with other key melodic features, such as tonality.

The evidence for tonal influences on melodic memory is also robust. One way in which tonality influences memory, and an effect comparable to the research just described, is that tonally strong melodies are better remembered than tonally weak or atonal melodies (Boltz 1991; Croonen 1994; Dowling 1991; Dowling *et al.* 1995; Halpern *et al.* 1998; Watkins 1985). Croonen (1994), for instance, demonstrated that listeners' accuracy in a standard-comparison melody task was significantly influenced by the tonality of the stimuli, with strongly tonal sequences better remembered than weakly tonal melodies.

A second, albeit less researched finding, involves the presence of key-distance effects in memory (Bartlett and Dowling 1980; Bharucha and Krumhansl 1983; Krumhansl *et al.* 1982; Krumhansl and Castellano 1983). Bartlett and Dowling (1980), for instance, had listeners' recognize comparison melodies that were exact transpositions of standard melodies from non-exact transpositions when the comparisons were in the same key, a related key, or an unrelated key. These researchers observed that it was harder to distinguish non-transposition comparisons from standards (i.e., higher false alarm rates) when the melodies were in the same or related keys, as opposed to unrelated keys. Interestingly, this effect did not occur for transpositions, suggesting that memory for melodies contains relatively separable stores for tonal information versus interval information.

Other evidence exists for key distance effects in musical memory, although not explicitly for melodic materials (Bharucha and Krumhansl 1983; Krumhansl *et al.* 1982; Krumhansl and Castellano 1983). Krumhansl *et al.* (1982), for instance, found that recognition memory for chords was influenced by the tonal context in which these chords were embedded, such that the key distance of the tonal context and the key of the to-be-remembered chords predicted the probability that a given chord would be recognized, as well as memory confusion errors and asymmetries in confusion errors. Accordingly, there is robust evidence for key distance effects in memory, both for melodic and harmonic sequences.

Conclusion

Melody has, over the years, been the focus of intensive investigation in research in music cognition. Somewhat ironically, despite these years of study our understanding of melodic structure can be described simply, with respect to two principal components—the underlying tonality of the melody, and the rising and falling pattern in pitch of the melody. The importance of these two components has, of course, been recognized since the beginning of the study of music in an experimental context, although it is only in recent years that formal models of these components have arisen. With the advent of these models, of course, has come the ability to make explicit predictions regarding how these components might predict listeners' melodic processing, including aspects such as perceptual organization and perceived similarity, as well as listeners' memory for melodic materials.

How might these models be applied to studying perceptual organization and melodic memory? One of the principal limitations of previous work examining tonality and contour in musical processing is that such research did not typically provide any formal characterization of the structure of these factors, and so could not make explicit predictions as to when such factors would play a role, or the relative strength of their role in such situations. For instance, contour relations between melodies were often characterized as being simply same or different, and tonality was typically determined on the basis of diatonicism of the melody.

Unfortunately, such characterizations ignore the idea that there are gradations to the degree

to which melodies are related. Contour similarity studies (Eerola and Bregman 2007; Eerola *et al.* 2006; Eerola *et al.* 2001; Quinn 1999; Schmuckler 1999), for instance, have all convincingly demonstrated that one can compare melodic contours on a continuous, as opposed to dichotomous (e.g., same versus different), basis. Similarly, work in tonal perception (e.g., Smith and Schmuckler 2004; Takeuchi 1994) demonstrates that tonality is not simply all-or-none, but can be characterized in terms of degrees of tonal strength, with some passage more tonal than other passages.

As for perceptual organization and memory, the utility of directly assessing the relatedness between stimuli in their contour and tonal structure is obvious. Perceptual organization, for instance, either in the stability of a specific organization, or the ease with which differing groupings can be formed, should be predictable by the level of similarity between competing organizations. In fact, there is already evidence for this finding, in terms of the previous discussed possible explanations for the scale illusion, or in explaining the discrepancy between Krumhansl and Schmuckler's (1986b) and Thompson and Mor's (1992) research on the perception of multiple tonalities.

Similarly, memory for melodies should be predictable based on the measured degree of contour and tonal similarity between melodies. In the typical standard-comparison memory task, for instance, greater contour or tonal similarity between melodies should be reflected in decreased accuracy overall, and possibly in false alarm rates in particular. Again, there are findings indicative of just such effects. Schmuckler (1997, for instance, observed that listeners' memory for melodies was influenced by the expectedness of the melody's ending (better memory for highly expected endings) and the tonal coherence of that ending (better memory for more tonally coherent endings). Although none of this work explicitly employs assessments of tonality and contour as predictors for memory and memory confusions, it is nevertheless consistent with the notion that such factors can be quantified to make such predictions. Clearly, then, further work investigating the utility of tonal and contour models in predicting perceptual organization and melodic memory has a great deal of potential in providing insight into our understanding of melodic processing quite generally.

CHAPTER 10

Memory for music

Bob Snyder

Introduction

This chapter will focus on musical memory: on how adult listeners form mental representations of music, and on how those representations affect music listening. The chapter will be divided into three sections, which will outline general concepts of memory, address research and theory about musical expectations, and consider listeners' ability to remember various aspects of music. The study of memory in music listening is relatively recent, although the scientific study of human memory dates back to the end of the nineteenth century (Ebbinghaus 1885/1964). The ways in which mind and brain are used in the perception and comprehension of music appear to be much in line with the way they are used in processing in other domains, although there are theories proposing that music is partly modularized in cognition and brain organization (Peretz and Zatorre 2005).

Memory in general

Let us start by defining some of the basic constructs that have been developed in the study of memory. Human memory is said to be *encoded*; events in the world (including events in the body and brain) may cause changes in the detailed micro-structure of the brain that persist over varying amounts of time. These changes are thought to take the form of differences in the strength of connections at gaps (*synapses*) between nerve cells (*neurons*). These connections regulate the flow of electrical charges between neurons. The term *encoding* indicates that these changes assume a form that is different from the things or events that cause them. This is true not only in the sense that neural connections arising through exposure to events in the real world are not the same as those events, but also in the sense that events are encoded in a previously existing context of their meaning to a particular person. In order to persist, a memory must, to some extent, be related to what an individual already knows.

Memory has been defined in different ways that refer to different *modes of functioning*, generally in relation to the time-spans over which it persists. Following research into very brief (250 msec) memory for visual images that yielded the concept of *iconic* memory (Sperling 1960), an analogous concept of a very brief auditory or 'echoic' memory was proposed (Crowder and Morton 1969). Echoic memory is posited as a very brief *sensory* image of an auditory stimulus that persists for a second or two at most; however, the distinction between echoic and auditory short-term memory is not always clear. (Crowder 1993).

A construct with a much more extensive history is that of short-term memory (STM). STM is said to exist on a time scale of seconds, ranging from approximately 4–30 seconds, though it is usually on the order of 4–8 seconds. STM has been referred to as the 'specious present' (James, 1890), and is the window of time within which the present moment of perception and thought are grasped. In addition to this *temporal* limit, STM may also have a *capacity* limit (Cowen 2005) on the actual number of items that can persist as STM at one time. This number was originally proposed by Miller (1956) as 7 ± 2, but has recently been scaled down to a usual maximum of 4 or less (Cowen 2005), although capacity can be increased by practice (Ericsson and Kintsch 1995). This is a very small number which seems to be contradicted by everyday experience.

Part of the explanation for this lies in the *associative* nature of human *long-term* memory; memories for items and events contiguous in space or time may become connected, and the occurrence or recall of one such item may *cue* the recall of an associated item.

The idea that memory is associative has a long provenance in western thought, from at least the mid-eighteenth century. Associations are now thought to consist of connections between networks of neurons in the brain (Hebb 1949), in that a group of items related by association can form a single consolidated item in long-term memory. This larger item can then be recalled (activated as STM) in its entirety, a process that can occur on multiple levels. In this way a kind of hierarchical compression occurs, which allows the most efficient use of the limited capacity of conscious STM; George Miller coined the term *chunking* for this process. A memory chunk is a group of 3–4 items related by association; a musical grouping consisting of 3–5 notes would be a chunk, and a phrase consisting of several of these groupings would be a higher-level chunk. It should be noted that the limitations of chunking are implicated in both the recall and the formation of memories. Chunks or prominent items in chunks can be used to cue other chunks, allowing for the recall of longer sequences. Memorability appears related to how 'chunkable' a sequence is, which will depend on the amount of repetition of items, and to boundaries formed by discontinuities or changes in a sequence; the more clearly a sequence can be subdivided in units of chunkable size, the more likely it is to be recalled. Chunking in music is often related to perceptual grouping processes (Bregman 1990; Lerdahl and Jackendoff 1983). The idea of chunking accounts for a great deal of how immediate human memory can have such a limited capacity, yet be so effective.

Everyday use of the term 'memory' refers not to short-term memory, but to *Long-Term memory* (LTM). LTM differs from STM in several ways. Long-term memories persist over a much longer time-period, even a lifetime, as their formation involves lasting structural change in the brain. Moreover, unlike STM, almost all the contents of long-term memory are not conscious at any given moment, although situational associations may cue memories into consciousness. There are distinctions within LTM that must be further considered. First, there is a distinction introduced by Tulving (Tulving 1972) between so-called *episodic* and *semantic* long-term memories: a distinction between memories of situations and events (*episodic* or autobiographical memory), and general knowledge of facts (*semantic* memory), the latter being more abstract and arising through the experience of repeated similar episodes (Schank 1982). Episodic memory is dynamic, and may be changed by the very act of remembering (Roediger *et al.* 2007, Chapter 8). These two types of memory appear to constitute two ends of a continuum extending from recollections of particular episodes through increasingly general models of types of situations to abstract knowledge representations that no longer have roots in any particular experiences. In music cognition research, *episodic* memory is typically tested in recognition or, more rarely, recall tasks. *Semantic* memory tests usually involve requiring participants to make judgments about types of events they judge likely in particular musical situations. This type of semantic memory is referred to as a *schema*, a general expectation about types and distributions of events (Bartlett 1932/1995; also see Gjerdingen 1988, pp. 3–10). Schemas appear to underlie structural regularities in music such as tonality and metre, as well as standardized musical forms.

A further distinction important for LTM is that between *explicit* and *implicit* memory (Cohen and Squire 1980), a distinction between memories that may be accessible to consciousness and those that are not. One of the major discoveries of the last one hundred fifty or so years about the human mind is that much of the activity of the brain and the mind is not available to awareness (Ellenberger 1970) but remains implicit, evidenced particularly in the acquisition of skills. Many kinds of physical skills, such as knowing how to ride a bicycle or produce a clear tone on a musical instrument, require memory for their execution, but those memories are not available to consciousness, and cannot be described verbally. More recently, another form of implicit long-term memory has been proposed—implicit *perceptual* representations (Mandler 2004). This form of memory is involved

in unconscious statistical learning (Reber 1993) that keeps a record of regularities in the environment, and structures unconscious expectations about environmental events. Schemas are describable in terms of this kind of implicit memory, being involved in, e.g., the unconscious generation of expectations about musical events as a piece unfolds. Making such schemas *explicit* is one of the goals of the formal study of music. Implicit perceptual memory is the basis for much of *recognition* memory, though many types of activities involving memory may have both explicit and implicit components which are not easy to tease apart in experiment.

From a biological point of view, it seems that the primary function of LTM is not to construct highly detailed and accurate representations of the past, but to provide a generalized model of the world that will be useful to guide future behavior. Long-term schematic memories tend to be structured in terms of generalized *categories* (McAdams 1989; Snyder 2000). Musical long-term memories and expectations are thus often structured in terms of general categorical schemas such scale-steps, durational categories, etc. This means that listeners tend to not have exact detailed memories of music, but more generalized memories about the *kinds* of events that were heard; hence a listener's repertoire of categories of musical events (knowledge in memory) will affect what they can and do remember.

Short-term and long-term memory appear qualitatively different, yet there must be some mechanisms that allows the integration of information across both domains of memory. The idea of STM has thus been augmented by a more complex notion of 'working memory' (Baddeley 1986). Developing research on STM has revealed that most uses of this type of memory draw on long-term memory in various ways (e.g. Cowen 2005). Generally when we use STM, the contents of awareness draw on already existing knowledge, and this knowledge is in the form of long-term memories. In the most prevalent current theory of working memory (Baddely 1986), such memory consists of several parts, which are thought of as separate memory systems. These are a 'visuo-spatial sketchpad' (used for visualization), a 'phonological loop' (involved in speech production), and a 'central executive'(which sequences thinking and planning). This last is perhaps the least well-understood of the constructs associated with the concept of working memory. The originator of the idea, Baddeley, has himself recently suggested a new component, the episodic buffer (Baddeley 2003). There are probably other forms of working memory as well, for instance for motor movements, non-speech sounds, etc. (Jonides and Smith 1997, pp. 263–265). Some of the aspects of pitch memory mentioned below would qualify as forms of working memory. It may well be that the construct of working memory is an umbrella for a number of distinct memory phenomena that all have limits in the time range of several seconds; indeed, it may simply be a particular kind of persistence in many different processing systems in the brain (Crowder 1993).

At any given time, most of long-term memory is not accessible to consciousness. In order to explain certain kinds of memory phenomena, it has been suggested that there are degrees of unconsciousness, expressed in the construct of *activation* (Cowen 1988). The neural networks that are the basis for long-term memory can be active to a greater or lesser degree; at any particular moment, most will be inactive; some will be in a state of activity but not involved in current consciousness, while some will be active *and* involved in consciousness, a situation that will change from moment to moment. Memory can be *semi-activated* (Chafe 1994); memories at this lower degree of activation may be involved in mental activity, but not in consciousness. Experiments have shown that prior exposure to certain kinds of stimuli can affect later performance on another test, even when a participant is unaware of having experienced the original stimulus (Bornstein 1989). It seems that memory networks established by the original stimulus have been *primed* into semi-activity, which, although remaining below the level of consciousness, can affect ongoing thought and perception, providing a basis for *expectation*. An expectation (which may be more, or less, conscious) is thought to be a group of networks (a *schema*) that have been *cued* and *primed* into semi-activity by current ongoing experience. The concept of expectation is important here because it is a primary mode in which listeners utilize memory in listening to music, and because it is thought to be one of the sources of emotional responses to music (Meyer 1956; Huron 2006).

Musical expectations

Listeners acquire a variety of schematic expectations (manipulation of which may influence profoundly the affective experience of music) from repeated exposure to statistical relations between various elements in music. Bharucha (1994) makes a distinction between *schematic* expectations (based on a listener's knowledge in semantic memory of the style, genre, etc. of a heard piece) and *veridical* expectations (arising from repeated exposure to a particular piece of music, and hence a form of episodic memory); both types of expectation involve LTM. Huron (2006, p. 228) adds the notion of *dynamic* expectations, arising from local events in the ongoing music in the short-term, which would involve STM (this type of expectation would arise for instance when hearing a piece for the first time). Musical knowledge and/or training would affect all of these kinds of expectation.

In the domain of pitch, most musical cultures use *scales*, which are ways of dividing pitch space into a relatively small number of *degrees* or categories. It has been suggested that one motivation for this is the general limitations of STM mentioned above. In fact, most scales in use in musical cultures worldwide consist of 5–7 different pitches or scale degrees, a number of elements that is consistent with the suggestions about STM capacity made above (Dowling 1978). Within the Western musical traditions, a considerable amount of research has been conducted on listeners' expectations concerning scale degrees. Listeners are frequently able to infer the 'key' or tonal center (central scale degree) of music. This is thought to arise through learning based on the statistical distribution of the occurrence of particular scale-degrees in music (that listeners are able to learn the statistical relations between melodic pitches—even in a relatively short time—has been established in a series of experiments by Saffran *et al.* 1999). Building on classic research by Krumhansl (Krumhansl 1990), Aarden established that listeners' expectations for the occurrence of a particular scale-degree do in fact conform to the distribution of scale degrees in actual music (Aarden 2003 cited in Huron 2006), expectations varying from moment to moment as a piece unfolds.

In addition, listeners have some very general schematic expectations about types of *sequences* of melodic events. Huron and his colleagues have described four patterns of statistical learning in experienced listeners, resulting in several proposed types of very general melodic schemas (Huron 2006); several of these were previously hypothesized by Meyer (1956) and Narmour (1990). Listeners expect *pitch proximity*, expecting a pitched musical event to be followed by an event relatively close to it in pitch. This is thought to be statistical learning based on the fact that the majority of melodic intervals in actual music consist of pitches that are close (within a m3) together (Dowling and Harwood 1986, p. 155). Second, listeners expect *post-skip reversal*, the expectation that after a large melodic interval, there will be a change of direction of melodic motion (Meyer 1956, Narmour 1990). Third, musician listeners expect *step-inertia*, a tendency for a small pitch interval to be followed by another small pitch interval in the same direction (Meyer 1956, Narmour 1990). Fourth, listeners expect late phrase *pitch declination*—that a phrase will move down melodically at the end. Objectively, melodic phrases tend on average to have an arch-like shape, with a rise in pitch at the beginning, and a fall at the end. Interestingly, listeners seem to expect melodic phrases to fall at the end, but not to rise at the beginning.

Rhythmic expectations are rooted in the experience of *pulse* or *tactus*, a regular framework of time-points or *beats* that typically organize our perception of the timing of events in music. Beats will more-or-less coincide with events in the music, but are cognitive entities inferred from those events. Pulse can be defined as a kind of basic expectation about when events in music will happen (see chapter 8). The range of musically usable tempi within which musical pulse is experienced is from about 30 beats per minute (bpm) to about 300 bpm. A listener will typically infer a *basic tempo* that falls within a range of approx. 60–150 bpm (Fraisse 1982), the range within which participants are best able to maintain a steady beat in tapping experiments.

Current theories of pulse suggest that it arises from patterns of oscillation set up in the brain that *entrain* to the pulse of a piece of music,

forming a dynamic memory within which unfolding temporal events are organized (Barnes and Jones 2000), and yielding a framework that guides immediate temporal expectations about when events are experienced as most likely to occur. This type of expectation is very local, existing on the time-scale of working memory. It is also robust, persisting in the face of small timing discrepancies or a temporary lack of confirming events in the music. Pulse may operate at multiple temporal levels that unfold at integer multiples and divisors of the basic pulse (Yeston 1976), but there is usually one level of pulse to which a listener will respond most strongly.

Much music, in addition to being organized around a regular pulse, is also organized at a higher time level into regular cycles of more, and less, accented beats (London 2004). This type of cyclical organization is referred to as *metre*; metrical organization is schematic, and generates expectations not only about when, but also what, kind of events will happen at what points in time. Like pulse, it is a cognitive structure that is inferred from actual events in music. Typical metrical cycles alternate between strong (accented) and weak beats. Metrical cycles in Western music exist within the span of STM, generally starting with a strong beat (downbeat), the most structurally important point in a metrical cycle. This is a point of metrical stability and closure and also the point where an event is most likely to occur (e.g. Huron, 2006, p. 178–9), being a focal point for temporal attending (Palmer and Krumhansl 1990; Jones *et al.* 2002). Just as the timing of events can deviate more or less from the expected beats of a pulse, the grouping of musical events can deviate more or less from the accent pattern of metre (Lerdahl and Jackendoff 1983). One typical way of creating a kind of metrical tension is by placing salient events, such as the first or last events of a grouping, on weak beats of the metre. Metrical organization can be ambiguous to a considerable degree, and many rhythmic sequences can be interpreted in several ways (Lee 1991).

Music and memory

Experiments conducted by Deutsch (1999) suggest that auditory *working memory* may consist of aspects of musical sounds, outputs of subsystems being combined in later stages of processing. Individual musical pitches use at least one of these subsystems. Listeners presented with two pitches that were the same or a half-step apart accurately judged pitches as the same or different when the pitches were up to 6 seconds apart in time, but accuracy decreased when other pitches were interpolated in the empty time interval. This *interference* effect was strongest when the intervening pitches were chosen from both the octaves above and below the comparison pitches, making the intervening pitch intervals very large, the large pitch intervals rendering difficult the formation of a memory framework to anchor the comparison pitches. Only interpolated sequences varying in pitch led consistently to memory interference , suggesting that memory for pitch is encoded by a specialized memory subsystem (Deutsch 1999). A few individuals (fewer than 1 in 1000) have an ability to accurately identify a pitch outside of any particular context, an ability referred to as 'absolute pitch' (AP). The basis for AP possession is still debatable, but it seems to be learned, learning occurring within a 'critical period' of development and being dependent on early musical training (Ward 1999; also Huron 2006 pp. 110–113, for a discussion). AP possessors are able to effortlessly encode their experience of musical pitch in the form of a (conceptual) pitch name, which resists interference much better than a sensory memory (Siegal 1970; see also Deutsch 2006).

A familiar melody can be presented at almost any tempo and at any pitch level and remain recognizable; hence memory encoding of familiar melodies is not an exact (episodic) copy of particular pitches and time intervals, but a higher-order abstraction (schema) of particular features of the melody. In addition to some surface-level aspects of the music, possible features encoded in memory include *interval*, *contour*, and *scale-step context* (position in a scale). Which of these features are more salient in melody recognition (as opposed to recall) has been tested in several ways. One technique for separating aspects of a remembered melody is octave scrambling, which destroys musical interval structure, but preserves the scale-step order of the pitches in a melody (Deutsch 1972). When familiar melodies are presented with their

pitches randomly scrambled to different octaves, they are generally unrecognizable. However, if the contour (up and down pattern) of the melodic line is preserved, they are more frequently recognized (Dowling 1978).

Listeners are often unable to tell the difference between exact and contour-preserving transpositions of novel melodies (Dowling 1994), for both tonal and atonal melodies. However, the importance of contour versus interval seems to decline the more well-learned a melody is. This is in line with results of studies that have found that processes of memory formation in listening are highly dynamic, not just as a consequence of longer-term learning processes but also in the very process of real-time listening itself. As Dowling *et al.* (2002 p. 273) note, 'The processing of a phrase, once heard, continues automatically [in memory] even while the listener hears new phrases. What the listener can remember having heard continually changes during continued listening.' In a study of melodic recall (Sloboda 1985) it was concluded that recall of simple melodies 'was never note-for note perfect'. In recalling these melodies, participants produced small variations that were harmonically and metrically consistent with the originals (musically trained participants relying somewhat more than did untrained participants on harmonic structure). This study confirms the idea that episodic memory for melody typically consists of an underlying abstract schema in which not all of the surface detail is necessarily retained.

In the perception of melodic intervals, it seems that each culture creates a set of melodic intervals that become standard perceptual categories that detemine the tones occurring in its music (see Chapter 2). These intervals are categorical in that considerable leeway is allowed in what is considered an acceptable rendition of a particular interval. Exactly how much leeway is acceptable is itself a cultural variable (Arom *et al.* 1997), and perception of interval categories is much clearer to musically trained than to untrained listeners (Burns 1999).

Tonality—the organization of music around sets of pitches of which a central pitch is established by its frequent occurence and appearance at salient points—has significant ramifications for musical memory (see Chapter 6). Sets of pitches constitute scales; groups of pitch categories or scale 'steps' to which a passage or piece of music is limited. Both the central pitch and the steps of a scale have varying degrees of perceptual stability, serving as cognitive landmarks in establishing a framework for listeners (Krumhansl 1990). Knowledge of scale step categories is a kind of implicit memory acquired by members of a musical culture through exposure to its music (Burns 1999).

The above-mentioned stability may not be operative in the perception of music that does not conform to tonal principles; in the experience of atonal melodic sequences the anchoring effects of tonality cannot be operative, leading some authors to maintain that atonal music theory has little basis in human perception (Francès 1988; Lerdahl 1988). Experiments by Francès (Francès, 1988) using groups of musicians familiar, and unfamiliar, with atonal idioms, showed that both groups had great difficulty identifying varied repetitions of twelve-tone series, especially in an actual musical context. Further experiments (Krumhansl *et al.* 1987) indicate that the structures of twelve-tone music are slightly more transparent to musically trained listeners familiar with the style.

Rhythm can be defined as the articulation of events within the time limits of working memory. As noted above, to form a perceptible pattern the events that comprise a rhythm must seem connected together in the present. It is not yet entirely clear how rhythmic sequences are encoded in memory, various models proposing different levels of hierarchical coding. As mentioned above, listeners attempt to establish a framework for rhythms by inferring beats at a regular time interval from events in the music (Povel 1984). Most rhythm experiments involving memory are recall tests where listeners are asked to reproduce a heard rhythm. As with pitch, memory for duration appears to be a categorical phenomenon (Clarke 1987); out of many possible durations, memory seems to gravitate towards a few simple durational relationships, with considerable leeway as to what constitutes a particular duration. Foundational research by Fraisse (Fraisse 1982) established that when rhythmic patterns involve more than one duration, listeners tend to hear durations as either long or short, with long durations being

over 400–600 msec. In addition, there appears to be a strong tendency for the long and short durations to be reproduced or remembered in a ratio of 2:1, a relationship that has been described as a durational schema (Povel 1981).

In general, listeners are better able to reproduce sequences of durations when they can be interpreted as having an underlying regular sequence of beats, often involving the use of one particular duration as the basis for the others (Povel 1984). It is also the case that sequences of durations are much easier to remember and reproduce when shorter durations are integral subdivisions of the longer durations. Although the perception and reproduction of rhythms is categorical, small within-category deviations of event onset times (nuances) can give performed rhythms a particular feel (Snyder 2000), referred to as expressive timing (Gabrielsson 1999). This means that a particular rhythmic pattern can be performed many ways without losing its identity as a pattern, as in swing in jazz (Collier and Collier 2002). This type of nuanced information is generally not a part of the episodic memory of rhythm in music; although subtle, such nuances are important parts of what makes rhythms dynamic and emotionally charged.

Long-term memory and musical form—hierarchical theories of long-term musical representation

Musical form can be defined as the timescale of musical phenomena that require some kind of long-term mental representation for their comprehension. The process of chunking can lead to hierarchical organization in LTM, and most theories of the structure of long-term representations of music use the concept of hierarchy to varying degrees, applied both to episodic memories and abstract schemas. Hierarchical levels in music may range from local groupings up to entire pieces.

When memory passes beyond the limits of STM, it is thought to persist in a more schematic form: to become a kind of reduction. Exactly what remains of actual musical details in musical LTM is an important question. Typically, theories of musical LTM reduction involve ideas of hierarchies of structural importance (Deutsch and Feroe 1981; Lerdahl and Jackendoff 1983), in which certain events in music are structurally more important than others, and these constitute the *gist* of a listener's memory representation (see Chapter 6). These salient structurally important events can be said to constitute the 'deep' level of structure in music, more rapidly changing details forming the musical surface or foreground.

The musical surface is segmented into units of cognitively manageable size (chunks)—the actual groupings, phrases, etc. of the music. Typically in tonal music the proposed deep structural events occur on metrically strong beats, are of longer duration, and are located on an important scale degree (Serafine *et al.* 1989), although the metaphor of hierarchical depth may be more applicable to some types of music than to others (Fink 1999). It should also be noted that although the metaphor of deep and surface structure is also used in generative linguistics, music is not held, in general, to embody specific and definite semantic meaning (though see Chapter 3). Current models of musical representation differ considerably as to the importance, and indeed the cognitive reality of deeper levels of structure.

Two prominent theories of musical mental representation (LTM) are Lerdahl and Jackendoff's (1983) Generative Theory of Tonal Music (GTTM) and the 'Cue Abstraction' theory of Deliège (Deliège and Melen 1997). The GTTM is a hierarchical theory of *tonal* music, and involves four different types of reduction: segmentation analysis, metrical analysis, time-span reduction, and prolongational reduction. The first two act as 'inputs' to the formation of the latter two, which involve larger time-spans and constitute a reduction of the most important tonal events, and a tonal tension-release structure. The mental representations posited by the GTTM represent an idealized 'final state' of largely unconscious (semantic) knowledge by a 'perfect' experienced listener (Lerdahl and Jackendoff 1983, p. 3).

Cue-Abstraction theory is more general, and is proposed as applicable to a wider range of music than to classical tonal music. In this theory, units of memory may be created by any strikingly distinctive features in the surface of the

music (called *cues*) over a range of time-spans, rather than just tonally significant events; these cues act as memory markers that represent larger segments of music. Cue abstraction theory proposes a simpler and looser hierarchality than the GTTM, a set of event hierarchies rather than tonal hierarchies. It privileges prominent surface details over deep structural events in the formation of musical LTM, and the importance of salience over tonal stability, though its operation at a range of time-spans allows it a degree of hierarchicality.

Because of the limitations of working memory, music can be immediately comprehended only on the time-scale of 5–8 sec. Hence the first step in a listener's construction of the form of a piece of music is the segmentation or chunking of the musical surface by identification of boundaries formed by points of change in the music. Many of the same factors that articulate musical units on lower levels such as phrases may also operate on higher structural levels; just as a musical phrase will be articulated by a change in the flow of events, a sectional boundary delineating a larger time-span may be articulated by an even stronger change, usually involving more musical parameters.

Both the GTTM and cue abstraction theory propose that segmentation is a foundation for the establishment of LTM representations, a proposal confirmed empirically by Deliège (1987). Experiments by Clarke and Krumhansl (1990) Krumhansl (1996), Deliège (1989), and Deliège *et al.* (1996) involving both classical and contemporary music established that listeners (both musicians and non-musicians) are often in considerable agreement about the location of major segmentation points in pieces of music.

Although an unconscious memory reduction is a theoretical entity, several experiments have been conducted to try to determine whether listeners have such representations. Building on an earlier experiment by Serafine (Serafine *et al.* 1989), experiments by Dibben (1994) and Bigand (1990) using composed reductions of short musical examples have produced some evidence of the cognitive reality of reductions in tonal music, at least on a modest time-scale. Dibben's results led her to conclude that cognitive representations of atonal music are associational rather than strictly hierarchical, echoing Imberty (1993).

Experiments by Deliège and others (Deliège and Melen 1997) established that listeners, both musicians and non-musicians, use surface features of music as memory cues. These experiments involved organizing randomly reordered segments of a previously heard piece on a timeline representing their original order (Deliège 1993; Clarke and Krumhansl 1990; Deliège and Melen 1997). Unlike segmentation experiments, where the performance of musicians and non-musicians are often comparable, in many of these experiments, musicians tended to do better than non-musicians, though for both groups judgments about segment location were more accurate near the beginning and end of pieces. Other experiments have explored the development of listeners' schemas for musical elements in particular pieces by requiring judgments about the similarity of fragments of music from the same piece. This approach proposes that thematic variants are categorized around abstract *prototypes* (generalized representations of thematic material) and that variants of a theme can be heard as similar (Zbikowski 1999). Deliège (2001) and Krumhansl (1991) performed experiments investigating listeners' ability to identify as yet unheard fragments of a partially heard piece. In both cases listeners were able to use what they had heard to identify unheard examples as being similar and as coming from the same piece. In a further experiment Deliège (1996) asked listeners (musicians and non-musicians) to compare a large set of small (1–2 measure) 'cells' from a Bach violin sonata to two different reference or 'prototype' cells. In general, listeners were able to identify the variants with the correct prototypes, although the non-musicians were found to have a narrower definition of similarity. From results of a similar experiment using pieces by Beethoven and Schoenberg, Lamont and Dibben (2001) concluded that the listeners had used *surface* features to relate fragments.

In summary, it appears that both musicians and non-musicians use surface features in constructing long-term mental representations of music. In effect, the existence and utility of larger-scale hierarchical memory reductions has not been firmly established, though most experiments on tonal structures have investigated relationships between events adjacent in time

rather than those separated by large spans of music (see Chapter 6). The use of deep structural features in ordinary (not analytically oriented) listening has been called into question by the results of several experiments. These experiments have explored the question of the role of memory in the perception of an entire piece of music, in part by addressing the question of what sort of information seems to be available in memory over the total duration of a piece as it unfolds in time. The results of these experiments would suggest that, for most listeners, the types of relationships between constituent parts of a piece that are described in theories such as that of Lerdahl and Jackendoff are not accessible in memory.

Experiments by Cook (1987) and by West Marvin and Brinkman (1999) explored whether the initial key of a piece was still accessible in listeners' memories at the end of the piece. Both studies found some evidence that listeners were able to undertake this task successfully, but only for pieces shorter than ca 30 seconds. This supports the view that tonal closure may be perceived most strongly over short time-spans (Levinson, 1997 but see also Gjerdingen, 1999 for a critique of Cook's study). However, West Marvin and Brinkman also found that participants were unable to indicate that pieces that ended in keys other than the initial key were less 'tonally closed' than pieces which ended in their initial key.

The results of several other studies (e.g. Karno and Konecni 1992) support the view that long-range relationships between musical materials are neither particularly accessible nor stable in memory. Further experiments by Clarke and Krumhansl (1990) Deliège (1993), Deliège *et al.* (1996) and Deliège and Mélen (1997) explored the ability of musically trained and untrained listeners to remember the order in which events had occurred after hearings of classical and post-tonal pieces. Although listeners' judgments of location of segments and segment-order were roughly accurate, they were less so for segments toward the middle of pieces, although musically-trained participants appeared better able to use higher-level schematic knowledge to achieve greater accuracy. It has to be noted that the results of these experiments do not prove that large-scale musical relationships cannot be encoded in memory. It is still hypothetically possible that the memory processes of an expert listeners, or more likely, performers, are capable of dealing with musical relationships over large time-scales. However, for most listeners, it seems likely that memory does not accurately encode these longer-term, larger-scale, longer-duration, hierarchical relationships.

Conclusions

Much about musical memory still remains to be understood, indeed, explored. New fields of research are continuing to extend what is known, as well as throwing up new questions. The field of neuroscience and the methods of neuroimaging have already shown great promise in identifying the areas and networks in the brain that are implicated in memory for music. Frontal, parietal, and premotor cortical areas, together with the cerebellum, are associated with working memory for musical pitch, while processing and representation of musical meaning appear to rely on areas of the middle temporal gyrus and left anterior temporal areas (Koelsch and Siebel 2005). Similarly, the study of the effect of emotion on cognitive and memory processes is very much at an early stage, but can be expected to provide fruitful insights into the nature of musical memory. Many studies have shown that emotion, or affect, might be one of the most significant factors that determine how and what we remember (see Dolan 2002 for an overview), and given that music is strongly associated with the modulation of emotional state, it can be expected that the study of musical memory will provide critical evidence about the nature of human memory in general (see Juslin and Sloboda 2001).

PART 3

Responses to music

Edited by Donald A. Hodges

CHAPTER 11

Bodily responses to music

Donald A. Hodges

BODILY responses are among the core, common experiences of music. To observe people at a rock concert or watching a marching band, is to observe heads nodding, feet tapping, and bodies swaying. Along with these observable behaviours are a host of reactions to music that occur beneath the skin, such as changes in heart rate, blood pressure, and blood chemistry. The experience of listening to music involves highly complex interactions among cognitive, affective, and bodily processes that take place within a personal–social–cultural context.

The purpose of this chapter is to explore bodily responses to music. At the outset, it is important to provide some operational definitions, as the terminology in the literature is not used uniformly. Following these definitions, the main body of the chapter will be devoted to reviews of research literature. Although various types of bodily responses to music are discussed in a linear, segmented fashion, it must be remembered that they occur in a holistic fashion.

Definition of terms

For simplicity, bodily responses are divided into physiological and physical responses. Behavioural responses might also be considered, but as they are dealt with in other chapters, they will not be discussed here. Even as these two categories are being defined, it is important to note that such operational definitions are somewhat arbitrary. Although experiences can be categorized for ease of understanding, the normal experience is one of integrated response, with no sharp boundaries between them. Given this caveat, for the purposes of this chapter the categories are defined as follows:

- *Physiological responses* include internal bodily processes, such as heart rate. Although occasionally these internal processes are reflected in observable changes, for the most part detection requires some type of monitoring device.
- *Physical responses* are external, readily observable, reflexive motor movements such as foot tapping. These responses occur naturally, without specific training. Physical responses that require training, for example training a new music student to tap a foot to keep the beat while performing, will not be covered in this chapter.

Physiological responses

What follows in the next section are extremely succinct reviews of the literature under the various physiological responses measured. Findings of research related to music listening responses are generally organized into those studies reporting increases, decreases, or no change in responses. This simplistic approach masks an underlying complexity that will be discussed in a concluding section. Because this concluding discussion will deal with general principles affecting more than one type of physiological response, comments in the brief review sections are kept to a minimum.

The effects of music on heart or pulse rate

A significant amount of research supports the position that listening to music can cause changes in heart rate (e.g. Bernardi *et al.* 2006; Blood and Zatorre 2001; Savan 1999). In general, stimulative music—characterized by fast, loud, staccato passages—tends to cause an increase in heart rate (HR) or pulse rate (PR), while sedative music—characterized by slow, soft, legato passages—tends to cause a decrease. However, some researchers found that any music, whether stimulative or sedative, tends to increase HR or PR (Krumhansl 1997; Rickard 2004).

In only a slightly fewer number of studies did researchers report that music caused no changes in HR or PR (e.g. Davis 1992; Gupta and Gupta 2005; Pujol 1994). In Iwanaga *et al.* (1996), HR did not change in response to stimulative music, but did decrease during sedative music.

The effects of performing music on heart rate are much less studied. Measurements of pulse rate in 24 orchestral musicians of the Vienna Symphony were made during rehearsals and public performances (Haider and Groll-Knapp 1981). Maximum pulse rates during performances reached 151 beats per minute. Pulse rates were up to 8 beats higher in concerts than during rehearsals and fluctuated widely depending on the character of the music being performed, with tempo being a salient feature. For example, during a Rachmaninoff symphony, one trumpet player went from a resting pulse rate of 68 to a peak of over 150. Often, peaks occurred just prior to an entrance. Abel and Larkin (1990) found that student musicians had increased heart rates in anticipation of a graded performance.

The effects of music on skin conductivity

Galvanic skin responses (GSR), now more often referred to as electrodermal activity or skin conductance, are temporary, primarily negative, fluctuations in the electrical resistance of the skin. Measured by a psychogalvanomoter, usually attached to the fingers and/or palm of the hand, the GSR is a result of mental activity, most often of an affective nature (Venables 1987). An increase in GSR readings indicates a decrease in resistance, which in turn indicates an increase in arousal. Significant changes in GSR in response to music listening were found in numerous studies (e.g. Khalfa *et al.* 2002; Lundqvist *et al.* 2000; Rickard 2004). In other studies, no meaningful changes in GSR were found in response to music listening (Jellison 1975; Keller and Seraganian 1984).

The effects of music on blood pressure

Stimulative music increased blood pressure in Bernardi *et al.* (2006), Krumhansl (1997) and Pignatiello *et al.* (1989). In a number of studies, music decreased blood pressure; most often sedative music had this effect, though some stimulative music did so too (Lorch *et al.* 1994, Savan 1999). Noteworthy is the fact that self-selected music was found to be effective in lowering blood pressure (Geden *et al.* 1989; Oyama *et al.* 1987a; Updike and Charles 1987). Confounding these results are studies that reported no meaningful change in blood pressure as a result of listening to music (Gupta and Gupta 2005; Strauser 1997), which in some cases was self-selected (Geden *et al.* 1989; Schuster 1985). In a related study, music students experienced an increase in blood pressure in anticipation of a graded performance (Abel and Larkin 1990).

The effects of music on biochemical responses

A relatively new area of investigation has been the effect of music listening on hormone levels found in blood, urine, or saliva. The basis for this work is the field of psychoneuroimmunology, a field that explores interactions between nervous and immune systems (Hall 1989). The majority of published reports presented in Table 11.1 indicate meaningful changes in biochemicals in response to music listening or musical experiences.

Collectively, this line of research supports the central contention of psychoneuroimmunology, namely that mental and bodily responses are intertwined in a symbiotic relationship. This is well illustrated in three examples. Choral singers had increases in SigA of 159 per cent during rehearsal and 240 per cent during performance,

Table 11.1 Biochemical responses to music

Biochemical	Response to music	Sources
Secretory immunoglobulin A (SIgA)	Increased	Beck *et al.* 2000, Charnetski and Brennan 1998, Kreutz *et al.* 2004, Lane 1991, McCraty *et al.* 1996, Rider *et al.* 1991, Rider and Weldin 1990, Tsao *et al.* 1991
	Decreased	Miluk-Lolasa *et al.* 1994
	No change	Oyama *et al.* 1987a, Rider *et al.* 1985
Cortisol	Increased	Beck *et al.* 2000, Gerra *et al.* 1998, VanderArk and Ely 1992, 1993
	Decreased	Bartlett *et al.* 1993, Beck *et al.* 2000, Kreutz *et al.* 2004, Leardi *et al.* 2007, McKinney *et al.* 1997a, Tsao *et al.* 1991
	Increased in music majors but decreased in non-music majors	VanderArk and Ely 1992, 1993
Interleukin-1	Increased	Bartlett *et al.* 1993
Adrenocorticotropic hormone (ACTH)	Increased	Gerra *et al.* 1998
	Decreased	Oyama *et al.* 1987b
Neutrophils and lymphocytes	Decreased	Rider and Achterberg 1989
Norepinephrine	Increased	Gerra *et al.* 1998, Kumar *et al.* 1999, VanderArk and Ely 1992, 1993
Growth hormone	Increased	Gerra *et al.* 1998
Epinephrine	Increased	Kumar *et al.* 1999, VanderArk and Ely 1992, 1993
	No change	Gerra *et al.* 1998
Melatonin	Increased	Kumar *et al.* 1999
Serotonin	No change	Kumar *et al.* 1999
Prolactin	No change	Gerra *et al.* 1998, Kumar *et al.* 1999
Beta-endorphins	Increased	Gerra *et al.* 1998, Goldstein 1980
	Decreased	McKinney *et al.* 1997b
Dopamine	The release of dopamine in response to music, indicating a pleasure response, has been implicated by activations of mesolimbic structures involved in reward processing including the nucleus accumbens (NAc) and the ventral tegmental area (VTA), as well as the hypothalamus and insula (Blood and Zatorre 2001, Brown *et al.* 2004, Menon and Levitin 2005).	
Oxytocin	Although oxytocin has been mentioned in connection with lullabies and mother–infant bonding (Freeman 1995), such reporting is anecdotal and no published research studies have been identified.	
Genetic stress hormone markers	Participants in a recreational music-making programme experienced reversal in 19 of 45 genetic stress hormone markers (Bittman *et al.* 2005).	

with a corresponding decrease in cortisol of 30 per cent during rehearsal and an average increase of 37 per cent during performance (Beck *et al.* 2000). When patients with Alzheimer's disease underwent four weeks of music therapy sessions, melatonin, norepinephrine, and epinephrine all increased, while serotonin, and prolactin did not (Kumar *et al.* 1999). Among 18–19-year-olds, a meaningful increase was observed in beta-endorphins, ACTH, norepinephrine, growth hormone, and cortisol after listening to techno music (Gerra *et al.* 1998). Classical music induced an improvement in emotional state, but no meaningful changes in hormonal concentrations. This line of research is central to the practice of music medicine and is further explored in Chapter 49.

The effects of music on respiration

An increase in respiration or breathing rate was found in several studies (Blood and Zatorre 2001; Iwanaga and Moroki 1999). Ries (1969) correlated increases with preference and Haas *et al.* (1986) found that breathing rates entrained with musical rhythm. Researchers found no change in respiration rate as a result of listening to music (Davis 1992; Davis-Rollans and Cunningham (1987) and Iwanaga *et al.* (1996) found that respiration did not change to stimulative music but did decrease to sedative music.

The effects of music on finger, peripheral skin, or body temperature

Meaningful changes in skin temperature in response to music listening have been reported (Lundqvist *et al.* 2000; Rickard 2004). Beyond the fact that listening to music can affect temperature changes, there is very little consistency in results. In some studies, temperature increased—to sedative music (Kibler and Rider 1983; Peach 1984), to stimulative music (Lundqvist *et al.* 2000; Standley 1991), or to any music (Rickard 2004). In other cases, temperature decreased (Krumhansl 1997; Savan 1999). In only three reports did music not affect skin temperature (Guzzetta 1989; Kibler and Rider 1983; Zimmerman *et al.* 1988).

The effects of music on muscular tension

Muscular tension is most often measured by electromyography (EMG) and is related to tension-release patterns in music. The majority of studies found that muscular tension changes in response to music listening (Blood and Zatorre 2001; Rickard 2004). Only two published studies report no changes in EMG while listening to music (Davis and Thaut 1989; Scartelli 1984). Nielsen (1983, 1987; cited in Gabrielsson and Lindstrom 2001) reported that the more tension in the music, the harder subjects squeezed on a pair of tongs. Sears (1958) found that sedative music decreased tension more quickly than stimulative music increased tension. Carrick *et al.* (2007) found that listening to certain music had the potential to increase postural stability.

Chills

The following studies found that music listeners reported chills, often accompanied by shivers, tears, lump in the throat, or pilomotor (goosebump) responses (Craig 2005; Goldstein 1980; Panksepp 1995; Rickard 2004). Blood and Zatorre (2001) discovered that as the intensity of chills increased, so did blood flow to areas of the brain involved in mediating reward, motivation, emotion, and arousal. More than 80% of Sloboda's (1991) subjects reported having chills to music. Guhn *et al.* (2007) found that HR and skin conductance increased in musical passages that elicited the most chills. This confirmed findings by Craig (2005), Rickard (2004), and Panksepp (1995), but contrasted with Blood and Zatorre (2001).

The effects of music on blood volume

Two studies (Davis and Thaut 1989; Krumhansl 1997) found significant changes in blood volume in response to music listening, while two studies (Jellison 1975; Pignatiello *et al.* 1989) did not.

The effects of music on gastric motility

More formally known as peristalsis or gastric motility, stomach contractions move food along

the alimentary canal. Presumably, music could speed up or slow down this process. Two studies (Chen *et al.* 2005; Demling *et al.* 1970) support the contention that music can affect gastric activity. Beyond that, there is no consensus on the relationship between type of music and its effect on digestion.

Miscellaneous studies

Blood-oxygen

Music had noticeably positive effects on blood oxygen saturation levels (Cassidy and Standley 1995) and varied according to the stimulation rates and intensity (Lovett *et al.* 1952).

Ankle jerk

Subjects' ankles jerked in response to music (Harrer and Harrer 1977).

Pupillary reflex

Music had a significant effect on pupillary reflex, with dilation occurring during stimulative music and constriction during sedative music (Slaughter 1954).

Zygomaticus activity

Happy/positive music elicited increased zygomaticus activity (smile muscle) compared to sad/negative music (Lundqvist *et al.* 2000; Witvliet and Vrana 2007).

General discussion of physiological responses to music

From this cursory review of research findings, it is apparent that there is overwhelming support for the notion that listening to music affects physiological responses. Furthermore, there is general, though by no means unanimous, support for the notion that stimulative and sedative music tend to increase and decrease physiological responses, respectively. The reason this relationship is not stronger is most likely due to personal preferences.

Music listening experiences are highly idiosyncratic, as each person possesses an individual history (e.g., amount of musical training) and personality, and each listening experience occurs in varying situations. One of Fridja's (1988) laws of emotion is the Law of Situational Meaning: emotions arise in response to the meaning structures of a given situation; different emotions arise in response to different meaning structures (p. 349). Imagine, then, that one hears the same piece of music, say the slow movement of Bach's Concerto for Two Violins in d minor, BWV 1043, performed at a funeral and then a few weeks later at a wedding. Undoubtedly, the reactions would be significantly different.

As is evident from the foregoing reviews, there is not enough research on the effects of personal preference on physiological responses to clarify the issue and some of it is contradictory. For example, Iwanaga and Moroki (1999) found that type of music (i.e., stimulative or sedative) had a differing effect on heart rate, respiration rate, and blood pressure, but music preference did not. Nevertheless, the concept that personal preference is influential is firmly enough accepted to be utilized in the use of music in medical treatment (e.g., anxiolytic music for the treatment of pain and anxiety) (Spintge and Droh 1992; see Chapter 49 this volume for more details on medical applications and Chapter 15 for the role of preferences in general).

Once it is accepted that physiological processes change in response to music listening, what do such changes signify? Does an increase in heart rate, for example, necessarily indicate a positive response or could it just as easily indicate a negative response? Attaching specific physiological responses to specific emotional responses has not received much attention nor had much success. Increased smile muscle activity while listening to happy music as opposed to sad music is one of the few examples (Lundqvist *et al.* 2000). Carefully designed studies, with increased attention to personal preferences and idiosyncrasies, may lead to an enhanced understanding of the influence of music on physiological responses. Currently, the most advanced work is being conducted under the rubric of music medicine.

Physical responses

Anthropologists have documented that music and movement are linked in peoples all over the world (Blacking 1995). Many activities, such as dancing, marching, exercising, and working to

music exhibit a synchronization and entrainment between auditory input and motor output (Brown *et al.* 2006). Our brains and bodies are wired to respond to sound and to rhythmic sounds in particular (Koepchen *et al.* 1992). Furthermore, entraining our bodies to musical rhythms brings pleasure (Levitin 2006). Listening to music activates the following brain regions in a sequential order:

1 the auditory cortex initially analyses sound;
2 frontal regions process musical structure;
3 the mesolimbic system, involved in arousal and pleasure, is activated and produces dopamine, further activating the nucleus accumbens; and
4 the cerebellum and basal ganglia process rhythm and meter leading to movement (Menon and Levitin 2005).

When we listen to music our bodies naturally respond with largely involuntary gestures, such as head nodding and foot tapping.

Audiomotor systems are interconnected such that musical patterns elicit and entrain strong motor responses (Baumann *et al.* 2007; Thaut 2003; Thaut *et al.* 1999). For example, subjects are able to finger tap synchronously with heard rhythms, even making adjustments when changes in tempo are below the threshold of detection (Tecchio *et al.* 2000). Such effects may be enhanced by mirror neurons (Nelissen *et al.* 2005; Rizzolatti *et al.* 1996). These are neurons in the brain that fire both when an action is performed and when it is observed in someone else. More recent work indicates that mirror neurons may also be triggered by auditory stimuli in what is called 'action-listening'. Lahav *et al.* (2007) demonstrated that non-pianists who learned to perform a brief excerpt and then who heard the same pattern without performing any physical action had activations in bilateral frontoparietal motor-related networks.

In the vast majority of musical experiences around the world, physical responses are a natural phenomenon. Only in a few situations, such as Western classical music concerts, is there an attempt to control these responses. One might speculate that the relatively immobile audience posture during Western classical music concerts, followed by a wild burst of applause after a performance judged to be stellar, might be, in part, a reflection of pent up physical responses.

Physical responses to music begin in the final trimester before birth (Parncutt 2006) and continue throughout infancy with the singing of lullabies, the playing of 'musical' games such as pat-a-cake and peek-a-boo, and the presence of crib mobiles and musical toys. Rhythmic and timing interactions between parent and child can be illustrated by the 'I'm gonna gitcha' game (Stern 1982). The parent chants: 'I'm gonna gitcha I'm gonna gitcha I'm gonna gitcha Gotcha!' At each repetition the pitch and loudness increase, while the amount of time between each repetition progressively elongates. Activities such as this are so important that they form the basis for acquiring cognitive expectancies and for interrelating cognition and affect (Beebe *et al.* 1982; Thaut *et al.* 2005).

The human body consists of multiple oscillators that create the rhythms that drive the body and control behaviour (Brown and Graeber 1982). These interaction rhythms are important to music and dance but are essential to all human interactions (Scheflen 1982). The intentional application of rhythmic entrainment to motor behaviours has been made with Parkinsonian and stroke patients, allowing them to regain walking, reaching, and grasping skills (see Chapter 49 this volume).

Conclusion

In the book entitled *How Musical is Man?*, Blacking (1973) eloquently captures the symbiotic relationship between music and human beings in the first and last chapters: 'Humanly organized sound' and 'Soundly organized humanity'. In the first chapter, Blacking contends that music is a product of human behaviour resulting from biological processes and cultural agreement. The brain's ability to imagine, create and perceive patterns of sounds combines with social conventions to give us music. Music, for Blacking, is 'sound that is organized into socially accepted patterns' (p. 25). Above all, music exists because human beings impose sonic order rather than accept passively the sounds that nature provides.

Having stressed that music is humanly organized sound, Blacking then counters with 'Soundly organized humanity'. He acknowledges that music affects bodily processes but concentrates

his discussion primarily on the effects of music on social behaviours. Although the focus in the current chapter has, of course, been on the former, Blacking's main point is essentially the main point of this chapter: the music we create in turn affects us in profound ways. Even though the narrower focus of this chapter is on bodily responses, Blacking's larger view is also important to keep in mind. That is, bodily processes are influenced by the larger personal–social–cultural circumstances in which they occur. Lomax (1968), Merriam (1964) and many others have provided considerable field data from around the world to underscore the concept of music embedded in social context.

Main themes in this chapter are that bodily responses to music are among the core experiences of music. They are hugely complex, with a myriad of response types interwoven into the fabric of thoughts, feelings, and social context. Bodily responses are highly idiosyncratic as each person brings a unique self to a music listening situation. Researchers have made significant strides in ferreting out the details of these responses and in collaboration with practitioners have made progress in utilizing this knowledge, particularly in music therapy and music medicine applications. With all this, however, the richness and complexity of the human experience leaves much yet to be discovered.

While recognizing strides already made, the following ideas are offered as a means of advancing our knowledge of how humans react bodily to music to a new level of understanding:

- Greater consensus on terminology and standardization of protocol would be helpful. Some of the contradictory findings reported in the literature review must surely be due to these inconsistencies.
- Another explanation for contradictory findings may be that in some circumstances participants were emotionally responding to the music, while in others they were not (see Chapter 12 this volume for more discussion of this point). This is a confound that needs to be kept in mind in studies of bodily responses to music.
- Moving steadily toward more naturalistic musical experiences would be enlightening. Although it may appear as we as if are very far away from field studies, we may be closer than one might imagine. More than 25 years ago, members of the Vienna Symphony were monitored for heart rate and brain wave activity during rehearsals and public performances (Haider and Groll-Knapp 1981). Since then, ambulatory assessment has become a new and developing field. Using digital technology with hand-held PCs, researchers are now able to monitor such physiological responses as heart rate, blood pressure, blood glucose, and so on while subjects are engaged in routine activities (Fahrenberg 2001). Applying this technology to music listeners in all manner of naturalistic settings should be possible. In fact, in a recent experiment whose results are not yet known, a conductor, five members of a symphony orchestra, and fifteen audience members were all wired with sensors to record heart rate, muscle tension, respiration, and galvanic skin response during a performance (Dyer 2006). Findings may allow for comparisons of physiological responses as the music is expressed in conducting gestures, performer's reactions to those gestures, and audience responses to both.
- Paradoxically, we must pay increased attention to the idiosyncratic nature of responses while also gaining clarity in our understanding of corporate responses. Balancing personalized responses with the group dynamics involved in audience responses is a challenge that has not received much attention. For example, it is easy to imagine that one's bodily responses would be highly influenced by being one of thousands of wildly cheering fans at a rock concert.
- Advancing technologies are giving us an ability to gain increasingly refined views of bodily responses, particularly physiological responses, but this must not let us become myopic. Fine-grained details must be viewed within a social context.

None of these suggestions are made cavalierly. Surmounting inherent problems will be exceedingly difficult. Nevertheless, continuing to measure heart rate responses to 15 different 1-minute musical excerpts during a laboratory experiment is not likely to advance understanding much beyond what we already know. It will

be most interesting to read a review of this literature at some point in the future to see what innovative strategies researchers have devised to bring deeper understanding to these most basic of human responses to music.

CHAPTER 12

Emotional responses to music

Patrik N. Juslin

MUSIC has been linked to the emotions at least since Ancient Greece, and emotions do figure prominently in people's reported motives for listening to music. People use music to change emotions, to release emotions, to match their current emotion, to enjoy or comfort themselves, and to relieve stress. Yet, despite the ubiquity of music in everyday life today (see Chapter 40 this volume), emotional responses to music are still regarded as elusive. Why does music touch us so deeply? In this chapter, I will consider the best possible answers to this question that the psychology of music can currently provide. While music philosophers, musicologists, and aestheticians have written a lot about musical emotions (Budd 1985), psychologists have been slow to catch up due to both conceptual and methodological problems (Juslin and Sloboda 2001). Hence, this chapter will focus mainly on research carried out during the last decade.

It is important to make a distinction between *perception* and *induction* of emotions. We may simply perceive an emotion in the music, or we may actually feel an emotion in response to the music. This distinction is often, but not always, made in modern research. It is important to make the distinction for two reasons. First, the underlying mechanisms may be different depending on the process involved. Secondly, the types of emotions usually induced by music may be different from the types of emotions usually perceived in music. This chapter focuses on induction of emotions, whereas perception of emotions is discussed in Chapters 13 and 35.

The definition and measurement of emotions

A natural point of departure is to define the concept of emotion. Emotions belong to the field of affect. Based on an emerging consensus in the affective sciences (e.g. Davidson *et al.* 2003), *affect* is regarded as an umbrella term, which includes various affective phenomena such as preference, emotion, and mood. Affect simply refers to the fact that these phenomena are valenced—events are evaluated as positive or negative by the individual.

Although researchers do not agree on a precise definition of *emotions*, they agree about the characteristics. Emotions are described as brief (lasting minutes to a few hours) but intense responses to potentially important events or changes in the external or internal environment that involve certain subcomponents:

- cognitive appraisal (e.g., you appraise a situation as 'dangerous'),
- subjective feeling (e.g., you feel 'afraid'),
- physiological response (e.g., your heart starts to beat faster),
- expression (e.g., you shout),
- action tendency (e.g., you run away), and
- regulation (e.g., you try to calm yourself).

In principle, each of these six components can be used to measure emotions, though researchers debate the extent to which the components are 'synchronized' during an emotional response. Many researchers assume that people are always

in *some* affective state. When the states are intense and involve salient stimuli, we tend to call them 'emotions', whereas when the same states are less intense, and their causes are not immediately apparent, we tend to call them 'moods'. The states have been conceptualized both as discrete categories and as dimensions such as valence and arousal.

Primary issues and methods

The fundamental issues to address in the study of music and emotion are: does music induce emotions? If so, which emotions does music typically induce? Under what circumstances do musical emotions commonly occur? How does music induce emotions? Are musical emotions different from other emotions? Could musical emotions have implications for our health? It is fair to say that music psychologists are only beginning to answer most of these questions.

There are several methods that may be used to investigate musical emotions, such as listening experiments (Waterman 1996), questionnaire studies (Juslin and Laukka 2004), diary studies (Sloboda *et al.* 2001), qualitative interviews (DeNora 2000) and brain imaging (Blood and Zatorre 2001). Since each method has both advantages and disadvantages, the best overall approach might be to combine various methods in a kind of 'method triangulation'. In addition, the componential approach to measurement of emotions is slowly gaining ground in music psychology; that is, music researchers increasingly realize the need to measure several emotion components to be able to draw valid conclusions about emotional responses (Scherer and Zentner 2001). However, such approaches are still available mainly in the laboratory. Field studies continue to rely mostly on self-report, even though there are techniques for ambulatory measurement of physiological responses that could be used (Fahrenberg and Myrtek 1996). As observed already by William James (1884), the physiological response may be the aspect that gives emotions their distinct phenomenological feeling, providing the 'heat' of the emotions: 'What kind of an emotion of fear would be left, if the feelings neither of quickened heartbeats nor of shallow breathing . . . were present, it is quite impossible to think' (pp. 193–194). Thus, it is recommendable to complement self-reports of emotions with physiological measurements (see Chapter 11). Evidence suggests that more intense emotions to music tend to involve more pronounced physiological reactions (Rickard 2004), including 'chills' (Panksepp 1995).

Does music really induce emotions?

Although most musicians and listeners would seem to take the emotional powers of music for granted, it has been the matter of some controversy whether music really can evoke emotions (e.g. Kivy 1990). Strong empirical evidence has been slow to emerge, though an increasing number of studies have now obtained evidence in terms of different emotion components such as self-reported feeling (e.g. DeNora 2000; Gabrielsson 2001; Juslin and Laukka 2004; Pike 1972; Waterman 1996), physiology (e.g. Davis and Thaut 1989; Krumhansl 1997; Nyklíček *et al.* 1997; Vaitl *et al.* 1993), activation of brain regions similar to those of other emotions (e.g. Blood and Zatorre 2001, Brown *et al.* 2004; Menon and Levitin 2005), emotional expression (e.g. Sloboda 1991, Witvliet and Vrana 2007), action tendency (e.g. Fried and Berkowitz 1979; Harrer and Harrer 1977) and regulation (e.g. Becker 2001; Gabrielsson 2001). There is also preliminary evidence of synchronization among the various emotion components (Lundqvist *et al.* in press). Most of the evidence cited above was collected in Western societies, so cross-cultural studies are urgently needed.

It should be noted that many studies have relied only on self-report, which may be subject to *demand characteristics*, i.e., the total sum of cues that convey the researcher's hypothesis to the participant and thus may influence the participant's behaviour (Orne 1962). It is therefore promising that several studies have found effects of musically induced emotions on so-called implicit measures such as writing speed, word association, and decision time, which may be less sensitive to demand characteristics (Västfjäll 2002). The continued exploration and use of such indirect measures is recommended. Measuring emotions in the voice as a response to music is another hitherto unexplored approach (Juslin and Scherer 2005).

What is the prevalence of musical emotions?

To estimate the prevalence of musical emotions (i.e., the relative frequency of occurrence in the population of interest), it is necessary to capture the emotions as they spontaneously occur in daily life. The *experience sampling method* (ESM) is a useful tool in this context. Sloboda *et al.* (2001) conducted a pilot study to test the validity of the ESM with regard to music. Eight participants received an electronic pager and a diary. During a week, the pager was activated randomly once every two hours by a central computer. When they were paged, the participants were required to fill out the diary to describe the nature of any experiences of music that had occurred since the last paging. Findings suggested that music was heard during 44 per cent of the recorded episodes, that few of these episodes involved music listening as the main focus, and that music experiences tended to make the listeners more positive, more alert, and more focused in the present—particularly when personal choice over the music was involved. These results were replicated and extended in more extensive study, featuring 32 participants, by Juslin *et al.* (in press). Their participants were required to carry a small palmtop computer, which randomly gave off seven signals each day over a time period of two weeks. Music occurred in 37 per cent of the sampled episodes. In 64 per cent of the episodes that featured music, the participants reported that the music influenced how they felt. This is roughly similar to the retrospective, aggregated estimate provided in a survey study by Juslin and Laukka (2004), in which participants reported that they experienced emotions on average 55 per cent of the time they listened to music. Musical emotions were most frequent in the evening and during weekends. Overall, the results suggest that, although emotional responses to music are common, the occurrence of music does not itself necessarily guarantee that a listener will be moved by the music.

A much debated but little investigated issue is which emotions music can induce. Can music induce the full range of human emotions in listeners? In principle, depending on the specific music, the person listening, and the situation, it would indeed appear possible that music can induce just about any emotion that may be felt in other realms of human life. The wide range of emotions found in Gabrielsson's (2001; Table 19.1) study of strong experiences with music suggests that this is the case. However, given the rare nature of such experiences, a more interesting question is perhaps which emotions music *commonly* evokes in listeners. A handful of survey studies have provided preliminary estimates of the prevalence of particular emotions (Juslin and Laukka 2004 Table 4; Sloboda 1992 Table 1; Wells and Hakanen 1991 Table 1) and suggest that happiness, love, calm, sadness, excitement and nostalgia are relatively frequent emotional responses to music. However, these studies share two problems: they rely on retrospective and aggregated self-reports that may not be reliable and they do not directly compare musical with non-musical emotions, so that the 'uniqueness' of musical emotions can be assessed.

The previously mentioned ESM study by Juslin *et al.* (in press) provided estimates of occurrence of 14 emotional states in response to music as well as other stimuli during a 2-week period. Figure 12.1 shows the relative frequency (%) of emotions caused by music and emotions caused by other stimuli, respectively. As can be seen, emotions such as *calm–contentment*, *happiness–elation*, and *interest–expectancy* were generally common, whereas emotions such as *disgust–contempt* were not so common. A comparison of musical with non-musical emotion episodes indicated that *happiness–elation* and *nostalgia–longing* were significantly more frequent in episodes with musical emotions, whereas *anger–irritation*, *boredom–indifference*, and *anxiety–fear* were significantly more frequent in episodes with non-musical emotions. The remaining differences were not significant. Although the difficulties involved in translating experiences of emotions into verbal labels should be kept in mind, the results from both this and the above studies suggest that music may evoke a range of both basic and complex emotions, something that a satisfactory theory of musical emotions must be able to explain.

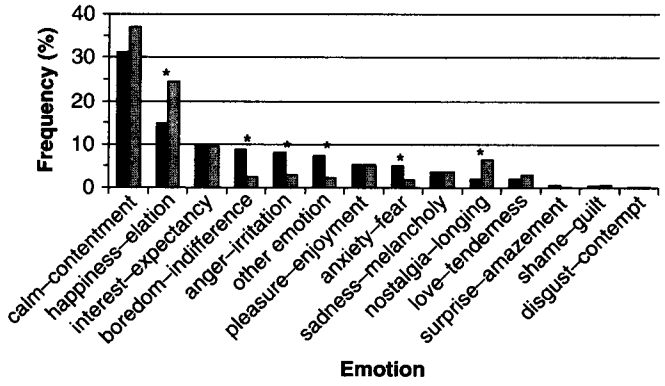

Fig. 12.1 The relative frequency (in percentages) of felt emotions for (a) non-musical emotion episodes (dark bars) and, (b) musical emotion episodes (light bars) during a 2-week period of experience sampling (from Juslin *et al.* in press). The number of response alternatives was limited by the computer software used. * $p < .05$.

Which factors influence musical emotions?

Factors that influence emotions in association with musical events have mostly been studied in an explorative fashion, and the factors may be grouped in terms of whether they are related to the music, the individual listener, or the situation.

Musical factors

Whereas the musical features involved in the expression and perception of different emotions are fairly well mapped by now (see Chapters 13 and 35), the features that induce emotions have been less investigated (though there might be some overlap depending on the induction mechanism, see later this chapter). I predict that it will be difficult to find direct and simple links between musical features and emotions. The musical features must rather be related to possible induction mechanisms. An excellent example is Sloboda's (1991) attempt to link emotional reactions to music to specific events in the music: 83 participants, aged 16–70, most of them performers, were asked to specify particular pieces of music to which they could recall having experienced various physical manifestations frequently associated with an emotion. Having identified such pieces, which came mainly from classical music, they were then asked to specify the exact location within the music that provoked these reactions. Most participants reported whole pieces, movements, or sections of movements, which suggests an emotional response to the 'overall' character of the music (Table 3 in Sloboda 1991). Such a response might reflect 'emotional contagion' based on the emotional expression of the piece (Juslin and Västfjäll in press). However, roughly a third of the participants were able to locate their reaction within a theme or smaller unit. The data showed that musical events associated with 'tears' (i.e., crying, lump in the throat) commonly contained melodic appoggiaturas and melodic or harmonic sequences; events associated with 'shivers' (i.e., goose pimples, shivers down the spine) usually contained a new or unprepared harmony; and events associated with 'heart reactions' contained syncopations and prominent events occurring earlier than prepared for. The results were related to Meyer's (1956) notion that musical expectancies, and violations of these, play an important role in emotional responses to music.

Individual factors

Individual differences between listeners appear to be larger for induction of emotions than for perception of emotions, though little research has focused on individual differences in musical emotion induction. Still, research has revealed a number of factors in the individual that may

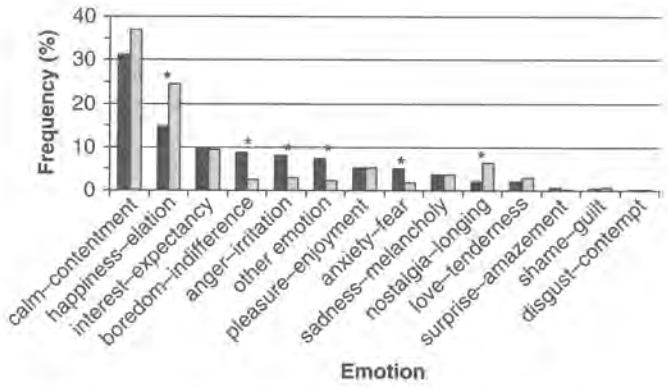

Fig. 12.1 The relative frequency (in percentages) of felt emotions for (a) non-musical emotion episodes (dark bars) and, (b) musical emotion episodes (light bars) during a 2-week period of experience sampling (from Juslin *et al.* in press). The number of response alternatives was limited by the computer software used. * $p < .05$.

Which factors influence musical emotions?

Factors that influence emotions in association with musical events have mostly been studied in an explorative fashion, and the factors may be grouped in terms of whether they are related to the music, the individual listener, or the situation.

Musical factors

Whereas the musical features involved in the expression and perception of different emotions are fairly well mapped by now (see Chapters 13 and 35), the features that induce emotions have been less investigated (though there might be some overlap depending on the induction mechanism, see later this chapter). I predict that it will be difficult to find direct and simple links between musical features and emotions. The musical features must rather be related to possible induction mechanisms. An excellent example is Sloboda's (1991) attempt to link emotional reactions to music to specific events in the music: 83 participants, aged 16–70, most of them performers, were asked to specify particular pieces of music to which they could recall having experienced various physical manifestations frequently associated with an emotion. Having identified such pieces, which came mainly from classical music, they were then asked to specify the exact location within the music that provoked these reactions. Most participants reported whole pieces, movements, or sections of movements, which suggests an emotional response to the 'overall' character of the music (Table 3 in Sloboda 1991). Such a response might reflect 'emotional contagion' based on the emotional expression of the piece (Juslin and Västfjäll in press). However, roughly a third of the participants were able to locate their reaction within a theme or smaller unit. The data showed that musical events associated with 'tears' (i.e., crying, lump in the throat) commonly contained melodic appoggiaturas and melodic or harmonic sequences; events associated with 'shivers' (i.e., goose pimples, shivers down the spine) usually contained a new or unprepared harmony; and events associated with 'heart reactions' contained syncopations and prominent events occurring earlier than prepared for. The results were related to Meyer's (1956) notion that musical expectancies, and violations of these, play an important role in emotional responses to music.

Individual factors

Individual differences between listeners appear to be larger for induction of emotions than for perception of emotions, though little research has focused on individual differences in musical emotion induction. Still, research has revealed a number of factors in the individual that may

potentially affect emotional responses to music, such as the listener's age, gender, personality, musical training, music preference and current mood (for a review, see Abeles and Chung 1996). Familiarity with the music tends to induce stronger emotional responses (Bartel 1992), which may explain why listeners respond stronger to self-selected than to experimenter-selected music (Harrer and Harrer 1977). Musical training might lead to less emotional involvement due to increasingly analytic listening (Harrer and Harrer 1977; but see also Lehmann 1997 for contradictory findings). Behne (1997) suggested that there may be different individual 'listening styles'. His proposals were based on cluster analyses of data from a questionnaire, which aimed to study musical experiences. Examples of such listening styles were 'emotional' ('I pay attention to what feelings are expressed through the music'), 'distancing' ('I try to follow the musical lines of a particular instrument'), 'sentimental' ('I remember things of the past'), and 'compensating' ('it makes me feel better').

Situational factors

Factors related to the situation of a musical event could be categorized in different ways. Gabrielsson (2001) divided them into 'physical factors' (e.g., acoustical and visual conditions, time, place), 'social factors' (e.g., listening alone or together with others, type of audience, co-performers), 'special occasions and circumstances' (e.g., vacation), and 'performance conditions' (e.g., music well-rehearsed or not). Only recently have researchers begun to explore the ways that music actually figures in the everyday life of ordinary people (Part 9 of this volume), but it is becoming increasingly clear that key to an understanding of musical emotions is to describe the complex interplay between the music, the listener, and the situation. Juslin *et al.* (in press) noted that emotional responses to music occurred in all kinds of locations, partly because the participants were able to bring their favourite music anywhere (thanks to devices such as mp3 players). However, the prevalence of specific emotions varied depending on the situation. For example, some emotions such as *happiness–elation*, *pleasure–enjoyment*, and *anger–irritation* occurred frequently in 'social' settings, whereas others such as *calm–contentment*, *nostalgia-longing*, and *sadness–melancholy* occurred frequently in more 'solitary' settings. This highlights the need to use representative samples of situations in order to obtain accurate estimates of the prevalence of specific emotions.

How does music induce emotions?

Most scholars acknowledge that this is the primary issue (e.g., Dowling and Harwood 1986, p. 202). Yet a literature search reveals that few studies make any attempt to test a theory about the psychological mechanism that underlies emotional responses to music. In fact, apart from Meyer's (1956) treatise (arguably the most cited book on this subject ever), most theories of musical emotions focus on the expressive properties of music that allow listeners to *perceive* emotions (e.g., Clynes 1977; Cooke 1959; Juslin 2001; Langer 1957).

One problem with musical emotions is that the conditions for eliciting emotions appear to be different from those in everyday life: in the paradigmatic case, an emotion is evoked when an event is appraised as having the capacity to influence the goals of the perceiver. Since music would not appear to have any capacity to further or block goals in life, researchers have been forced to come up with an alternative explanation that makes more sense in a musical setting. (However, musical induction of emotions through a cognitive appraisal may occur sometimes, such as when our 'goal' to go to sleep at night is 'blocked' by a neighbour playing loud music.)

A theoretical framework

Building on the work of the pioneers in this field (Berlyne 1971; Meyer 1956) as well as on more recent research (Juslin and Sloboda 2001), Juslin and Västfjäll (in press) presented a theoretical framework featuring six mechanisms through which music can induce emotions. One could conceive of these mechanisms as consisting of a number of (more or less) distinct brain functions that developed gradually and in a specific order during evolution. Because the mechanisms

depend on functions with different evolutionary origins, each mechanism should possess unique characteristics. The framework focuses on the following mechanisms:

Brainstem reflex refers to a process whereby an emotion is induced by music because one or more fundamental acoustical characteristics of the music are taken by the brainstem to signal a potentially important and urgent event. All other things being equal, sounds that are sudden, loud, dissonant, or feature fast temporal patterns induce arousal in the listener. Such responses reflect the impact of simple auditory sensations (i.e., music as *sound* in the most basic sense). The perceptual system is constantly scanning the immediate environment in order to discover potentially important changes or events. Sounds that meet certain criteria will thus lead to an increased activation of the central nervous system in the early stages of auditory processing. The precise physiological processes underlying such brainstem responses are not completely understood, although evidence suggests that they occur in close connection with the reticular formation of the brainstem and the intralaminar nuclei of the thalamus, which receive inputs from the auditory system. The brainstem is an ancient structure of the brain that sub-serves a number of sensory and motor functions including, but not limited to, auditory perception and the mediation and control of attention, emotional arousal, heart rate, breathing, and movement (Joseph 2000). It may thus influence physiological processes related to emotions (e.g., pulse, respiration), such that the listener's arousal level increases or decreases.

Evaluative conditioning (EC) refers to a process whereby an emotion is induced by a piece of music simply because this stimulus has often been paired with other positive or negative stimuli (De Houwer *et al.* 2001). For example, a particular piece of music may have occurred repeatedly together in time with a specific event that always makes you happy, such as meeting one of your friends. Over time, through repeated pairings, the music itself will eventually evoke happiness even in the absence of the friendly interaction. There are few studies of EC with music (but see Blair and Shimp 1992), though EC has a number of features that are interesting in regard to music. First, EC can occur even if the participant is unaware of the contingency of the two stimuli. In fact, it has been found that EC can be both established and induce emotions without awareness (e.g. Martin *et al.* 1984). Secondly, EC appears to be fairly resistant to extinction, as compared to classical conditioning. Music often occurs in situations where music listening is not the main activity (Sloboda *et al.* 2001) and where subtle conditioning processes outside awareness might easily occur.

Emotional contagion refers to a process whereby an emotion is induced by a piece of music because the listener perceives the emotional expression of the music and then 'mimics' this expression internally (Juslin 2001). Emotional contagion has mostly been studied regarding facial expression (Hatfield *et al.* 1994), but Neumann and Strack (2000) also found evidence of contagion from emotional speech. Because music often features expressive acoustical patterns similar to those that occur in emotional speech (for a review, see Juslin and Laukka 2003), it has been argued that we get aroused by the voice-like aspects of music via a process in which a neural 'module' responds quickly and automatically to certain stimulus features, which leads us to mimic the perceived emotion internally (Juslin 2001). While the notion of emotional contagion via music admittedly remains somewhat speculative, a recent functional magnetic resonanace imaging (fMRI) study by Koelsch *et al.* (2006) found that music listening activated brain areas related to a circuitry serving the formation of pre-motor representations for vocal sound production (no singing was observed among the participants). Koelsch *et al.* concluded that this could reflect a mirror-function mechanism, similar to the so-called 'mirror neurons' proposed as a possible explanation of emotional contagion via other non-verbal channels (Preston and de Waal 2002).

Visual imagery refers to a process whereby an emotion is induced in a listener because he or she conjures up visual images (e.g., of a beautiful landscape) while listening to the music. The emotions experienced are the result of an interaction between the music and these images. The precise nature of this process remains to be described, but listeners appear to conceptualize the musical structure through a metaphorical non-verbal mapping between the music and

'image-schemata' grounded in bodily experience (see Lakoff and Johnson 1980); for instance, hearing melodic movement as 'upward'. Listeners might respond to mental images much in the same way as they would to the corresponding stimuli in the 'real' world, for instance reacting with positive emotions to a beautiful nature scene. Mental imagery in relation to music has mostly been explored in the context of music therapy (Toomey 1996-1997). Helen Bonny developed a method, *guided imagery and music* (GIM), where a 'traveller' is invited to 'share' his or her images as they are experienced in real time during a programmed musical sequence (Bonny and Savary 1973). Characteristic of visual imagery as an induction mechanism is that the listener is able to influence the process to a considerable extent. Although images might come into the mind unbidden, often a listener may conjure up, manipulate, and dismiss images at will.

Episodic memory refers to a process whereby an emotion is induced in a listener because the music evokes a personal memory of a specific event in the listener's life (Baumgartner 1992). This has been referred to as the 'Darling, they are playing our tune' phenomenon (see Davies 1978). Research has revealed that music often evokes memories (Gabrielsson 2001; Sloboda 1992). When the memory is evoked, so too is the emotion associated with the memory. Such emotions may be intense, perhaps because the physiological response patterns to the original events are stored in memory along with the experiential contents. Many listeners use music to remind them of valued past events, suggesting that music may serve an important 'nostalgic' function in everyday life. Music plays a very prominent role in adolescents' lives in regard to the development of a self-identity (e.g., Saarikallio 2007). Hence, one could expect episodic memories associated with music to be particularly emotionally vivid and frequent with regard to music from young adulthood, as indeed seems to be the case. Schulkind *et al.* (1999) found that older adults preferred, knew more about, as well as had stronger emotional responses to music popular during their youth than to music popular later in life.

Musical expectancy refers to a process whereby an emotion is induced in a listener because a specific feature of the music violates, delays, or confirms the listener's expectations about the continuation of the music (Meyer 1956; see also Narmour 1992). For instance, the sequential progression of E-F# sets up the expectation that the music will continue with G#. If this does not happen, listeners familiar with the musical idiom may become surprised. The expectations are based on the listener's previous experiences of the same style of music. Although Meyer's theory is highly regarded, it has not stimulated much research on emotions (but see Sloboda 1991), perhaps because the theory is difficult to test. For instance, a musical piece may evoke several different musical expectations at different levels of the music, and these expectations may also be different for different listeners. However, support for Meyer's theory was found by Steinbeis *et al.* (2006), who used subjective and physiological measures to capture emotional responses to unexpected events in music (see Figure 12.2).

Only a few of the above mechanisms have been tested in regard to music, but one thing seems clear: there is no single mechanism that can account for all instances of musical emotion. A crucial goal for future research is to develop a process model of the induction process, though given the large number of mechanisms, such an endeavour is a formidable undertaking. A first step could be to specify the precise characteristics of each mechanism. By synthesizing theory and findings from different domains outside music, Juslin and Västfjäll (in press) were able to provide the first set of hypotheses that can help researchers to distinguish among the proposed mechanisms. The hypotheses concern characteristics such as the information focus, key brain regions, ontogenetic development, cultural impact, induced affect, induction speed, degree of volitional influence, and so forth (see Juslin and Västfjäll, in press, Table 4).

Implications of the framework

One implication of the novel framework is that it may resolve disagreements in the field. Specifically, apparent contradictions of different approaches may be reconciled by observing that they focus on different mechanisms. Hence, the framework may help to resolve previous disagreements about which emotions music can induce,

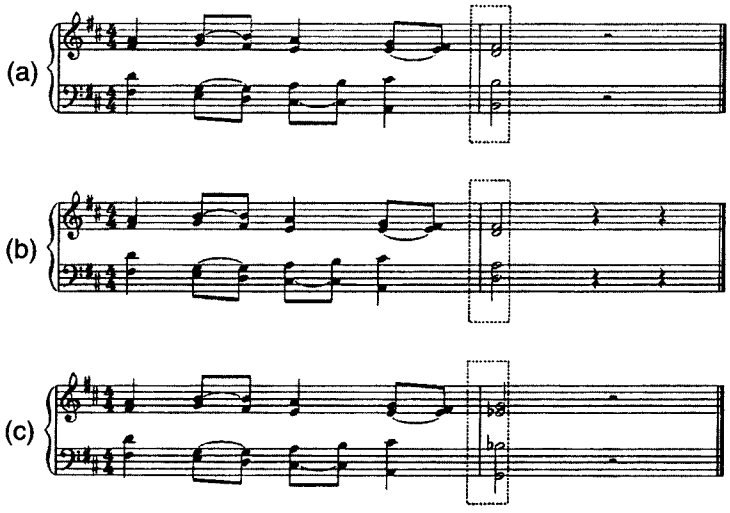

Fig. 12.2 Examples of musical stimuli used to induce emotions through the musical expectancy mechanism (from Steinbeis *et al.* 2006). (a) is a cadence from an excerpt of an original composition by JS Bach with an unexpected event enclosed within the box. (b) and (c) are identical to version (a) except for the harmonic events within the boxes, which were manipulated to be either more expected (b) or less expected (c) than the original. Reproduced by permission of the MIT Press.

how early musical emotions develop, whether listeners are active or passive in the causal process, how much time it takes to induce an emotion through music, and whether musical emotions are innate or learned responses—it depends on the mechanism concerned.

The most important implication of the proposed framework for future research in the field is that it will not be sufficient to induce and study musical emotions *in general*. In order for data to contribute in a cumulative fashion to our knowledge, researchers must try to specify as far as possible the mechanism involved in each study. Otherwise studies will produce results that are inconsistent or that cannot be given a clear interpretation. One example is provided by the recent flurry of research on the neuropsychological correlates of emotional responses to music (Peretz 2001). Numerous brain regions have been reported in previous studies of music and emotion (e.g., the thalamus, cerebellum, hippocampus, amygdala, prefrontal cortex, Broca's area, nucleus accumbens, visual cortex, and supplementary motor areas). However, different brain regions have been implicated in different studies for reasons that are unclear. One likely explanation is that most studies have simply presented 'emotional music' to listeners without manipulating (or at least controlling for) the underlying induction mechanism. This makes it difficult to understand what the obtained neural correlates reflect in each study. Hence, Juslin and Västfjäll (in press) argue that musical emotions cannot be studied without respect to how they were evoked. An important task for the future is to develop standard paradigms and tasks that can reliably induce specific emotions in listeners through each of the mechanisms above.

Conclusions

The study of music and emotions is fraught with considerable controversy and disagreement. Current debates in the field revolve around such questions as which emotions music induces, whether there are uniquely musical emotions, and what the relationship is between perceived and induced emotions. An important direction for future research is to consider how emotions might be one of several features of an aesthetic response to music—the appreciation of music

as 'art' (see Chapter 14 this volume). Real-world research has revealed that music is intentionally used by listeners to regulate their moods and emotions, and that positive emotions tend to dominate in their responses. The latter result has stimulated interest in effects of music on physical health and subjective well-being: can the emotional effects of music be used in health interventions that target biochemical substances, such as cortisol, oxytocin, dopamine, and serotonin? The development of such applications would obviously benefit from a better understanding of the underlying mechanisms. The framework discussed earlier may hopefully contribute to more hypothesis-driven approaches to exploring different mechanisms of musical emotions. Other possible applications of research on emotional responses to music include music therapy, film music, marketing, health care, and the gaming industry. In fact, several current applications of music presume its effectiveness in evoking emotions, yet we are only beginning to understand the mechanisms that make this possible. More often than not, music is intentionally designed to stir our emotions, exploiting whatever means available, and we have seen that music might induce emotions in many different ways. Hence, one answer to the question 'why does music move us?' is 'because we *want* music to move us and have designed it so that it will do it with the maximum effect'. However, rather than 'destroying the magic', an understanding of how music evokes emotions will only increase our never-ending fascination with music.

CHAPTER 13

The relationship between musical structure and perceived expression

Alf Gabrielsson

THE relationship between structure and expression in music has been discussed by philosophers and music theorists ever since antiquity, but empirical research did not start until about one hundred years ago. Most of this research is limited to Western classical music.

Musical structure is an umbrella term for a host of factors such as tempo, loudness, pitch, intervals, mode, melody, rhythm, harmony and various formal aspects (e.g. repetition, variation, transposition). They are designated by different symbols in the common musical notation. Most symbols represent categories with allowance for performance variation within the respective category. Listeners' perception of expression is thus affected both by the composed/notated structure and by the actual performance. However, performance aspects will not be further discussed here as they are treated elsewhere in this volume (Part 7).

Listeners' perception of expression—for instance, to perceive sadness in the music—should be distinguished from listeners' own reactions (that is, feeling sad themselves); the latter are treated elsewhere (Chapter 12). However, the border between these two alternatives is sometimes blurred, and the relationship between them may vary (Evans and Schubert 2008; Gabrielsson 2002; Juslin and Laukka 2004; Kallinen and Ravaja 2006; Konečni *et al.* 2008).

Absolutism versus referentialism

Meyer (1956) made a distinction between absolutism and referentialism (other terms are formalism vs. expressionism, or autonomous vs. heteronomous music). Absolutism focuses on intra-musical relations; music is considered self-contained, refers only to itself. Referentialism implies, on the contrary, that music refers to extra-musical phenomena such as emotions, events, or characters.

Music critic Eduard Hanslick claimed that music consists of tone sequences which have no other content than themselves (Hanslick 1989, p. 162), and composer Igor Stravinsky held that 'if music appears to express something, this is only an illusion' (cited in Fisk 1997, pp. 280–281). However, the distinction between absolutism and referentialism is rather vague. Hanslick and Stravinsky later added several modifications to their seemingly dogmatic statements, and 'absolute meanings and referential meanings can and do coexist in one and the same piece of music' (Meyer 1956, p.1).

In the present chapter emphasis will be on *perceived* expression rather than expression somehow inherent in the music. The listener may apprehend music as 'pure' music (absolutism) or as expression of emotions, characters,

events or whatever, and may very well alternate, consciously or unconsciously, between different approaches during the course of a piece. Focus will be on referential meaning, leaving questions about intra-musical relationships and structural listening to other chapters in this volume (Part 2); see Clarke (2005) for further comments on autonomous music and structural listening.

Expression of emotion

Among referential meanings, expression of emotion is the most common alternative. It has been discussed for centuries, as in the 'doctrine of the affections' (*Affektenlehre*) during the Baroque era and during Romanticism with its emphasis on expression of the subjective and emotional in music. Musicologist Deryck Cooke claimed that music is a language of emotions (1959, pp. 32–33), and philosopher Susanne Langer argued that 'music can *reveal* the nature of feelings with a detail and truth that language cannot approach' (1957, p. 235).

The following is a condensed review of empirical research on emotional expression in music. More complete reviews appear in Gabrielsson and Juslin (2003) and Gabrielsson and Lindström (2001).

Stimuli

Generally, subjects listened to pieces of music or other tonal stimuli and reported perceived expression. Stimuli were usually recordings of selected pieces of music, sometimes live music (e.g., Hevner 1935; Rigg 1937a), or synthesized tone stimuli. Using real music means good ecological validity but limits conclusions regarding the effects of separate structural factors since they are usually confounded in musical contexts. An alternative that allows more definite conclusions is to systematically vary one or more structural factors in short sound sequences (e.g., Scherer and Oshinsky 1977); however, the ecological validity is then limited. A further, commendable alternative is to systematically vary different structural factors (tempo, mode, form, etc.) in real pieces of music (e.g., Hevner 1935, 1936, 1937; Juslin 1997; Kamenetsky *et al.* 1997; Karno and Konečni 1992; Lindström 2006; Peretz *et al.* 1998; Rigg 1940a, b; Schellenberg *et al.* 2000), and thus try to combine the advantages of the before-mentioned strategies.

Response format

Subjects reported perceived expression using:

(a) free phenomenological descriptions (e.g. Huber 1923; Tagg 2006) or free choice of descriptive terms/adjectives (Imberty 1979);

(b) choice among descriptive terms provided by the investigator (e.g. Gundlach 1935; Hevner 1935; Wedin 1972a);

(c) combination of free descriptions and choice among descriptive terms (Rigg 1937a);

(d) ratings of how well selected descriptive terms apply to the music in question (e.g. Gabrielsson 1973; Nielzén and Cesarec 1982; Tillman and Bigand 1996;Wedin 1969); Collier (2007) used ranking of emotion words;

(e) nonverbal methods, for instance, pressing a pair of tongs to indicate perceived tension (Nielsen 1983, 1987), finger pressure on a sentograph to study expression of different emotions (Clynes and Nettheim 1982; Gabrielsson and Lindström 1995; de Vries 1991); or

(f) various technical or computerized devices to allow continuous recording of perceived tension (e.g., Fredrickson 2000; Fredrickson and Coggiola 2003; Krumhansl 1996; Madsen 1998; Madsen and Fredrickson 1993) or various emotions (Krumhansl 1997; Schubert 2004).

Analysis

Free descriptions were subjected to content analysis. Listeners' choices among descriptive terms were analyzed regarding the frequency of chosen terms and inter-subject agreement. Ratings were usually analyzed by multivariate techniques, such as factor analysis, cluster analysis, multidimensional scaling or correspondence analysis in order to find a limited number of fundamental dimensions. Although the labels of these dimensions vary somewhat between different studies, they are in general interpretable in accordance with the valence-arousal model of emotion (Russell 1980; Russell and Feldman

Barrett 1999). There are also indications of a potency dimension (Kleinen 1968; cf. Osgood *et al.* 1957); a dimension related to body posture and gestures (Bigand *et al.* 2005); and a dimension reflecting stylistic differences between classical and popular music (Wedin 1969, 1972b). Further proposals include a distinction between energy arousal and tension arousal (Ilie and Thompson 2006; Schimmack and Grob 2000) and attempts to identify subtle dimensions beyond valence and activation (Collier 2007).

The relationship between the composed structure and perceived expression was studied by

(a) analyzing the musical score in relation to perceived expression (e.g. Gundlach 1935; Imberty 1979; Krumhansl 1996; Nielsen 1983; Thompson and Robitaille 1992);

(b) having musical experts judge the selected pieces with regard to structural properties (e.g. Kleinen 1968; Wedin 1972b);

(c) using various devices for measuring the acoustical properties of the music (e.g. Schubert 2004; Todd 1994); or

(d) using systematic manipulation of the musical stimuli and noting the effects on perceived expression (references given under Stimuli).

Expression of emotion: effects of separate musical factors

The effects of separate musical factors are summarized in Gabrielsson and Lindström (2001). The following is an abbreviated version of this summary, with some new references added.

Tempo, note density

Among factors affecting emotional expression, tempo—that is, perceived beat/pulse rate—is usually considered the most decisive.

Fast tempo may be associated with expressions of activity/excitement, happiness/joy/pleasantness, potency, surprise, flippancy/whimsicality, anger, uneasiness and fear.

Slow tempo may be associated with expressions of calmness/serenity, peace, sadness, dignity/solemnity, tenderness, longing, boredom, and disgust.

Both fast and slow tempo may thus be associated with many different expressions dependent on presence and level of other structural factors. However, in terms of the valence-arousal model, fast tempo is generally associated with high(er) activation, slow tempo with low(er) activation, while both of them may be associated with either positive or negative valence.

A related factor is note density, the number of notes per unit of time (e.g. per second). Tempo and note density may sometimes be additive—fast tempo combined with high note density results in still higher activation, slow tempo combined with low note density results in still lower activation—and may sometimes present an ambiguous picture as when high note density appears in combination with slow tempo (Gabrielsson 1988).

Mode, key

Major mode may be associated with happiness/joy, minor mode with sadness. Major mode may also be associated with expressions as graceful, serene, and solemn, minor mode with expressions as dreamy, dignified, tension, disgust, and anger.

While differences between fast and slow tempo are mainly associated with difference in activation, differences between major and minor mode are thus mainly associated with difference in valence, positive or negative. However, major mode is not a necessary condition for perceived happiness; a piece in minor mode in fast tempo may very well sound happy (e.g., the *Badinerie* in JS Bach's Second Suite for Orchestra). Using scales as stimuli, Collier and Hubbard (2001a) claim that pitch height and direction of pitch movement (contour) may be more important than mode for expression of happiness.

The common belief that certain keys are associated with certain moods has no empirical support (Powell and Dibben 2005).

Loudness

Loud music may be associated with expressions of intensity/power, excitement, tension, anger, and joy, soft music with softness, peace, tenderness, sadness, and fear. On the whole, loud music seems associated with high activation and potency, soft music with low activation and maybe submissiveness.

Large variations of loudness may suggest fear, small variations happiness or activity. Rapid changes in loudness may be associated with playfulness, pleading or fear, few or no changes with sadness, peace, and dignity.

Timbre/spectrum

Tones with many higher harmonics may suggest potency, anger, disgust, fear, activity, or surprise, thus usually high activation. Tones with few, low harmonics may be associated with pleasantness, boredom, happiness or sadness, and tones with suppressed higher harmonics may suggest tenderness and sadness, thus usually low(er) activation.

Pitch

High pitch may be associated with expressions as happy, graceful, serene, dreamy, exciting, surprise, potency, anger, fear, and activity. Low pitch may suggest sadness, dignity/solemnity, vigour, excitement, boredom, and pleasantness. Large pitch variation may be associated with happiness, pleasantness, activity, or surprise, small pitch variation with disgust, anger, fear, or boredom.

Intervals

For melodic (successive) intervals some results indicate that large intervals sound more powerful than small ones, the octave is perceived as positive and strong and the minor second as the most sad interval. For harmonic (simultaneous) intervals, results concerning consonance and dissonance are similar to corresponding results under Harmony.

Melody

Melodic range

Wide melodic range may be associated with joy, whimsicality, uneasiness, and fear, narrow range with expressions as sad, dignified, sentimental, tranquil, delicate, and triumphant.

Melodic direction (pitch contour)

Ascending melody may be associated with dignity, serenity, tension, happiness, fear, surprise, anger, and potency. Descending melody may be associated with expressions such as exciting, graceful, vigorous, sadness, boredom and pleasantness.

Melodic motion

Stepwise motion may suggest dullness, intervallic leaps excitement; stepwise motion leading to melodic leaps may suggest peacefulness (Thompson and Robitaille 1992). Activity (sense of instability and motion) may be conveyed by a greater occurrence of minor seconds, tritones, and intervals larger than the octave. Potency (vigour and power) may be expressed by a greater occurrence of unisons and octaves (Costa *et al.* 2004).

Harmony

Simple, consonant harmony may be associated with expressions as happy/gay, relaxed, graceful, serene, dreamy, dignified, serious, and majestic; complex and dissonant harmony with expression of excitement, tension, vigour, anger, sadness, and unpleasantness.

Tonality

Melodies composed to sound joyful, dull, and peaceful were tonal, while angry melodies could be atonal. Sad and angry melodies used chromatic harmony (Thompson and Robitaille 1992).

Rhythm

Regular/smooth rhythm may be perceived to express happiness, dignity, majesty, and peacefulness; irregular/complex rhythm may express amusement, uneasiness, and anger; varied rhythm may express joy. Firm rhythm may be associated with expressions of sadness, dignity, and vigour; flowing/fluent rhythm with expressions such as happy/gay, graceful, dreamy, and serene.

Articulation

Staccato may be associated with gaiety, energy, activity, fear, and anger, legato with sadness, tenderness, solemnity, longing, and softness.

Pauses

Perception of rests is dependent on musical context. Silences (rests) following tonal closure

were identified more quickly and perceived as less tense than silences following music lacking such closure (Margulis 2007).

Musical form

High complexity (melodic/harmonic/rhythmic) is associated with tension or sadness, low complexity with relaxation, joy, or peace. High complexity combined with low dynamism may express melancholy and depression, high complexity combined with high dynamism may express anxiety and aggressiveness. Low complexity and average dynamism may be associated with positive emotions. Repetition, condensation, sequential development, and pauses may mean increased tension. Disruption of global form (changing the order of sections/movements in a musical work) may have little effect on (unknowing) listeners' perception of expression or general evaluation.

Expression as function of many factors

As seen above, each structural factor may influence many different expressions. This means, conversely, that each expression may depend on many different structural factors as displayed in the extensive Table 26.2 in Gabrielsson and Juslin (2003). This table provides a systematic exposition of how different expressions—happiness/joy/gaiety, sadness/gloom, tension, potency, activity/energy/excitement, relaxation/calm/softness/peace, solemnity/dignity, anger, fear, tenderness/love, boredom, disgust, and surprise—are affected by different structural features. To take but one example: perceived tension is related to dissonance, high sound level, ascending melody, increased note density, harmonic complexity, rhythmic complexity, lack of melody, and various formal properties such as repetition, condensation and sequential development.

Expression of emotion: summary and implications

The above review shows a complex picture. It seems that any structural factor may indicate a number of different emotional expressions. Results seem most clear-cut regarding effects of tempo/speed, loudness, and timbre/spectrum: increase in any of them results in higher activation, decrease in lower activation (by increase in timbre is meant relatively more higher harmonics). Tempo and loudness, in particular, seem to reign over most other factors, and generally the activation dimension seems more salient and easier to judge than the valence dimension. The effects of pitch height seem more ambiguous than those of loudness or tempo; for instance, while the effects of fast tempo and/or high loudness are associated with high activation, high pitch may be associated with both high and low activation.

The most distinct results thus concern effects of basic variables in human audition (loudness, timbre, pitch) and motion (tempo/speed). With regard to more typical 'musical' variables results are less clear, or there is less research available. The typical major-happy and minor-sad associations may be overruled by interaction with tempo (as exemplified under Mode above) and do not appear until the age of 7–8 years (e.g., Gerardi and Gerken 1995). There are still only tentative results regarding perceived expression of different intervals, and their effects may be modulated by differences in tempo, loudness, and other factors (Gabrielsson and Lindström 2001, p. 243). There is further little research on perceived expression of different kinds of melodic and rhythmic progression and practically none regarding harmonic progression. Aspects of musical form are frequently discussed in relation to structural listening, but their influence on perceived expression is little investigated.

Perceived expression is never determined by a single factor but is a function of many factors which may work in additive or interactive ways. Several studies identify interactions *post hoc*; for instance, intensity x pitch height and pitch height × tempo interactions regarding valence (Ilie and Thompson 2006), scale direction x tempo regarding happiness (Collier and Hubbard 2001b), and triple interaction rhythm x contour x melodic progression in ratings of happiness (Lindström 2006). However, there are only a few studies planned to study the presence (or not) of specific interactions (e.g. Langner and Goebl 2003; Makris and Mullet 2003; Schellenberg *et al.* 2000).

Most studies have utilized music with the 'same' expression throughout, whereas an essential part of music's appeal lies in variation of emotional expression. Many of the most intense expressions are related to (sudden or gradual) changes in, say, loudness (e.g. crescendo, diminuendo), tempo (accelerando, ritardando), timbre, pitch level, rhythm, melodic and harmonic progression, or in various combinations of these factors. Therefore an important topic for continued research is refinement of techniques for continuous recording of expression (Schubert 2001, 2002, 2004; Vines *et al.* 2005). Free phenomenological descriptions may be used as a complement. However, certain subtleties in musical expression may never be captured in a strict scientific manner, nor be adequately verbalized; they may only be accessible in direct experience.

On the other hand some results indicate that listeners are able to perceive the 'correct' expression even in excerpts lasting only one second or less (Bigand *et al.* 2005; Peretz *et al.* 1998). It also seems that, on the whole, perceived emotional expression is not, or only marginally, influenced by differences in gender or musical experience (e.g. Bigand *et al.* 2005; Bigand and Poulin-Charronnat 2006; Fredrickson 2000; Kallinen 2005; Makris and Mullet 2003; Robazza *et al.* 1994; Wedin 1969); there are, however, some indications that women may find music more emotionally expressive than men (e.g. Kamenetsky *et al.* 1997)

Other referential meanings

Beyond emotions, music may also be perceived to express, reflect, or represent many other phenomena. (For discussion about definitions of expression, representation, or depiction, see Davies 1994; Scruton 1997).

Program music

Program music flourished during Romanticism, as in works by Berlioz, Liszt, and Richard Strauss. However, composers were aware of music's limited possibilities to represent objects and events and rather referred to the feelings associated with the program (Benestad 1978, p. 233).

Listeners who do not know the program are as a rule unable to provide a 'correct' description of the intended events or situations but are better at perceiving the intended emotional expression (e.g. Brown 1981; Rigg 1937b). However, Osborne's (1989) subjects seemed to capture several aspects of the representations and expressions in Richard Strauss' *Alpine Symphony*.

One may also speak of program music in another sense: programs made up by the listeners themselves. Listeners may perceive a narrative in music they listen to ('this music is about '). Delis *et al.* (1978) argued that listeners construct a story in relation to the music in order to better remember it.

Human character, personality, identity

In ancient Greece it was believed that music reflected human character and that these expressions would be imitated by the listener. Plato and Aristotle therefore gave advice concerning which modes, instruments, and rhythms ought to be used in education.

Clynes (1987, 1995) hypothesized that composers' character and 'presence' are reflected in unique patterns of timing and dynamics (composers' 'inner pulse'). Empirical tests regarding the existence of such patterns have provided mixed results (Clynes 1995; Repp 1990; Thompson 1989).

Tagg (2006) found striking differences between music perceived as 'male' or 'female'. In comparison with male tunes, female tunes were slower, more legato, had longer phrases, no repeated notes, static bass line, rare offbeats/syncopation, no brass or percussion, and the tonal idiom was classical/romantic compared to rock and jazz in male tunes. A 'male vs.female' factor, as well as some other human characteristics, was also observed in an exploratory study by Watt and Ash (1998). They claimed that music is assigned attributions that normally would be assigned to a person and went on to speculate that 'music creates a virtual person' (*ibid.* p. 49). In fact, many subjects perceive the music to reflect their own personality, how they think and feel; this provides a strong confirmation of their own identity (Gabrielsson and Lindström Wik 2003).

Music may reflect and be used to express not only personal but also social, cultural, and gender

identity (e.g. Dibben 2002; Folkestad 2002; Martin 2006; Ruud 1997; Tarrant *et al.* 2002). Immigrants are eager to preserve their own music in the new country, and teenagers may use certain music to mark their belonging to youth culture in general or to a particular group of people.

Motion, dynamic forces

It is generally agreed that we may perceive motion in music. However, there is much discussion whether it refers to real motion, self-motion, virtual motion, or is entirely metaphorical. For discussions and overviews, see Bharucha *et al.* (2006, section 4), Clarke (2005), Eitan and Granot (2006), Jackendoff and Lerdahl (2006, section 4.3), and Shove and Repp (1995); see also Gjerdingen (1994) for a neural network model of apparent motion in music.

In music theory it is common to speak of tonal/harmonic motion in the sense that unstable tones/chords 'move' to (resolve to) stable tones/chords, typically in connection with perception of tension and release (e.g. Lerdahl and Krumhansl 2007). The concept of tension is thus related to structural listening but may also mediate emotional expression (Nielsen 1983).

Musicologist Ernst Kurth (1930) thought of music as a play of dynamic forces, gravitational forces between tones and chords, attracting or repelling each other; melody is perceived as a streaming force filled with kinetic energy. Larson and VanHandel (2005) defined three musical forces—musical gravity, musical magnetism, musical inertia—and operationalized them as short melodic patterns that were judged by listeners with regard to experienced 'strength' of the presented pattern completions. Results indicated that listeners' judgements were influenced by musical inertia and musical gravity.

While the above examples are mainly concerned with structural (intra-musical) listening, certain designations in scores (e.g. accelerando, ritardando, alla marcia, grazioso) refer to motion in a more concrete sense, and listeners find it natural to use motion labels as bouncing, dancing, flowing, rocking, swinging, and so on in descriptions of music (Gabrielsson 1973, 1988; Madison 2006). Tempo, articulation, and rhythm patterns seem obvious candidates underlying such motion characters (*cf.* 'galloping rhythm', 'fluent rhythm ', 'uneven rhythm', etc.), but there is still little systematic research on what factors in musical structure affect perceived motion. Eitan and Granot (2006) asked subjects to describe imagined motion of a visualized person when listening to brief melodic figures varying in dynamics, pitch contour, pitch intervals, attack rate, motivic pace, and articulation. The manipulations affected several variables in the listeners' motion imagery, such as lateral and vertical direction, distance change, speed change, and energy level of motion.

It is also generally agreed that there is a close link between motion and emotion: 'Motion is heard in music, and that motion presents emotion characteristics' (Davies 1994, p. 229), 'musical affect arises in large part from its relation to physical patterns of posture and gesture' (Jackendoff and Lerdahl 2006, p. 65). Jackendoff and Lerdahl point out that many terms used for description of emotional expression are also used to describe gestures and postures and discuss possible underlying factors in musical structure and performance. (One may add that it is sometimes felt more natural and easier to describe music in terms of motion rather than emotion.) Here, then, is a domain awaiting pertinent empirical research.

Social conditions and organization

Philosopher Theodor W. Adorno speculated that music's formal properties may reflect organization and forces of society; for instance, tensions in society would be reflected in rupture of musical form (Benestad 1978, p. 329). While Adorno never sought empirical evidence, Lomax's (1968) large-scale investigation of folk song styles in 233 cultures throughout the world provides many examples of how music can reflect economic and social conditions and attitudes; for comments, see Dowling and Harwood (1986, p. 226).

Religious faith, transcendental phenomena

Music as expression of religious faith is a worldwide phenomenon. In Western music history, examples range from simple community singing

to masterpieces such as J. S. Bach's passions, Handel's oratories, or masses by Haydn, Mozart, and Beethoven.

Philosopher Arthur Schopenhauer regarded music as an expression of the Will, a never-ending striving toward existence that can never be quite fulfilled and therefore causes human suffering, and Friedrich Nietzsche viewed music as expression of Dionysian character and the will to life and power; see further in Benestad (1978) and Budd (1985).

Further comments on structure

There is only scattered research on structural variables connected with the referential meanings treated in this section. However, since many of these meanings—program music, motion, character, identity, religious faith—also have obvious emotional connotations, it is reasonable to expect that the structural variables underlying emotional expression are largely pertinent to them as well.

Finally, we should not forget that many people enjoy music simply for its expression of beauty. However, there seem to be no empirical investigations in music psychology directly focusing on structural factors underlying perceived beauty in music.

CHAPTER 14

Aesthetics

David Huron

Introduction

Aesthetics is commonly defined as the study of beauty, and its opposite, ugliness. Some philosophers conceive of aesthetics as applying solely to the arts or to artistic experience. However, most aesthetic philosophers construe the discipline as applying more broadly to beauty and ugliness in general. The term 'aesthetics' first appeared in a book by Alexander Baumgarten in 1735, yet philosophical discussions of beauty extend back thousands of years. Commentaries on 'good' and 'bad' music can be found in both ancient Greek and ancient Chinese sources.

Beginning in the 1960s, the field of cognitive science became increasingly influential in the philosophy of mind. While much of this influence relates to the nature of thought, reasoning, and consciousness, the impact of cognitive science has expanded to other areas of philosophy, including aesthetics. In this chapter, no effort will be made to provide a comprehensive survey of ideas related to musical aesthetics. Instead, it focuses more narrowly on how cognitive science has influenced—and continues to influence—modern thinking in musical aesthetics. This chapter concludes by arguing that cognitive neuroscience is poised to overtake philosophical aesthetics: rather than *influencing* aesthetic philosophy, aesthetic philosophy is receding to a sideline 'advisory' role, while cognitive science takes an unaccustomed leadership position.

Philosophical antecedents

In the West, the most influential writer on aesthetics has been the German philosopher Immanuel Kant (1724–1804). Kant laid out two pillars in Western aesthetics. First, he distinguished aesthetic pleasure from other forms of pleasure. Aesthetic pleasure is not some other type of pleasure in disguise: for example, art is not the sublimation of food, sex, warmth, companionship, or some combination of other existing pleasures. Second, Kant argued that aesthetic emotions are 'disinterested'; when we experience an aesthetic pleasure, there are no utilitarian or ulterior motives underlying this experience. A mother's appreciation of the beauty of her daughter cannot be regarded as a purely aesthetic appreciation, since her experience is apt to be tainted by parental pride. Unlike garden-variety emotions, for Kant, aesthetic emotions serve no practical purpose.

In music, Kant's ideas were developed and extended by the famed Austrian music critic Eduard Hanslick (1825–1904). In *Vom Musikalisch-Schönen* (On the beautiful in music) (1854) Hanslick proposed a highly influential view that would later prove to be compatible with a core concept in cognitive science. Hanslick challenged the (then) prevailing beliefs that music somehow represents or expresses feelings. He proposed that sensation is imaginatively interpreted by the listener, and that this aesthetic contemplative process then leads to possible emotions. In short, aesthetic judgement precedes and leads to aesthetic feelings. Until recently, Hanslick's views have defined the principal parameters in debates concerning musical aesthetics. All major philosophers in the aesthetics of music have started by engaging with Hanslick's ideas: see for example Susanne Langer (1942), Peter Kivy (1990), Roger Scruton (1997), Jerrold Levison (1990, 2003) and Stephen Davies (1994).

Experimental antecedents

Most aesthetics scholars have followed a rationalist approach that emphasizes exegesis of existing theories and critical philosophical discussion. Independent of this philosophical tradition, aesthetics questions have also been addressed by empirically oriented scholars pursuing various avenues of scientific experimentation. In fact, the advent of experimental aesthetics coincides with the start of modern experimental psychology. One of the founders of modern experimental psychology, Wilhelm Wundt (1832–1920) carried out a number of experiments related to aesthetic experience. Wundt (1863) showed that arousal is related to stimulus complexity and proposed that aesthetic pleasure is evoked when the art object is optimally complex—neither too simple nor too complicated.

Aesthetics experiments were similarly carried out by another early experimental psychologist, Gustav Fechner (1801–1887). In his *Vorschule der Ästhetik* (Elementary aesthetics) Fechner suggested that 'half of aesthetics' originates in learned associations (1876, pp. 89–90). A lullaby may evoke feelings of comfort solely because of a learned association between the tune and formative experiences of being comforted by a caregiver. A German émigré to the United States, Max Meyer (1873–1967), carried out a key experiment showing that listeners prefer familiar music over unfamiliar music. Meyer (1903) showed that repeated listening to a novel musical work tends to increase reported satisfaction. While the Gestalt psychologists carried out relatively few experiments, they did produce a number of empirical demonstrations of various perceptual principles and suggested that these principles can be observed in both visual art and music (see, e.g. Koffka 1935).

A long-standing preoccupation in experimental musical aesthetics relates to the perception of consonance and dissonance. The ancient Greeks observed that euphonious sonorities appear to involve component tones whose frequencies are related by simple integer ratios. Both Hermann von Helmholtz (1877) and Carl Stumpf (1883) speculated about possible physiological origins for consonance and dissonance. Robert Lundin (1947) proposed that consonance and dissonance preferences are cultural in origin and arise primarily from the relative frequency of exposure to different sound combinations and the prevailing attitudes toward those sounds within a given social environment. By the 1970s, ample evidence pointing to both physiological and cultural factors influencing judgements of the euphoniousness of a sonority had accumulated. Regarding the physiological basis, a significant breakthrough occurred in the 1960s with the work of Donald Greenwood (1961) and Reinier Plomp and Willem Levelt (1965). These and subsequent researchers showed that at least some of the phenomenal experience musicians call 'dissonance' can be traced to mechanical interference within the organ of hearing. Regarding the influence of enculturation and familiarity on stimulus preference, mainstream psychology remained unaware of the pioneering work of Meyer and Lundin. Experimental research by Wilson (1975, 1979) and others unwittingly re-established what Zajonc (1980) later dubbed the 'mere exposure effect'. Over the past century, over 200 experiments have shown that familiarity has a marked impact on preference—especially when the listener is unaware that the sounds are familiar.

Among several notable empirically grounded volumes on the science of aesthetics, perhaps the most comprehensive attempt is found in the work of the Canadian psychologist Daniel Berlyne. In his 1971 book, *Aesthetics and psychobiology*, Berlyne extended Wundt's observations concerning the relationship between complexity, arousal, and pleasure. In particular, Berlyne linked Wundt's observations with contemporary neurophysiological research on pleasure. Berlyne proposed how the phenomenal experience of pleasure might be related to arousal and complexity. He distinguished two pleasure-inducing effects: one source of pleasure arises from moderate increases in arousal, while a second source of pleasure arises from inhibition or reduction of arousal from an uncomfortably high level. Together, these sources result in an inverted-U function when hedonic value (pleasure) is plotted against arousal level.

More recent experimental investigations by Vladimir Konečni and his colleagues have tested the common assumption that large-scale formal structures contribute to the aesthetic experience. For example, scrambling the order of variations

in JS Bach's *Goldberg Variations* or the sections of a sonata-allegro movement by Mozart does not produce less aesthetically pleasing experiences for listeners (Gotlieb and Konečni 1985; Karno and Konečni 1992). Similarly, Nicholas Cook (1987) carried out an experiment suggesting that beginning and ending in the same key ('tonal closure') fails to evoke a greater sense of completion, coherence or pleasure for passages that are longer than roughly 2 minutes. Where Konečni and Cook have questioned existing ideas about form, other research has identified large-scale structures that occur cross-culturally. For example, Ollen and Huron (2004) carried out an analysis of patterns of musical repetition in music from 50 cultures, and found a cross-cultural preference for early repetition (e.g., AAABAABA rather than ABAABAAA). Huron (2006) noted that this pattern is consistent with the twin goals of pursing increasing predictability while avoiding habituation.

Despite a long history, the experimental tradition in aesthetics has had comparatively little influence among aesthetic philosophers. This is especially true in the case of musical aesthetics, where the influence of empirical approaches has been negligible or irrelevant. Among many music scholars, empirical ideas regarding musical pleasure have been regarded as naive, and indeed, some of the claims justify this wary reception.

Cognitive revolution

In contrast to the limited impact of experimental aesthetics on mainstream musical aesthetics, the cognitive revolution has proved to be an inspiration to a number of aesthetic philosophers (e.g., Raffman 1993; Madell 2002; Butler 2004; Robinson 2005). Before discussing the relationship between cognitive science and aesthetics, it is useful to distinguish two different conceptions of cognitive science.

Prior to the cognitive revolution, Anglo-American psychology was dominated by behaviourism, a perspective that emphasized sensation, motor behaviour, and learning. Influenced by linguistics and computer science, cognitive psychologists juxtaposed themselves against behaviourism by emphasizing the thoughtful and imaginative aspects of mental life. For example, rather than viewing emotions as types of reflexes, cognitive psychologists tended to view emotions as originating in cognitive appraisals (Arnold 1960; Averill 1980). That is, emotions were evoked by conscious or unconscious evaluations that depend on underlying conceptualizations. According to this view, judgement precedes emotion.

Until the mid 1990s, cognitive science was typically regarded as opposed to more biological approaches to understanding the mind. Early cognitive science also excluded or sidelined the role of affect or emotion. However, over the past two decades, the sciences of the mind have been converging into what Joseph LeDoux has referred to as 'the united kingdom of cognition and emotion' (1996, p. 39). Cognitive science has moved away from a strictly cognitivist perspective to embrace insights from ethology, evolutionary psychology, psychophysiology, genetics, biochemistry, and neuroimaging. The cognitive perspective remains an important component of contemporary cognitive science, but it no longer occupies the core to the exclusion of other perspectives. In short, cognitive science has become increasingly less cognitive.

This transformation of the field has repercussions for understanding the cognitive science of aesthetics. We can talk about two schools: the first might be called the 'old school' or *cognitivist* approach, while the second might be called the 'new school' or *cognitive neuroscience* approach. This distinction is important because there are two contrasting aesthetic traditions that both claim to be influenced by cognitive science.

The old school, or cognitivist view, has been especially congenial with Hanslick's formalist aesthetics. The traditional cognitivist view has been that cognitive appraisal precedes emotion: conscious or unconscious evaluation is the immediate source of evoked emotion. This view is consistent with Hanslick's argument that sensations are imaginatively interpreted, and that a contemplative process subsequently leads to possible emotions. Music evokes emotion only after passing through a cognitive/interpretive filter. Musical meaning and aesthetic evaluation precede musical affect.

This cognitivist view has become especially popular in literary aesthetics. British literary scholar Christopher Butler (2004), for example,

has applied a cognitivist perspective in his compelling account of the pleasures evoked by narrative. However, such cognitivist approaches appear to be more useful in accounting for literature and representative art than for abstract art or instrumental music. For those art forms in which narrative content is foremost, the evoked pleasures do seem to align well with cognitive–appraisalist conceptions of emotion.

However, the cognitivist conception of emotion has been criticized by both psychologists and philosophers. Experimental studies have provided ample demonstrations that at least some emotions can be evoked without cognitive appraisals (Zajonc 1980; see Cornelius 1996, for review). Criticisms of a purely cognitivist perspective on emotions have been echoed by some music philosophers, notably Malcolm Budd (1985) and Geoffrey Madell (2002).

The existing experimental evidence suggests that emotions can be evoked with or without the involvement of cognitive appraisals. On the one hand, emotions can be evoked through conscious ruminations (as, for example, when jealousy is evoked by interpreting a telephone bill as suggesting that one's spouse has been talking to a former love-interest). However, emotions can also be evoked without the intervention of conscious thought (as in a startle response evoked by the slamming of a door or hearing a tone of voice suggestive of aggression).

Such unconscious/automatic responses can also be observed in behaviours that would normally be regarded as 'higher level' mental processes such as sympathy and empathy. Several philosophers (e.g. Roger Scruton) have argued that responding sympathetically to (say) grief is not the same as feeling grief. However, modern neuroscience appears to contradict this claim. Watching someone cut their finger can generate 'gut feelings' in the viewer that closely mimic the negative feelings experienced by the person whose finger is injured. The discovery of so-called 'mirror' neurons suggests that some complex emotions can be experienced with little or no cognitive mediation (Rizzolatti and Craighero 2004). In short, cognitive neuroscience implies that there exist both cognitive and non-cognitive pathways to the evoking of emotion.

Neo-hedonism

The idea that the principal appeal of art is the evoking of pleasure (hedonism) has not been a popular idea among Western aesthetics philosophers. However, recent cognitive neuroscience has given new life to this old idea. Perhaps the most important achievement of cognitive science has been the discovery that the mind, like the body generally, holds a series of specialized structures (Fodor 1983). A popular metaphor is that the mind is structured like a Swiss army knife. Many of the debates that have preoccupied aesthetics philosophers arise from the empirically incorrect assumption that the mind is unitary and homogeneous (see also Griffiths 1997). Since the mind is capable of propositional thinking, it is easy to suppose therefore that musical experience must arise from propositional thought; since the mind forms associations, musical experience must arise from deciphering associations, and so on.

In modern cognitive neuroscience, such claims are regarded as *cumulative* rather than mutually exclusive. For any given stimulus, the modular mind applies propositional, associational, representational, empathetic, narrative, and other mental processes simultaneously. While the experience of beauty and ugliness can involve cognitive appraisals, not all such experiences *require* cognitive appraisal. In short, the cognitive appraisals of the sort envisioned by Hanslick's followers are sufficient though not necessary conditions for the experience of musical beauty.

Plural pleasures

The idea of concurrent parallel mental processes has transformed our understanding of the phenomenon of pleasure. There are many behaviours that can evoke pleasure, such as scratching an itch, quenching a thirst, solving a puzzle, successfully predicting a future event, feeling virtuous, emptying one's bladder, conversing with a friend, receiving praise, putting cold hands in warm water, and so on. Physiologists have begun to trace the unique neurological pathways associated with different pleasures, from the pleasure of eating chocolate to the 'runner's high'.

Pleasure centres in the brain were discovered accidentally half a century ago by James Olds and Peter Milner (1954). In addition to these neuroanatomical discoveries, a number of endogenous molecules have been implicated in the experience of pleasure. These include dopamine, oxytocin, serotonin, alpha-, beta-, and gamma-endorphins, alpha-, and beta-neoendorphin, dynorphin A and B, big dynorphin, methionine enkaphalin, leucine enkaphalin, and others (e.g. Pert 1997). Each endogenous molecule evokes a subtly different form of pleasure, and each is released under a number of unique circumstances. For example, oxytocin is released in various interpersonal situations associated with pleasure, including hugging, romantic eye contact, breast feeding, and sex.

In crafting a pleasurable event, people rarely confine themselves to evoking one form of pleasure. The most common pattern of behaviour is to combine several pleasures into a single experience: a person might drink a beer *and* smoke a cigarette *and* converse with friends *and* watch a football game—all at the same time. Current neuroscience indicates that the pleasures evoked by imbibing alcohol, inhaling nicotine, reinforcing social bonds, and prevailing over a perceived enemy have different neurological origins. Yet all may be evoked concurrently in the environment of the sports bar.

A useful metaphor for this hedonic pluralism is the dinner party. You might decide to cook an especially nice meal, but it is unlikely that you will stand alone at the kitchen counter feasting on your carefully prepared Coquille Saint Jacques. Instead, you will probably invite a friend to share in the meal (social pleasure), purchase flowers to embellish the table setting (visual pleasure), light scented candles (olfactory pleasure), put on recorded music (auditory pleasure), and so on. What begins as the crafting of a gustatory pleasure quickly expands into a multifaceted hedonic experience. When given the opportunity, we heap pleasure upon pleasure upon pleasure.

The discovery of multiple pleasure pathways has repercussions for philosophical debates concerning hedonism. Among aesthetic philosophers, the standard rebuttal of hedonism is that it suggests that all pleasurable experiences can be reduced to a single value (see e.g. Kagan 1998). Hedonism implies that pleasures are interchangeable—implying, for example, that a sexual orgasm is equivalent to so many chocolate cookies. The most common argument against hedonism is that the positive emotions evoked by feeling virtuous are simply incommensurate with a sensory pleasure, such as viewing a flower. Geoffrey Madell summarizes this anti-hedonic argument by noting that the pleasure of listening to good music is phenomenologically different from the pleasure of gorging on junk food (2002 p. 89). However, two discoveries have given new life to the hedonic argument: (1) evolutionary psychologists have offered compelling arguments that all emotions (including jealousy, shame, pride, etc.) are evolutionary adaptations that promote survival and procreation, and (2) neurophysiologists have assembled evidence that the brain contains multiple pleasure systems. The neo-hedonic rejoinder to the classic objection to hedonism is that the biology of pleasure is not unidimensional and has multiple independent sources. Pleasures can be equated only when they engage the same endocrine or neurotransmitter pathways.

If pleasures are multidimensional, it is likely that musically evoked pleasure is itself multifaceted. Consider some of the ways by which sounds are thought to evoke pleasure:

- Listeners prefer stereo reproduction over monaural reproduction.
- Familiar sounds are preferred over unfamiliar sounds (Meyer 1903; Zajonc1980).
- Novelty-seeking is a rewarded behaviour in many circumstances (Berlyne 1971).
- Infant-directed singing has many features in common with infant-directed speech and these features are known to be preferred by infants (Unyk *et al.* 1992).
- The traditional practice of voice-leading is thought to capitalize on brain rewards for successful parsing of auditory scenes (Huron 2001).
- People experience pleasure from displays of extraordinary musical skill or virtuosity (Kubovy 1999).
- Experienced listeners regularly take pleasure in recognizing musical quotations or allusions to other works.

- Musically induced 'shivers' or frisson is reported by listeners as distinctly pleasurable (Sloboda 1991; Panksepp 1995; Gabrielsson and Lindstrom 1993; and others). Huron (2006) has suggested how such experiences might evoke pleasure.
- Listeners are consoled by and take pride in music whose style or genre is consistent with a sense of self-identity or social belonging.

This list represents only a partial catalogue of plausible pleasures that might be evoked (in various combinations) by music. As with studies investigating the specific pleasures involved in chocolate consumption or the 'runner's high', it seems likely that future research will trace the particular neurological pathways involved in each of the various forms of musically evoked pleasure. It appears that musical sounds are capable of activating multiple pleasure pathways in the brain. In the manner of the dinner party, musicians can assemble a unique mixture of pleasures into a single musical experience.

Indirect evidence in support of this 'plural pleasures' hypothesis can be found in an experiment by Avram Goldstein (1980). Goldstein exposed listeners to frisson-inducing musical passages and had them rate the pleasantness of the experience. Half of the listeners received an injection of an inert saline solution while the remaining listeners received injections of naloxone, an opiate receptor antagonist. Goldstein's results suggest a reduction in musically induced pleasantness for some of the naloxone-injected listeners compared with the control group. However, the pleasantness of the musical experience was not entirely eliminated, suggesting that musically induced pleasure is not restricted to neural mechanisms that result in the release of endogenous opiates. The implication is that there may be more than one way for music to evoke pleasure.

Evolutionary aesthetics

For Hanslick, the principal problem in musical aesthetics is explaining musical beauty rather than explaining musical feeling. For the psychologist, however, Hanslick's views imply an 'essentialist' conception of music. For Hanslick, the beauty is somehow *in* the music, rather than evoked *by* the music. For most psychologists, there is nothing in the world that is objectively ugly or beautiful. Humans find darkness threatening and sunshine pleasant, but a bat will have the reverse experience. We enjoy the smell of roses more than the smell of a dead carcass, and are disgusted to discover that our pet dog has the opposite experience. In the words of Donald Symons (1992), 'Beauty is in the adaptations of the beholder.'

Feelings have a deep structure in evolution by natural selection. The feelings evoked on any given occasion can be traced to proximal causes; but the feelings themselves are generated by brain mechanisms that evolved so as to improve the organism's inclusive fitness. We love life and fear death because these feelings contribute to our survival. We fall in love and protect our children because these feelings contribute to reproductive success. According to current orthodoxy in biology and evolutionary psychology, the feelings evoked by art ought to be traceable to one or more underlying evolutionary mechanisms. This logic has led a number of scholars to offer evolutionary accounts of aesthetic experience (see Chapter 1).

Charles Darwin himself launched a history of speculation regarding the possible evolutionary benefits of music and art. In the past half century, new evolutionary aesthetics theories have appeared almost monthly. Evolutionary theories of art are both speculative and controversial. Part of the controversy arises from the ease of 'storytelling'. As Paul Griffiths has noted, 'adaptive hypotheses are too easy to form and too difficult to test' (1997, p. 71). While evolutionary theorizing appears to be an open invitation to unbridled speculation, as Jon Elster has noted, 'The first step toward finding a positive answer is telling a plausible story' (1989, p. 8).

In recent decades, many evolutionary stories regarding art have been proposed. Eibl-Eibesfeldt (1989), for example, has argued that people tend to prefer landscapes that resemble the primordial savanna environments of hominid evolution. Cross-cultural studies suggest that aesthetic preferences favour environmental conditions that have been conducive to survival, not in the contemporary world, but in the Pleistocene world of human evolution. Other theories have been proposed by Ellen Dissanayake (1988),

Nancy Aiken (1998) and others. In the case of music, possible evolutionary origins for music have been discussed by Geoffrey Miller (2000), Ian Cross (2001/2003), David Huron (2001/2003), and Steven Mithen (2006).

Most of the evolutionary accounts that have been offered regarding the origin of music propose a single function (such as sexual selection). This makes sense. If music does indeed have an evolutionary origin, it would have begun by conferring a single pre-eminent adaptive advantage. However, as we have seen above, there is a tendency to amalgamate multiple pleasures into a single human experience. Modern music-making is apt to engage a plethora of pleasure-evoking mechanisms and so it may prove difficult to untangle any presumed original purpose from the agglomerated mix of hedonic mechanisms assembled in modern music-making.

From a life sciences perspective, there are a limited number of stories that can be told that will reconcile art with biology. One story is that music and art might have originated as adaptive pleasures, where the art-related activity increased inclusive fitness in some (non-obvious) way. For example, music might have played an adaptive role through social bonding, sexual selection, or by facilitating language learning. In this case, we would have to conclude that Kant was wrong: aesthetic pleasures are indeed utilitarian. A second alternative story is that music-related behaviours might be non-adaptive forms of pleasure-seeking. Music might simply commandeer a pleasure pathway that is intended to serve some other purpose. In this case, music would be akin to nicotine or heroin addiction: Art is just a fancy way of tickling pleasure mechanisms that exist to reward other behaviors. A third alternative story is that music-related behaviours are biological 'spandrels'. That is, they are incidental artefacts that necessarily accompany other adaptive behaviours. Music might be akin to a benevolent form of sickle-cell anaemia (which is an artifact of a heterozygotic genetic strategy to protect against malaria infection). Music, for example, might simply be a non-functional artefact of brain mechanisms whose purpose is to promote language development.

For many people, none of these ideas is especially appealing. The idea that music is biologically ordained seems far-fetched and problematic. Similarly, the idea that music is a non-adaptive form of pleasure-seeking (like cocaine use) is equally unsavoury. Finally, the idea that music is a physiological accident (like the non-functioning appendix) is anti-climactic. While these ideas invite opinion, the origin or purpose of music is ultimately an empirical question that will be resolved only through future scientific research.

Conclusion

Cognitive science has brought into relief what appears to be a fundamental disagreement between modern psychology and traditional Western aesthetics. The bedrock of conventional Western aesthetics has been the notion, promulgated by Kant, that there are unique aesthetic pleasures that exist aside from utilitarian pleasures. Evolutionary psychologists and biologists argue that the brain mechanisms that generate emotions represent evolved adaptations.

Over the past two decades, a number of aesthetics philosophers have been inspired by the 'old school' cognitive revolution. In particular, early cognitive science lent credence to the contemplative–appraisalist view of musical aesthetics advocated by Hanslick. However, the subsequent development of cognitive science is raising significant challenges for aesthetic philosophy in general. From the perspective of modern cognitive neuroscience, the disembodied, non-utilitarian notion of aesthetic pleasure posited by Kant cannot easily be reconciled with biology (see also Huron 2006).

Over the course of history, many of the problems addressed under the rubric 'philosophy' have been ceded to newly emerging scientific disciplines. Questions formerly considered part of 'natural philosophy' have shifted to the realm of biology and geology. Cosmology was taken over by physics and astronomy, and questions regarding human behaviour passed to the domains of the social and behavioural sciences. If evolutionary psychologists are correct, then questions concerning the experience of beauty and ugliness may soon slip from the grasp of philosophy. Only time will tell whether we are witnessing the passing of the aesthetics baton from philosophy to empirical science.

CHAPTER 15

Musical preferences

Alexandra Lamont and Alinka Greasley

THIS chapter explores our current understanding of why we like and choose to listen to the music that we do. We begin by carefully defining terms and considering methods, moving on to discuss the biological influences of arousal and other personality traits on music preference, questions of style discrimination, and finally the cultural influences of experience upon preference. The chapter evaluates existing models of music preference and considers further directions and challenges in the field.

Introduction

Liking for music in general is a strong human trait which can be as rewarding as food, sex, or drugs (e.g. Blood and Zatorre 2001; Panksepp and Bernatzky 2002). Certain features of music such as consonance are also liked from early infancy (Trainor and Heinmiller 1998), and these uniquely human preferences for music are not found in primates (Lamont 2005).

Research into liking for different kinds of music reveals a multitude of different concepts, sometimes used interchangeably. Over the last two decades, researchers have generally adopted Price's (1986) definition of preference as choosing or giving advantage to one thing over another. A relatively constant distinction has emerged between the concepts of *taste* (a relatively stable valuing) and *preference* (a shorter-term commitment), occupying opposite ends of a continuum (Abeles and Chung 1996). More recently, definitions of preference have also included specific notions of temporality: 'a person's liking for one piece of music as compared with another at a given point in time', while taste is held to reflect 'the overall patterning of an individual's preferences over longer time periods' (Hargreaves *et al.* 2006, p. 135). In practice, shorter-term experiences of preference inform longer-term judgements of taste and vice versa, in a cycle of reciprocal feedback (Hargreaves *et al.* 2006).

A further implicit distinction exists between research focusing on liking for specific pieces of music and that which explores liking for styles of music. Some theoretical explanations attempt to bring these two dimensions together (for example experimental aesthetics: see North and Hargreaves [2000a]). However, most of the research tends to confound responses to the piece and the style level, or to draw broader conclusions about style preference from research using specific pieces.

This chapter will thus adopt a broad definition of musical preference as referring to the music, whether style or piece, that people like and choose to listen to at any given moment *and* over time, highlighting these important dimensions throughout.

Methods of studying musical preferences

The moment of choice can be measured at a number of levels and using a diversity of measures (see also Abeles and Chung 1996). These measures can take place either in artificial laboratory settings, in more ecologically valid contexts, or somewhere in between (such as imagining a real-life setting and one's likely responses to it in the laboratory).

First, behavioural choices include listeners' psychophysiological responses to a given piece of music, short-term decisions about which piece to listen to, or real-life patterns of

engagement with music over longer time spans as shown by concert attendance or music purchasing. Comparisons between two or more musical stimuli can be studied in infants, children and adults using preferential looking/listening paradigms (Trehub 2006) or variations on the Operant Music Listening Recorder (Greer *et al.* 1974; North and Hargreaves 2000b), which measures the amount of time a participant spends listening to different styles of music playing simultaneously through different channels. A further behavioural method involves playing extracts of music to participants and asking for different kinds of behavioural as well as verbal response (e.g. Marshall and Hargreaves 2007).

Secondly, choices can be expressed verbally in either spoken or written form, using rating scales or semantic differentials (either in response to a range of music provided or more abstractly in response to descriptions or names of types or pieces of music), individual preference nominations, or through interviews. The most common verbal report measure is the rating scale, typically requiring individuals to rate their preference for a list of predetermined musical styles on Likert scales. Several music preference scales have been developed, for example Litle and Zuckerman's (1986) Music Preference Scale, consisting of 60 established music categories from the US record industry, or Rentfrow and Gosling's (2003) Short Test of Musical Preferences, although these have not been used systematically throughout the literature. Another popular technique is in-depth interviewing of participants to uncover the richness and complexity of their everyday musical tastes (e.g. DeNora 2000).

The few studies combining different methods (e.g. Hargreaves 1988) show that different measures have different uses: self-report measures (particularly rating scales) are more suited to describing general long-term preferences, while behavioural measures seem more useful in discriminating between examples within a particular style. There thus tends to be a relatively low correlation between results, and verbal measures do not predict behaviour consistently. It is important to consider the choice of methods alongside research questions, and to consider how far methods limit the generalizability of results.

Arousal and biological influences on music listening behaviour

At a biological level, music that we prefer seems to affect us differently. Some physiological responses to familiar and unfamiliar music are similar (e.g. Craig 2005; Lai 2004), but Blood and Zatorre (2001) found that when listeners reported more intense 'chills' or highly pleasurable intense experiences, areas of the brain responsible for reward, emotion and arousal were more strongly activated. One explanation for music preference focuses on the notion of arousal as the underlying motivator for music listening behaviour.

Experimental aesthetics

Berlyne's psychobiological theory (1971), see also Chapter 14 this volume) argues that preference results from the interaction between an individual's level of arousal (held to be relatively stable) and the arousing properties of the music itself (more variable). Researchers have explored the musical characteristics which contribute to its arousal potential, including prototypicality, complexity, familiarity, tempo, and volume (North and Hargreaves 1995a, 1996b; Russell 1986). This research typically presents participants with simple, often artificially contrived and always experimenter-selected, musical stimuli and then measuring their verbal or behavioural preferences (North and Hargreaves 1997a, 2000b). Short-term preference for certain types of unfamiliar music can be consistently related to characteristics of that music. For example, North and Hargreaves (1995a) found a positive linear relationship between liking and familiarity for new age music, and an inverted U-shaped relationship between liking and subjective complexity of the musical examples.

This complements recent neuropsychological evidence about the arousing effects of music on the brain (see Chapter 11 this volume). It also assumes that preference expressed in an experimental setting for a given piece will be reflective of more generalized preference for a given musical style. Using Beatles songs performed in different musical styles, North and Hargreaves (1997b) found style was a more important determinant of liking than song: liking for *Yesterday* in a jazz

style, for example, related more to listeners' liking for jazz than to their liking for *Yesterday*. This suggests there is some merit in using pieces as representative of given styles, but most research has not addressed this explicitly.

One strength of this approach in explaining preference is that listeners' individual ratings of familiarity and subjective complexity with the music are assessed within each study, thereby accounting for the effects of prior experience on liking. However, it is limited through the use of pieces of music that are typically and intentionally unfamiliar to the listeners, together with the assumption that preferences for a piece reflect more general durable style preferences. Furthermore, although Berlyne argued that familiarity and exposure should change individual preference, little research has explored changing preferences over time. The effects of repeated exposure have been studied over relatively short time spans, from hours to weeks (e.g. Peretz *et al.* 1998; Hargreaves 1984), yet developmental evidence suggests that stylistic preferences change in response to a complex set of experiential factors over the lifespan (e.g. Hargreaves and North 1999; see also Chapter 22 this volume). It is important not to over-interpret preferences expressed at a given moment in time as being representative of more enduring patterns of taste (see also Lamont and Webb in press).

Individual differences

Research has also explored the notion that different individuals have unique, preferred levels of arousal which explain their global music preferences for style. Temperament differences predict differences in preferential listening behaviour, even at 8 months of age. Trehub *et al.* (2002) found that infants who listened longer to a soothing version of a nursery song were rated by their mothers as calm and easy-going, while those who preferred a playful version of the same song were rated as highly active. Research with adults in this individual differences tradition typically employs established personality measures together with questionnaire-based music preference measures such as Litle and Zuckerman's Music Preferences Scale (1986), looking for correlations between the two.

Factors related to extraversion typically relate to preference for particularly arousing styles of music. For example, sensation seekers with high levels of optimal stimulation prefer more intense and/or complex styles of music like hard rock, soft rock, folk and classical music (Litle and Zuckerman 1986). Preference for highly arousing music such as heavy metal, rock, dance and rap correlates with high levels of resting arousal and sensation-seeking (McNamara and Ballard 1999). Preference for hard rock music is linked to excitement-seeking and extraversion (Pearson and Dollinger 2004), high levels of psychoticism and impulsiveness (Rawlings *et al.* 1995), and a relative dislike of other forms of music (Rawlings and Ciancarelli 1997). Conversely, preferences for 'softer' forms of music are associated with lower levels of psychoticism and extraversion (Rawlings *et al.* 1995). Pearson and Dollinger (2004) found that highly intuitive people showed a greater preference for classical, jazz, soul and folk music.

Some research has attempted to explain the connection between music preference and personality in relation to characteristics of the music rather than style labels. For example, Rentfrow and Gosling (2003) presented data indicating that music preferences can be organized into four independent dimensions:

1 Reflective and complex
2 Intense and rebellious
3 Upbeat and conventional, and
4 Energetic and rhythmic.

They then explored correlations between these dimensions and personality, self-views and cognitive ability ratings, finding a number of significant relationships. For example, people who preferred reflective and complex music also had active imaginations, valued aesthetic experiences, and viewed themselves as intelligent and tolerant; people who preferred upbeat and conventional music were more extrovert, agreeable, conservative, and less open to new experiences. They present a number of associations, some of which appear rather spurious (for example, why should people who like energetic rhythmic music be more likely to eschew conservative ideals?), but which they suggest may in time set the groundwork for a comprehensive theory of music preferences.

Rentfrow and Gosling's (2003) study reflects a comprehensive attempt to analyse the relationship between liking for music and aspects of personality. However, they note carefully that cultural and environmental influences also shape the music that an individual will like. Other personality researchers provide evidence that personality traits and music preferences are linked by a third factor of musical experience. For example, Rawlings and Ciancarelli (1997) found that preferences for popular and rock music, associated with extraversion and less openness to experience, were accompanied by a less intense interest in music and less musical training (see also Pearson and Dollinger 2004). This suggests that the influence of experience on personality and on music preference has yet to be fully explored.

The validity of the rating scale approach which has dominated this research depends on sufficient awareness of the differences between musical styles and style labels. Litle and Zuckerman's (1986) scale included specific stylistic examples for guidance, but both their examples and styles are culturally and historically specific (see Rawlings and Ciancarelli 1997). Rentfrow and Gosling (2003) derived their scale from empirical data about spontaneously nominated categories of liking, rated by judges and compared with industry categorization processes, and finally tested for familiarity: 29 out of 30 participants could provide preference ratings for the 14 items, which they suggest confirms their validity. However, no matter how carefully labels are constructed, the fundamental problem remains that rating scales reflect a reductionist approach. Qualitative approaches show that adults typically report preference for many different styles of music, which they often label idiosyncratically (Greasley and Lamont 2006). This sophistication and level of complexity presents an enduring challenge for the field.

Summary and evaluation of arousal-based explanations

In addition to the issues raised above, both experimental aesthetics and individual differences approaches focus exclusively on the intra-individual level. They thus remain unable to identify the nature of the relationship between temperament and personality dimensions and musical preferences. For example, personality type may be a direct cause of musical preferences, or, as suggested above, may influence individuals' levels of engagement with music and musical activities which, in turn, affects their musical preferences. To our knowledge, none of the research has yet addressed these interactions. Finally, this emphasis on the intra-individual level neglects the social context in which the music listening is taking place.

Towards a more contextually grounded understanding of musical preferences

Konečni (1982) argued that experimental researchers often treat music as if it existed in a social vacuum, and that it is vital to consider social interactions, emotions, moods, and other environmental factors in order to understand music choices. This raises the necessity of explaining how listening behaviour changes as a function of its immediate social and non-social antecedents, concurrent cognitive activity and resultant emotional states.

More naturalistic research has drawn on real musical stimuli and attempted to simulate real-life situations to account for both the music and the listening context. For example, North and Hargreaves (1996a, b, c, 2000b) investigated the reciprocal relationship between listener and context. Specific musical variables (mostly arousal potential) were manipulated, but the experimental conditions were naturalistic settings such as yoga classes, aerobics classes, and a university cafeteria. Listeners preferred highly arousing music during periods of exercise and arousal-moderating music when relaxing.

However, although causal relationships can be established using experimental methodology, even these more naturalistic investigations appear to be treating the 'social' as an experimental variable. Sloboda (1999) argues that the continuing use of a traditional positivist paradigm (presenting listeners with music chosen by the experimenter, in an environment controlled and constructed by the experimenter) may be responsible for slow progress in the scientific understanding of responses to music. He argues

that music listening is 'intensely situational' (p. 355) and thus context becomes central. This has led to another recent shift in approach towards a focus on capturing people's everyday musical practices and preference behaviour in the contexts in which they naturally occur.

Preferred music in everyday life

Studies have begun to investigate people's use of music in everyday contexts (Juslin and Laukka 2004; North *et al.* 2004; North and Hargreaves 2007; Sloboda *et al.* 2001). Typically using Experience Sampling Methodology (ESM), participants are contacted (via pagers or mobile telephones) at random intervals during the day and asked to complete response sheets about their music listening. Although these studies predominantly focus on the functions of music in everyday life, the results emphasize the concept of choice. People choose different types of music for different reasons (i.e., they have specific goals and purposes that music engagement fills), and their motivations for music listening are context-dependent. Personal favourites also change over time, and daily favourites reflect situational and emotional 'fit' while long-term favourites are more connected to personal life histories (Lamont and Webb in press). Sloboda *et al.* (2001) also found that greater personal choice was more likely to be associated with positive valued outcomes such as increased arousal, present-mindedness, and positivity. These findings underline the value of researching people's self-chosen uses of music (see also Chapter 40 this volume).

Reflecting on preferred music

An alternative approach is articulated by research that explores people's own music and the meaning of this to them as individuals, using social constructionist methods such as interviewing and ethnography. From such a perspective, music does not simply act as a stimulus on an individual, but rather its meaning and effects become stabilized through discourse, consumption practice, and patterns of use over time (DeNora 2000).

For example, Batt-Rawden and DeNora (2005) explored the therapeutic uses of music in everyday life using a unique methodology involving both researcher-chosen and participant-chosen music, repeated music listening over long time spans, and repeated in-depth interviews. This study led to a heightened awareness from participants of the ways in which they use music in everyday life (see also Carlton 2006; Sloboda *et al.* 2001). Greasley and Lamont (2006) also found differences between more and less engaged music listeners in terms of listening behaviour, preferences, and self-awareness. Less musically engaged adults lacked a strong commitment to any musical style, and were more likely to listen to an eclectic mix of music acquired from friends. Conversely, more musically engaged adults showed strong commitments to musical styles and a sense of necessity and urgency about buying or obtaining music. They expressed a detailed awareness of the styles they did and did not like listening to, and a thorough and explicit understanding of the effects that different styles of music would have on them.

Effects of musical preferences

We next consider the impact that musical preferences can have on other areas of life in two ways. The first relates to the use of *any* kind of preferred music to achieve certain non-musical goals. The second relates to the preference for *specific* kinds of music.

Preferred music listening has been shown to be particularly effective in achieving physical and psychophysiological goals, such as pain management and relief. It leads to enhanced control over, and effective distraction from, pain-inducing stimuli under laboratory conditions, when compared with non-preferred or experimenter-selected music (Mitchell *et al.* 2006; Mitchell and MacDonald 2006). Similar effects in reducing pain, anxiety and agitated behaviour have been found both in clinical settings (MacDonald *et al.* 2003; Siedliecki and Good 2006; Sung and Chang 2005) and in chronic pain in everyday life settings (Mitchell *et al.* 2007). Listening to preferred music rather than experimenter-chosen music or silence produces lower heart rate and perceived exertion and fatigue rates (Pothoulaki and Natsume 2006), and improves cognitive performance in

driving simulation tasks (Cassidy 2006). Thus listening to preferred music has powerful effects on aspects of behaviour outside voluntary control as well as on mood and affect. In these cases, the nature of the musical stimulus has no bearing whatsoever on the physical and psychological effects.

Other uses of musical preferences are more closely tied to the particular music that an individual or a group shows preference for. During adolescence, musical preferences play an important role in the formation of identity through processes of in-group behaviour and impression management (Finnäs 1989; Tarrant *et al.* 2004). The social identity effect of musical preferences in bringing people together operates even when participants are unaware of precisely what musical preferences the in- and out-groups have (Bagakiannis and Tarrant 2006). Although specific music often has particular effects on different groups, these strong effects are more marked in adolescence; young adults are more willing to share and tolerate others' music, and this tolerance increases later in adulthood (Carlton 2006; Greasley and Lamont 2006). However, even in adulthood, musical preferences can be used in interpersonal perception to give messages about people's personalities (Rentfrow and Gosling 2006). This catalytic or self-directed effect of music in identity can be contrasted with the emblematic outward-directed effect of music, such as anthems, as symbols of national, ethnic, or cultural identity (Hammarlund 1990, cited in Folkestad 2002). In multicultural situations, the kind of music someone likes can play a significant role in the processes of adjustment to a new culture and retaining links to the old (Ilari 2006; O'Hagin and Harnish 2006).

Explaining and predicting music preferences

Although there has been a great deal of research exploring different facets of musical preference and taste, only two explicit models of music preference (LeBlanc 1982; Hargreaves *et al.* 2006) have attempted to tie these together.

LeBlanc's interactive theory of music preference (1982) is a complex and comprehensive attempt to represent the influence of 'input information' (the musical stimulus and the listener's cultural environment) and listener characteristics and behaviour. The approach is useful in formally identifying the large number of types of variables that fall into the three broad categories. For example, the listener's cultural environment includes the variables of media, peer group, family, educators and authority figures, and incidental conditioning. The model traces a trajectory through listener characteristics such as attention and mental processing through to a preference decision at a given moment, which then influences subsequent behaviour (e.g., acceptance and then repetition of the stimulus). While the detail is potentially useful, the fact that every variable potentially interacts with every other means, as LeBlanc concedes, that this is unlikely to serve as a usable predictive model. However, subsequent research has attempted to weight the relative contributions of the various factors, and LeBlanc *et al.* (2000) found that musical features accounted for more variation in children's expressed musical preferences, followed by 'culture' and finally age (see Chapter 22 this volume).

Hargreaves *et al.* (2006) developed a far simpler reciprocal feedback model of musical response, consisting of the interactions between the three broad variables of *music*, *listener*, and *situations and contexts* to evoke a given *response*. Drawing on experimental aesthetics, musical features include a reference system (genres, styles, etc.), collative variables (complexity, familiarity) and prototypicality. The listener is characterized in terms of individual differences (gender, age, personality) as well as musical knowledge, preference and taste, and identity. The listener's response to the music is also affected by physiological (engagement, arousal, active listening), cognitive (attention, expectation, discrimination) and affective (emotional, mood, liking) factors. Finally, situations and contexts include social and cultural contexts, everyday situations, and the presence or absence of others.

Both models express a tripartite division between music, listener, and context as well as a large number of interactions both between and within levels of analysis. However, culture should not be treated as a variable but rather as the medium through which all real-life experiences

are mediated (Cole 1996; Lamont 2006). The models also say little about the outcome of musical preferences. LeBlanc's preference decision leading to rejection or acceptance (in the latter case resulting in freely chosen repetition and heightened attention) is simply linked back to the listener's cultural environment and musical stimulus input. Similarly, the concept of reciprocal feedback simply argues that listener and music, listener and situation, and situation and music 'interact'.

Discussion

Musical preferences serve a range of important functions for individuals and groups, and preferred music can play an important role in physical and psychological well-being. These clearly go beyond the simple behavioural outcome of repeated exposure, and have far-reaching effects ranging from the personal to the cultural.

While experimental research has addressed some important questions in relation to our understanding of musical preferences, there still remain many unanswered issues. The complexities lie largely in the interactive nature of musical preference. Even a single preference expressed at a given moment in time between one of two experimenter-selected pieces of music is likely to be affected by a host of factors, which will vary from individual to individual and may lead to a range of different outcomes. Attempting to isolate and examine these within a positivist approach can be a daunting and potentially fruitless challenge, which may explain why some of the more successful approaches to understanding musical preferences, both experimental and qualitative, appear rather content-free in terms of the *music* that is being preferred.

Furthermore, the complexity and flexibility in the ways that people categorize and label music is a critical issue for the field. As listeners argue about how particular pieces of music, particularly those they like, should be labelled into styles (Greasley and Lamont 2006), research asking participants to tick boxes of music preference categories is not likely to inform us significantly about the underlying meanings of those preferences, except, perhaps, in situations where the 'tick box' approach has validity, such as internet dating, cf. Rentfrow and Gosling (2006). The particular categories employed are also likely to change rapidly along with changes in musical style (Hargreaves and North 1999), limiting comparability between different studies. An approach that prioritizes listeners' own constructions and interpretations of music circumvents some of these problems, and may prove more fruitful in explaining these less stable elements of musical preferences.

The temporal dimension of preference is another central issue, and while we have highlighted the temporal dimensions of decision-making throughout, it is harder to tease out practical implications for a theory of musical preferences. The two models of music preferences reviewed here adopt very different perspectives on temporality: LeBlanc systematically specifies the precise moment of choice but says less about the longer-term concomitants of that choice, whereas Hargreaves and colleagues attempt to capture longer-term dimensions while remaining vague about the choices which are being represented. A more considered explanation of the temporal dimension (where preferences originate, are shaped, grow, and die down—in essence, how reciprocal feedback actually works) is still required (cf. Lamont 2006).

Finally, adopting a cultural psychological approach of treating culture and context more thoroughly as a medium for musical preferences rather than a variable within a model may have the potential to address some of the unresolved issues in this field. Naturalistic and longitudinal methods of enquiry may be more valuable here. For example, interviewing people at home with their music collections (Greasley and Lamont 2006) enables them to interact with music in a far more contextualized manner, encouraging participants to reflect on the wide range of interacting factors influencing preference (see also Batt-Rawden and DeNora 2005).

To conclude, the privileged position of preferred music in individuals' lives is something that future research needs to be sensitive to. A colleague undergoing chemotherapy told us how she actively decided *not* to bring her favourite music into hospital, despite her specialist's exhortations that it would help alleviate her pain. She was concerned that over time listening to her favourite music in this context would lead

to a negative association between the music and the treatment, thus 'spoiling' its potential as a source of pleasure (Chris Banks, personal communication). This kind of real-life engagement with music is not easily explained by inverted U-shapes or artificial distinctions between listener, music and context, yet it is such real-life challenges that future research must find better ways of explaining.

PART 4

Music and the brain

Edited by Aniruddh D. Patel

CHAPTER 16

The neurobiological basis of musical expectations

Laurel J. Trainor and Robert J. Zatorre

Introduction

As recently outlined by Huron (2006), we have evolved a brain that rewards accurate prediction. The evolutionary advantages of accurately predicting future events in the world are clear. Over half a century ago, Leonard Meyer (1956) presented his theory that emotional responses to music arise through expectations set up by musical patterns. However, for the most part, music is not about events in the world. What is the link between music and brain mechanisms for prediction? Meyer noted that some chords are more likely to follow other chords in Western musical structure: a melodic fragment sets up expectations for how it will continue. He proposed that low probability realizations give rise to physiological responses, such as changes in heart rate, breathing, and skin responses at an unconscious level, and thus spark emotional responses. Interpretation of the physiological responses in the context of the music gives rise to conscious emotional experience. Meyer proposed that most musical expectations were probably the result of familiarization with a particular musical genre. Indeed, a number of psychological studies have since asked Western listeners to rate their expectations of melodic continuations, and these studies show that people base their expectations on the rules of Western musical theory, whether or not they are explicitly aware of these rules (e.g. Krumhansl 1997; Tillmann *et al.* 2006; Tillmann and Lebrun-Guillaud 2006; Unyk and Carlson 1987). On the other hand, Eugene Narmour (1990) presented his implication–realization model of musical expectation, which included a substantial set of innate, universal, bottom-up principles that should apply to all musical genres regardless of whether or not the listener is familiar with the genre. In testing people's expectations of various continuations of melodic patterns, Schellenberg (1997) was able to simplify Narmour's principle to two main ones. All else being equal, expect the next note to be proximate in pitch to the preceding note, and expect a reversal in pitch contour after relatively large intervals, but a continuation of pitch contour after relatively small intervals.

Recent neuroscientific work on musical processing is beginning to reveal the brain mechanisms by which expectations are set up and by which musical events are evaluated. In this chapter we will explore how the auditory system processes incoming information and generates perceptual representations that allow it to make predictions about future sound events from past context, and how music appears to make use of this general processing mechanism. We will focus on expectation formation in auditory cortex because this is where the most research has been done, but there is also evidence for prediction mechanisms at subcortical levels and at levels beyond sensory areas. We do not provide a complete review of the literature, but rather present a framework for thinking about the

neurological basis of expectation and prediction in musical processing using selected examples.

Physiological measurement of auditory expectations: predicting *what* will happen next

When a neuron depolarizes or fires, the flow of sodium and potassium ions in and out of the cell membrane results in the creation of electrical field potentials. When a large number of neurons whose axons point in the same direction, as between cortical layers, depolarize at the same time, a field potential is created that is large enough to be measured in a non-invasive way using an array of sensors across the scalp. When the electroencephalogram (EEG) is measured in response to an event such as a sound, it is referred to as an event-related potential (ERP). When occasional changes are made to a stream of repetitions of one sound, or when a change is made to a category of sounds, a frontally negative component is superimposed on the ERP wave form (Figure 16.1) that peaks between 150 and 250 ms, depending on the type of change. This component is called the mismatch negativity, or MMN, because it occurs only when there is an occasional mismatch between the expected stimulus and the presented stimulus (Kujala *et al.* 2007; Näätänen *et al.* 2007; Picton *et al.* 2000). MMN is typically measured by subtracting the average response on the frequent standard trials from the average response on deviant trials (the occasional change trials). Although MMN can be influenced by attention, it occurs automatically and cannot be stopped by top-down conscious processing.

In the present context, MMN is of great interest because it reflects a process in the auditory system for predicting future sound events on the basis of the recent past, and the brain's reaction when those predictions are not fulfilled. We propose here that music fundamentally relies on expectation–realization processes, and that these processes are reflected in the MMN, whose main generators are in secondary auditory cortex (Schönwiesner *et al.* 2007). However, it should be kept in mind that there is a frontal contribution to the MMN response, that lower areas of the nervous system also employ expectation mechanisms (e.g., Csépe *et al.* 1989; Kraus *et al.* 1994; Ruusuvirta *et al.* 1995; Sonnadara *et al.* 2006b), and that some later ERP components reflecting conscious processing of music are also sensitive to expectations (e.g., Trainor *et al.* 2002; Desjardins *et al.* 1999).

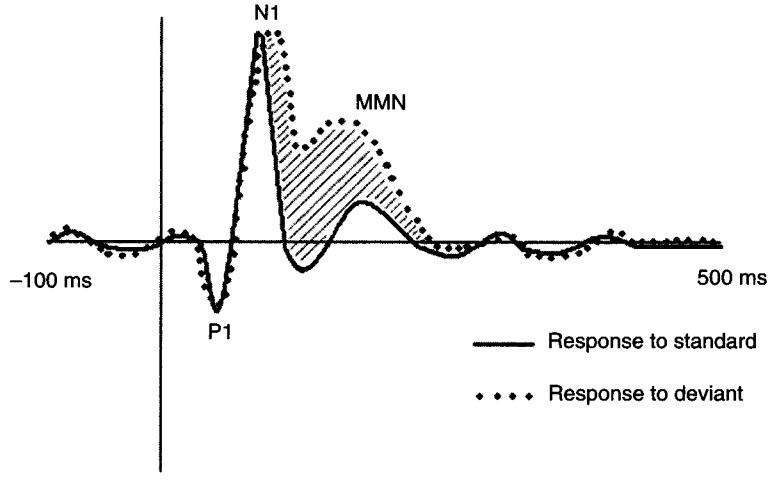

Fig. 16.1 Stylized rendition of the mismatch negativity event-related potential (MMN). Occasional deviants in a repeating stream of standard tones elicit an extra negativity (MMN) in the wave form of the deviants in comparison to standards. Note that negative deflections are depicted in the upwards direction.

neurological basis of expectation and prediction in musical processing using selected examples.

Physiological measurement of auditory expectations: predicting *what* will happen next

When a neuron depolarizes or fires, the flow of sodium and potassium ions in and out of the cell membrane results in the creation of electrical field potentials. When a large number of neurons whose axons point in the same direction, as between cortical layers, depolarize at the same time, a field potential is created that is large enough to be measured in a non-invasive way using an array of sensors across the scalp. When the electroencephalogram (EEG) is measured in response to an event such as a sound, it is referred to as an event-related potential (ERP). When occasional changes are made to a stream of repetitions of one sound, or when a change is made to a category of sounds, a frontally negative component is superimposed on the ERP wave form (Figure 16.1) that peaks between 150 and 250 ms, depending on the type of change. This component is called the mismatch negativity, or MMN, because it occurs only when there is an occasional mismatch between the expected stimulus and the presented stimulus (Kujala *et al.* 2007; Näätänen *et al.* 2007; Picton *et al.* 2000). MMN is typically measured by subtracting the average response on the frequent standard trials from the average response on deviant trials (the occasional change trials). Although MMN can be influenced by attention, it occurs automatically and cannot be stopped by top-down conscious processing.

In the present context, MMN is of great interest because it reflects a process in the auditory system for predicting future sound events on the basis of the recent past, and the brain's reaction when those predictions are not fulfilled. We propose here that music fundamentally relies on expectation–realization processes, and that these processes are reflected in the MMN, whose main generators are in secondary auditory cortex (Schönwiesner *et al.* 2007). However, it should be kept in mind that there is a frontal contribution to the MMN response, that lower areas of the nervous system also employ expectation mechanisms (e.g., Csépe *et al.* 1989; Kraus *et al.* 1994; Ruusuvirta *et al.* 1995; Sonnadara *et al.* 2006b), and that some later ERP components reflecting conscious processing of music are also sensitive to expectations (e.g., Trainor *et al.* 2002; Desjardins *et al.* 1999).

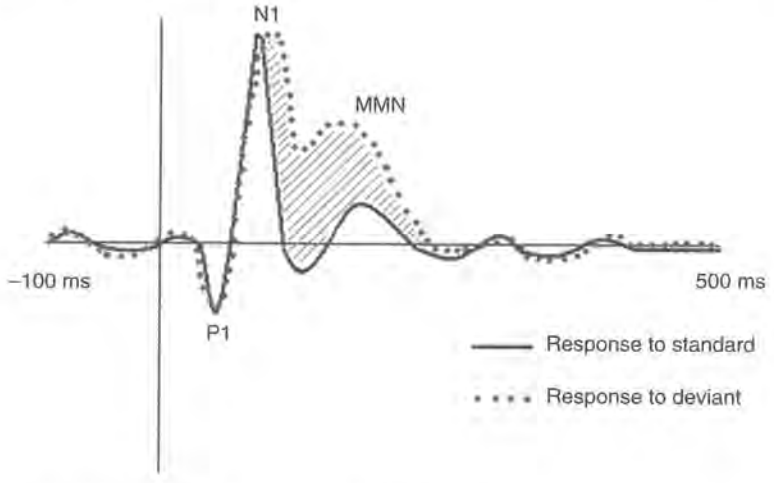

Fig. 16.1 Stylized rendition of the mismatch negativity event-related potential (MMN). Occasional deviants in a repeating stream of standard tones elicit an extra negativity (MMN) in the wave form of the deviants in comparison to standards. Note that negative deflections are depicted in the upwards direction.

Acoustic expectations reflected in the MMN response

Mismatch responses reflect a general mechanism in auditory cortex in that MMN has been measured in response to changes in virtually every basic sound feature. Across these different types of change, the larger the change, the larger and earlier the MMN tends to be, and the more rare the deviant, the larger the MMN. Occasional changes in the frequency or pitch of a tone elicit robust MMN (see below). Changes in timbre also elicit MMN (Tervaniemi *et al.* 1997b; Toiviainen *et al.* 1998), as do changes in duration, whether of a few milliseconds (e.g., Desjardins *et al.* 1999; Trainor *et al.* 2001, 2003a; Uther *et al.* 2003) or hundreds of milliseconds (e.g., Kaukoranta *et al.* 1989; Jaramillo *et al.* 2000). Changes in the spatial location of sounds produce MMN (e.g., Paavilainen *et al.* 1989; Sonnadara *et al.* 2006a). Interestingly, both increases and decreases in intensity elicit MMN (Näätänen *et al.* 1989; Näätänen 1992), and even the omission of an expected sound can elicit MMN (Raij *et al.* 1997; Tervaniemi *et al.* 1994), indicating that MMN is not the result of the recruitment of additional neurons required to process a new stimulus, but rather the reflection of expectation violation processes.

What makes the MMN response so interesting is that it is elicited not only in response to the basic sound features indicated above, but also to changes in more complex stimulus features. For example, a change in speech phoneme category in the presence of multiple exemplars of each category elicits MMN (Kujala *et al.* 2001), as does a change in the order of tones in a pattern (e.g., Tervaniemi *et al.* 1997a). Furthermore, the MMN response is sensitive to complex statistical properties of the input, such as the conjunction of simple features. When a number of standard stimuli are presented that vary in simple features such as frequency, intensity and location, the presentation of a sound with a novel combination of these features elicits MMN (Näätänen and Winkler 1999). MMN is also sensitive to abstract rules governing the conjunction of features. When many standard stimuli are presented that vary in frequency and intensity, but follow the rule that stimuli with higher frequency also tend to be more intense, MMN is elicited when this rule is violated (e.g., with a high-frequency, low-intensity sound) (Paavilainen *et al.* 2003).

Interestingly, the mismatch response to each sound feature gives rise to a slightly different pattern of electrical activation across the scalp, suggesting that the location of the neurons generating the MMN is in a slightly different place for each feature (e.g., Giard *et al.* 1995). This suggests that there is not one central MMN mechanism that processes all types of expectations but rather that there are many MMN processors, each specialized for a different sound feature. Thus, expectations for future sound events, and the evaluation of the realization of these expectations, is a widespread type of processing that is applied in many different places in auditory cortex. Furthermore, as will be discussed below, there is evidence that more than one MMN process can occur at the same time. In the next section, we focus on MMN studies probing expectancies in musical contexts.

Expectations in musical contexts

Melody, the perceptual grouping of successive pitches into a coherent pattern, is central to musical structure. Although melodies are structured somewhat differently across different musical systems, there are universal features of melodies that probably evolved from basic constraints of the auditory system. One perceptually important feature is the contour, or up/down pattern of pitch changes without regard to the exact size of the pitch changes. Pitch contour is not specific to music as it is also important in the perception of linguistic information, playing a role in intonation, stress and, in the case of tone languages, lexical identity. However, melodies are also processed in terms of the exact size of the pitch intervals between tones, and unlike contour, interval processing does seem to be quite specific to music. In any particular musical system, pitch is not a continuous variable, but rather, only a small number of discrete intervals are used. For example, in the Western tonal musical system, the major scale defines one of the most common set of intervals used for composition. Other musical systems use different interval structures in their scales,

but virtually all scales rely on octave equivalence and a small set of tones per octave (Dowling and Harwood 1986).

Melodic expectation arises in several ways. First, with a familiar melody, we can make predictions about the pitch of the next note that is expected based on a long-term memory representation. Second, when we hear music in a particular style, whether familiar or not, we can extract the statistical regularities and make predictions based on those. Third, whether or not a melody is familiar, we can make predictions about next notes that are based on our knowledge of universal melodic features. Fourth, we can use our culture-specific knowledge of what notes are likely to follow other notes in the music style with which we are familiar (Huron 2006; Hannon and Trainor 2007).

How might melodic expectations arise from the cortical system that handles pitch information? In order for expectations to develop, the system must first extract stable representations of the incoming input, and code relevant features in an invariant fashion (Whitfield 1985). The solution to this computational problem seems to lie in the hierarchical arrangement of sensory processing streams, which allow for different levels of abstraction to be computed at each level of processing. In the case of a melody, the interval information must be abstracted from individual tones which may vary in their fundamental frequency from one instance to another. In turn, the pitch of the individual tones must itself be computed in such a way as to achieve perceptual constancy, ignoring irrelevant variation in surface features. Substantial evidence now exists that pitch invariance is computed in an area of belt cortex lateral to primary cortex, in both monkeys (Bendor and Wang 2005), and humans (Zatorre 1988; Johnsrude *et al.* 2000; Griffiths *et al.* 1998; Penagos *et al.* 2004; Krumbholtz *et al.* 2003). This region then feeds information into more distal portions of the processing stream, both anterior and posterior to the pitch-sensitive region, where melodic features are processed (Zatorre 1985; Zatorre *et al.* 1994; Patterson *et al.* 2002). The hierarchy of processing must eventually make contact with long-term memory systems where both implicit knowledge about general patterns, and specific knowledge about a particular musical piece, are stored. Expectations could thus arise from the interplay between the feedforward sensory abstraction mechanism, and the feedback received from stored internal representations.

MMN responses reflect musical expectations at a number of levels. Violation of both contour and interval expectations set up by a melodic context give rise to MMN, even in non-musicians. Saarinen *et al.* (1992) presented standard tone pairs where the pitches of the tones varied from trial to trial, but the pitch always rose from the first to the second tone. In deviant tone pairs the pitch fell from the first to second tone. Thus, despite the fact that standards varied in absolute pitch, the auditory cortex generated an expectation for rising contour. Tervaniemi *et al.* (2001) showed that contour expectations are also generated with a more complex inverted-U-shaped contour. Given that pitch contour is important in both speech and music, it is perhaps not surprising that the brain is set up to automatically predict contour based on current context in musicians and non-musicians alike. However, Trainor *et al.* (2002) showed that non-musicians also form expectations for particular intervals in the absence of absolute pitch information. Specifically, when presented with a standard 5-note melody that was transposed to different pitch levels (keys) on successive repetitions, occasional changes to the last note that altered the interval size but not contour led to robust MMN. Such mismatch responses are typically larger and earlier in musicians than in non-musicians (Figure 16.2), (Fujioka *et al.* 2004), indicating either genetic differences between musicians and non-musicians or the plastic effects of musical training. However, at the same time, these results suggest that even in the absence of musical training, auditory cortex automatically encodes music-specific melodic information and creates expectations for future events.

In polyphonic music, two or more melody lines occur at the same time. Fujioka *et al.* (2005) demonstrated that separate memory traces are formed for each melody, and that predictive processes within each stream can be measured with MMN. On 25 per cent of trials one note was raised by a tone or a semitone in one melody, and on another 25 per cent of trials one tone

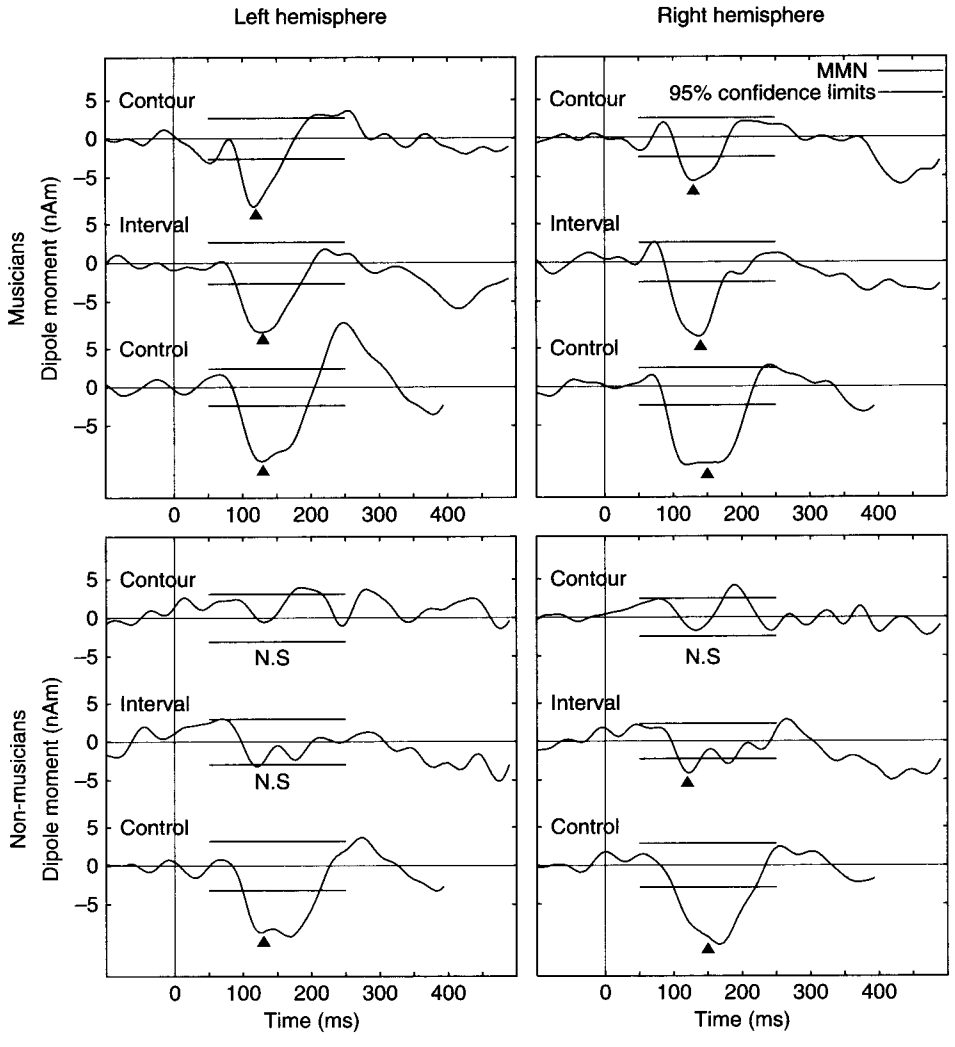

Fig. 16.2 MMN to occasional changes in the contour or interval of a melody. Source space wave forms in auditory cortex from MEG data are shown. Musicians are shown in the upper panel and non-musicians in the lower panel. In both groups, an MMN response can be seen to changes in pitch interval and to changes in pitch contour, but MMN amplitude is much larger in musicians than in non-musicians. MMN is also seen in the control condition where the pitch of a single repeating tone is occasionally changed. However, in the control condition there are no differences between musicians and non-musicians. Reprinted with permission from Fujioka *et al.* (2004).

was lowered by a tone or a semitone in the other melody. Thus, the overall deviance rate was 50 per cent, so if separate streams were not formed, no MMN response would be expected because standard and deviant trials were equally probable. However, significant MMN was found for changes in both melodies, indicating that the two melodies were encoded separately. In the case of two simultaneous melodies, as with single melodies (Fujioka *et al.* 2004), musicians showed more robust MMN responses than non-musicians. Interestingly, for both groups, high and low melodies were not encoded equally well, as MMN was larger for the higher voice, consist-

ent with the compositional practice of putting the melody in the highest voice, and with people's superior perception of the highest voice (Crawley *et al.* 2002). In a follow up study, Fujioka *et al.* (2008) showed that the superiority of the higher voice is a very general phenomenon, also holding in the situation where each of the two voices consists of a single pitch. Finally, across a number of studies, no difference in MMN amplitude or latency was found for changes that went outside the key of a melody compared to changes that remained within the key (Trainor *et al.* 2001; Fujioka *et al.* 2004, 2005), suggesting that some aspects of culture-specific musical structure are processed beyond the auditory areas responsible for MMN generation.

While we have focused on the MMN as a neural correlate of musical expectancy, it is important to note that there are culture-specific aspects of musical expectancy which are processed in brain areas beyond the auditory regions responsible for MMN generation. For example, in Western musical structure chords follow each other according to genre-specific syntactic rules. Koelsch and his colleagues have demonstrated that a syntactically unexpected chord, such as a Neapolitan chord at the end of a cadence where a tonic chord is expected, gives rise to an early right anterior negativity (ERAN) (Koelsch *et al.* 2000; cf. Patel *et al.* 1998). ERAN is similar to MMN, but occurs somewhat later, is sensitive to harmonic expectations (Koelsch *et al.* 2001), and appears to involve inferior frontolateral cortex (Broca's area) (Maess *et al.* 2001). ERAN is also elicited by unexpected modulations in key (Koelsch *et al.* 2003). As with MMN responses to single and polyphonic melodies (Fujioka *et al.* 2004, 2005), ERAN responses to unexpected chords are present in both musicians and nonmusicians, although larger in musicians (Koelsch *et al.* 2002a). Furthermore, ERAN for unexpected chords is present even when other factors such as simple note repetition and degree of dissonance are controlled for (Koelsch *et al.* 2007; Leino *et al.* 2007). Finally, functional magnetic resonance imaging (fMRI) studies reveal that musical syntax activates a network of brain regions that resembles that for linguistic syntax (e.g., Koelsch *et al.* 2002b; cf. Patel 2003), suggesting further that music makes use of general processing properties of the cortex.

In summary, MMN and ERAN responses demonstrate that, for musical input, the brain is continually using the recent past to predict the future, and the magnitude of these responses reflects the degree to which these expectations are not fulfilled. MMN is sensitive to changes in acoustic features and patterns of sounds, and several MMN processes can occur simultaneously. ERAN is sensitive to culture-specific knowledge that is built up through exposure to a particular music system.

The early development of musical expectations in infants

ERP responses to sound are very immature in infancy, reflecting the protracted development of the auditory cortex that extends into the teenage years (Huttenlocher and Dabholkar 1997; Moore 2002; Moore and Guan 2001; Ponton *et al.* 2000; Shahin *et al.* 2004; Trainor *et al.* 2003). Despite this great immaturity, robust mismatch responses can be measured from infants, suggesting that infant MMN is among the first developing cortical responses to sound (Näätänen *et al.* 2007). We argued in the introduction that being able to accurately predict the future is of paramount importance to survival. From this perspective, it makes sense, then, that mismatch responses would be among the earliest cortical responses, as they may be essential for optimal wiring of the brain through experience.

In very young infants, the ERP wave form is dominated by a frontally positive, anterior-negative slow wave. Interestingly, when a repeating sound is changed in pitch (e.g., Leppänen *et al.* 1997), fine temporal structure (e.g., Trainor *et al.* 2003), or vowel category (Dehaene-Lambertz and Baillet 1998), the slow wave increases in positivity (see Figure 16.3). An adult-like MMN emerges around 4 months of age or so in response to sound feature changes (He *et al.* 2007a; Trainor *et al.* 2001, 2003a) (see Figure 16.3). The slow wave and adult-like MMN probably represent different processes as both can be seen in infants of intermediate age (He *et al.* 2007a). Furthermore, the MMN in 4-month-olds increases with larger pitch

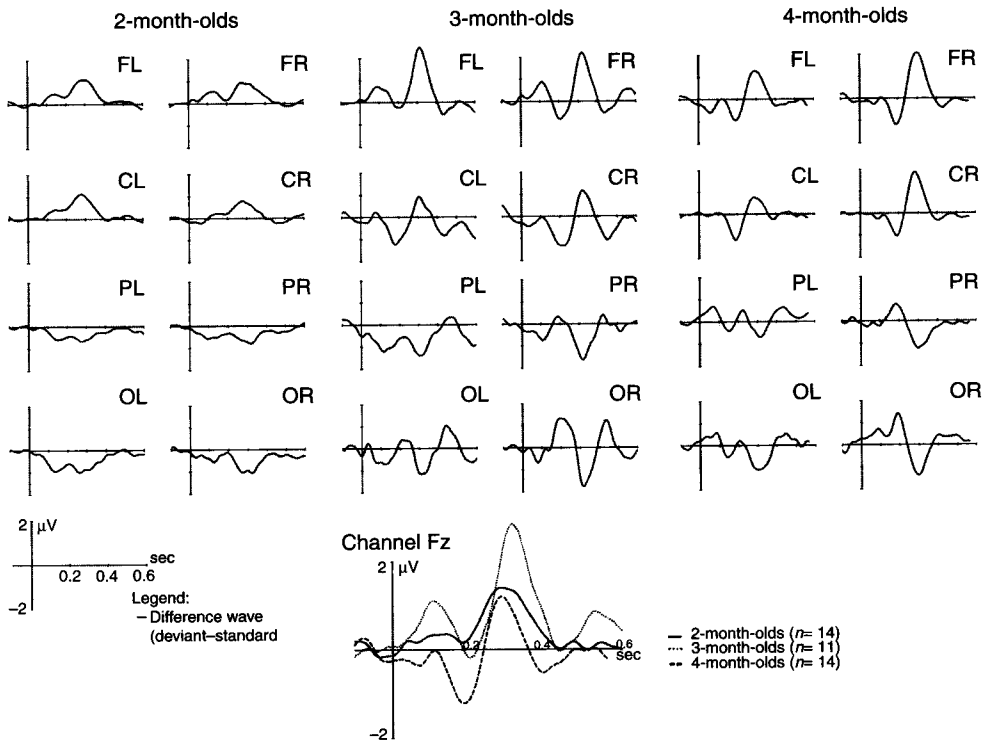

Fig. 16.3 Difference waves (deviant–standard) to occasional half-octave changes in the pitch of a repeating standard tone in 2-month-olds, 3-month-olds and 4-month-olds at different scalp locations: F, frontal; C, central; P, parietal; O, occipital; L, left; R, right. In 2-month-olds, a slow positive difference wave is seen. In 3- and 4-month-olds a faster negative response resembling adult MMN can be seen followed by a positivity resembling P3a in adults. Both components reverse polarity at the back of the head. MMN becomes larger with increasing age. Reprinted with permission from He *et al.* (2007).

changes and remains robust at fast presentation rates, similar to adult MMN (He *et al.* in press).

These mismatch responses allow investigation of the developmental origins of musical expectations. These studies are just beginning. To date, it is clear that a repeating tone of one pitch sets up expectations for future repetitions of that pitch in infants (e.g., Alho *et al.* 1990; Ceponiené *et al.* 2002; He *et al.* 2007a, in press; Leppänen *et al.* 1997; Morr *et al.* 2002). Furthermore, 4-month-olds show robust MMN responses to the pitch of occasional deviants with missing fundamental components, indicating that they integrate the frequency content of complex tones into a single percept (He and Trainor 2007). Of most interest for musical processing, 4-month-olds also exhibit an MMN response when there is a change in a sequential pitch pattern (He *et al.* 2007b). Specifically, when the order of tones in a repeating two-tone sequence is occasionally reversed, a clear MMN is seen.

In sum, mismatch responses are among the earliest cortical responses to sound. The groundwork has now been established so that future studies can investigate in much more detail how musical expectations develop in the auditory cortex of human infants, and examine questions such as the effects of particular auditory experience on the development of these expectations.

changes and remains robust at fast presentation rates, similar to adult MMN (He *et al.* in press).

These mismatch responses allow investigation of the developmental origins of musical expectations. These studies are just beginning. To date, it is clear that a repeating tone of one pitch sets up expectations for future repetitions of that pitch in infants (e.g., Alho *et al.* 1990; Ceponiené *et al.* 2002; He *et al.* 2007a, in press; Leppänen *et al.* 1997; Morr *et al.* 2002). Furthermore, 4-month-olds show robust MMN responses to the pitch of occasional deviants with missing fundamental components, indicating that they integrate the frequency content of complex tones into a single percept (He and Trainor 2007). Of most interest for musical processing, 4-month-olds also exhibit an MMN response when there is a change in a sequential pitch pattern (He *et al.* 2007b). Specifically, when the order of tones in a repeating two-tone sequence is occasionally reversed, a clear MMN is seen.

In sum, mismatch responses are among the earliest cortical responses to sound. The groundwork has now been established so that future studies can investigate in much more detail how musical expectations develop in the auditory cortex of human infants, and examine questions such as the effects of particular auditory experience on the development of these expectations.

Temporal expectations and auditory–motor interactions: predicting *when* events will occur

As music unfolds over time, the brain extracts rhythmic regularities and sets up expectancies for when events will occur as well as for what the events will be. Time structure in music involves two aspects. First, there is the sequence of sound events and silence durations, which is referred to as the *rhythmic pattern*. Second, when a pattern contains temporal regularities, listeners infer an underlying regular hierarchical beat structure (what you tap your foot to), called the *metrical structure*. Metrical structure is not given in the stimulus, and there may not actually be sound events on some beats; rather, metre is derived by the brain from temporal regularities in the rhythm pattern. Metrical structure is hierarchical, with the strong beats being spaced progressively further apart in time at higher levels of the hierarchy, such that you can clap or tap, for example, on every beat, every second beat, or every fourth beat of a rhythm pattern organized into binary groups. The strong expectancies set up by metrical structure are evident in that the sense of a beat can continue past the end of a piece of music. One plausible theory as to how this happens is that neural circuits in the brain act as oscillators that can adjust their phase and frequency to some extent in response to the input from rhythmic patterns (Large and Jones 1999). Evidence for the neurological instantiation of temporal expectancy comes from studies of the induced gamma band response. Gamma band activity is in the range of 40–80 Hz, and can be extracted from an EEG recording by doing a Fourier analysis. The evoked gamma-band response occurs shortly after the onset of a sound and is tightly time-locked to the sound onset (e.g., Ross *et al.* 2005). The induced gamma-band response, on the other hand, is only loosely time-locked to the sound, and therefore has a different phase on every trial (e.g., Tallon-Baudry *et al.* 1996). The induced gamma-band response appears to reflect processes of intrinsic temporal expectation as it can be measured at points in time where a sound is expected, even if the sound event is not realized and there is only silence (Snyder and Large 2005). Furthermore, the induced gamma-band response is larger in musicians than in non-musicians, especially for sounds of their instrument of practice, and it also develops to a greater extent over the course of a year in young children taking music lessons compared to children not studying music (Shahin *et al.* 2008).

Temporal expectancies are important both in listening to music and in performing music (Large and Palmer 2002). A number of researchers have noted the close interaction between movement and auditory rhythm (Phillips-Silver and Trainor 2007, 2008; Trainor *et al.* in press; Repp 2005; Todd *et al.* 2007), even in infants (Phillips-Silver and Trainor 2005) and in non-human species (Todd *et al.* 2007). Indeed the close connection between music and dance suggests that musical rhythm might have evolved from rhythmic movement. A number of researchers, working on both speech and music, have postulated that *perception* of timing involves interactions between auditory and motor systems (Hickok and Poeppel 2004; Phillips-Silver and Trainor 2005, 2007, 2008; Repp 2005; Warren *et al.* 2005). This idea is related to research in vision, where similar neural responses exist both to observing an action and to performing the action (Rizzolatti and Craighero 2004).

A number of recent imaging studies dealing with musical perception and production suggest that the two processes may be closely intertwined; for instance, MEG data show that activity in the vicinity of the primary motor cortex could be evoked in pianists when they listened passively to well-known melodies (Haueisen and Knosche 2001). Two other fMRI studies (Bangert *et al.* 2006; Baumann *et al.* 2005) also reported that neural regions overlapped when pianists either listened to music without playing it, or played on a keyboard without any feedback; the overlap included the premotor cortex, supplementary motor area and the posterior auditory cortex. Increased motor excitability in the primary motor cortex of pianists has also been observed as they listened to a known piano piece, compared to a piece they were not trained on (D'Ausilio *et al.* 2006).

The phenomena are not limited to trained musicians, but can also be found amongst non-musicians. For example, a common pattern of EEG activity in auditory and motor areas was found in a task in which non-musicians were trained to play a simple melody on a keyboard (Bangert and Altenmuller 2003). The effect was only apparent when sound–movement mappings were congruent, and not when the learning did not result in a consistent assignment of key-presses to sounds. Similarly Lahav *et al.* (2007) used fMRI to show that premotor cortex and Broca's area were active when non-musicians heard melodies that they had previously learned to play, but not upon hearing equally familiar but motorically untrained melodies. Other studies have also noted premotor cortex activity during music listening under less specific circumstances, such as in melodic discrimination (Brown and Martinez 2007), or while listening to consonant musical excerpts (Koelsch *et al.* 2006). These effects have been interpreted as reflecting possible subvocal rehearsal, a phenomenon also suggested to occur during musical imagery tasks (Zatorre and Halpern 2005). Thus, it is now fairly well established that auditory–motor coactivation can be observed in musicians and in non-musicians, either spontaneously, or more specifically when there is a direct learned mapping between movement and sound.

Of most interest with respect to the involvement of auditory–motor interactions in the prediction of *when* events will happen, is the idea that interactions between posterior auditory cortices and premotor cortices might mediate the cognitive representations that are responsible for integrating feedforward and feedback information during performance and perception (Zatorre *et al.* 2007). Indeed, higher-order temporal organization (metricality) might emerge from the temporal predictions that are enabled by this system. Evidence for this comes from Chen *et al.* (2006) who found that the degree to which auditory input modulates motor behaviour and premotor cortex activity is enhanced by metrical saliency (the intensity of accented beats). In other words, increased predictability of auditory events in music leads to greater auditory–motor interaction. In a related study (Chen *et al.* 2008), a similar region of premotor cortex was also found to be recruited as subjects reproduced progressively more complex rhythmic movements. These studies manipulated the abstract metrical structure of the rhythms, and therefore the organization of the movement sequences (i.e., their predictability). One hypothesis to account for these results is that what modulates premotor activity in these instances is not the direct mapping of sounds to movements, but rather, the selection of movements based on the auditory cue. The dorsal segment of premotor cortex would, according to this view, be involved in extracting higher-order features of the musical sound, including its rhythmic metrical structure, therefore allowing implementation of temporally organized actions. Listening to music may activate motor programmes directly associated with producing the music, for example when a musician knows the piece he or she is listening to; but perhaps more interesting, listening to music also appears to engage auditory–motor interactions that extract higher-order metrical information. This latter mechanism may be critical in setting up the temporal expectancies that are essential for musical understanding (Huron 2006). As such, the interplay between auditory processing streams and the premotor system could be thought of as the temporal counterpart of the pitch-based expectancies discussed above, which rely on the interplay between auditory and memory systems.

Future directions: understanding the neurobiology behind music expectations and emotional responses

In 1956, Meyer argued convincingly that music induces emotional experiences through physiological responses to musical expectations and the degree to which they are realized. In the present paper, we argue that music makes use of general brain mechanisms devoted to encoding the recent past, predicting the future, and dynamically adjusting the encoding of the recent past when the prediction is not accurate. We suggest, further, that such predictive processes

are essential for adaptation, plasticity, and learning, because evaluation of the success of the prediction provides a learning signal by which neural networks can change in order to more accurately and usefully encode the sensory input. We provided extensive physiological evidence from EEG, fMRI and MEG studies that music makes use of these general-purpose mechanisms, and that musical structure constantly engages the brain in a game of prediction. Some aspects of musical prediction, such as using statistical properties of recent input, are probably relatively independent of specific experience with a musical system whereas others, such as predicting the next chord in a sequence, probably rely on experience with a specific musical system. In particular, the framework that we have presented, in which MMN responses to unexpected events occur automatically and without attention, can explain why a note or chord that is musically unexpected continues to evoke an emotional response even when we are familiar with the piece and know at a conscious level that the unexpected chord is coming.

Huron (2006) suggests that not only does the brain make predictions about the future, but that there are intrinsic reward systems for correct prediction. With less expected musical realizations, a physiological arousal occurs, but, after appraisal, it is evident that there are no 'bad' consequences from the poor prediction because music is not about events in the world. So the emotion we feel tends to be strong and positive. To date, there is little physiological data linking violation of musical expectation and emotional responses. However, one study revealed that subjective ratings of tension and emotion, electrodermal activity, and an early negativity in the ERP all increased more for very unexpected than for somewhat unexpected sound events (Steinbeis *et al.* 2006). It remains for future research, however, to uncover the pathways in the nervous system that link the perception of unexpected events with our emotional responses to them.

CHAPTER 17

Disorders of musical cognition

Lauren Stewart, Katharina von Kriegstein, Simone Dalla Bella, Jason D. Warren and Timothy D. Griffiths

Introduction

The study of the neural underpinnings of musical perception and cognition has advanced greatly since Critchley and Henson published their edited volume *Music and the brain* (1977). Technical advances in functional neuroimaging and the development of theoretical models of musical processing (Peretz and Coltheart 2003) have allowed us to gain an understanding how musical processing occurs in the normal human brain. In parallel with this, the development of musical assessment tools such as the Montreal Battery for the Evaluation of Amusia (MBEA) (Peretz 2003) and the use of MRI to precisely define where lesions occur, allow us to determine which parts of these normal networks are critical for individual aspects of musical processing.

Here we present a comprehensive overview of case studies of acquired disorders of musical listening. The precise details of many of these published case studies are given in a previous review of disordered musical listening (Stewart *et al.* 2006). The current chapter draws general principles from those case studies, as well as presenting and commenting on a number of additional cases of disordered musical production.

Acquired deficits in musical listening

The identification of cases of acquired disorders of musical listening based on symptom profiles in individual patients constitutes the traditional 'symptom-led' approach. An alternative approach to the clinical study of musical deficits has been advocated, based on the study of cases selected on the basis of a particular brain lesion, rather than clinical symptoms: the 'lesion-led' approach. Tables 17.1 and 17.2 refer to symptom-led and lesion-led reports respectively. In the discussion that follows, lesion-led cases will be considered as an adjunct to our primary focus on symptomatic disorders of musical listening.

Examination of the individual cases listed in Table 17.1 demonstrates that a deficit in musical listening can arise as a consequence of a central disturbance of auditory processing: of all the musical listening deficits documented, none could be attributed to a peripheral hearing deficit. As Figure 17.1 shows, the brain lesions that produce deficits in musical listening are widely distributed, with a preponderance of locations in the right hemisphere. However, even though right-sided lesions are more commonly associated with deficits in pitch and other domains, left sided lesions can also produce deficits in these aspects of musical listening. The preponderance of right hemispheric lesions associated with musical listening deficits may, at least partially, reflect a sampling bias: individuals with left hemisphere damage are often aphasic and testing of non-linguistic skills is often difficult and rarely a priority. The majority of cases are attributable to cerebrovascular events, though other pathologies such as focal cerebral degeneration ('progressive amusia') are represented

(Confavreux *et al.* 1992). Because of the nature of these lesions, musical listening disorders are rarely 'pure': over half the cases are associated with disorders of speech perception, and approximately a third of cases with disorders of environmental sound perception. In most cases available data on speech processing are limited, preventing clear comment about the general association of directly related speech deficits (e.g. perceptual dysprosody) or other deficits in the speech domain. There is some evidence to suggest that the earlier stages of an acquired deficit in musical listening (e.g. less than one year after onset) tend to be accompanied by more deficits in listening to other classes of sounds suggesting a disorder in musical listening that can emerge as an isolated deficit following the recovery phase of a more generalized auditory agnosia.

Figure 17.1 shows that many areas are implicated in more than one function. However, it is clear that the necessary bases for music processing are separable: within the domain of music, relatively isolated deficits of pitch (Peretz *et al.* 1994), temporal (Mavlov 1980), timbral (Kohlmetz *et al.* 2003), mnemonic (Peretz 1996) and emotional (Griffiths *et al.* 2004) processing have all described. More fine-grained dissociations also occur: for instance, between pitch interval and pitch contour (Liegeois-Chauvel *et al.* 1998; Peretz 1990) and between rhythm and metre (Di Pietro *et al.* 2004; Wilson *et al.* 2002).

Pitch: interval

Deficits in the analysis of pitch intervals (the detection of a pitch change and/or the discrimination of the direction of a pitch change) are most strongly associated with lesions involving lateral Heschl's Gyrus (HG) and non-primary auditory cortical areas in Planum Temporale (PT) and the parieto-temporal junction (Figure 17.1). The detection of pitch differences and the discrimination of pitch direction are functionally

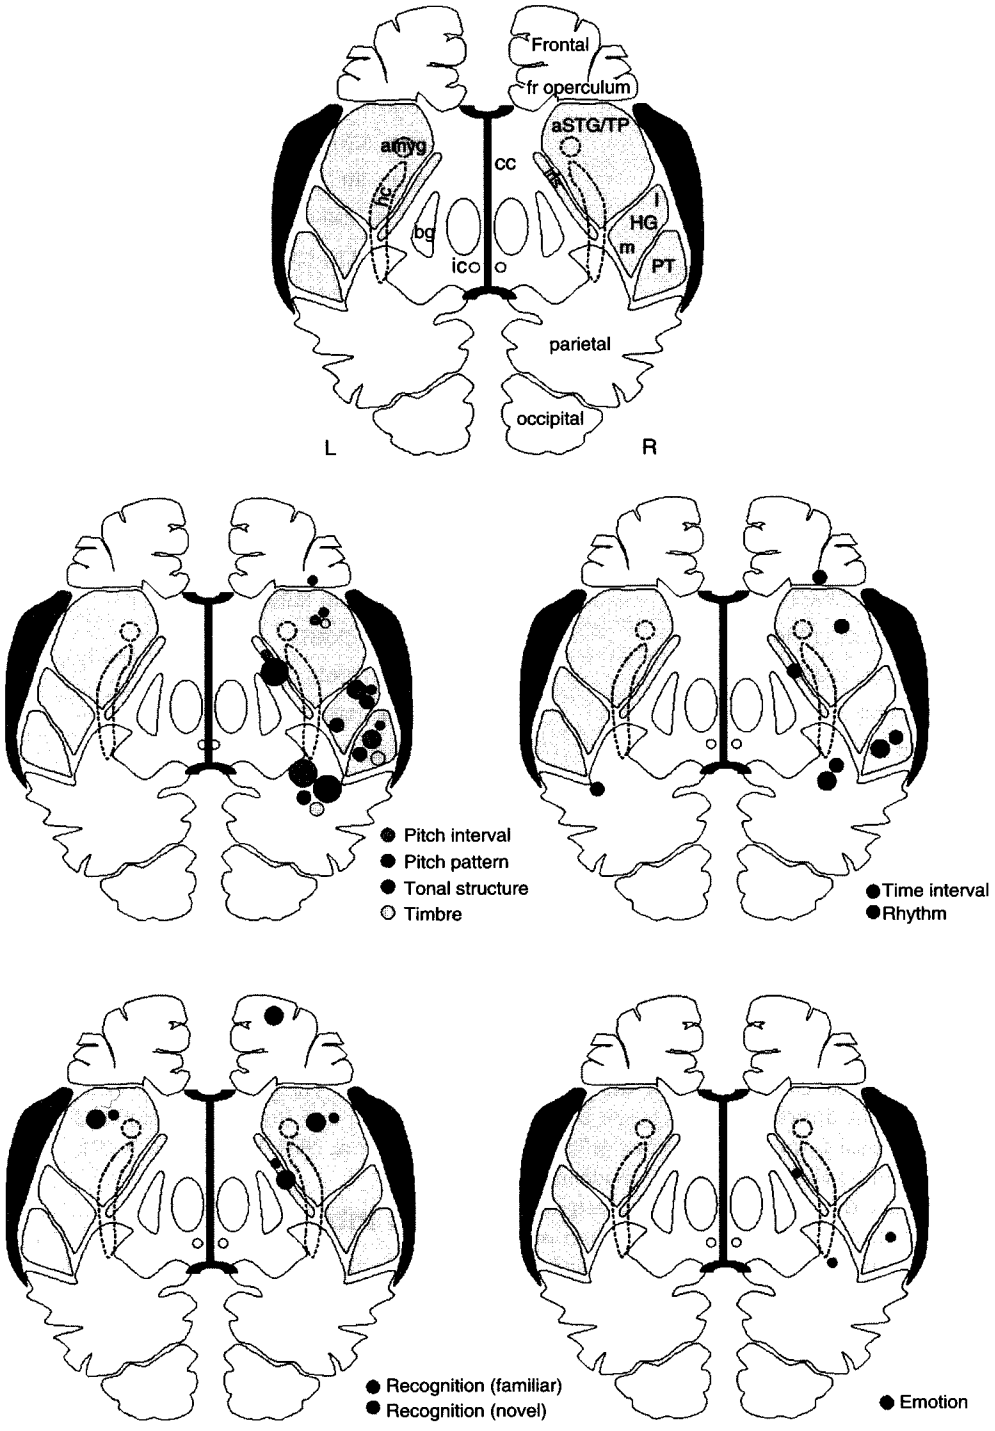

Fig. 17.1 Critical brain substrates for musical listening disorders. This data is based on the symptomatic cases of musical listening disorder (Table 17.1). The detailed analysis of these cases is

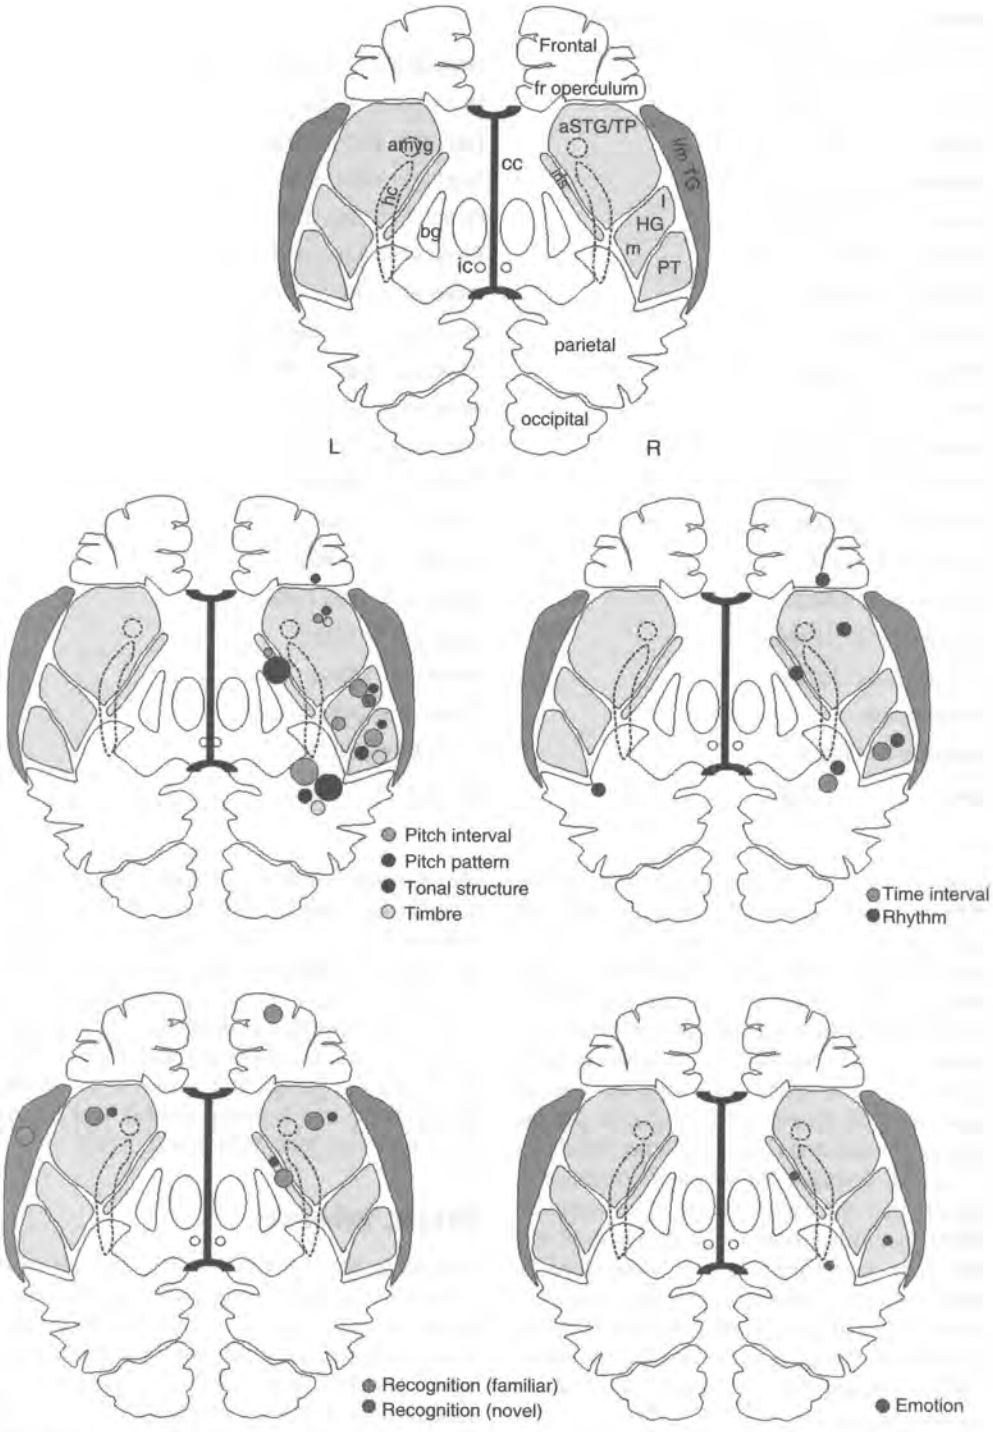

Fig. 17.1 Critical brain substrates for musical listening disorders. This data is based on the symptomatic cases of musical listening disorder (Table 17.1). The detailed analysis of these cases is

separable, but have been distinguished only infrequently in symptom-led studies. Where it has been specifically assessed, impaired pitch-difference detection is generally associated with involvement of subcortical structures and ascending auditory pathways or primary auditory cortex in medial HG (Habib *et al.* 1995, Hattiangadi *et al.* 2005, Terao *et al.* 2006, Tramo *et al.* 2002) while impaired pitch-direction discrimination is generally associated with involvement of lateral HG (Lechevalier *et al.* 1984, Tanaka *et al.* 1987, Terao *et al.* 2005, Tramo *et al.* 2002).

These data are congruent with evidence from temporal lobectomy series (Table 17.2). Right-lateral HG resection leads to deficits in the detection of pitch-change direction in pure tones (Johnsrude *et al.* 2000) and complex tones (Zatorre 1988) These findings, especially the latter, suggest that aspects of pitch perception, as opposed to the sensory representation of frequency- and time- domain properties of the stimulus, depend on the integrity of cortical areas beyond primary auditory cortex.

Pitch: pattern

Deficits in the analysis of pitch patterns, such as melodies, are common in acquired disorders of musical listening (Table 17.1). The deficits are most often associated with lesions posterior to HG, in PT and the parieto-temporal junction, and anterior to HG in anterior superior temporal gyrus (STG) (Figure 17.1). These lesions are more common on the right. Melody discrimination has also been widely assessed in the lesion-led literature (Table 17.2): right but not left temporal lobectomy impairs discrimination of pitch pattern, even where HG is not included (Milner 1962). However, inclusion of HG produces deficits in melody perception over and above those due to the resection of the temporal lobe anterior to it (Samson and Zatorre 1988, Zatorre 1985). In a study comparing resections involving posterior versus anterior STG (Liegeois-Chauvel *et al.* 1998), posterior resection was associated with more severe impairment of pitch pattern perception; this effect could not be attributed to involvement of HG. Right anterior temporal lobe resections have also been associated with impaired working memory for pitch (Zatorre and Samson 1991) which is likely to affect perception of long-term structure in melodies, and more specifically, discrimination tasks requiring comparisons between sequential stimuli.

Pitch contour (the pattern of 'ups' and 'downs' in a melody) and the associated absolute pitch values can be considered as corresponding to psychologically distinct 'global' and 'local' levels of pitch processing, respectively (Dowling and Harwood 1985). These levels can be probed by tasks which require discrimination of melodies with different pitch contour ('global' tasks) or different absolute pitch values with the same contour ('local' tasks), respectively. A 'pure' global task would require transposition

presented in supplementary Table 1 of Stewart *et al.* (2006). Five cartoons are shown, each depicting the brain in a schematic axial section that includes all key anatomical areas involved in music listening (identified on the top cartoon); the corpus callosum (black), superior temporal plane (light grey) and middle/inferior temporal gyri (dark grey areas, in exploded view) are coloured for ease of identification. Musical functions have been grouped as follows: pitch processing (pitch interval, pitch pattern, tonal structure, timbre); temporal processing (time interval, rhythm); musical memory (familiar and novel material); and emotional response to music. Each group of functions is assigned to a separate cartoon; individual functions are identified to the right of the corresponding cartoon. Raw data from Stewart *et al.* (2006) have been thresholded; the presence of a coloured circle corresponding to a particular function in a region indicates that at least 50 per cent of studies of the function implicate that region. The size of each circle is scaled according to the proportion of studies of the function implicating that region. Metre is not represented as no brain area was implicated in 50 per cent or more of cases. amyg, amygdala; aSTG, anterior superior temporal gyrus; bg, basal ganglia; cc, corpus callosum; fr, frontal; hc hippocampus; HG, Heschl's gyrus; i, inferior; ic, inferior colliculi; ins, insula; l, lateral; m, medial; PT, planum temporale; TG, temporal gyrus. See colour plate section. This figure is taken from Stewart L, Von Kriegstein K, Warren JD and Griffiths TD. Disorders of musical listening. *Brain* 2006, 129, 2533–2553, by permission of Oxford University Press.

between the melodies compared (like a shift in key) to prevent the use of any local information. However, this renders the task much harder for non-musicians and the MBEA does not employ it. Peretz (1990) showed that patients with right cerebral hemisphere strokes could process neither global nor local information in melodies, while patients with strokes involving the left hemisphere could process global but not local information. Isolated impairments of local processing were observed, but isolated impairments of global processing were not, leading Peretz to propose an influential hierarchical model of co-operation between the hemispheres. According to this model, the right hemisphere derives pitch contour which is then elaborated upon by the left hemisphere which fills in the detailed pitch structure. In the model, prior contour processing is necessary for absolute pitch values to be processed: lesions involving the right hemisphere therefore compromize the processing of both contour and the absolute values of pitch whereas lesions involving the left hemisphere prevent absolute pitch values being added to the contour provided by the right hemisphere. This model was supported by the findings of a temporal lobectomy series (Liegeois-Chauvel *et al.* 1998). However, other neuropsychological and functional imaging evidence suggests that hemispheric differences are less clearcut (Schuppert *et al.* 2000, Stewart *et al.* 2008).

Pitch: tonal structure

Tonal structure refers to rule-based patterns of pitch determined by key. While both tonal and atonal pitch patterns exhibit global and local structure, tonal structure is specific to tonal music (i.e., most Western music composed before the twentieth century). The most widely used test of this type of processing is the key violation task in the MBEA, which assesses the ability of subjects to detect notes that are out of key. Deficits in tonal analysis have been associated with damage involving a predominantly right-sided network of non-primary auditory cortical areas including lateral HG, PT, parieto-temporal junction, insula, anterior STG and frontal operculum (Figure 17.1). The frontal opercular involvement is proportionately greater

relative to its involvement in other aspects of pitch processing, but the number of studies is small.

Timbre

Timbral perception has a number of dimensions that can be related to different acoustic properties of the incoming sound, and lesions affecting any or all of these dimensions could in principle lead to a deficit of timbre perception. Many clinical studies include reports of perceptual alterations in the perceived quality of music (often described as unpleasant, 'flat' or 'mechanical' in nature) or inability to recognize musical instruments, which might represent specific deficits of timbre perception. However, timbre as a distinct functional component of music has only been assessed infrequently in the clinical literature. This evidence suggests that a network of areas in the right superior temporal lobe that overlaps closely with areas implicated in pitch-pattern analysis is critical for normal timbre perception (Figure 17.1). Timbral deficits have generally been observed in conjunction with pitch-pattern deficits, however timbral deficits with spared pitch-pattern perception have also been described after strokes involving right STG (Kohlmetz *et al.* 2003, Mazzucchi *et al.* 1982). The deficits may extend to the discrimination of timbre in voices and environmental sounds (Mazzucchi *et al.* 1982).

These findings from the symptom-led literature are mirrored by studies of temporal lobectomy series (Table 17.2). Right temporal lobectomy leads to deficits in the perception of timbral change when this is in the spectral dimension (Milner 1962, Samson and Zatorre 1994), temporal dimension (Samson and Zatorre 1994), or both (Samson *et al.* 2002). This last study also suggested a subtle effect of left temporal lobectomy deficit on the processing of timbre associated with melodies but not single notes.

Temporal structure: time interval, rhythm and metre

Like pitch perception, the perception of timing information in music can be analysed hierarchically: the lowest level of temporal processing that we consider here corresponds to the detection of simple durational differences in a tone or detection of a silent interval between two tones. These basic timing elements can be built into more complex structures embedded in metre and rhythm. Schuppert and colleagues (2000) propose a hierarchal scheme where metre and rhythm can be considered as global and local properties in the time domain. The symptom-led evidence implicates predominantly right-sided non-primary auditory cortical areas posterior to HG in the perception of time-interval differences, and bilateral areas widely distributed beyond HG in the perception of rhythm (Figure 17.1). Evidence from lesion-led studies broadly supports a bilateral organization: impaired durational processing has been described following right temporal lobectomy (Milner 1962) and impaired gap detection following left temporo-parietal strokes (Robin *et al.* 1990). Impaired detection of rhythmic violations has been described in left temporo-parietal stroke (Robin *et al.* 1990) and left hippocampal sclerosis (Samson *et al.* 2001), while other studies have not demonstrated laterality differences (Peretz, 1990, Schuppert *et al.* 2000, Shapiro *et al.* 1981). At least some of these apparent discrepancies in lateralization may reflect task effects: for example, the detection of rhythmic errors in familiar tunes (Prior *et al.* 1990, Samson *et al.* 2001) may require musical processing that is not required for the discrimination of simple rhythmic patterns.

Comparatively few studies of metrical processing have been conducted and evidence for a critical brain substrate remains inconclusive. This is likely to be due at least in part to the difficulty of assessing metre reliably, particularly in subjects without formal musical training. In the small symptom-led literature, impairments of metre perception have been associated with individual lesions widely distributed in both cerebral hemispheres. This pattern has been echoed in lesion-led studies. In temporal lobectomy series, Liegeois-Chauvel *et al.* (1998) found metrical impairments following left and right anterior temporal lobe resections, while Kester *et al.* (1991) found a specific decrement in performance following right but not left anterior temporal resection. Ayotte *et al.* (2000) and Peretz *et al.* (1990) both found that stroke patients with heterogeneous left and right hemisphere strokes

were not impaired relative to neurologically normal control subjects, while Schuppert *et al.* (2000) found that both left and right hemispheric stroke patients were impaired relative to controls.

Memory: familiar and novel material

Impaired recognition of familiar tunes is described in a number of studies (Ayotte *et al.* 2000, Griffiths *et al.* 1997, Johannes *et al.* 1998, Lechevalier *et al.* 1984, Peretz *et al.* 1998, Peretz and Gagnon 1999, Peretz *et al.* 1994, Piccirilli *et al.* 2000, Satoh *et al.* 2005, Wilson *et al.* 2002). In all these cases, recognition problems were accompanied by impaired pitch-pattern perception. However, perception and recognition can sometimes dissociate. Patients may have intact perception but impaired recognition (Eustache *et al.* 1990 (case 1), Peretz 1996) or the converse (Eustache *et al.* 1990 (case 2); Schuppert *et al.* 2000).

Figures 17.1 demonstrates that deficits in the perception and recognition of familiar tunes may occur with damage in either cerebral hemisphere involving the anterior STG and insula (Lechevalier *et al.* 1984, Peretz *et al.* 1998, Peretz and Gagnon 1999, Peretz *et al.* 1994, Satoh *et al.* 2005). In the lesion-led literature, familiar-tune recognition was found to be deficient specifically in association with damage involving the right insula (Ayotte *et al.* 2000).

Impaired recognition of novel material is tested in the incidental memory test from the MBEA, which assesses implicit encoding and retrieval of novel musical material. Clinical impairments of musical incidental memory are associated with damage involving a bilateral network of areas that closely overlaps the network implicated in the recognition of familiar tunes (Figure 17.1), and extends into left middle and inferior temporal cortex. In temporal lobectomy series, incidental memory deficits have been described following both right and left anterior resections (Samson and Zatorre 1992, Zatorre 1985).

Emotion

Most people listen to music purely for the aesthetic pleasure it brings. A loss of enjoyment in musical listening is a common presenting complaint in clinical disorders of musical listening. In many cases, this loss of pleasure is accompanied by a perceptual derangement: 'like an out of tune child's dulcimer', (Griffiths *et al.* 1997), 'mechanical' (Griffiths *et al.* 2006), or 'instruments [may lose] their distinctive features of timbre and sound dull' (Piccirilli *et al.* 2000). Associated impairments of pitch-pattern perception (Habib *et al.* 1995) and generalized auditory agnosia (Mazzucchi *et al.* 1982) have been documented. The most consistent association of altered emotional response to music across studies is damage involving the right posterior temporal lobe and insula (Figure 17.1). However, few clinical studies have specifically assessed musical emotion.

Just as perception and recognition for musical material may dissociate, so too may perception and emotional response to music. Isolated deficits of musical emotional response have been described: the patient of Griffiths *et al.* (2004) had been used to experiencing an emotional transformation while listening to Rachmaninov preludes (the 'shiver down the spine' phenomenon) but this was lost following an infarction involving left amygdala and insula. In a temporal lobectomy series (Gosselin *et al.* 2005), patients who had undergone resections of the left or right medial temporal lobe, including the amygdala but sparing the STG, found fearful music less scary than a group of matched controls. Conversely, intact emotional response despite impaired music perception has also been observed (Lechevalier *et al.* 1984, Peretz *et al.* 1998, Peretz and Gagnon 1999). The patient of Peretz *et al.* (1998) still derived pleasure from music, and was able to classify tunes as happy or sad and to discriminate tunes based on emotional tone despite severe perceptual and recognition impairments.

Developmental deficits in musical listening

Case reports of lifelong tone deafness go back more than a century (Grant-Allen 1898), but it has only been in the last five years that the condition has undergone systematic investigation using the same tools that have been applied to

acquired disorders of musical listening. The disorder was first characterized in this way by Peretz and colleagues using the MBEA and given the label 'congenital amusia' (Ayotte *et al.* 2002). This is not the same as what is commonly known as 'tone-deafness', a term which many people apply to themselves, mostly based on the belief that they cannot sing in tune (Sloboda *et al.* 2005, Cuddy *et al.* 2005). Infact, given normal brain development and opportunities for informal singing, the majority of the population can sing in tune (but see Bradshaw and McHenry 2005, Dalla Bella *et al.* 2007 for evidence that singing output may be impaired despite normal perception). Those with congenital amusia, on the other hand, cannot sing in tune, but this is likely to be a consequence of them having a true perceptual agnosia, in which the perception of music is abnormal in the presence of normal hearing and otherwise preserved cognition.

Pitch

Formal characterization of musical perception using the MBEA (Ayotte *et al.* 2002) demonstrates consistent deficits in the domain of pitch-pattern perception (pitch contour, absolute pitch value and key structure). Foxton *et al.* (2004) carried out tests in which types of pitch pattern that are more basic than melody are assessed. The group of subjects identified as having amusia using the MBEA were found to have abnormal perception of pitch change and pitch direction, the most striking changes being demonstrated for pitch direction. Most subjects in the amusic group had thresholds for the identification of pitch direction that were well above a semitone and likely relevant to the perception of Western music. This finding has been recently replicated in an independent group of amusic individuals (Griffiths *et al.* 2007). Given that pitch direction can be thought of as a 'building block' for contour (the pattern of 'ups' and 'downs' in a melody), this work suggests a fundamental deficit in pitch processing that is below the level of melody processing. However, the presence of such a causative deficit would predict that the deficit could be overcome by creating melodic sequences with large intervals. The fact that this is not the case (Foxton *et al.* 2004) argues against a simple low-level deficit in pitch direction as a single causal mechanism for melodic deficits in amusia. However, it remains possible that an inability to analyse pitch direction leads to a failure to develop normal pitch-pattern perception.

Temporal structure

Subjects who have been recruited on the basis of lifelong musical difficulty and score below threshold on the pitch subtests of the MBEA may also have problems with 'following the beat' and with dancing, consistent with a deficit in the analysis of metre and rhythm. Hyde and Peretz (2003) found that although subjects with congenital amusia had a deficit in detection of pitch changes in an otherwise monotonic sequence, their detection of a change in the timing of a note in an otherwise regular sequence was normal. A subsequent study in a different group of amusics (Foxton *et al.* 2006) replicated the finding of normal detection of timing deviation within simple rhythms, but showed that when subjects were required to detect the same deviation in a melodic, as opposed to monotonic context, their performance was impaired. The results support a model in which the abnormal perception of pitch pattern in amusia also affects the perception of the temporal structure of music. It is also worth noting that the amusic individuals so far studied have been recruited using adverts that conceptualize musical difficulties in terms of tune rather than time. In contrast, a large number of individuals screened using an internet version of the scale and rhythm subtest of the MBEA (www.delosis.com/listening/home.html) suggest that certain individuals have specific difficulties with time, but not tune (unpublished observations). This is a potentially novel subtype of amusia with a distinct cognitive and neural basis.

Emotion

A recent questionnaire-based study (McDonald and Stewart 2008) shows that, as a group, those with developmental amusia do not implement music in their everyday lives in the same way as age, gender and training matched controls. They regard the presence of music in public places more negatively than controls and report

significantly fewer emotional responses to music. However, there is considerable individual variation with respect to this. For instance, some amusics report enjoyment of music while others find it unpleasant. The dissociation between the perception of music and its self-reported emotional effects is consistent with evidence from normal functional imaging and clinical studies of acquired lesions that suggest distinct substrates for perception and appreciation but the reasons for such variability are presently unknown.

Neural substrate

The brain basis for congenital amusia has not been extensively investigated. These individuals do not have a history of neurological damage, and structural brain imaging using MRI reveals no gross structural differences. The technique of voxel-based morphometry allows structural MRI data from two or more groups of individuals (e.g. amusic versus non-amusic individuals) to be interrogated with regard to potential regional differences in grey and white matter density. Recent studies have demonstrated structural differences in the inferior frontal lobe and temporal cortex (Hyde *et al.* 2005, 2007; Mandell *et al.* 2007) and EEG studies of responses to pitch changes have demonstrated normal N1 responses to tones but abnormal N2-P3 responses at longer latency (Peretz *et al.* 2005). The N1 response arises from the PT whilst the longer latency responses have a number of more distributed generators. Congruent with the work based on structural MRI, this work suggests brain abnormalities in amusia that may occur in areas quite distinct from auditory cortex. Further studies will be required to ascertain the locus and nature of the abnormality in these developmental cases.

Acquired disorders of musical production

Music production deficits such as impaired singing (vocal amusia or oral-expressive amusia), or deficient music performance on an instrument (expressive instrumental amusia or musical apraxia) have been generally referred to as 'expressive amusia' (Benton 1977). Although cases of musical production deficits have been described since the nineteenth century (reviewed in Benton 1977), there is a paucity of studies of instrumental amusia (Botez and Wertheim 1959; McFarland and Fortin 1982). For this reason, the following discussion will focus on acquired deficits in singing.

Impaired vocal performance (e.g., poor singing of well-known songs) consequent to brain damage has been documented in skilled professional singers and in nonmusicians (for reviews, see Ackermann *et al.* 2007; Gordon *et al.* 2006; Marin and Perry 1999). Early case reports indicate that lesions of the right-hemisphere fronto-insular cortex disrupt the ability to sing, hum or whistle a tune (Mann 1898, 1933; Jossmann 1926, 1927, cited in Benton 1977; Botez and Wertheim 1959). For example, Mann (1898 cited in Benton 1977) reported impaired abilities to sing and whistle songs in a professional singer following injury of the right frontal lobe. Despite the dramatic vocal expression disorder, the patient was still able to recognize familiar songs and did not show any signs of aphasia. Similar cases of musicians exhibiting poor singing in absence of language disorders and with relatively spared music perception and recognition were reported by Jossmann (1926, 1927) and Botez and Wertheim (1959). These findings are consistent with the observation that unilateral inactivation of the right hemisphere (i.e., with the Wada test, see Gordon and Bogen 1974) alter the ability to sing, hum or whistle a tune. Unfortunately, however, most of these case descriptions are anecdotal, thus lacking systematic assessment of music production and perception abilities.

More systematic studies of singing deficits (both symptom-led and lesion-led) are included in Tables 17.1 and 17.2. Confavreux *et al.* (1992) report on a patient who suffered focal cerebral degeneration of right-hemisphere regions involving the anterior temporal gyrus and the insula. Music perception abilities were relatively preserved in the presence of impaired singing and expressive aprosody in speech. More recently, Schön and collaborators (2004) presented the case of IP, a tenor singer with right hemisphere lesions distributed in the inferior frontal gyrus, posterior temporal lobe and inferior parietal lobe. IP is a pure case of vocal amusia exhibiting a specific deficit of in the production of musical intervals. In contrast, production of

rhythm and contour were spared, as was musical perception and language abilities. In order to examine the role of the right and left hemispheres in pitch and rhythm vocal production, Alcock *et al.* (2000) examined vocal performance and music perception in a group study of patients with unilateral left- or right-hemisphere lesions. They found that left-hemisphere patients were mostly impaired in perceiving and reproducing rhythms, without difficulties in singing the correct pitch. Right-hemisphere patients, in contrast, had great difficulties in pitch production and perception tasks, with less marked rhythm processing disorders than left-hemisphere patients. Additional evidence confirming that the right hemisphere is engaged in pitch production comes from two recent single case studies in which acoustical measures of singing proficiency were obtained (Murayama *et al.* 2004; Terao *et al.* 2006). In sum, evidence from symptomatic case studies and lesion-led reports, in general, confirm what has been described in early reports, that the right hemisphere (mostly the frontal-insular regions) is central to vocal musical pitch production. In addition, vocal performance disorders can occur in a pure form in absence of perceptual and linguistic deficits, and may concern very specific aspects of music vocal production (e.g., interval production) while leaving other functions intact.

Further evidence indicating a predominant right-hemisphere involvement in vocal pitch performance comes from neuroimaging and TMS studies. In an fMRI study, Riecker *et al.* (2000) found that speech and singing without lyrics engage opposite hemispheres (at the level of anterior insula), with a left-hemisphere dominance for speaking and a right-hemisphere dominance for singing. A similar lateralization pattern was yielded by a PET study in which speaking and singing with words were contrasted (Jeffries *et al.* 2003). In addition, when TMS was applied over left-hemisphere regions traditionally related to speech production (e.g., near Broca's area) speech was disrupted; similar stimulation over homologous brain areas in the right hemisphere impaired singing, at least for some of the participants (Epstein *et al.* 1999; Lo and Fook-Chong 2004; Stewart *et al.* 2001).

A classical interpretation of these findings is that singing familiar songs engages right-hemisphere regions in contrast to propositional speech which engages the left-hemisphere. This account has gained credence from clinical reports that patients suffering from motor aphasia are still able to sing previously learned songs with well-articulated and linguistically intelligible words (e.g., Assal *et al.* 1977; Yamadori *et al.* 1977). However, the evidence is not clear-cut. Poor singing often emerges in association with linguistic deficits resulting from left-hemisphere damage (e.g. Benton 1977). Furthermore, bilateral hemispheric involvement in sung performance is substantiated by evidence that lesions in either of the two hemispheres impair sung performance (Kinsella *et al.* 1988; Prior *et al.* 1990), that both right- and left-hemisphere anesthetization interfere with singing (Borchgrevink 1980; Zatorre 1984), and that singing without words do no elicit any lip-opening asymmetry, as a measure of laterality (e.g., Cadalbert *et al.* 1994; Hough *et al.* 1994). Finally, clinical observations that motor aphasics can articulate words better when singing than when speaking were not fully corroborated by recent systematic studies (Hébert *et al.* 2003; Racette *et al.* 2006). In sum, it is likely that singing is characterized by less strict lateralization than is speech.

Conclusion

Like any cognitive faculty, music is multifaceted and the identification of the neural basis of any complex faculty must proceed, hand in hand, with an elucidation of its cognitive architecture. The past decade has seen an evolution in the theoretical models of musical processing, allowing the development of theoretically motivated instruments for the systematic evaluation of musical disorders. Such developments have allowed reports of musical disorders to evolve from historical anecdotes to systematic, verifiable accounts which can play a critical role in contributing to our understanding of the cognitive neuroscience of music.

CHAPTER 18

Music, musicians, and brain plasticity

Gottfried Schlaug

Musicians and non-musicians: their brains differ

Playing a musical instrument is an intense, multisensory and motor experience that is typically initiated at an early age and requires the acquisition and practice of a wide range of skills over the course of a musician's lifetime. Considering the early age at which they commence training and the continuous practice that maintaining such exacting skills demands over time, musicians make an ideal human model for studying the brain effects of acquiring highly specialized sensorimotor (Elbert *et al.* 1995; Amunts *et al.* 1997; Gaser and Schlaug 2003; Schlaug 2001; Schlaug *et al.* 2005; Hund-Georgiadis and von Cramon 1999; Meister *et al.* 2005; Bengtsson *et al.* 2005); auditory (Besson *et al.* 1994; Gaab and Schlaug 2003; Keenan *et al.* 2001; Pantev *et al.* 1998, 2001; Schlaug *et al.* 1995a, b; Schneider *et al.* 2002; Zatorre *et al.* 1998); auditory–spatial and visual–motor (Sergent *et al.* 1993; Münte *et al.* 2001); and auditory–motor (Lotze *et al.* 2003; Bangert *et al.* 2006; Zatorre *et al.* 2007) skills.

Strongest effects are found in primary domain regions

Several studies have found evidence for structural differences in brain regions that are directly involved with some of these skills, such as the primary auditory cortex and auditory association cortex (Schlaug *et al.* 1995a; Zatorre *et al.* 1998; Schneider *et al.* 2002; Gaser and Schlaug 2003) most likely related to important skills of fine spectral and temporal discrimination and pitch categorization. Further examples include structural differences in primary sensorimotor cortex and closely related premotor and supplementary motor regions, which are essential for preparation, execution, and control of precise, independent finger movements (Elbert *et al.* 1995; Amunts *et al.* 1997; Gaser and Schlaug 2003; Bangert and Schlaug 2006), and in the midsagittal side of the corpus callosum (Schlaug *et al.* 1995b; Ozturk *et al.* 2002; Lee *et al.* 2003), which is likely related to interactions between both hemispheres necessary for independent movements of right and left hand. These structural between-group (musicians vs non-musicians) differences mirror structural changes seen in primary motor and cerebellar cortices of experimental animal models that have been subjected to long-term learning of complex motor skills over several months (Anderson *et al.* 2002). Micro-structural changes included increases in the number of synapses and glial cells, increased density of capillaries in primary motor cortex and the cerebellum, and new brain cells in the hippocampus after long-term motor training in adult rats (Black *et al.* 1990; Isaacs *et al.* 1992; Anderson *et al.* 1994; Kleim *et al.* 1996; Kempermann *et al.* 1997; van Praag *et al.* 1999). The sum of these micro-structural changes could amount to structural differences that are detectable on a macro-structural level (see Anderson *et al.* 2002; Bangert and Schlaug 2006).

Most cross-sectional studies comparing the brains of adult musicians with those of matched

non-musicians, have used either age of commencement of musical training or intensity/duration of practice throughout a musician's career as predictors of regional differences suggesting that the longer and the more intensely musicians practiced, the more pronounced the between-group differences were (Elbert *et al.* 1995; Amunts *et al.* 1997; Schlaug 2001; Sluming *et al.* 2002; Schneider *et al.* 2002; Gaser and Schlaug 2003; Bangert and Schlaug 2006). Although these correlations suggest a causal relationship, it is still not a substitute for a longitudinal study proving that the between-group differences are due to training and are not related to genetic causes.

Relating structural differences to functional imaging correlates

Results of functional imaging studies are not always congruent with structural brain imaging studies. Although several studies have reported that musicians have more grey matter and greater cortical thickness in primary and auditory cortex (Heschl's gyrus) (Schneider *et al.* 2002; Gaser and Schlaug 2003), functional studies have actually shown stronger responses in secondary and tertiary auditory brain regions comparing musicians with non-musicians. Interestingly, non-musicians seem to show stronger activation of primary auditory regions (Besson *et al.* 1994; Trainor *et al.* 1999; Shahin *et al.* 2003; 2004; Gaab and Schlaug 2003; Bosnyak *et al.* 2004). Similar results were found in the motor system. Most functional imaging studies comparing musicians with non-musicians have shown that musicians have either less, or more focused activation in the primary motor cortex than non-musicians and more variable levels of activation in motor association regions such as the premotor and supplementary motor areas (Hund-Georgiadis and von Cramon 1999; Jancke *et al.* 2000; Krings *et al.* 2000; Haslinger *et al.* 2004; Meister *et al.* 2005). This contradiction between the pronounced between-group structural differences and within-group structural changes in primary auditory and motor cortices on one hand and the lower degree of functional activation of these regions on the other hand, has not been fully understood. Some argue that as a system becomes more plastic and expands its representation, it may work more efficiently with fewer neurons and thus has less of a metabolic demand or less of a blood flow demand than a naive subject (a non-instrumentalist) might have while performing a behaviourally matched complex motor sequence (Hund-Georgiadis and Von Cramon 1999; Krings *et al.* 2000; Jancke *et al.* 2000; Koeneke *et al.* 2004; Meister *et al.* 2005).

Structural differences are also found in an extended network of multimodal sensorimotor integration regions

Structural brain differences comparing musicians with matched non-musician controls have also been found beyond primary domains in regions such as in the inferior frontal gyrus, the superior parietal lobe including the intraparietal sulcus, the inferior lateral temporal lobe, and the cerebellum (Sluming *et al.* 2002; Hutchinson *et al.* 2003; Gaser and Schlaug 2003), yet the functional role of these differences/changes in extra-primary domain regions is not fully understood. It is possible that parietal regions might play a role in multisensory encoding such as in the integration of auditory information with other sensory (e.g. visual) information. The prominent activation of the superior parietal lobule in musical sight-reading (Sergent *et al.* 1992) may be reflective of the sensorimotor transformation of a visuospatial representation (musical notation) to a pattern of intended movements and position of fingers on the keyboard. Stewart and colleagues (2003) were able to show that the superior parietal lobe (SPL) showed activity changes when comparing functional images obtained while musically naive subjects played melodies from notation before and after a 15-week training period that involved reading music and playing the keyboard. This is further support for the notion that the SPL is involved in the sensorimotor translation of visual–spatial representation into a motor programme.

Strong structural differences in the frontal lobe, particularly in the left inferior frontal gyrus (IFG), have been found in two independent studies (Sluming *et al.* 2002; Gaser and Schlaug 2003). The left IFG has also been found to be activated in various functional imaging

studies using musical tasks. The interest in the inferior frontal lobule has been sparked further in recent years, as more studies have found this region to be a critical link in the auditory–motor network. However, the frontal lobe also plays a more general role in music-making which can range from integration of individual auditory events into larger units, making predictions about and recognizing alterations in sequential auditory–perceptual events, and in mapping actions to their associated sounds (Koelsch *et al.* 2002; Levitin and Menon, 2003; Lotze *et al.* 2003; Bangert and Altenmueller 2003; Bangert *et al.* 2006; Lahav *et al.* 2007; Zatorre *et al.* 2007).

It is possible that the specific and continuous engagement of this multimodal sensorimotor integration network and the induced changes in this network across a musician's career may be the neural basis for some of the cognitive enhancements attributed to musical training. A form of cross-modal plasticity, induced by musical training, could affect extra-musical behavioural and cognitive tasks when those tasks engage regions that are altered through long-term music-making. Evidence for this hypothesis does already exist in the form of finding parietal activation with mathematical tasks (Chochon *et al.* 1999) that coincides with regions of activation induced by music making and musical sight-reading in particular (Sergent *et al.* 1992; Stewart *et al.* 2003), or the congruence of activations in the inferior parietal cortex with musical memory task and language tasks, both utilizing network components of the phonological loop (Gaab *et al.* 2003, 2006). Other examples include IFG activation while performing sequential, non-musical mental operations (Sluming *et al.* 2007) or while performing various speech and language tasks but also while performing musical tasks of auditory-motor mapping, integration of individual

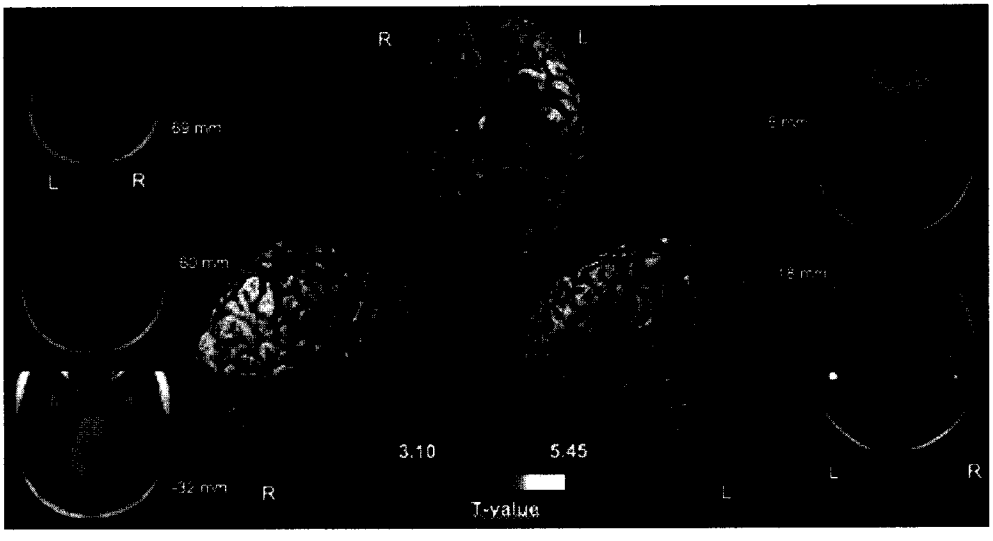

Fig. 18.1 A voxel-based morphometric study showing grey matter volume differences between three groups. Only voxels exhibiting a significant positive correlation between musician status (professional musician > amateur musician > non-musician) and increased grey matter volume are shown here, and those have been overlaid on the rendered cortical surface of a single subject. The distinction between professional and amateur musicians in this study was based on whether or not the keyboard player's main profession was being a musician (e.g., music teacher, performer). There was also a clear separation between both groups in terms of average practice intensity across their careers, with professional keyboard players having approximately double the amount of practice time than the group of amateur musicians. (This figure was adapted from Figure 1 in Gaser and Schlaug [2003]). See colour plate section.

studies using musical tasks. The interest in the inferior frontal lobule has been sparked further in recent years, as more studies have found this region to be a critical link in the auditory–motor network. However, the frontal lobe also plays a more general role in music-making which can range from integration of individual auditory events into larger units, making predictions about and recognizing alterations in sequential auditory–perceptual events, and in mapping actions to their associated sounds (Koelsch *et al.* 2002; Levitin and Menon, 2003; Lotze *et al.* 2003; Bangert and Altenmueller 2003; Bangert *et al.* 2006; Lahav *et al.* 2007; Zatorre *et al.* 2007).

auditory events into larger units, or making predictions about and recognizing alterations in structured musical sequences (Koelsch *et al.* 2002, 2005; Patel 2003; Tettamanti and Weniger 2006; Lahav *et al.* 2007).

Within-musician differences—stronger evidence for a causal effect

Further support for brain plasticity as an explanation for the anatomical differences between adult musicians and non-musicians comes from comparisons of musician groups that play different instruments. Pantev and colleagues (2001) found more pronounced cortical responses to trumpet and string tones in the respective players of those instruments, suggesting that perceptual markers of brain activity differ as a function of the instrument played and constantly heard (Pantev *et al.* 2001). In the absence of longitudinal data examining causal relationships, the search for structural brain differences within a heterogeneous group of musicians is a valuable alternative to support the notion of structural brain adaptation. For example, string-players strongly differ from keyboard players in the specific fine motor (hand/finger) skills required for playing their instruments. While string players need highly developed fine motor skills of their left hand and more gross motor skills of the right, keyboard players require highly developed fine motor skills of both hands but with greater facilities in their right hand since the left hand frequently functions as more of an accompaniment in keyboard music. When comparing string and keyboard players, Bangert and Schlaug (2006) found gross anatomical differences in the precentral gyrus (Figure 18.2). Further, the majority of the adult keyboard players had an elaborate configuration (known as 'Omega Sign') of the precentral gyrus on the left more than in the right hemisphere, while most of the adult string players had this 'atypicality' only on the right. Although a genetic cause for the Omega Sign atypicality in this strongly right-handed group of musicians (i.e., a differential hemispheric expression favouring string playing in those who have a prominent

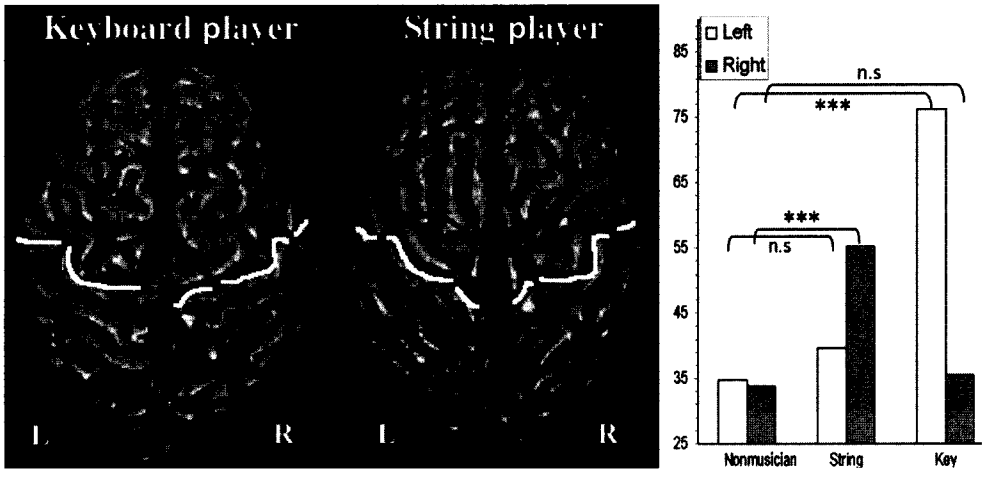

Fig. 18.2 Brain surface renderings of one typical keyboard and one typical string player. The central sulcus is marked with a white line. The portion of the precentral gyrus containing the gyral configuration similar to that of the inverted Greek letter 'Omega' is found within the red circles. In the two examples, a prominent omega sign can be seen on the left more than the right in the keyboard player, and only on the right in the string player. Across the entire group, we found significantly more prominent 'Omega signs' in the right hemisphere of string players compared to the right hemisphere of non-musicians and in the left hemisphere of keyboard players compared to the left hemispheres of both non-musicians and string players. See colour plate section.

Omega Sign in the right hemisphere and keyboard playing in those who have a prominent Omega Sign in their left hemisphere) cannot be completely ruled out, a correlation between the degree of the Omega Sign's prominence and the musicians' age at commencement of musical training, as well as with the cumulative amount of practice time accrued across the years strongly argues for a structural plasticity mechanism.

We also tested whether or not morphological differences between musicians and non-musicians (more elaborate motor cortex and larger midsagittal corpus callosum) have neurophysiological correlates. The larger midsagittal callosal size might reflect a more elaborate interaction between both hemispheres facilitating independent finger movements of both hands. Using transcranial magnetic stimulation (TMS), Ridding *et al.* (2000) found a reduced transcallosal inhibition and Nordstrom and Butler (2002) reported a reduced intracortical inhibition (ICI) and facilitation (ICF) in musicians. Although finding neurophysiological differences between musicians and non-musicians supports the notion that anatomical differences have neurophysiological correlates, these TMS results were counter-intuitive and contrary to what was expected. We used TMS to assess the interhemispheric interaction in a group of 21 right-handed adults (7 keyboard players, 7 string players and 7 non-musicians). We found that keyboard players have a stronger inhibition from the left to the right (LtoR) hemisphere while string players have a stronger inhibition from the right to the left (RtoL) hemisphere. The degree of inter-hemispheric inhibition (IHI) correlated with the size of the fourth and fifth segment (midbody) of the corpus callosum that contains fibres connecting primary sensorimotor cortex (Figure 18.3 c and d). Non-musicians showed similar IHI from either hemisphere. Since inhibitory interneurons in the primary motor cortex are known to mediate transcallosal inhibitory input to the homologous area in the opposite hemisphere, our results suggest that strengthening the activity of these inhibitory interneurons may be one mechanism by which different regions of the brain exert inhibitory control over those homologous regions in the opposite hemisphere. In addition, in within- and between-group comparisons, string players had significantly greater intracortical facilitation (ICF) in (1) their right hemisphere than their left, and (2) the right hemisphere of non-musicians. The stronger ICF in string players' right hemisphere (controlling the left hand) most likely points to neural processes providing excitatory input to the corticospinal neurons involved in precise, fine motor control of the left hand (Nair *et al.* 2006).

Cognitive and brain changes when children learn to play a musical instrument

To determine whether the structural and functional differences seen in adult musicians reflect adaptations due to musical training during sensitive periods of brain development, or are instead markers of musical interest and/or aptitude that existed prior to training, it is necessary to examine children and/or adults before the onset of instrumental music training and compare them to a group of control subjects not planning to play and practice regularly on a musical instrument. For the past five years we have been conducting a longitudinal study of the effects of music training on brain development and cognition in young children (Overy *et al.* 2004; Norton *et al.* 2005; Koelsch *et al.* 2005; Schlaug *et al.* 2005). We have tested a large group of 5–7-year-old children prior to initiation of music lessons (baseline), approximately two-thirds of whom chose to take piano lessons and one third chose string lessons. We also tested a slightly smaller, untreated control group matched to the instrumental group in age, socio-economic status (SES), and verbal IQ. Each child underwent a battery of tests (for details see Norton *et al.* 2005). We found no pre-existing cognitive, auditory perceptual, motoric, or structural brain differences between the children that entered the instrumental group and those that entered the control group at baseline (Norton *et al.* 2005), thereby making it unlikely that children who choose to learn an instrument do so because they have an atypical brain. After an average follow-up interval of 15 months, we found significantly greater change scores in the instrumental group than in the control group in skills directly linked to

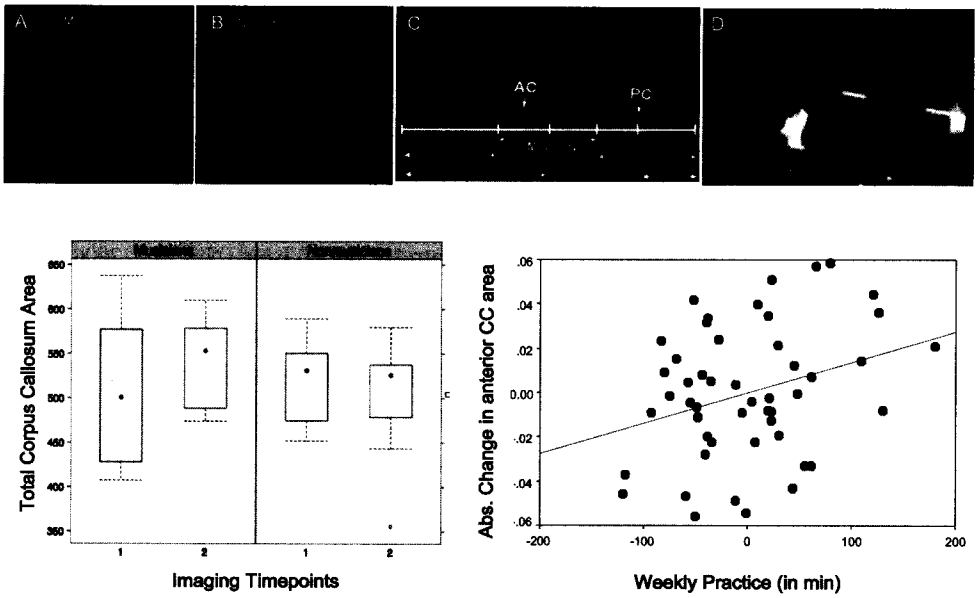

Fig. 18.3 Corpus callosum differences in adults (musicians vs non-musicians) and changes over time in children. (A) and (B) Show the midsagittal slice of an adult musician (A) and non-musician (B) showing a difference in the size of the anterior and midbody of the corpus callosum. (C) and (D) Show the major subdivisions of the corpus callosum and locations of the interhemispheric fibers connecting the motor hand regions on the right and left hemisphere through the corpus callosum. (E) and (F): The mean (dot inside box plots) midsagittal corpus callosum size of the 5–7-year-old children at baseline (time point 1) and after 15 months of musical training (time point 2) shows slightly opposite trends with the instrumental group showing an increase in the midsagittal corpus callosum area. The anterior portion of the corpus callosum (segments 1–4, see Fig. 18.3c) showed a significant correlation with the amount of weekly practice ($p = 0.034$; partial $r^2 = 0.094$). See colour plate section.

instrumental music training: fine motor skills and auditory discrimination skills including both rhythmic and melodic discrimination. At this time point, no significant between-group differences were seen in non-primary domains such as verbal and visuospatial skills (Forgeard *et al.* submitted). However, our analyses did reveal trends for between-group differences in several of the extra-primary domains or transfer domains (e.g., verbal skills), suggesting that a longer period of observation might lead to significant between-group differences in these transfer domains. Children with higher intensity of practice had stronger trends in these outcome variables. Brain imaging data also support this trend. There was a strong trend for a greater increase in midsagittal corpus callosum size in the instrumental group than in the control group and there was a correlation between practice intensity and change in the anterior corpus callosum (Figure 18.3 e and f).

In addition to our longitudinal study of 5–7-year-old children learning to play a musical instrument, we also have preliminary data on a cross-sectional study of 9–11-year-old instrumentalists with an average of 4–5 years of music training and a group of non-musicians matched in age, handedness, and SES. Preliminary results from this cross-sectional study showed that the instrumentalists also performed significantly better in skills directly linked to instrumental music training: fine motor skills and auditory discrimination skills including both rhythmic and melodic discrimination. In addition, we

instrumental music training: fine motor skills and auditory discrimination skills including both rhythmic and melodic discrimination. At this time point, no significant between-group differences were seen in non-primary domains such as verbal and visuospatial skills (Forgeard *et al.* submitted). However, our analyses did reveal trends for between-group differences in several of the extra-primary domains or transfer domains (e.g., verbal skills), suggesting that a longer period of observation might lead to significant between-group differences in these transfer domains. Children with higher intensity of practice had stronger trends in these outcome variables. Brain imaging data also support this trend. There was a strong trend for a greater increase in midsagittal corpus callosum size in the instrumental group than in the control group and there was a correlation between practice intensity and change in the anterior corpus callosum (Figure 18.3 e and f).

In addition to our longitudinal study of 5–7-year-old children learning to play a musical instrument, we also have preliminary data on a cross-sectional study of 9–11-year-old instrumentalists with an average of 4–5 years of music training and a group of non-musicians matched in age, handedness, and SES. Preliminary results from this cross-sectional study showed that the instrumentalists also performed significantly better in skills directly linked to instrumental music training: fine motor skills and auditory discrimination skills including both rhythmic and melodic discrimination. In addition, we

found between-group differences in other domains such as verbal skills and visual pattern matching skills with the instrumentalists performing better on these tests. Furthermore, the 9–11-year-old instrumental group had significantly more grey matter volume that was regionally pronounced in the sensorimotor cortex bilaterally. These between-group differences suggest that a longer duration of musical training and also a longer duration of observation in longitudinal studies together with a higher practice intensity makes it more likely to find significant within-group and between-group structural changes.

There is a widespread view that learning to play a musical instrument in childhood stimulates cognitive development and leads to the enhancement of skills in a variety of extra-musical areas which is commonly referred to as transfer (Bangerter and Heath 2004; Bruer 1999). The most commonly observed form of transfer occurs when there is a close resemblance between the training domain and the transfer domain (typically referred to as 'near transfer'), (e.g., fine motor skills that develop while learning to play a musical instrument lead to increased speed and accuracy in typing). While near transfer effects are relatively common, it is notoriously difficult to demonstrate far transfer, where the resemblance between training and transfer domains is much less obvious (e.g., learning to read and perform with precision from musical rhythm notation and understanding fractions in math). Evidence of far transfer from instrumental music training has previously been claimed in the areas of verbal, spatial, mathematical, and IQ performance (Rauscher *et al.* 1993, 1997; Rauscher and Zupan 2000; Chan *et al.* 1998; Vaughn 2000; Hetland 2000; Ho *et al.* 2003; Schellenberg 2004; Fauvel *et al.* 2006). In a randomized experimental study, Schellenberg (2004) showed that a group of 6-year-olds who received keyboard or voice lessons for 36 weeks had significantly larger (although modest) increases in full-scale IQ and standardized educational achievement tests than matched groups of children receiving either drama lessons or no lessons. Schellenberg argued that music lessons simply function as additional schooling—requiring focused attention, memorization, and the progressive mastery of technical skills: it is well established that schooling increases IQ (Ceci and Williams 1997). In our 9–11-year-old cross-sectional comparison, we found differences in several but not all domains. The linear relationship between practice intensity and outcome variables in several far transfer domains strongly suggests a causal relationship, but is not absolute proof of it. The possibility of a causal link between music training and enhanced performance on transfer outcomes was confirmed for near transfer in our longitudinal study after a 15-month observation period. The trends that we observed in other domains suggest that a longer observation period and/or higher intensity of training and practice may be required in order to see effects in far transfer domains.

Making music specifically engages and changes a seeing-hearing-doing (mirror neuron) network

Musicians and non-musicians show strong differences in a functional brain network that is activated while listening to music. In addition to primary and secondary perceptual regions, this functional network also includes regions in the parietal and frontal lobes. Figure 18.4 shows this extensive functional network in a group comparison of adult musicians and non-musicians, and in 5–7-year-old children prior to music training, all of whom performed the same rhythmic discrimination task while their brain activity was being measured with functional magnetic resonance imaging (fMRI). Normal maturational changes can be seen in the comparison between the adult non-musicians and the musically naive children, while maturational changes modulated by musical experiences result in a different pattern of activation.

The additional regions activated in adult musicians include the parietal lobe (around the intraparietal sulcus), the posterior middle frontal gyrus (Brodmann area 6), and the inferior frontal gyrus (Brodmann areas 44, 45, and 47). In the paragraphs below, I will concentrate on discussing frontal lobe differences, since these regions show the most pronounced between-group differences.

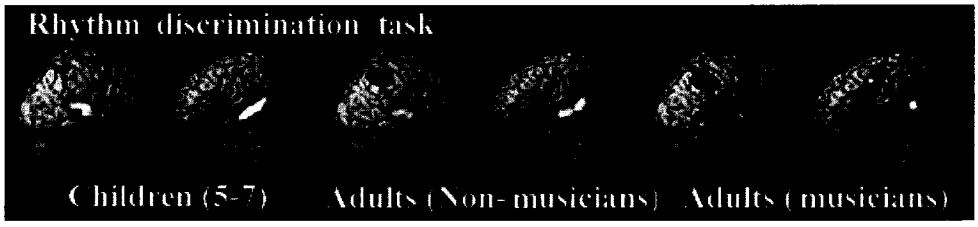

Fig. 18.4 Cerebral activation pattern of a rhythm discrimination task – modulated by maturation and experience. Statistical parametric images superimposed onto a surface rendering of a standardized anatomical brain depict significant activations during a rhythmic discrimination task in a group of 5–7-year-old, musically naive children, adult non-musicians, and adult musicians. The children showed prominent superior temporal gyrus activation on both sides. The adult groups show an extended pattern of activation involving polar and posterior planar regions of the superior temporal lobe as well as the parietal lobe, parts of the frontal lobe, and the cerebellum. Adult musicians differ from adult non-musicians by having less activation of the primary auditory cortex, but more activation of frontal regions bilaterally, particularly in the inferior frontal gyrus. See colour plate section.

Using functional imaging, it has been found that instrumental practice leads to the establishment of an auditory and visual–sensorimotor network (Bangert and Altenmueller 2003; Bangert *et al.* 2006). Listening to sounds of (and/or seeing) well-learned actions elicits involuntary activity in a network of brain regions (Haueisen and Knösche 2001; Kohler *et al.* 2002; Keysers *et al.* 2003; Hasegawa *et al.* 2004; Haslinger *et al.* 2005; Bangert *et al.* 2006; D'Ausilio *et al.* 2006; Lahav *et al.* 2007). A prominent component of this brain network is the posterior inferior frontal gyrus (IFG) (commonly referred to as Broca's region). It has been shown that the IFG is activated when one sees meaningful, goal-directed actions or hears action-related sounds including grasping food (Rizzolatti *et al.* 1996), imitating hand gestures (Buccino *et al.* 2004a), playing of guitar chords (Buccino *et al.* 2004b), hearing action words (Pulvermuller *et al.* 2005; Aziz-Zadeh *et al.* 2006), hearing instrumental sounds that are associated with motor actions (Lahav *et al.* 2007), as well as when the action is executed. These are functions and properties of a system that is commonly described as mirror neuron system. Mirror neurons were originally described by Rizzolatti *et al.* (1996) in region F5 in monkeys which is considered to be the precursor or homolog of Broca's region or the posterior IFG in humans (Rizzolatti and Arbib, 1998). 'Audiovisual' mirror neurons seem to encode the action abstractly, independent of the information source (auditory or visual) from which evidence regarding the presence of the action is taken (Keysers *et al.* 2003). These 'auditory–visual' mirror neurons exemplify high-level abstraction in the representation of actions—an identical neural system becomes activated whenever a particular action is heard, seen or performed. It is of particular interest that two, independent, voxel-based morphometric studies found more grey matter volume in the inferior frontal gyrus in musicians compared with non-musicians (Sluming *et al.* 2002; Gaser and Schlaug 2003; see also Figure 18.1) which in addition to parietal regions (supramarginal gyrus and superior parietal lobule) and more dorsal premotor regions constitute this network of multimodal–sensorimotor integration. Listening to, seeing notation for, and watching performances of music that one knows how to play, and actually playing that music all appear to engage this putative human mirror neuron system.

Conclusions

Making music not only engages primary auditory and motor regions and the connections between them, but also engages regions that integrate and connect areas involved in both auditory and motor operations as well as in the integration of other multisensory information.

Fig. 18.4 Cerebral activation pattern of a rhythm discrimination task – modulated by maturation and experience. Using functional imaging, it has been found that instrumental practice leads to the establishment of an auditory and visual–sensorimotor network (Bangert and Altenmueller 2003; Bangert *et al.* 2006). Listening to sounds of (and/or seeing) well-learned actions elicits involuntary activity in a network of brain regions (Haueisen and Knösche 2001; Kohler *et al.* 2002; Keysers *et al.* 2003; Hasegawa *et al.* 2004; Haslinger *et al.* 2005; Bangert *et al.* 2006; D'Ausilio *et al.* 2006; Lahav *et al.* 2007). A prominent component of this brain network is the posterior inferior frontal gyrus (IFG) (commonly referred to as Broca's region). It has been shown that the IFG is activated when one sees meaningful, goal-directed actions or hears action-related sounds including grasping food (Rizzolatti *et al.* 1996), imitating hand gestures (Buccino *et al.* 2004a), playing of guitar chords (Buccino *et al.* 2004b), hearing action words (Pulvermuller *et al.* 2005; Aziz-Zadeh *et al.* 2006), hearing instrumental sounds that are associated with motor actions (Lahav *et al.* 2007), as well as when the action is executed. These are functions and properties of a system that is commonly described as mirror neuron system. Mirror neurons were originally described by Rizzolatti *et al.* (1996) in region F5 in monkeys which is considered to be the precursor or homolog of Broca's region or the posterior IFG in humans (Rizzolatti and Arbib, 1998). 'Audiovisual' mirror neurons seem to encode the action abstractly, independent of the information source (auditory or visual) from which evidence regarding the presence of the action is taken (Keysers *et al.* 2003). These 'auditory–visual' mirror neurons exemplify high-level abstraction in the representation of actions—an identical neural system becomes activated whenever a particular action is heard, seen or performed. It is of particular interest that two, independent, voxel-based morphometric studies found more grey matter volume in the inferior frontal gyrus in musicians compared with non-musicians (Sluming *et al.* 2002; Gaser and Schlaug 2003; see also Figure 18.1) which in addition to parietal regions (supramarginal gyrus and superior parietal lobule) and more dorsal premotor regions constitute this network of multimodal–sensorimotor integration. Listening to, seeing notation for, and watching performances of music that one knows how to play, and actually playing that music all appear to engage this putative human mirror neuron system.

Conclusions

Making music not only engages primary auditory and motor regions and the connections between them, but also engages regions that integrate and connect areas involved in both auditory and motor operations as well as in the integration of other multisensory information.

Professional instrumentalists learn and repeatedly practice associatiing hand/finger movements with meaningful patterns in sound, and sounds and movements with specific visual patterns (notation) while receiving continuous multisensory feedback. Learning to associate actions with particular sounds leads to functional but also structural changes in frontal cortices. In considering the putative functions of the inferior frontal regions, including its hypothesized role as a supramodal hierarchical processor, auditory–motor mapping region, and hub of the mirror neuron system, it may not be surprising to see that some of the most pronounced differences between musicians and non-musicians, both structurally and functionally, are indeed, in the inferior frontal region. Training this network and changing it as a result of that training has a cross-modal effect on other behavioural/cognitive operations that draw on this network. This cross-modal plasticity in multimodal brain regions may explain some of the cognitive enhancements and/or far transfer effects that have been associated with long term instrumental music training.

CHAPTER 19

Music and the brain

Three links to language

Aniruddh D. Patel

Introduction

A major theme in the neuroscience of music over the past decade has been the existence of specialized cognitive and neural mechanisms involved in music processing (Peretz and Coltheart 2003). Research with brain damaged patients has been particularly important in demonstrating that music involves a neurocognitive system with many components, and that certain components can be selectively damaged without obvious effects on other cognitive abilities. These findings point to some degree of brain specialization for music, specialization that emerges even in the absence of any explicit musical training (Bigand and Poulin-Charronnat 2006).

One can recognize that music is a unique confluence of component abilities, yet still search for connections between music cognition and processes involved in other cognitive domains, such as language, visuospatial thinking, or mathematics. Such comparative work can be revealing about the mechanisms underlying music processing, and can provide new avenues for exploring how these mechanisms work in the brain.

The goal of this chapter is to acquaint the reader with some of the evidence for links between music and language, and to encourage further exploration along these lines (see Patel 2008 for a fuller treatment). The focus is on perceptual processes, and on links between mechanisms involved in the processing of instrumental music and of ordinary, day to day language.

Sensory encoding of sound

There is growing evidence that musical abilities and training have repercussions for language skills. For example, musical abilities predict unique variance in the ability to perceive and produce subtle phonetic contrasts in a second language (Slevc and Miyake 2006) and in the reading abilities of young children in their first language (Anvari *et al.* 2002). Furthermore, musical training enhances the ability to interpret affective prosody (Thompson *et al.* 2004). Are these benefits simply a non-specific consequence of musical training on attention and executive functioning, or are there more specific links between musical abilities and language processing? Support for the latter view has emerged recently via neuroscientific investigations of brainstem encoding of sound. These studies suggest that musical abilities and/or training sharpen the brain's encoding of linguistic sound at a very early stage of processing.

The human brainstem contains many subcortical processing nuclei, which perform a significant amount of neural processing before sound reaches the cortex. Importantly, these lower brain centres are connected to cortical areas via both bottom-up and top-down connections (cf. Figure 1 of Patel and Iversen 2007). The latter ('corticofugal') connections provide one possible mechanism by which long-term auditory experience may influence early brain responses to sound, via mechanisms of neural plasticity.

Wong *et al.* (2007) first demonstrated an influence of musical abilities on linguistic sound encoding. These researchers examined the

processing of linguistic pitch contours in Mandarin Chinese syllables by musically trained and untrained native English speakers (neither of whom was familiar with Mandarin). The participants listened passively to Mandarin monosyllables with different lexical tones while their brainstem responses were recorded using electroencephalography (EEG). The researchers found that the musicians showed superior brainstem encoding of the linguistic pitch patterns. They also found a positive correlation between the quality of sensory encoding and amount of musical training, suggesting a role for musical experience (rather than innate differences between musicians and non-musicians) in shaping the sensory encoding of linguistic sound.

An impact of musical abilities on linguistic pitch processing seems intuitively plausible because music places strong demands on the control and/or perception of pitch. However, speech also makes extensive use of structured auditory patterns not based on pitch (e.g., timbre-based differences between phonemes). Do musical abilities have any impact on the sensory encoding of timbre-based aspects of language sounds? Recent results by Musacchia *et al.* (2007) address this issue. Like Wong *et al.* (2007), these researchers measured auditory brainstem responses to speech using EEG, but this time to a familiar English syllable ('da') with no salient pitch variation. They found that musicians had earlier brainstem responses than non-musicians to the onset of the syllable. Interestingly, when the syllable was presented as a multimodal event (sound + video of a face saying the syllable), the latency of the brainstem response was shortened for both musicians and non-musicians, but the musicians still showed an earlier response than the non-musicians. The authors suggest that this difference in response latency indicates that musicians had more synchronous neural responses to sound onset, which is a sign of a high-functioning peripheral auditory system.

The superior encoding of linguistic sounds by musicians may be one possible mechanism underlying the linguistic benefits of musical abilities (cf. Tallal and Gaab 2006; Patel and Iversen 2007). These findings may also be relevant to research which has examined the impact of musical training on the cortical processing of linguistic pitch patterns. These studies have examined how well individuals can detect a deviation in voice fundamental frequency (F0) at the end of a spoken utterance. Using EEG, these studies have focused on cortical event-related potentials (ERPs) which occur with a latency of a few hundred milliseconds after the onset of the deviant event. Research with French-speaking adults (Schön *et al.* 2004) and 8-year-old children (Magne *et al.* 2006) has shown that musically trained listeners are better at detecting such deviations, and show enhanced cortical ERPs to these events. In fact, even when listening to sentences in a foreign language (Portuguese), French adults with musical training are better at detecting such deviations, and show substantially shorter latency in their cortical ERPs to those deviations (Marques *et al.* 2007). One notable finding of this line of research is that the influence of musical training on cortical responses emerges remarkably quickly: 8-year-old children with just 8 weeks of musical training differ from their musically untrained counterparts in their cortical ERPs to intonational deviations in speech (Moreno and Besson 2006).

Further work is needed to clarify the relationship between subcortical and cortical enhancements to linguistic sound processing associated with musical training. Since connections in the auditory pathway flow both bottom-up and top-down, experimental studies are needed to disentangle patterns of cause and effect at different levels of the nervous system as the brain changes in response to musical training. Ideally, such studies would measure subcortical and cortical ERP responses to linguistic pitch patterns within the same individuals as they undergo musical training programmes, and relate these measures to behavioural performance on pitch-related language tasks. Baseline measures of brain responses to linguistic sound (prior to musical training) would be desirable, to show that differences between musically trained and untrained groups are not present prior to training (cf. Norton *et al.* 2005).

Processing of melodic contours

Humans readily recognize a pitch pattern transposed upward or downward in frequency

(e.g., the same melody played on a piccolo or a tuba). This sensitivity to relative (vs absolute) pitch patterns seems commonplace to us, yet a cross-species perspective reveals that this is a rare ability (McDermott and Hauser 2005). Most birds and non-human primates, for example, gravitate to absolute pitch cues in identifying pitch sequences, and extensive training is often needed before sensitivity to relative pitch can be demonstrated.

This specialization in human brains for sensitivity to relative pitch may be related to the importance of relative pitch in spoken intonation. A listener needs to be able to hear the similarity of intonation patterns when spoken in different pitch registers. For example, a child learning English needs to understand that a rising pitch at the end of an intonation contour can signal a question, whether the utterance is produced by another child or by an adult (with a much lower average F0). Similarly, the child needs to learn that a salient pitch excursion on a word in a sentence signals that the speaker is trying to put focus on that word (as in 'give me the RED toy'), even though the precise size of the pitch excursion may differ from one speaker to the next. Thus speech intonation perception requires processing of melodic contour: the general patterns of up and down in a pitch sequence, independent of exact interval sizes or absolute pitch height (Dilley 2005).

Many experiments on music have shown that melodic contour is an important component of music perception. For example, Dowling and colleagues have shown that melodic contour (vs the pattern of precise intervals in a melody) plays a role in immediate memory for unfamiliar melodies among adults (e.g., Dowling *et al.* 1995). Furthermore, melodic contour is one of the first aspects of music to be discriminated by infants (Trehub *et al.* 1984), and 5-year-old children rely heavily on contour in melody perception (Schellenberg and Trehub 1999). Studies of patients with brain damage indicate that the right superior temporal gyrus plays an important role in musical melodic contour perception (Peretz and Zatorre 2005, but cf. Stewart *et al.* 2008).

Given the importance of melodic contour in both speech and music, it is natural to ask whether melodic contours are processed by similar brain mechanisms in the two domains. Early evidence for this idea was provided by Patel *et al.* (1998), who studied two individuals with acquired amusia subsequent to cortical brain damage. The amusics were tested for their ability to discriminate between sentences that differed only in their intonation contour. Two types of sentence pairs were tested. In 'statement–question' pairs, the intonation contours differed at the end of the sentence (e.g., 'He likes to drive fast cars' spoken with a pitch fall or rise on 'cars'). In 'focus–shift' pairs, the intonation contours differed within the sentence (e.g., 'Go in front of the bank, I said' spoken with a salient pitch accent on 'front' or 'bank'). The amusics were also tested for their ability to discriminate tone sequence analogues of intonation patterns. These analogues were created by replacing each syllable in a sentence with a tone whose pitch was fixed at the frequency midway between the highest and lowest F0 of the syllable. Discrete tones were used rather than gliding tones (which would mimic intonation contours more precisely) in order to make the stimuli more music-like. The salient finding from this study was that for both amusics, performance on the linguistic intonation task was very similar to performance on the tone sequence task, suggesting shared processing of melodic contours across the two domains. (One amusic, whose problem was primarily with recognition of familiar music, did well on both tasks, while the other amusic, who had more basic problems with perception and discrimination of musical patterns, did poorly on both tasks.) Examination of the lesion profiles of the amusics suggested that right inferior frontal brain areas were important for the task of remembering and discriminating melodic contours (cf. Zatorre *et al.* 1994).

In contrast to these findings, subsequent research with musically tone-deaf individuals painted a different picture. Before discussing this work, it is worth briefly describing musical tone deafness (or congenital amusia). Congenital amusia (henceforth, 'amusia') is not due to brain damage and appears to be developmental in origin. Amusic individuals report life-long problems with music perception. (Note that it is important to distinguish amusia from the informal label of 'tone-deafness' that many people apply to themselves, usually to indicate that they

do not sing well, cf. Cuddy *et al.* [2005]). For example, amusics have difficulty judging if two melodies are the same or different, in detecting when music is out of key (including their own singing), and in recognizing what should be familiar tunes from their culture (Ayotte *et al.* 2002). These problems cannot be attributed to hearing loss, lack of exposure to music, or to any obvious non-musical social or cognitive impairments. The core deficit in this disorder concerns pitch processing (Foxton *et al.* 2004; Hyde and Peretz 2004). It appears that there is a genetic basis for this disorder (Drayna *et al.* 2001; Peretz *et al.* 2007), and evidence from neuroimaging has revealed specific structural differences between normal and amusic brains in right inferior frontal cortex and right superior temporal gryus, as well as in left frontal and temporal cortical areas (Hyde *et al.* 2007; Mandell *et al.* 2007).

Amusia presents an excellent opportunity to study the relationship between melodic contour processing in speech and music. Ayotte *et al.* (2002) first examined speech intonation perception in congenital amusia, using the stimuli and methods of Patel *et al.* (1998). The amusics had no problem discriminating sentences with different intonation contours. In contrast, they had difficulty discriminating the tone sequence analogs of intonation. These results suggested that amusics were unimpaired in speech intonation perception, and prompted Peretz and Coltheart (2003) to include melodic contour analysis as a domain-specific aspect of musical processing, not shared with speech.

Subsequent work, however, has re-opened the issue of speech intonation perception in amusia. Lochy *et al.* (2004) tested a group of amusics using methods very similar to those of Ayotte *et al.* (2002), but with different results. This time, about 30 per cent of the amusics had significant difficulty discriminating linguistic statements from questions, whereas they did well discriminating sentences with focus on different words. The critical difference between these tasks is that the statement-question task requires discriminating the direction of pitch movement on the same word (up versus down), whereas the focus-shift task simply requires detecting a salient pitch movement within a sentence, because different words bear the large movement in the two members of a focus-shift pair. That is, sensitivity to the direction of pitch movement is irrelevant to the focus-shift task: as long as one can detect a pitch change, and can remember that this change happened on the same or different words in the two sentences, one can solve the task.

These findings were intriguing because psychophysical work on amusia has revealed a salient deficit for the perception of pitch direction (Foxton *et al.* 2004; Griffiths *et al.* 2007). That is, an amusic individual may be able to detect that pitch has changed, but not be able to discriminate an upward from a downward change. Lochy *et al.*'s findings suggest that such direction discrimination deficits may be relevant for speech intonation perception. Given the differences between the findings of Ayotte *et al.* (2002) and Lochy *et al.* (2004), it is important to determine which results replicate. Recently, Patel *et al.* (2008) replicated Lochy *et al.*'s findings with a different group of amusics, finding that about 30 per cent had problems with statement-question discrimination but not focus-shift discrimination. Notably, this replication occurred in a different language (English-speaking amusics, vs the French-speaking amusics of Lochy *et al.*). An important question raised by the results of Lochy *et al.* (2004) and Patel *et al.* (2008) is why only a subset of amusics (~30 per cent) exhibit intonation perception deficits. Does this subset have a qualitatively different kind of deficit from amusics without such problems, or are they simply at the end of a continuum such that all amusics would show intonation perception problems if pitch contrasts are made subtle enough? These questions await further research, but the current findings are sufficient to indicate that melodic contour processing in speech and music may in fact have overlapping neural substrates.

Syntactic processing

Music and language involve hierarchically structured sequences built from basic units via rich combinatorial principles. That is, both are syntactic systems. Native listeners have implicit knowledge of these combinatorial principles, knowledge which requires no formal training

and which can readily be demonstrated via judgements of the well-formedness of novel sequences and via a range of implicit tasks (Bigand and Poulin-Charronnat 2006).

Despite these general similarities, however, it is also clear that musical and linguistic syntax differ in important ways. For example, fundamental grammatical categories in language (such as nouns and verbs) have no analogue in music, and the function of linguistic syntax in indicating 'who did what to whom' also has no musical parallel. Instead, (Western) musical syntax is based on selecting a set of seven discrete pitches within each octave and creating a musical 'key' by using these pitches in such a way that a hierarchy of structural importance is created among them. This leads to certain pitches and chords being perceived as more stable than others. These stable elements act as cognitive reference points, with one (the tonic note or chord) being the most stable (Krumhansl 1990). This syntax functions to build patterns of tension and resolution in musical sequences (Lerdahl and Jackendoff 1983, Lerdahl and Krumhansl 2007). Thus it is clear that musical syntax is not simply a trivial variant of linguistic syntax.

For many years, the evidence from neuroscience seemed to favour the independence of musical and linguistic syntax in the brain. Specifically, research on the neuropsychology of music provided clear cases of dissociations between linguistic and musical syntactic abilities following brain damage. For example, Peretz (1993) documented a case of a non-aphasic man with bilateral temporal lobe damage (due to strokes) who lost sensitivity to musical key, even though his basic perception of pitch patterns was intact. This is one of several well-documented cases of 'amusia without aphasia' (cf. Marin and Perry 1999).

Yet in direct contrast to these findings, neuroimaging research has pointed to overlap in the syntactic processing of language and music. An early study which directly compared brain responses to musical and linguistic syntactic processing in the same individuals was conducted by Patel *et al.* (1998). The researchers used ERPs to compare brain responses (from musicians) to linguistic syntactic and musical syntactic incongruities. The linguistic incongruities involved manipulations of phrase structure in sentences, and the musical incongruities involved out-of-key chords in chord sequences. The linguistic incongruities generated a late positive ERP component known as the P600, previously known to be associated with syntactic processing in language (Osterhout and Holcomb 1993). The main finding of interest was that the out-of-key chords generated a P600 which was statistically indistinguishable from the 'linguistic' P600. The authors interpreted this to mean that processes involved in syntactic integration were shared across the two domains. In addition to the P600, out-of-key chords also elicited an early right anterior–temporal negativity (RATN) which had not been reported in previous neuroimaging studies of music. The functional significance of this component was not well understood, though it was thought to be involved in musical syntactic processing.

Subsequent ERP work by Koelsch *et al.* (2000) examined brain responses to out-of-key chords in non-musicians, and found an early right anterior negativity (ERAN), which had a shorter latency than the RATN and a more anterior and bilateral scalp distribution. Many subsequent studies by Koelsch and colleagues have found the ERAN to be reliably elicited by structurally unexpected chords, in both musicians and non-musicians, and in the absence of any task related to detecting these chords.[1] Furthermore, elicitation of the ERAN does not require the use of an out-of-key chord: it can also be elicited by a structurally unexpected chord from within the key of the preceding sequence. This rules out auditory sensory incongruity as the driving force behind the elicitation of this component (Koelsch *et al.* 2007).

What is the relationship between the ERAN and the RATN? As suggested by Koelsch and Siebel (2005), it seems likely that they represent the same underlying brain process, and that the earlier latency of the ERAN is related to the temporal predictability of the chord sequences

[1] Another ERP component that is often elicited by out-of-key chords is a negativity peaking around 500 ms after the onset of the target chord (the 'N500'). For possible links between mechanisms involved in this brain response and in language processing, see Steinbeis and Koelsch (2007).

that have typically been used in studies of the ERAN. That is, most such research has used isochronous sequences of chords, rendering the temporal onset of each successive chord quite predictable in time. In contrast, when more temporally variable musical contexts are used (as in Patel *et al.* 1998, and Koelsch and Mulder 2002), an early right negative component is elicited that is more similar to the RATN in latency and scalp distribution. Thus the precise latency and distribution of early right negativities to music is likely to be subject to rhythmic influences.

More interesting from the current standpoint are questions about the relationship of the ERAN to brain mechanisms involved in linguistic syntactic processing. Using MEG, Maess *et al.* (2001) localized the generators of the ERAN to Broca's area and its right hemisphere homologue, suggesting an overlap with language processing. Other research using functional magnetic resonance imaging (fMRI) also implicated Broca's area in the processing of syntactic (harmonic) structure in music (e.g. Tillmann *et al.* 2003). Yet the neuroimaging evidence for overlap between linguistic and musical syntax stood in sharp contrast to evidence from neuropsychology for dissociations between linguistic and musical syntactic abilities following brain damage, as discussed above. Thus it became clear that a theoretical framework was needed which could accommodate both the neuroimaging evidence (for overlap) and the neuropsychology evidence (for dissociation).

Patel (2003) proposed one such framework based on the idea that language and music have distinct and domain-specific syntactic representations (such as words and their syntactic features in language, and chords and their harmonic relations in music), but that activating these representations as part of online processing draws on a common pool of limited neural resources. This idea was termed the 'shared syntactic integration resource hypothesis' (SSIRH). The SSIRH posits that linguistic and musical syntactic representations are stored in distinct brain networks (and hence can be selectively damaged), whereas there is overlap in the networks which provide neural resources for the activation of stored syntactic representations. It was hypothesized that such resources are needed when dealing with difficult structural integrations, because such integrations require the rapid and selective activation of items with low activation levels in representation networks (e.g., structurally unexpected words or chords).

How does this proposal map onto neural architecture? At the moment the answer to this question is not known. In its original formulation, the SSIRH combined the functional proposal outlined above with a rough localizationist proposal, namely that that neural resources reside in frontal brain regions, while syntactic representations reside in posterior regions. Hence syntactic processing is conceived of as involving the reciprocal interaction of frontotemporal regions (cf. Tyler and Marslen-Wilson 2007). Further research using localizationist techniques (such as fMRI) is needed to address this issue.

A principal motivation for developing the SSIRH was to generate predictions to guide future research into the relation of linguistic and musical syntactic processing. One salient prediction regards the interaction of musical and linguistic syntactic processing. In particular, because the SSIRH proposes that linguistic and musical syntactic integration rely on common neural resources, and because syntactic processing resources are limited (Gibson 2000), it predicts that tasks that combine linguistic and musical syntactic integration will show interference between the two. In particular, the SSIRH predicts that difficult harmonic integrations in music will interfere with concurrent difficult syntactic integration in language (Patel 2003). This idea can be tested in paradigms in which a harmonic and a linguistic sequence are presented together and the influence of harmonic structure on syntactic processing in language is studied.

Koelsch *et al.* (2005) conducted one such study, in which short sentences were presented visually in a word-by-word format simultaneously with musical chords, with one chord per word. In some sentences, the final word created a grammatical violation via a gender disagreement. (The sentences were in German, in which many nouns are marked for gender. An example of a gender violation used in this study is: 'Er trinkt den kühlen Bier', 'He drinks the$_{\text{masculine}}$

$cool_{masculine}$ $beer_{neuter}$.) The chord sequences were designed to strongly invoke a particular key, and the final chord could either be the tonic chord of that key or an unexpected out-of-key chord from a distant key (e.g., a D-flat major chord at the end of a C-major sequence). The participants (all non-musicians) were instructed to ignore the music and simply judge if the last word of the sentence was linguistically correct.

Koelsch *et al.* focused on early ERP negativities elicited by syntactically incongruous words and chords. Previous research on language or music alone had shown that the linguistic syntactic incongruities were associated with a left anterior negativity (LAN), while the musical incongruities were associated with an ERAN (Gunter *et al.* 2000; Koelsch *et al.* 2000). For their combined language–music stimuli, Koelsch *et al.* found that when sentences ended grammatically but were accompanied by an out-of-key chord, a normal ERAN was produced. Similarly, when chord sequences ended normally but were accompanied by a syntactically incongruous word, a normal LAN was produced. The question of interest was how these brain responses would interact when a sequence had simultaneous syntactic incongruities in language and music. The main finding was that the brain responses were not simply additive. Instead, there was an interaction: the LAN to syntactically incongruous words was significantly *smaller* when these words were accompanied by an out-of-key chord, as if the processes underlying the LAN and ERAN were competing for similar neural resources. In a control experiment, Koelsch *et al.* showed that this was not due to general attentional effects because the LAN was not influenced by a simple auditory oddball paradigm involving physically deviant tones on the last word in a sentence. Thus the study supported the prediction that tasks which combine linguistic and musical syntactic integration will show interference between the two processes. Further behavioural studies by Slevc *et al.* (in press) and Fedorenko *et al.* (in press) using simultaneous presentation of sentences and musical sequences have provided additional evidence for the interaction of linguistic and musical syntactic processing, even in the absence of any explicit music-related task (cf. Patel in press for descriptions of these studies). Like the study of Koelsch *et al.* (2005), these studies have included control conditions to check that the interactions observed are not simply due to attentional factors.

One line of research which awaits exploration involves within-subjects comparisons of syntactic processing in language and music using fMRI. Such work could help localize shared resource networks for syntactic integration within specific regions of the brain.

Future directions

This chapter has discussed three points of contact between music and language processing in the brain. Many other areas of possible overlap await investigation, including the neural mechanisms involved in processing phrase boundaries, and the mechanisms involved in the affective appraisal of musical and linguistic sequences (for further discussion of these topics, see Patel 2008). Another little-explored area concerns the relationship between the neural mechanisms involved in the generation of novel linguistic and musical sequences (cf. Brown *et al.* 2006).

Conclusion

The extent to which music processing overlaps with mechanisms used in other cognitive domains is an active area of research and debate (e.g., Peretz 2006; Patel 2008). One fertile line of work that has grown out of this debate concerns relations between music and language processing. The evidence reviewed in this chapter suggests that music and language may have a number of common processes which act on distinct types of information, e.g., on musical melodies vs linguistic intonation contours, or on chord progressions vs sequences of words. Thus the distinction between the domain specificity of information vs the generality of processing is an essential conceptual tool for research that examines the relationship between music and other cognitive domains (cf. Massaro 1998 for an application of this distinction to the study of speech processing).

Comparative music–language research is still in its infancy. The ultimate promise of such work

is not simply to resolve debates over modularity, but to gain a deeper understanding of the mechanisms humans use to make sense out of sound. This requires doing justice to both the differences and the similarities between the domains.

PART 5

Musical development

Edited by David J. Hargreaves

CHAPTER 20

Prenatal development and the phylogeny and ontogeny of music

Richard Parncutt

Introduction

Prenatal musical development involves the acquisition of perceptual, cognitive, motor and emotional abilities and information that may influence later musical development. I argue in this chapter that research in this area can shed light on the origins of musical behaviours, not only in human prehistory (phylogeny) but also within the lifespan of an individual (ontogeny).

Ontogenetically, the infant is surprisingly sensitive to patterns of sound and movement that adults perceive as musical (Chapter 21 this volume). The origin and evolutionary function (if any) of this sensitivity is unclear. One possibility is that musical patterns are similar to perceptual patterns to which the fetus is regularly exposed before birth: the fundamental frequency trajectory of the mother's voice, its relationship to breathing, and the rhythm of her heartbeat and footsteps (Parncutt 1989, 1993).

In spite of a recent renaissance of research on the phylogeny (origins) of music (summarized by Mithen 2005), no theory currently enjoys broad acceptance. One possibility involves classical conditioning of the fetus during the third trimester by passive exposure to sounds, movements and hormonal changes within the mother's body (Parncutt, in press). Since (changes in) maternal emotional states regularly trigger both (changes in) the patterns of sound and movement to which the fetus is exposed and (changes in) blood hormone levels, the fetus may associate these with each other, giving emotional connotations to patterns of sound and movement.

The importance of the prenatal phase for general psychological development was emphasized by Smotherman and Robinson (1990) and by Hopkins and Johnson (2005). The fetus responds actively to changes in its intrauterine environment in ways that influence its later behavioural and biological development. The prenatal phase may be regarded as a *developmental niche* (cf. Super and Harkness 1986) with its own unique characteristics but also lying on the same developmental continuum as postnatal niches. Although no-one would question that sensation, emotion, cognition and motor abilities have prenatal origins (Hall and Oppenheim 1987), most empirical research about these abilities in the late twentieth century ignored the prenatal period, while at the same time repeatedly asking nature–nurture questions that can only be answered by studying the prenatal epigenesis[1] of behaviour.

[1] The word 'epigenesis' (rather than genesis) refers to the role of both nature (genetics) and nuture (environment), and the interaction between them, in the prenatal emergence of behaviour.

It is problematic to use the term 'music' in conjunction with fetal development. Neither the fetus nor the infant discriminates between music (including singing) and speech; *motherese*[2] (Papousek 1996), the playful vocal-gestural interaction between infants and carers, is a mixture of both. Because motherese is not music but may represent music's origin, the term *protomusic* is appropriate (cf. Fitsch 2006)—by analogy to *protolanguage*, the common ancestor of a group of related languages. For similar reasons, it is misleading to speak of 'womb music'[3] or of 'playing music to cows' (Uetake *et al.* 1997), since the sound patterns presented in such studies are not perceived as music (i.e. not as culturally situated) by the experimental participants. Those patterns may nonetheless have musically interesting physiological, behavioural or cognitive affects.

This chapter focuses on musically relevant psychological aspects of prenatal development: the development of perception, cognition and emotion, the relationships between them, and the musical and musicological implications of those relationships. The chapter begins by surveying relevant fetal sensory abilities: hearing, the vestibular sense of balance and acceleration, and the proprioceptive sense of body orientation and movement. All those senses are relevant for musical development, since in all known cultures music is inseparable from bodily movement and gesture, whether real (Blacking 1995) or implied (Tolbert 2001). The chapter goes on to consider what sounds and other stimuli are available to the fetus: what patterns are the earliest to be perceptually learned? It then considers psychological and philosophical issues of fetal attention, 'consciousness', learning and memory. The chapter closes with speculations about the possible role of prenatal development in the phylogeny of musical behaviours.

[2] I use the term *motherese* rathar than *infant-directed speech* to emphasize the two-way nature of this form of communication (including the active role of the infant) and the musically central role of women (especially in discussions of the phylogeny of music). Of course men (not only fathers) and women other than mothers can and should also speak motherese.

The ontogeny of music

Fetal auditory, vestibular and proprioceptive abilities

All human sensory systems begin to function before birth (Hepper 1992). The acoustical stimulation to which the fetus is exposed is more diverse and carries more information relative to corresponding discriminatory abilities than visual, tactile, olfactory or gustatory (biochemical) stimulation. In that sense, hearing may be regarded as the dominant sensory modality in the prenatal phase, and infancy as a transition from auditory to visual dominance.

The fetus can hear throughout the second half of gestation. Because the fetal inner ear is filled with fluid, much of the sound heard by the fetus is transmitted to the inner ear through the skull by bone conduction (Gerhardt *et al.* 1996; Sohmer *et al.* 2001). The cochlea begins to process sounds at about around 20 weeks gestation; the cochlea reaches adult size at 25 weeks, but continues to develop until birth (Bibas *et al.* 2008). Motor responses to sound begin during the same period (Joseph 2000). At 20 weeks, the fetus is sensitive to a narrow band of spectral frequencies around 300 Hz (Hepper and Shahidullah 1994). As the fetus develops, its auditory abilities—including the perceptible range of spectral frequencies, the discrimination of frequencies and rapid sequences of events, and the storage and recognition of pitch–time patterns—gradually improve and may approach adult levels at birth (Joseph 2000), even though brain myelination is not complete until several years later.

It is physically impossible for the fetus to localize sound sources (Parncutt 2006). First, the fetal head does not cast an acoustic shadow at the relatively low frequencies that are transmitted into the amniotic fluid. Second, interaural time differences are smaller for the fetus than for an adult due to the smaller head size and the faster speed of sound in liquid. The fetus therefore has no access to information about the direction from which sounds emanate. Prenatal sound is monophonic and omnidirectional.

The vestibular system (or organ of balance) begins to function at about the same time as the cochlea. The cochlea and vestibular system

lie at opposite ends of the (bony/osseous) labyrinth in the temporal bone or inner ear. The vestibular system consists of three semicircular canals that are sensitive to angular accelerations (rotation), and the saccule and utricle which each contain otoliths (dense structures) that are sensitive to gravity and linear accelerations (horizontal movement in the utricle, vertical in the saccule). The membranous labyrinth grows quickly and attains adult size by the middle of the gestation period; the otic capsule ossifies between 18 and 24 weeks (Nemzek *et al.* 2000).

Fetal motility and proprioception

An overview of fetal motor development was given by de Vries and Hopkins (2005). Fetal motility begins at about eight weeks' gestation, when the fetus begins to move through the amniotic fluid and to extend and flex its limbs. From then on, the movement repertoire of the fetus gradually expands. Some movements may be regarded as adaptations to the prenatal environment, while others prepare the fetus for postnatal life. In the third trimester, different sleep–wake states are associated with different movement repertoires and different sizes and frequencies of movement. Movements are not confined to the limbs, but also include startles, breathing movements, jaw openings, sucking, swallowing, facial, tongue and laryngeal movements.

As movements develop, so too does *motor control*. Motor control generally involves an interaction between the neural signals that control muscle activity and sensory feedback about the limb location and muscle tension. The spinal reflex arc begins to function during the first trimester, enabling motor signals to bypass the brain, speeding up motor reflexes.

Development of motor control occurs in parallel with development of *proprioception*—the sense of the relative position and motion of parts of the body. Since musical meaning involves the perception of gesture (Tolbert 2001), which in turn depends on proprioception, the prenatal development of proprioception may be relevant for the later emergence of musical abilities.

Gestures also play an important role in motherese (Trevarthen 1985). As they get older, infants increasingly understand the meaning of the physical and vocal gestures of their carers and learn to imitate them. It would be surprising if this striking postnatal development did not depend in some way on prenatal exposure to patterns of sound, movement and emotion.

The fetal auditory environment

The fetal auditory environment is rich and varied, and provides many opportunities for prenatal perceptual learning. The fetus is exposed to sounds from both inside and outside the mother's body. Internal sounds include her voice, breathing, heartbeat, digestion, body movements, and footsteps (Lecanuet 1996). Of these, the voice is most often audible (Fifer and Moon 1994). The internal sounds tend to be louder than the external sounds: Richards *et al.* (1992) found the mother's voice to be about 8 dB louder to the fetus than the voices of her conversational partners. The fetus is also exposed to patterns of movement that are coupled to sound patterns, such as when the mother walks.

Both internal and external sounds are muffled (low-pass filtered) as they pass through the mother's body and amniotic fluid. Spectral components in the approximate range 100–1000 Hz are attenuated relatively little and may even be slightly amplified, even if their original is external (Richards *et al.* 1992). When the fetus is exposed to speech, either internally from the mother or from an external source, muffling makes vowels more salient (audible) than consonants and the fundamental frequency contour more salient than spectral information (timbre, phonemes) (cf. Smith *et al.* 2003)—consistent with the important role of pitch contour in music perception (Dowling and Fujitani 1971).

Fetal 'consciousness'

The fetus is not conscious in the everyday sense of *reflective* consciousness, that is, the ability to reflect upon perceptual experience. It does however have a range of abilities that may be considered part of a broad definition of consciousness, including perception, cognition, and emotion; sleep–wake cycles (Nijhuis *et al.* 1982); preferences; and attention. Newborns are capable of demonstrating preferences by the rate of sucking on a pacifier (DeCasper and Fifer 1980),

suggesting that the fetus could also demonstrate preferences if a suitable empirical method could be developed. Kisilevsky *et al.* (2004) investigated the heart rate and movement of fetuses in response to a musical stimulus and observed a change at about 33 weeks, suggesting an ontogeny of attention.

According to the *levels of consciousness* approach (Zelazo 2003), adult reflective consciousness comprises separable components that are acquired at specific ages. The ability to label objects (including people) is acquired at the age of about 1 year, to distinguish self and from others at 2, to reflect about ideas or theories and apply rules at 3, and to reflect about self and others at 4. Since neither the newborn nor the fetus has any of these abilities, we may assert that the fetus is not conscious in the everyday sense. Attempts to ascribe consciousness to the fetus may be regarded as projections of adult reflective consciousness—animistic projection, anthropomorphism (Parncutt 2006).

Prenatal learning

Learning may be defined as acquisition of information that affects later behaviour. Fetal learning has been repeatedly demonstrated by the empirical paradigms of *habituation* and *classical conditioning*.

In habituation, an organism is exposed several times to the same stimulus and gradually stops reacting to it; in everyday language we would say the organism gets used to the stimulus or the stimulus becomes uninteresting for the organism. Leader *et al.* (1982) observed fetal habituation to a repeated vibrotactile stimulus at 22–30 weeks gestation. In a different habituation paradigm, Shahidullah and Hepper (1994) found that the fetus can discriminate between sounds at 35 weeks better than at 27 weeks.

Other empirical studies have demonstrated that the fetus is capable of associating stimuli with each other by classical conditioning. In that paradigm, stimuli are paired with each other in a temporal sequence, and after several such pairings the organism begins to expect the second stimulus as soon as the first is presented.

Classical conditioning may be regarded as the basic mechanism underlying *statistical learning*. All higher organisms are sensitive to statistical properties of their environment: given many occurrences of event A in different contexts, they learn the probability that it will be accompanied by (or co-occur with) event B, that is, the probability that event A predicts event B: conditional probability (Fiser and Aslin 2002). Saffran *et al.* (1996) demonstrated that 8-month-old infants can learn statistical properties of nonsense speech during only two minutes' exposure. Since statistical learning is such a fundamental means of picking up information about the environment for all organisms, we may safely assume that humans begin to learn statistically before birth.

Transnatal memory

Transnatal memory is postnatal retention of prenatally acquired information. If the above arguments concerning fetal (lack of) consciousness are correct, transnatal memory is always implicit, that is, not under any form of conscious control—unlike an adult's memory for a telephone number, which normally requires conscious effort.

Transnatal memory for stimulus patterns presented repeatedly to different fetal sensory modalites can last for weeks or months and may therefore be considered to be a form of long-term memory (Hepper 1991, 1992; Hopkins and Johnson 2005; Mastropieri and Turkewitz 2001). In experiments to measure the duration of transnatal memory, a given stimulus pattern is presented repeatedly before birth (e.g. a specific piece of music), or a pattern to which the fetus is naturally exposed (e.g. the mother's voice) is used as an experimental stimulus. When the same pattern is presented for the first time after birth, or in a specific new way, the reaction of the infant is observed and compared with its reaction to unfamiliar control stimuli.

Episodic memory involves memory for a specific event. The existence of *transnatal episodic memory* is suggested by reports of therapeutic patients in trance states who seem able to recall prenatal events or the experience of their own birth. Hartogh (2003) questioned the validity of such evidence. In general, memories are affected by relevant knowledge and by cultural and social context, and can easily be constructed (Harris et al. 1989). Since episodic memory in humans

normally depends on language, and since prenatal episodic memory has no known evolutionary function, prenatal episodic memory is unlikely to exist. That does not necessarily prevent prenatal regression therapy from having a useful therapeutic function.

The phylogeny of musical behaviour

Recent research about the origins of music (summarized by Mithen 2005) has considered many scenarios. One involves prenatal exposure to the internal sounds and movements of the mother's body, which are associated with her changing physical and emotional state (Parncutt in press). The claim is that the associations between sound, movement and emotion upon which music is based are ultimately of prenatal origin.

Emotion

Strong emotions are generally associated with reflexes, instincts or drives that promote survival and reproduction (Tinbergen 1989), such as hunger, sex, fear, pain, disgust, jealousy, surprise, and anger. Music is exceptional in that it communicates strong emotions that are marked by changed states of consciousness and spiritual experiences (Gabrielsson and Lindström Wik 2003), although it has no clear survival value. A plausible theory of the origins of music should be consistent with this fundamental contradiction.

It is often supposed that music is emotional because it is associated with social behaviour and group survival (e.g., Dean and Bailes 2006). However, evolutionary theory primarily explains the behaviour of isolated pairs of individuals (e.g. reciprocal altruism) rather than groups considered as a whole (Boyd and Richerson 1988; Trivers 1971), and such an approach cannot easily explain music's *strong* emotionality and spirituality.

Musical emotions are associated with learned patterns of sound and movement. A possible source of those associations is motherese (Dissanayake 2000), whose vocabulary of gestural meanings evidently includes a universal component (Kuhl *et al.* 1997; Papousek 1996). The question arises as to the origin of those gestural meanings.

Infant musical skills: innate or learned?

Another surprising thing about music is that all humans, including infants, possess basic musical skills. A plausible theory of the origins of music should be consistent with the documented musical abilities of infants. Trehub and Hannon (2006) proposed that

> infants' music perception skills are a product of general perceptual mechanisms that are neither music- nor species-specific. Along with general-purpose mechanisms for the perceptual foundations of music, we suggest unique motivational mechanisms that can account for the perpetuation of musical behavior in all human societies.
>
> Trehub and Hannon (2006, Abstract)

Prenatal associations between patterns of sound, movement and emotion could underlie such 'general perceptual mechanisms' and 'unique motivational mechanisms'. If so, they may explain the nature and origin of musical emotion.

Several sources of evidence suggest that the musical abilities of infants are at least partially inborn. Amusia can be inborn or genetically determined in a small proportion of the population (Ayotte *et al.* 2002). Children of deaf parents prefer infant-directed singing over adult-directed singing, suggesting an innate component—or at least an inborn preference for exaggeration (Masataka 1999). The development of musical ability is affected by prenatal testosterone levels (Sluming and Manning 2000).

Models of the interplay between genes and environments (Garcia Coll *et al.* 2004) suggest that behaviours and skills such as musicality are neither inborn nor innate, but a mixture of the two. Several empirical studies cited in this chapter are consistent with the prenatal learning of protomusical skills. For example, newborns respond to the emotional content of speech, but only in their maternal language, suggesting that their ability to recognize that emotion was acquired before birth (Mastropieri and Turkewitz 2001). The claim that musical skills

are *largely* learned may be valid throughout the lifespan. In early life, the gestural vocabulary of motherese may be largely learned from prenatal exposure to the internal sounds of the mother's body. Later, musical expertise may depend primarily on the total accumulated duration of practice (Howe *et al.* 1998).

Fetal–maternal communication

Bonding (secure attachment) between primary caregiver and infant plays an important psychological and physiological role in early development (Schore 2001). The idea that maternal–infant bonding is an evolutionary adaptation is consistent with high rates of infant mortality among both non-human primate and human hunter-gatherer populations (>50%: Denham 1974). Maternal–infant bonding generally increases the chance of infant survival, but not necessarily of surviving infanticide or of preventing abandonment when chances of survival are particularly low (Hausfater 1984). Prenatally acquired knowledge about maternal emotional states may promote postnatal bonding and survival by helping the infant to communicate its needs appropriately (cf. Broad *et al.* 2006) and may in that sense be adaptive. Other factors being equal, the chance that an infant will survive to reproductive age will increase if infant demands on the mother or other carers do not radically exceed their momentary capabilities or resources.

Infant-mother bonding is two-way and reciprocal (Lee 2006): each party is at some level sensitive to the physical and emotional state of the other. Empirical research is beginning to document the infant's active perception of the mother: compare Stern's (2002) cognitive, psychoanalytic approach with Trevarthen's (1980) concept of intersubjective communication. To successfully monitor the mother's physical and emotional state, the infant must have prior knowledge about the relationship between maternal state and behaviour. The fetus has constant access to two reliable sources of information about the physical and emotional state of its mother: behavioural (sound and movement) and biochemical (blood hormone concentrations).

Regarding behavioural information, all patterns of sound and movement that are audible within the body in everyday situations, including vocalization, respiration, circulation, movement, footsteps and digestion, depend on physical and emotional state (Mastropieri and Turkewitz 2001). The human fetus has access to three behavioural sources of information about maternal state: sound patterns, linear and rotational acceleration of the fetal body, and relative movement of the fetal limbs. These are perceived by the fetal auditory, vestibular and proprioceptive systems respectively.

Regarding biochemical information, the hormones involved in the maternal–fetal interaction arise from three different sources: the placenta, maternal organs and fetal organs (Power and Schulkin 2005). The placenta and fetal membranes produce a large number of steroids that regulate and balance both maternal and fetal physiology. They include progesterone and oestrogen, which play a role in maintenance of pregnancy and support of the embryo/fetus (Albrecht *et al.* 2000); testosterone, which affects fetal development (Matt and MacDonald 1984); oestrogen, related to female secondary sex characteristics (Nelson and Bulun 2001); corticotropin-releasing hormone, which influences the duration of pregnancy (Hillhouse and Grammatopoulos 2002); relaxin, which facilitates birth (Klonisch *et al.* 1999); and placental lactogen (somatomammotropin), which influences nutrient (carbohydrate, lipid) levels in the maternal blood (Walker *et al.* 1991). In an evolutionary approach, hormonal manipulation of maternal nutrient supply represents an early stage of parent–offspring conflict (Wells 2003).

Hormone production in the mother involves a mixture of regular adult hormonal processes and processes specific to pregnancy. Regarding the former, externally caused stressors (flight-fight reaction) lead to stimulation of the adrenal gland, which secretes adrenaline (epinephrine) and noradrenaline (norepinephrine) into the blood, which in turn increases blood sugar, muscle tension, and blood pressure. Stress also causes the release of corticotropin-releasing hormone (CRH) and the production of glucocorticoids that affect immune responses (Elenkov *et al.* 1999). CRH is also associated with anxiety and depression (Steckler and Holsboer 1999), and cortisol is associated with fear and stress (Kalin *et al.* 1998). Oxytocin is

more specific to reproduction and is associated with orgasm, birth and breastfeeding (Newton 1978).

That the fetus is sensitive to hormone concentrations in the maternal blood is clear from studies that demonstrate the effect of those concentrations during pregnancy on postnatal development. For example, postpartum concentrations of testosterone, estradiol, androstenedione and cortisol correlate with the children's later levels of physical aggression (Susman *et al.* 2001). Molecules that pass the blood–brain barrier include oxygen, carbon dioxide, alcohol, and steroid hormones, of which there are five main groups: progestagens, glucocorticoids, mineralocorticoids, androgens, and oestrogens (Pardridge and Mietus 1979). The permeability of the blood–brain barrier to steroid hormones depends on the molecule and involves different temporal delays (Zloković *et al.* 1988). The placenta is permeable to nutrients, oxygen, alcohol, antibodies and steroid hormones with different temporal delays of seconds, minutes or hours (Bajoria *et al.* 1998; Bajoria and Fisk 1998).

Thus, both evolutionary–biological and developmental–psychological approaches predict that the fetus perceives changes in patterns of sound and movement within the mother's body (behavioural information) following everyday changes in maternal state. The corresponding changes in maternal hormone levels are delayed by passage through the placental and fetal blood–brain barriers (biochemical information). The behavioural change thus predicts the biochemical change, allowing classical conditioning to occur—just as, in Pavlov's famous experiment, the footsteps of a master bringing food to a dog predict the appearance of the food.

Any stimulus can be associated with any other by classical conditioning, and all animals are capable of classical conditioning. The human fetus is no exception (Smotherman and Robinson 1990). The fetus must therefore learn to associate the behavioural information described above with the corresponding biochemical information. The theory of classical conditioning predicts that after several repetitions of such a sequence the fetus will begin to respond emotionally to the behavioural patterns—before the arrival of the biochemical information. While the time interval between behavioural and biochemical information in this scenario is presumably of the order of minutes, classical conditioning may also occur for longer interstimulus intervals of the order of hours (Garcia *et al.* 1974).

Prenatal influences on postnatal behaviour

Prenatally established associations can influence postnatal behaviours and the development of musical culture in the context of *motherese*, *play* and *ritual*. In all three cases, *operant conditioning* (Skinner 1938) may be the underlying mechanism. Patterns of sound and movement that occur by accident in these behaviours may be similar to patterns of sound and movement that were prenatally linked to emotion. The triggering of associated emotions may reinforce the actions or behaviours that produced the patterns of sound, increasing their frequency of occurrence. Since motherese, play and ritual are social activities whose participants were subject to similiar prenatal conditioning processes, this theory predicts that such behaviours and associated emotions will generally be socially shared, enabling the development of music as a form of social behaviour.

On this basis, we might expect to find associations between sound, movement and emotion in all prenatally hearing animals. The reason why non-human animals are not musical in the human sense is presumably that only humans possess reflective consciousness, which emerged at least 60 000 years ago and enabled a cultural explosion (Mithen 2005). Reflective consciousness may be regarded as a co-requisite for the ability to conceptualize the past and future in relation to the present, which enables deliberate/intentional planning and action (Noble and Davidson 1996). According to this view, prenatal associations between sound, movement and emotion became 'music' when humans acquired the ability to deliberately manipulate shared emotions using sound—that is, to perform.

Conclusions

Recent research in music psychology has tended to avoid questions of prenatal development due to the practical and ethical difficulties associated

with empirical investigations and the dubious quality of much of the available research literature. This period of restraint may be coming to an end as researchers realize that the prenatal period could be a source of answers to central questions in music psychology, and as developing empirical technologies make it increasingly possible to carry out methodologically sound empirical investigations.

The relevant empirical literature is expanding rapidly, but it is spread over many different disciplines, and many central issues remain to be critically addressed by independent research groups. The present theory presented on the origins of music may be internally consistent and logical, but further empirical work will be necessary to investigate the details of the hypothesized prenatal associations and their effect on postnatal behaviour.

Since our knowledge of music's emergence in the context of ritual will always be limited, any theory of music's phylogeny will always be speculative. The ontological question of how prenatal learning affects postnatal musical development will become increasingly accessible to empirical investigation, as non-invasive observational techniques improve. An improved understanding of the interaction between genes and environment in psychological development (e.g. Bakshi and Kalin 2000), combined with new approaches to fetal behaviour (such as preferences) and prenatal influences on postnatal behaviour (including transnatal memory), will lead to new insights that will confirm, complement, challenge or overthrow the ideas presented in this chapter.

CHAPTER 21

Music lessons from infants

Sandra E. Trehub

WHAT can we learn about music and about musicality from infants? Sceptics may question the possibility of deriving fruitful answers to such questions from immature beings whose hearing is deficient (relative to adults) and whose exposure to 'good' music, even conventional music, is limited. This chapter is aimed at less sceptical readers—those who are open to the possibility of *nature* making some contribution to our musical beginnings and to our subsequent development. It is organized as a series of lessons that emerge from empirical research over the past few decades.

Their world is alive with the sound of music

Preverbal infants hear a steady stream of incomprehensible but highly melodious speech. This speech, known variously as *motherese, parentese*, or infant-directed speech, is characterized by exaggerated prosody, including elevated pitch, expanded pitch contours, large dynamic range, and rhythmic regularity (Fernald 1991). The most striking aspects of maternal speech—its effusiveness and positive affective quality—are also the most difficult to quantify. At periodic breaks in the flow of mellifluous speech, infants sigh, yawn, gurgle or coo, all of which function as contributions to the dyadic conversation.

Research to date has largely emphasized the common melodic and rhythmic features in speech to infants, even across cultures (Fernald *et al.* 1989). It has become clear, however, that unique or person-specific musical features are also evident in speech to infants. In one study (Bergeson and Trehub 2007), sequences of intervals, or tunes, were transcribed from recordings of several mothers as they interacted with their infants (4–7 months of age) on different occasions. The observed intervals were unrelated to conventional musical intervals, but highly trained listeners agreed on the transcriptions. Mothers used a handful of tunes consistently, usually with different content, on different occasions. Moreover, each mother's tunes were distinct from those of every other mother, justifying their designation as *signature tunes* (Bergeson and Trehub 2007). It seems, then, that infants receive regular exposure to specific speech melodies in the context of interactions with their primary caregiver.

Aside from the musical speech that infants hear, they also hear a good deal of singing (Trehub *et al.* 1997). Mothers (and many fathers and grandparents) the world over sing to infants in the course of providing care (Trehub and Trainor 1998). For the most part, they use a distinct musical genre for this purpose—lullabies and play songs. Although music for adults often differs substantially from one culture to another, music for infants has many cross-cultural similarities. For example, lullabies from foreign musical cultures are readily recognizable as such (Trehub *et al.* 1992), perhaps by virtue of common features such as simplicity, repetitiveness, and falling pitch contours (Unyk *et al.* 1993).

Even more distinctive than the musical material for infants is the manner of singing to infants. Infant-directed singing is generally part of intimate interactions whose goals are playful,

soothing, or emotion-sharing. Although songs have prescribed pitch intervals and rhythms, performances for infants share some features with maternal speech, such as elevated pitch, slurred articulation of words, and positive vocal tone (Trainor *et al.* 1997).

Casual listeners readily distinguish infant-directed from non-infant-directed versions of the same song by the same singer (Trehub *et al.* 1993b, 1997). Surprisingly, each mother seems to perform the same songs at nearly identical pitch level and tempo on different occasions (Bergeson and Trehub 2002), qualifying, perhaps, as *signature performances.*

Maternal performances are irresistible

Presumably, the maternal style of speech and singing would not have persisted across cultures and historical periods if it did not achieve its intended goals, for example, soothing or accelerating sleep in the case of lullabies and joyful engagement in the case of play songs. Over the past couple of decades, investigators have sought infants' perspective on the sounds they hear. To do so, they devised procedures for ascertaining whether infants prefer one type of speech or music to another. The essence of these procedures is to present contrasting material that is linked to infants' gaze toward one of two loudspeakers. For example, infants' gaze at one loudspeaker results in the presentation of one sound pattern, which continues to play until they look away. Their gaze at the other loudspeaker results in the presentation of a contrasting sound pattern until infants look away. This procedure continues for a specified period, after which total gaze duration for each selection is compared. If infants look significantly longer to hear one of the selections, the presumption is that they preferred it to the other. In this manner, one can estimate their relative interest in and attention to the material. In some cases, investigators videotape the sessions to document observable affective responses.

Procedures such as these have revealed greater infant attention and positive affect to melodious motherese than to conventional adult speech (Cooper and Aslin 1990; Fernald 1985; Werker and McLeod 1989). In principle, familiarity with the maternal style could play a role in these preferences. Despite the popular notion that familiarity breeds contempt, the familiarity of music enhances its appeal (Szpunar *et al.* 2004).

Infants also prefer to listen to infant-directed than to non-infant-directed versions of the same song by the same singer (Trainor 1996). Evidence that 2-day-old infants with limited exposure to music or speech exhibit the same preference (Masataka 1999) rules out experiential factors. Prenatal exposure would have been minimal or absent for these particular infants because their deaf parents communicated by means of sign language. The findings are consistent with a *natural* or inborn preference for the maternal singing style and, in all likelihood, for the maternal speech style as well.

Young infants are poor at regulating their own state or arousal, so fussing and crying are frequent occurrences. At such times, caregivers intervene with non-verbal sounds (e.g., shush), singing, rocking, jiggling, feeding, or some combination of these. Singing is particularly effective at arresting, even preventing, such fussiness. Indeed, the effects of singing are evident in hormonal changes that reflect alterations in arousal or stress (Shenfield *et al.* 2003). Unfortunately, uninformed media reports and deceptive advertising—none of it based on solid scientific evidence—have convinced many parents that Mozart recordings are superior to their own humble performances. Such parents know that their songs 'work' in the sense of bringing comfort and joy to their offspring, but they worry that their performances lack the nutrients for the developing brain that are present in 'good' music.

More than meets the ear

The prevalence of recorded music makes it seem that music is a mere auditory phenomenon. For most of history, however, and for many remote communities in developing nations, music is commonly experienced through live performances in which the listener plays an active role. In such contexts, the performer's visual gestures are as critical as the sounds produced, and the audience typically moves in time with the music. Visual gestures (head and body motion), touch (e.g., holding, stroking), and movement (rocking,

swaying) are also integral to mothers' sung and spoken performances. There are suggestions that motherese and maternal singing evolved as ways of keeping infants content when mothers' eyes and hands were required for food gathering or other work (Falk 2004). One prediction arising from this perspective is that mothers should intensify their vocal expressiveness when expressive means in other modalities are unavailable. In fact, there is evidence that mothers use a higher pitch level and wider pitch range (i.e., prosodic enhancement) when they are unable to touch their infants (Nakata and Trehub in preparation).

The consequences of hearing *and* seeing recordings of their mother talking or singing are potent (Nakata and Trehub 2004). Under these circumstances, infants become quite still and stare at their mother's image for extended periods. Interestingly, they remain engaged significantly longer during bimodal singing episodes than during comparable speech episodes.

Infants and adults often integrate information from different modalities, which influences their perception of what they hear, see or feel. For example, when infants are bounced to an ambiguous drumming rhythm (i.e., no accented beats) on every second beat, they subsequently prefer listening to an accented version in duple metre rather than triple metre (Phillips-Silver and Trainor 2005). If they are bounced on every third beat, they subsequently prefer the rhythm in triple metre. Simply watching an adult move on every second or third beat does not induce the preference. Similarly, adults' encoding of rhythms is influenced by their own movement but not by observations of others' movement (Phillips-Silver and Trainor 2007). Perhaps mothers' typical practice of moving with infants as they sing helps infants encode the rhythms of their songs.

Consonance matters

Much of the research on infant music perception has been done with auditory patterns that lack the expressive qualities of maternal performances, including the demonstrably potent qualities of the human voice (Vouloumanos and Werker 2004, 2007). Undoubtedly, instrumental and synthesized music are less interesting for infants but such materials enable precise control over various features, which makes it possible to specify the features noticed or preferred. Such research has revealed that, from the newborn period on, infants prefer consonant sequences of harmonic intervals to dissonant sequences (Masataka 2006; Trainor and Heinmiller 1998; Trainor *et al.* 2002). Infants remain calm while listening to consonant instrumental music, but they show a variety of negative reactions when dissonant intervals replace many of the consonant intervals (Zentner and Kagan 1996). Infants are also proficient at detecting melodic changes, big and small, but they are considerably more accurate in the context of sequences with consonant melodic intervals than those with dissonant intervals (Schellenberg and Trehub 1996). The perfect fifth interval, which is ubiquitous across musical cultures (Sachs 1943), seems to be especially important for infant listeners (Trainor and Trehub 1993).

Musical memories

There have been no attempts to assess infants' memory for the songs that mothers sing at home, but there is evidence that infants retain some aspects of music heard regularly. When infants are exposed to a Mozart sonata periodically during a 2-week period, they subsequently distinguish it from another Mozart sonata (Saffran *et al.* 2000). More limited at-home exposure to synthesized folk melodies enables infants to distinguish those melodies from others (Trainor *et al.* 2004). In circumstances such as the latter, infants retain information about relative pitch but not absolute pitch (Plantinga and Trainor 2005). The salience of the musical selection and performing style may affect what infants remember. For example, infants retain absolute features from expressively sung lullabies after 2 weeks of periodic exposure (Volkova *et al.* 2006). Their short-term memory for music is influenced by a number of factors including its tonality (Trehub *et al.* 1990), temporal regularity (Bergeson and Trehub 2006), and degree of consonance (Schellenberg and Trehub 1996, Trainor and Trehub 1993).

From universal to cultural tuning

For the first several months of life, infants approach music with open or universal ears.

Like their adult counterparts, they perceive the equivalence of melodies across changes in pitch level, or transposition (Chang and Trehub 1977; Trehub *et al.* 1987) and across changes in tempo (Trehub and Thorpe 1989). Unlike their adult counterparts, who are differentially sensitive to familiar diatonic scales, infants experience no more difficulty detecting changes to melodies based on the Javanese pelog scale than to those based on Western diatonic scales (Lynch *et al.* 1990). Similarly, they perform as well on invented scales as on the major scale, provided the invented scales incorporate the principle of unequal step size (Trehub *et al.* 1999). Although infants are surprisingly proficient at detecting melodic changes (Trehub 2000), they are unlike adults in their insensitivity to the implications of key membership or harmony (Trainor and Trehub 1992). The available evidence indicates that such sensitivity requires years of culture-specific exposure to music, emerging between 5 and 7 years of age (Trainor and Trehub 1994) and exhibiting further development thereafter (Lamont and Cross 1994).

Infants also exhibit universal principles of rhythm perception such as the grouping of notes based on similarities in pitch, loudness, timbre, and temporal proximity (Thorpe *et al.* 1988; Thorpe and Trehub 1989. When the flow of music is interrupted briefly, infants prefer such interruptions between musical phrases rather than within phrases, indicating that they grasp aspects of musical phrasing (Jusczyk and Krumhansl 1993).

Simple metres with isochronous timing (i.e., equal durations between strong beats) such as duple and triple metre are thought to be inherently simpler than the complex metres that are common in many parts of the world (e.g., Eastern Europe, South Asia, Africa). Recent evidence suggests otherwise. For example, 6-month-old infants detect timing changes as readily in Balkan music with simple metres as in Balkan music with complex metres (Hannon and Trehub 2005a). When North American adults are exposed to the same materials, they detect the changes only in the context of simple metres, but adults of Balkan origin detect both types of changes (Hannon and Trehub 2005a). These findings negate the view of inborn predispositions or preferences for simple metres. Instead, they suggest that adults' long-term experience with Western rhythms interferes with their perception of foreign rhythms. By the time infants are 12 months of age, they exhibit adult-like difficulties with the complex metres (Hannon and Trehub 2005b). Unlike their adult counterparts, however, limited listening experience with complex metres is sufficient to overcome those difficulties. Not only does adults' experience interfere with their perception of foreign rhythms, it also interferes with their ability to learn such rhythms. Although passive listening is sufficient for 12-month-olds, adults may require more active listening, perhaps accompanied by movement. Guided moving to music, which influences adults' encoding of simpler rhythmic materials (Phillips-Silver and Trainor 2007), may help adults master the nuances of metrically complex music.

In sum

The story that emerges from infancy involves a rich musical environment, with mothers delivering performances that match the inclinations of their infants. Moreover, infants have predispositions or inborn preferences for musical features that are common across the world's cultures. Because musical systems across the world differ in notable respects, it makes sense that infants are open to the available alternatives. With increasing exposure to music, they gain expertise as listeners, but that expertise comes at the cost of diminished sensitivity to features that are irrelevant or infrequent in their own musical culture. Even when their listening skills begin to narrow in culturally appropriate ways, they remain flexible listeners and learners, which enables them to attain listening proficiency with foreign rhythms.

Much has been written about young children's ease of mastering the sounds of foreign languages and adults' difficulty in this regard. There may be parallels with regard to music, but the window of opportunity for music perception is unknown. Finally, there are hints that musical enculturation may occur more rapidly in the temporal domain than in the pitch domain. Evidence on the issue is limited, but it is consistent with the view that temporal processing is at

the heart of listening to music and other auditory events (Large and Jones 1999).

CHAPTER 22

Music in the school years

Alexandra Lamont

Introduction

Music is ubiquitous in young children's experiences (see Chapter 21 this volume), but as children get older their experiences become more diverse. Defining the trajectories of musical development is thus complex; explaining them is still more challenging. Beginning by considering definitions of development, this chapter first provides a selective overview of existing evidence on children's responses to musical elements and secondly evaluates our understanding of musical development in culture and context.

What is musical development?

Despite much research interest, there is still no overarching consensus on what musical development is. Sloboda (1985) distinguished between two types of musical development: enculturation (generalized and effortless) and training (specialized, deliberate and conscious). Many researchers now consider the development of musical competence (Deliège and Sloboda 1996), further subdefined into activities such as 'singing, graphic representation of music, melodic perception, and composition' (Hargreaves 1996 p. 145) or 'skills, understandings and attitudes' (McPherson 2006, p. v). Runfola and Swanwick (2002) argue that any explanation of musical development must incorporate the three areas of production, performance, and perception (see also Hargreaves and Zimmerman 1992).

Other forms of development have more clearly defined goals: for example, literacy development has an end point of being able to read. Becoming a musician is a more nebulous concept (MacDonald *et al.* 2002; Chapter 42 this volume), and not all children think of themselves as equally musical (Lamont 2002). Even research which adopts a relatively straightforward 'expertise' model of adult musicians has difficulty accounting for the diversity of findings in the musically more naive (Davidson 1994), and this may explain the imprecision in definitions. This chapter will take an inclusive approach to what musical development might encompass.

Developing musical understanding

First I review research on how children understand separate elements of music, individually (pitch/harmony, rhythm/metre, timbre) and in combination (structure, form, style), drawing on research that isolates and explores these experimentally and evidence from more ecologically valid tasks such as singing and composing.

Pitch, tonality, melody and harmony

Pitch includes tone chroma (individual notes), contour (high/low and patterns), and melodic and harmonic relationships between tones (tonality/tonal hierarchy) (see also Chapter 5 this volume). One early pitch capacity is absolute pitch, typically demonstrated by labelling individual pitches by note names. Absolute pitch is more easily acquired in early childhood (Takeuchi and Hulse 1993) and can be trained

more rapidly in children aged 4–5 than those aged 13–15 (Crozier 1997). Crozier suggests that through music training which emphasizes relative pitch skills, children unlearn absolute pitch. A second capacity relates to the psychophysical dimension of pitch height. Young children are unable to label pitch as 'high' and 'low', and much of their difficulty results from problems in analogical mapping between the musical and verbal concepts (Costa-Giomi and Descombes 1996). Although differences in pitch height can be perceived by infants (see Chapter 21), the terminology to describe the dimension of pitch height must be learned and takes time to stabilize.

Considering relationships between pitches, research has explored children's developing sense of tonality. Some studies find marked age differences: for example, Krumhansl and Keil (1982) showed an increasing sophistication in differentiation between and among diatonic and non-diatonic notes from 6 to 11 years (cf. Lamont and Cross 1994). Other studies find stable representations across this age range (Cuddy and Badertscher 1987), with children performing with less sophistication than musically trained adults. Training appears to accelerate the patterns of development found with age (Morrongiello and Roes 1990; Lamont 1998). Melodic expectancy studies using both perception and singing tasks show that for children aged 5–11 the best next note in a melody is one close in pitch, whereas a pitch reversal only emerges as a good next note at the age of 11 (Schellenberg *et al.* 2002). Preschoolers can detect mistunings to conventional tonal melodies (Trehub *et al.* 1986), but often fail to notice transpositions and contour-preserving changes as 'different' (Morrongiello *et al.* 1989), while out-of-harmony mistunings become detectable around the age of 7 (Trainor and Trehub 1994). In priming tasks, 6- and 11-year-olds make faster judgements about which vowel sound or instrument a target tone is sung or played on, or whether it is consonant or dissonant, when the target is a tonic chord (Schellenberg *et al.* 2005).

Converging evidence for developing pitch understanding comes from musical production tasks. Davidson (1985, 1994) shows a progression from contour schemes in songs at 3 years of age to fixed pitch reference points with older children. Bamberger's (1986, 1991) research also highlights qualitatively different ways of understanding pitch in context. 6–11 year olds without musical training organize melodies figurally into shapes, while highly trained 11- and 12-year-olds can use pitch formally in an abstract manner. Children's melodic improvisations show a similar developmental sequence: children aged 6–7 only use the first five diatonic tones, at 8–9 prefer tones presented in the initial stimulus, and at 10–11 create improvisations emphasizing the tonic triad; the oldest children are most likely to end with a tonic chord (Paananen 2006a, b).

In summary, young children possess certain fundamental pitch capacities, such as the ability to respond to absolute pitch, which become more refined and culturally specified with age. By 6 or 7, children have developed an implicit understanding of Western tonality almost equivalent to that of adults, and use this in listening judgements and decisions about creating music. Furthermore, a shift from context-dependency to context-independency in pitch relationships occurs between 6 and 11 (Lamont and Cross 1994; Paananen 2006a). Musical training accelerates the development of understanding of pitch and tonality, although often does not change it radically. Finally, although some studies find differences between 11-year-olds and adults, very little research has explored development beyond the age of 11.

Tempo, timing, rhythm and metre

There has been less research on children's understanding of the temporal aspects of music, and existing studies use many different methodologies. In listening tasks, little difference is found according to age or music training in children's abilities to detect temporal irregularities (Drake *et al.* 2000) or to segment according to changes in tone duration or pause duration (Drake 1993) between 4 and 12 years. In general, children perform slightly less consistently or accurately than adults (Drake and Bertrand 2003). Production tasks also indicate little developmental difference in children's ability to synchronize (Drake *et al.* 2000) or to reproduce simple binary and regular rhythmic patterns (Drake and Gérard 1989) between 5 and 12 years, although they are less

accurate than adults with ternary ratio rhythms and irregular patterns.

Evidence from children's invented notations of rhythms shows differences in understanding in middle childhood, moving from enactive action drawings to figural patterns and shapes; only children with training are able to focus on absolute durations and inter-onset intervals (Bamberger 1991). Children's compositions also show shifts from conventional metric patterns at age 5–8 to more speculative use of rhythm and metre at 9–11 (Swanwick and Tillman 1986; Brophy 2002; Paananen 2006c).

Certain fundamental features of temporal understanding are demonstrated relatively consistently across childhood, although others such as segmentation and the understanding (both perceptual and compositional) of more complex rhythmic ratios show gradual improvements with age and training. Again, although differences in understanding are found between children and adults, development beyond the age of 12 has not been explored.

Timbre

Very little research has been conducted on the development of timbre perception. One direct investigation of timbral sensitivity (Lowther 2004) finds rapid development between the ages of 3–8. Younger children make easy discriminations very accurately (e.g. comparing a triangle sound to a ratchet, or tuba to celeste), but are much less successful on more difficult comparisons (e.g. flute/clarinet). From children's qualitative responses, Lowther concludes that although performance increases with age, specific experiences of particular sounds are responsible for helping children make sense of timbral information.

Indirect information about timbre perception skills comes from research such as the priming paradigm used by Schellenberg *et al.* (2005, Experiment 2), finding that children aged 8–11 can discriminate between a piano and a trumpet. Despite the lack of concrete empirical evidence, timbre identification is often used as one indicator of exceptional musical ability in children, being presumed to indicate a high level of auditory discrimination (Shuter-Dyson 1999) linked to potential for learning.

Combinations of elements: musical structure and form

Brand (2000) has explored children's errors in learning to sing a new and unfamiliar song between the ages of 6 and 12. While older children learn the song more rapidly, all children irrespective of age or musical training make plausible errors in terms of song organization (e.g. more symmetrical phrases). Thus children attempt to organize the music they encounter into meaningful sections and familiar gestures, as in Davidson's 'pot-pourri' songs (1985). Oura and Hatano (1988) find 9–10-year-olds with around 5 years of musical experience can reproduce a novel melody as rapidly and accurately as trained adults (and more so than inexperienced adults). Thus familiar organizing principles such as tonality or repetition are seen to have been internalized and used in order to make sense of unfamiliar music.

Children's similarity judgements in terms of pitch and duration improve in accuracy between 5 and 11 years (Stevens and Gallagher 2004), although higher accuracy levels are found for pitch than duration. When given the opportunity to organize musical stimuli along the dimensions of pitch, contour, tempo, rhythm, timbre and loudness (Schwarzer 1997), young children focus on melody-unspecific features such as loudness (5–6-year-olds), tempo, and timbre (6–7-year-olds), while adults use more melody-specific features like contour. Children categorize short melodies analytically (using one musical element) rather than holistically (using combinations), and none of the younger children use pitch or contour relations. However, sorting tasks using real musical stimuli show that surface features such as dynamics and contour are commonly used, as well as underlying features such as tonal structure, by 10–11-year-olds (Koniari *et al.* 2001). Tonality can also be used to organize excerpts by younger children with musical training (Martin *et al.* 2003).

In a study directly comparing melody/tonality and rhythm/metre, Paananen (2006a) shows that children's improvisations at age 6–7 either focus on the surface (melodic/rhythmic figures) or deep (tonal or metrical hierarchy) structures, passing through a substage of beginning coordination between the two at 8–9 to a final substage

of integration at 10–11. Children's invented notations also become more specific and detailed with age in relation to various musical dimensions (pitch, rhythm, timbre), illustrating how symbolization is tied to musical understanding (Fung and Gromko 2001; Bamberger 2006).

This evidence is somewhat conflicting because of the variety of tasks employed. When making simple comparison judgements to artificial musical stimuli (e.g. Stevens and Gallagher 2004), young children can focus on isolated musical elements (cf. Paananen 2006a). However, when using more complex stimuli or real music (e.g. Koniari *et al.* 2001), children are better able to combine musical elements. Although children aged 5–6 can use different musical elements and structures in complex tasks, older children are better able to deal with more complex underlying structures of music, and this is also sometimes dependent on formal training. It may take until adulthood to fully integrate different musical features (Schwarzer 1997), but research has not yet explored this beyond the age of 11.

Musical structure and emotion

Adults' perception of emotion relies on the structural features of tempo and mode in Western music (see Chapter 11 this volume). With happy and sad musical excerpts from real music contrasting in tempo and mode, 3–4-year-olds are unable to distinguish them on any basis; 5-year-olds recognize emotions based on tempo changes, while 6–8-year-olds perform similarly to adults in recognizing emotional changes due to both tempo and mode (Dalla Bella *et al.* 2001). In more naturalistic studies, children aged 3–5 can recognize music that adults judged as happy, sad, angry and fearful (Nawrot 2003), although they sometimes confuse fear and anger (Terwogt and van Grinsven 1991).

While Dalla Bella *et al.* (2001) note that it is remarkable that 6-year-olds demonstrate full knowledge of the rules governing happy and sad emotions in music, it should be recalled that these are 'basic' emotions and there is room for further sophisticated development. More research is required, along the lines of the recent study by Stachó (2006) indicating that children aged 3–6 are significantly less able to decode the emotional content of different musical performances.

Style discrimination

Musical preferences can be shown even before birth (see Chapter 20 this volume). Three-year-olds mainly prefer child-oriented music like nursery rhymes or television themes (Lamont 2008), and can also discriminate between different styles of classical and popular music given an appropriately sensitive methodology (Marshall and Hargreaves 2007). However, little research has directly explored the development of children's understanding of style (cf. Hargreaves *et al.* 2006).

Children appear to experience phases of 'open-earedness', such as middle childhood, where they tolerate a large amount of musical styles (Hargreaves 1982), and 'closed-earedness', such as adolescence, where their preferences are far more constrained (LeBlanc 1991). For example, Boal-Palheiros *et al.* (2006) find children aged 9–11 like very unfamiliar and complex music (Boulez, Ligeti and Stockhausen) more than those aged 12–14. In adolescence, a narrow range of musical preference forms an important part of self-identity (North *et al.* 2000; Stålhammar 2003). The 'rebound of open-earedness' in early adulthood (LeBlanc 1991, p. 37) coincides with a phase of seriously acquiring music (Greasley and Lamont 2006). Music preferences still convey messages about other individuals, although more subtle judgements can be made (Rentfrow and Gosling 2006).

The rapidly changing nature of popular musical styles presents an empirical challenge (cf. Hargreaves *et al.* 2006). Furthermore, developmental effects are understood to be moderated by a large number of other factors influencing preference (LeBlanc 1982) which relate to the music itself, to the listener, and to the context (Hargreaves *et al.* 2006) (see Chapter 15 this volume).

Production and performance skills

Although all children sing, children's singing skill takes time to stabilize (Welch 2006). Their vocal ranges at the start of school are relatively constrained, with large individual differences in

skill (Leighton and Lamont 2006). Children's voices continue to change throughout childhood and adolescence, both continuously, for example the ability to sing in tune (Welch 1996) and qualitatively, for example physical changes in production capacity and vocal development in adolescence (Welch 1998).

Some children also learn to play an instrument, and the component skills are considered elsewhere (see Part 6 this volume; McPherson 2006). While research has revealed much about what is required to make progress with learning an instrument, there is still no real developmental perspective on this topic. McPherson and Davidson (2006) outline a set of learning principles for children of different ages (up to 5, 6–9, and 10 and above) but these are based more on common-sense suggestions (e.g. beginning at an early age, encouraging parents to sing and play musical games) than principled theorizing.

The process and product of children's compositions has been used to generate models of development (e.g. Barrett 1996; Davies 1992). Generally, children become more sophisticated and abstract in their musical compositions with age (Swanwick and Tillman 1986). Although it is often argued that creativity is not age-dependent or phase-related but rather dependent on context, some general changes can be charted (Burnard 2006). For example, early childhood is characterized by the importance of play, whereas middle childhood has wider social and educational influences, and adolescence prioritizes personal identity.

Finally, learning to read and write music is a highly culture-specific form of development (see Mills and McPherson 2006). Converting children's intuitive and invented notations into conventional Western staff notation is complex, and children often experience difficulties in matching sounds to symbols (McPherson and Gabrielsson 2002). Pedagogic approaches using meaningful wholes rather than individual isolated pitches are more effective in the earlier stages, perhaps reflecting children's musical understanding (Mills and McPherson 2006). However, arguably certain elements of music are better perceived analytically rather than holistically even by young children (cf. Schwarzer 1997) and so this approach may not be universally successful.

Theorizing development

A critical issue when considering all this research is the *causes* of differences in musical understanding. Adopting an individual differences approach, we would expect differences according to age, gender, and prior musical experience (over short and long time spans). Most research tends to seek, and generally finds, age-related differences. Some studies also include the effects of formal musical training. However, the field has not yet produced theoretical models of musical understanding which explain the range of musical behaviours coherently (cf. North and Hargreaves 2008; Runfola and Swanwick 2002). I next consider some of the challenges to theorizing musical development.

Musical development: one thing or many?

First, including different types of musical behaviour within a single theory presents a major theoretical challenge. As illustrated above, many differences in research findings can be ascribed to the particular tasks: building a composition requires different skills and poses different challenges to listening to two notes and deciding if they are the same or different, and explicit tasks also show slower rates of development than implicit ones (Schellenberg *et al.* 2005). To make progress on the relative 'rates' of development of different elements of music even within the field of musical understanding requires studies which explicitly include and compare these in real musical settings. For example, Stevens and Gallagher (2004) show that children can make better judgements based on pitch than duration, yet Schwarzer (1997) illustrated that when more potential musical elements are added children aged 5–6 choose neither of these dimensions. It is thus important that experimental demands do not unnecessarily constrain children's responses, and that researchers seek opportunities to allow children to demonstrate the full range of their understanding.

Should a theory of musical development be able to account for many different kinds of musical behaviour, including understanding alongside activities such as singing, playing instruments and composing? In developmental

psychology, existing grand theories of general development (Piaget 1953; Vygotsky 1978) have largely been abandoned in favour of more specific models such as theories of cognitive development (e.g. Halford 1992; Siegler 1996). In music, the generalizability of theories or models hinges on a balance between precision and explanatory power. As in mainstream developmental psychology, the current state of the field is disparate and lacking coherence (see also North and Hargreaves 2008). Broader approaches, like Hargreaves and Galton's model of artistic competence (1992) or Swanwick and Tillman's developmental spiral (1986), can provide a useful description of similarities in stages of understanding (loosely tied to age) across different musical activities. However, these remain at a purely descriptive level. More constrained musical models of specific musical skills or understanding (e.g. Paananen 2006a, b; Stevens and Gallagher 2004; Welch 1996) seem to be more successful in explaining musical behaviour and predicting development in a limited number of domains. It may be that an overarching theory of musical development is still out of reach—at any rate, such a theory will need to be a great deal more flexible than those currently in circulation.

Where is musical development going, and how does it get there?

Considering the process of development itself, as illustrated above, very little research has systematically attempted to map cross-sectional patterns over large enough age spans or fine enough levels of detail to be able to explain the directions or the motors of change. There are two main reasons for this. First, from a theoretical perspective, debate continues over whether development progresses linearly or in a stepwise fashion towards one or multiple end points (Bamberger 2006; Hargreaves 1996; Mills 2005; Swanwick and Tillman 1986). Secondly, most research is not methodologically designed in such a way to enable these questions to be answered. Most studies compare children of different ages (sometimes including adults). Differences imply either quantitative change resulting from exposure or qualitative change resulting from different ways of thinking, while similarities indicate no development. Furthermore, the period between 11–12 years of age and adulthood is rarely studied, and music training is rarely added as a developmental mechanism. As shown above, results seem highly dependent on the musical domain, the tasks administered, and the particular ages selected.

However, more interactive studies following children over short time spans highlight micro-level changes in their musical understanding. For example, Bamberger's (1991) detailed case study of an individual child's progress from a focus on the figural properties of melodies through to an awareness of formal features provides an insight into the process of change. This illustrates that the motor of change is the child's engagement and re-engagement with the musical material, in this case largely stimulated by a research/teaching intervention. Applying this kind of approach to more finely age- and experience-graded samples over longer time spans is necessary in order to be able to disentangle the theoretical questions of the relative contributions of age and experience which are becoming recognized as being so critical in musical development.

Natural development and cultural environments

The relative contribution of innately specified and culturally acquired aspects of musical development is another hotly debated issue. Much recent evidence supports the notion of certain aspects of musical understanding being innately specified, particularly considering elements like pitch in isolation. The cultural environment has been particularly weakly theorized in musical development: some simple approaches draw on connectionist principles to suggest that exposure predicts behaviour (Gruhn and Rauscher 2002), supported by evidence for linear patterns of development with age, for example in tonal sensitivity (Krumhansl and Keil 1982).

However, both natural and cultural approaches are rooted in a Western philosophical and psychological tradition where the individual child is either the 'motor' or the 'recipient' of development (cf. Burman 1994). For example, McPherson's explicit scope in exploring how biological, environmental, social, cultural and historical factors have shaped the acquisition of

musical skill, understanding and attitudes (2006) treats the child as a recipient of culture. Vygotsky's (1978) approach placed a far greater emphasis on the specific social and cultural experiences that individuals encounter and which shape their individual development. Given the fundamentally social nature of music in society, a more complex formulation of the learning process is required which accounts for the child as an active participant in culture. This aspect of cultural environment has been weakly theorized even in models which attempt to account for experience (e.g. Swanwick and Tillman 1986; see Runfola and Swanwick 2002). Such a goal may be achieved following Gruhn and Rauscher's suggestion to focus research on the 'micro-structure of cognition' (2002, p. 446).

Concluding remarks: the importance of context

The research carried out to date on the development of musical understanding (pitch, tonality, rhythm, metre, form, structure and style) and of musical activities (singing, instrumental learning, composing, and improvising) reveals a complex pattern of evidence. The principal debates in the field hinge around the types and breadth of development being considered, and the influences of nature and culture, age and experience. I conclude with some suggestions for future directions relating to the importance of context.

Elsewhere (Lamont 2002) I have argued for the usefulness of contextually grounded theories such as Bronfenbrenner's (1979) ecological systems theory in understanding children's developing spheres of influence and levels of engagement with music, ranging from the micro contexts of home and school up to the macro contexts of dominant beliefs in society. In similar vein, Burnard (2006) adopts a systems view in understanding influences on children's developing creativity. She identifies a 'superculture' of children's musical creativity, incorporating the overlapping spheres of culture, society, in- and out-of-school contexts to specify various microcultures to be investigated. These approaches provide more formalized and thus practical ways of identifying and exploring the significant contexts in children's and adolescents' lives which support and motivate many kinds of musical development.

A fuller consideration of context may also help address the empirical challenges of engagement and motivation for music. Not all children engage with music at school, with music tuition, or with music from different cultures or subcultures (e.g. Lamont *et al.* 2003; Stålhammar 2003). This provides a different impetus for developmental research. In addition to exploring the individual features of age and experience more systematically, it becomes vital to investigate the effects of different situations and settings on musical development of every kind. More flexible yet sensitive theories of musical development may offer solutions to these challenges, as well as informing us better about the ways in which children develop in and through music and the diversity of musical goals to which they aspire.

CHAPTER 23

The impact of music instruction on other skills

Frances H. Rauscher

Overview

As one can easily see from the chapters in this section of the Handbook, the area of children's musical development is diverse and exciting. The associated research programmes address some basic issues of human cognition and development, as well as some more applied concerns about children's musical understanding. The purpose of this chapter is to examine how making music may actually enhance children's abilities in other domains of reasoning. The goal is to integrate what is known about the area and to provide a substantive conclusion about the issue.

The Mozart effect

Our journey into the extra-musical benefits of music instruction must begin by clarifying what has been erroneously referred to as the 'Mozart effect'. The term 'Mozart effect' has been used to refer to the effects of music on children's behaviour, brain function, and overall intelligence. The phrase was initially introduced by the media in relation to a study using college students as subjects, not children (Rauscher *et al.* 1993). The study found that a composite score of three spatial tasks was higher for college students who first listened to a portion of a Mozart Sonata compared to 10 minutes of spoken relaxation instructions or silence. This facilitation lasted only 10–15 minutes. After a series of subsequent studies were unable to replicate the research using a variety of spatial tasks (for review see Chabris 1999), further analyses revealed that the effect was carried by the spatial–temporal task only (Rauscher and Shaw 1998). A meta-analysis that included 36 studies concluded that the Mozart effect 'is limited to a specific type of spatial task ... It is a moderate effect, and it is robust' (Hetland 2000a, p. 136). It is important to note that the original study made no mention of children's spatial abilities or general intelligence. To my knowledge, only three studies have examined the effect of listening to music on children's cognitive abilities, and the results are equivocal: one study found a significant effect (Ivanov and Geake 2003), whereas two studies did not (McKelvie and Low 2002; Schellenberg and Hallam 2005). The original report (Rauscher *et al.* 1993) was followed by an onslaught of media attention, with several articles extending the work to children and intelligence. Before long, the music industry began exploiting the findings. Compact discs with titles such as 'The Mozart Effect for Babies,' and even 'Mozart for Mutts' began appearing in music stores throughout North America and abroad. Indeed, there is very little research to suggest that children who listen to Mozart score higher on ability or intelligence tests than other children (see, for example, Rauscher and Hinton 2006). In fact, there is even evidence to support the notion that children who listen to popular music may score higher on a spatial–temporal task than children who listen to Mozart

(Schellenberg and Hallam 2005). From this and other studies, it appears that the Mozart effect is largely due to arousal or mood rather than to Mozart's music per se.

The effects of music instruction

This chapter, however, is not about the effects of listening to music. It is about the possible effects of music *instruction* on children's cognitive abilities. Before I begin to review the basic findings, however, two words of caution are warranted. First, several of the studies included in this chapter are *correlational.* A correlation between an intervention (e.g., music instruction) and an outcome measure (e.g., academic performance) offers no information about causality. Of course, two factors that are correlated may be causally related, although one cannot know how: A may cause B (music instruction may cause enhanced academic performance) or B may cause A (children with strong academic abilities may choose to study music). Two correlated factors may also be causally unrelated since a third factor may cause both. I therefore recommend a conservative approach to interpreting the findings of correlational studies.

Second, music should not be taught to students in order to improve their visuospatial or mathematical skills. As Hetland and Winner state,

> If the arts are given a role in our schools because people believe the arts cause academic improvement, then the arts will quickly lose their position if academic improvement does not result . . . The arts must be justified in terms of what the arts can teach that no other subject can teach.
>
> (2001, p. 3)

The studies presented here should not be used to advocate for school music programmes.

Let us now turn to the available research. Studies conducted over the past several decades have provided a wealth of information regarding the non-musical benefits of early music instruction. This line of research fits within the context of earlier discussions on the impact of early experience on children's intellectual development. During the eighteenth century the British empiricists, such as John Locke's *tabula rasa* view of the brain, linked intelligence to the natural powers of reason, implying that intelligence arises from experience and could be fostered in the right environment. In the nineteenth century, however, with the rise of rationalist science and, in particular, notions of natural selection and the study of heredity and genetics, attention was directed instead to the biological bases of intelligence. It was during this period that determinism and biological–maturational theories of intelligence took precedence. The 'nature vs nurture' debate was first articulated in the early twentieth century in terms rather similar to the framework it takes even today. Today, the debate concerning the nature of intelligence has focused on the complex effects of experience on the developing brain. New technologies, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have taken current debate beyond the historically oppositional framework of nature or nurture, emphasizing instead that intellectual potential and achievement are the result of complex, only partially understood interactions between the physical body and experience. Thus, in many ways, the study of the effects of music instruction on intelligence is only the latest episode in a long-running controversy, and one with extensive historical roots.

One of the earliest studies to experimentally examine the effects of instrumental instruction on children's cognitive abilities was performed by Irving Hurwitz and his colleagues (Hurwitz *et al.* 1975). First-grade children were assigned to one of two groups. The experimental group received Kodály music lessons for five days each week for seven months. The control group did not receive music instruction. The Kodály method emphasizes the development of rhythmical and motor skills. The purpose of the study was to examine the effects of this method on children's sequencing and spatial skills and reading ability. Children were tested using a variety of sequencing and spatial tasks, as well as two tasks measuring general verbal intelligence. The experimental group scored significantly higher than the control group on three of the five sequencing tasks and four of the five spatial tasks. No significant differences between groups

were found for either of the verbal measures. However, when the data were analysed according to sex, it was determined that the effect was carried by the boys in the study. Girls in the experimental and control groups did not differ on any of the items administered. To determine if reading ability was affected by Kodály music instruction, the authors compared the school records of children who received the instruction in the first grade to children who did not receive the instruction. Although there was no difference between the two groups on reading readiness at the beginning of the first grade, at the end of the first grade, after one academic year of Kodály instruction, the reading achievement scores of the children in the music group were significantly higher than those in the comparison group. When tested again at the end of the second grade, after two academic years of Kodály instruction, the Kodály group continued to score higher than the control group on reading achievement. Spatial and sequencing skills were not retested. Although the authors acknowledge that these positive results may have been due to the presence of a Hawthorne effect (wherein performance improves following any new intervention), they concluded that further research examining the mechanisms of transfer from music instruction to spatial abilities and reading achievement is warranted.

A more recent study also found that music instruction may improve spatial task performance (Rauscher *et al.* 1997). We assigned students from three preschools to music, computer, or no-instruction groups. The instruction groups received several months of instruction in either piano keyboard coupled with group singing sessions, group singing sessions only, or computer lessons. The purpose of the computer group was to control for the Hawthorne effect. Keyboard and computer lessons were provided individually each week for ten minutes, whereas group singing sessions occurred daily for 30 minutes. One hour each day was reserved for keyboard or computer practice. The children were tested using one spatial–temporal reasoning task and three spatial recognition tasks taken from the Wechsler Preschool and Primary Scale of Intelligence-Revised (WPPSI-R) (Wechsler 1989) before and after instruction began. The spatial–temporal task required the children to arrange pieces of a puzzle to create a meaningful whole. Placing the pieces together in the correct order resulted in a higher score. The spatial recognition tasks involved matching, categorizing, and recognizing similarities of objects that were physically presented to the child. Sequential order is not relevant for these types of tasks. Although the pre-test scores of the four groups did not differ, children in the keyboard group scored significantly higher on the spatial–temporal task only. There were no differences between groups on the spatial–recognition tasks. The singing, computer and no-instruction groups did not improve significantly on any of the tests administered. It should be noted, however, that the musical experience of the children in the singing group was quite different from that of the keyboard group. The singing group did not receive individual instruction. A music instructor played the piano while the children simply sang along, whereas the keyboard group learned how to read music. One therefore cannot conclude from this study that vocal instruction would not affect spatial–temporal task performance.

In a related study, Gromko and Poorman (1998) examined the spatial–temporal task performance of children following seven months of weekly singing and songbell instruction. The children's spatial abilities were pre- and post-tested using five subtests of the WPPSI. A composite score was then computed from these five subtests. Results indicated that the music group's gain scores (post-test minus pre-test) were significantly higher than the control group's gain scores. The researchers concluded that music training affects the development of spatial intelligence in young children.

Several other studies have found improvement in children's spatial skills following music instruction (Bilhartz *et al.* 2000; Costa-Giomi 1999; Graziano *et al.* 1999; Orsmond and Miller 1999; Rauscher 2002; Rauscher and Zupan 2000; Zafranas 2004). A relatively recent meta-analysis synthesized the results of 15 independent studies and concluded that 'music instruction has ... been clearly shown to enhance at least one kind of spatial skill and may in the future be shown to enhance others' (Hetland 2000b, p. 226). However, other areas of intelligence may also be affected by music instruction. For example, Gardiner

and his colleagues provided children with seven months of Kodály music instruction along with visual arts training (experimental group) (Gardiner *et al.* 1996). Their reading and maths scores were then compared to children who received the school's standard arts curriculum (control group). Although the pre-test scores of the experimental group were lower than the control group's grade averages for reading and maths, after the special arts training they scored equal to the control group in reading and above them in maths. The same result was found when the children were tested following an additional seven months of special arts training. Unfortunately, because the music and arts instruction were provided together, it is not possible to determine if the results were due to the music curriculum.

A recent study found that early music instruction emphasizing different musical skills produced different effects on cognitive performance (Rauscher *et al.* 2007). At-risk preschool children received piano, singing, rhythm, computer, or no instruction for two years. All children were pre- and post-tested using standardized intelligence, visuospatial, and auditory–perceptual tests. Although pre-test scores of the five groups did not differ, the three music groups scored significantly higher following instruction than the control groups on mental imagery tasks. The scores of the rhythm group, however, were significantly higher than all other groups on tasks requiring temporal cognition and mathematical ability. This suggests that the type of music instruction children receive has measurably different effects on cognition, with instruction in rhythm having the strongest impact on temporal and sequencing tasks.

Other studies have found advances in other abilities following music instruction. A positive relationship between reading and music instruction has been reported by several researchers (Anvari *et al.* 2002; Butzlaff 2000; Douglas and Willatts 1994). However, most of these studies were correlational rather than experimental and therefore cannot determine anything about causality. See Hurwitz *et al.* (1975), described above, for an experimental approach to understanding music's effects on reading. In two separate studies, Overy and her colleagues reported that fifteen weeks of rhythm-based music instruction improved the phonemic awareness and spelling abilities of dyslexic children (Overy 2000, 2003). In addition, one study reported that children who received music lessons for two or more years scored higher than controls on a mathematics achievement test (Cheek and Smith 1999). Two studies have found relationships between music instruction and verbal memory (Chan *et al.* 1998; Ho *et al.* 2003).

These diverse findings led Schellenberg (2004) to wonder if music instruction might affect general intelligence. This indeed appears to be the case: 144 six-year-olds were randomly assigned to four groups: two music-lesson groups (keyboard or voice) and two control groups (drama lessons or no lessons). Lessons were provided over a period of 36 weeks in groups of six. The Wechsler Intelligence Scale for Children (WISC-III) (Wechsler 1991), a test of general intelligence, was administered before and after the 36-week period. The keyboard and voice groups showed small but significant increases in IQ compared to children in the drama and no-lesson control groups combined. Schellenberg then examined differences across groups in individual WISC-III subtests, such as verbal comprehension and perceptual organization, and found significant advantage for the consolidated music group on 10 of 12 scales. Based on the number of experimental studies showing effects of keyboard instruction on spatial abilities, Catterall and Rauscher (2008) theorized that the students who received music instruction in Schellenberg's study might show greater improvement in the scales related to spatial ability than in other scales. To test this, we compared the verbal IQ and performance (i.e., spatial) IQ scores of the music and control groups separately. Since the numerical scales for verbal and performance IQ differ, we calculated the effect sizes associated with participating in music by dividing the music group's gain scores by the respective standard deviations of the control group's pre-test scores on the same measure. Music participation in Schellenberg's experiment showed an effect size of 0.45 on verbal IQ and a somewhat larger effect size (0.55) on performance IQ. An effect size of 0.30 is considered moderate but significant. Effect sizes above 0.50 are considered robust. These data suggest that the increase in general intelligence affected by

music lessons was due to gains in visual–spatial intelligence more than to gains in verbal intelligence. We concluded that the impact of music on general intelligence may be driven by gains in spatial intelligence.

Neurophysiological mechanisms

Playing a musical instrument requires instantaneous examination of what has already occurred in the performance (e.g., up-bow vs down-bow; fingering) as well as thinking ahead to prepare for future challenges. Researchers over the past few decades have examined the brain bases for these highly specialized skills. One of the most remarkable features about the brain is its ability to reorganize as a function of experience. Based on William James' suggestion at the end of the nineteenth century that learning may alter synaptic connectivity (James 1890), Donald Hebb formulated an important and innovative theory that views the brain as a dynamic system (Hebb 1949). Hebb's theory is often paraphrased as 'neurons that fire together wire together', although this oversimplification of the nervous system should not be taken literally. The theory is commonly evoked to explain learning in which simultaneous activation of cells leads to pronounced increases in synaptic strength—a phenomenon known as Hebbian learning. The advent of brain imaging technology has permitted remarkable gains in our understanding of how an individual's brain develops and produces uniquely human capacities. Imaging studies suggest that different amounts and types of environmental input can alter cortical structure and function. Specifically, an increasing amount of research suggests that early music instruction influences the brain, perception, and cognition.

The effects of music instruction are evident in anatomical differences in the brains of musicians versus non-musicians. Studies have shown that extensive practice on a musical instrument can induce cortical reorganization, perhaps due to Hebbian learning rules. This reorganization may consequently produce functional changes in how the brain processes information relevant to the particular area of expertise. If the extensive practice occurs early in development, the alterations in brain function may become hardwired and produce permanent changes in the way such information is processed. Such changes may represent the neural substrate of behavioural expertise. People who begin music instruction later may still develop considerable expertise, but perhaps without the cortical reorganization that occurs in those who begin earlier in life.

A study using structural magnetic resonance imaging reported that musicians who began instruction before age 7 had a larger cross-section of the anterior corpus callosum than non-musicians and musicians who began instruction after age 7 (Schlaug *et al.* 1995). No differences were found between non-musicians and musicians who began instruction after age 7, suggesting the importance of early music instruction for callosal plasticity. Schlaug and his colleagues proposed that the differences found reflect the need for greater interhemispheric communication of individuals performing complex bimanual motor sequences.

To examine differences in the motor cortex of musicians and non-musicians, researchers have examined the intrasulcal length of the posterior bank of the precentral gyrus (ILPG), a marker that roughly corresponds to the area of the motor cortex (Amunts *et al.* 1997). The researchers found a greater symmetry of the ILPG in the dorsal subregion of the motor cortex, a brain region that corresponds to the location of the functional hand motor area, of right-handed musicians (mostly pianists) compared to right-handed non-musicians. This symmetry is possibly due to a disproportionate increase in ILPG of the non-dominant (right) hemisphere as a function of the bimanual motor movements required for playing the piano. The ILPG was larger in both the left and right hemispheres in musicians than in non-musicians. The size of the ILPG in both hemispheres correlated positively with the age that music training commenced: pianists who began instruction at the earliest ages had the largest ILPGs.

A study using magnetoencephalography (MEG) provides further evidence for the influence of music instruction on plasticity. Dipole moments of the digits of the left hand were significantly larger in violinists compared to non-musicians (Elbert *et al.* 1995). Greater dipole

moments can indicate either a larger cortical representation for that function or enhanced coherence of nerve impulses in that region. Right-hand representation did not differ between string players and non-musicians. The largest effects were found for those who began before age 12. A follow-up MEG study found auditory cortex dipole moments for piano tones were enlarged in musicians relative to non-musicians (Pantev *et al.* 1998). Again, there was a positive correlation between effect size and when participants initiated instruction.

Taken together, these studies and others suggest that early music training alters brain structure and/or function relevant to cognition. However, it remains unclear whether these differences between the brains of musicians and non-musicians existed prior to music instruction, or whether they occurred as a function of music instruction. To determine whether these differences reflect plasticity due to music training or instead are markers of musical interest or aptitude, it would be informative to conduct an imaging study of children before music instruction began and again following the onset of instruction. The brain scans of those children could then be compared with those of children who are not studying a musical instrument. This study is currently underway (Norton *et al.* 2005). Using magnetic resonance imaging (MRI), the brains of young children were scanned prior to the onset of instrumental music instruction. Children who would not be receiving music instruction were also scanned. Spatial, verbal, motoric, and music perception tasks were also administered. Preliminary data revealed no pre-existing differences of any kind between the experimental and control groups. The children will continue to be examined on a yearly basis. The lack of any pre-existing differences in brain structure and cognitive task performance suggests that the morphological and cognitive dissimilarities between musically trained and untrained individuals may be an outcome of music instruction.

Cognitive transfer

Transfer occurs when a person applies knowledge or skills that have been learned in one context to new contexts. Researchers interested in transfer were initially guided by theories that emphasized the similarities between the initial learning experience and later learning. Thorndike (1913) proposed that the amount of transfer that could occur between two domains was dependent upon the similarity of the elements of the domains. The more equivalent the elements of the two domains, the greater the likelihood of positive transfer. Thus, transfer is always a function of the relationship between what is learned and what is tested.

Psychologists draw a distinction between near and far transfer. Near transfer involves applying the same knowledge or skill in very similar circumstances, such as using one's car-driving skills to drive a truck. Far transfer implies a big leap. A chess master carrying the notion of control of the centre from chess to political or military settings would count as far transfer. Not only are political and military settings quite different in general from chess despite chess's underlying military metaphor, but the meaning of 'centre' plays out differently. In chess, it is the centre area of the board. In the military context, centre might mean a centre of command, communications, munitions, or supply, for example. Any of these would make tempting targets.

Salomon and Perkins (1989) point out two distinct mechanisms of transfer, the low road and the high road. Low-road transfer occurs when perceptual similarities of one situation to another trigger the making of a connection. For example, consider a professional figure-skater who switches to roller-blading. The familiar action of pushing off on one foot, then gliding, and then pushing off with the other foot evoke all the old figure-skating habits. Low-road transfer depends on abundant practice with the skill or knowledge in question to set up the perceptual triggering. It is a phenomenon of experience. Consequently, there is not much far low-road transfer. Far low-road transfer can occur, however, when the same skill gets practiced over a variety of circumstances, gradually stretching from one context to another until it achieves high generality.

High-road transfer, on the other hand, depends upon the learners' deliberate and mindful abstraction of a principle. The chess master that applies chess skills to a military setting is engaging in high-road transfer from chess to

military strategy. In contrast to low-road processing, which is relatively spontaneous, high-road processing requires reflection. The transfer of musical skills to, for example, spatial–temporal tasks may therefore be an example of low-road far transfer. To determine if this is indeed the case one would need to somehow measure the overlap between the original domain of learning (e.g., playing a musical instrument) and the novel one (e.g., performing a spatial–temporal task). This undertaking would require a theory of how knowledge is represented and conceptually mapped across the domains.

Singley and Anderson (1989) argue that transfer between tasks is a function of the degree to which the tasks share *cognitive* elements. This hypothesis is hard to test experimentally until the task components are identified. Thus, a complete understanding of spontaneous transfer from music to another domain of reasoning (e.g., spatial–temporal reasoning or arithmetic) is possible only to the extent that the cognitive elements of the two domains can be identified. For example, the part–whole concept is a very important construct for many mathematical problems. This concept requires understanding the relationship between parts to wholes, such as when learning percentages, decimals, and fractions. In music, the part–whole concept is especially relevant in the conceptualization of rhythm. A literate musician is required to continually mentally subdivide the beat to arrive at the correct interpretation of rhythmic notation. The structure of the problem is essentially the same as any part–whole problem posed mathematically. Perhaps this relationship helps explain the finding that children who received instruction on rhythm instruments scored higher on part–whole mathematics problems than those who received piano or singing instruction (Rauscher *et al.* 2007). Further investigation into the components common to musical and mathematical knowledge will aid in the understanding of these possible transfer effects.

Schellenberg (2003) suggests that

> the ability to attend to rapidly changing temporal information, skills relevant to auditory stream segregation, the ability to detect temporal groups, sensitivity to signals of closure and other gestalt cues of form, emotional sensitivity and fine motor skills ... should be particularly likely to transfer to a variety of nonmusical domains.
>
> (p. 444)

Likewise, Norton *et al.* (2005, p. 131) state that the

> skills such as decoding visual information into motor activity, memorizing extended passages of music, learning music structures and rules, learning to make fine auditory spectral and temporal discriminations, and learning to perform skilled bimanual finer movements

may all contribute to the transfer of musical knowledge to other cognitive abilities. For example, both music and mathematics employ and manipulate symbols, they both investigate and develop patterns (numerical in the case of math, and tonal or rhythmic for music), and they are both abstract constructions. A trained musician finds order in what is essentially arbitrarily organized sound, and has conceptually constructed a system of patterns, relationships, regularities, series, proportions, fractions, subdivisions, and ratios, represented and understood with a complex array of symbols. Thus, a deep structural level overlap between musicianship and mathematical knowledge could be expected in a number of areas. Research grounded in transfer theory has indeed shown relationships between music instruction and a variety of cognitively related skills (see, for example, Gromko 2004). Although studies specifically testing transfer as a mechanism are extremely difficult to implement due to an insufficient understanding of the overlap of the cognitive components inherent in the two domains, I suggest that transfer remains a potential explanation for improved cognitive abilities following music instruction.

Conclusion

Traditionally, school curricula have been characterized by hard boundaries between disciplines. The studies presented in this chapter suggest that curriculum reform could aim at the development of more permeable boundaries between disciplines, so that spontaneous transfer

of skills and knowledge is facilitated. Zohar (1994) argues that thinking skills are likely to be enhanced if students receive explicit instruction to recognize the underlying logical structures of domains that underpin transfer. In addition to explicit teaching, it is possible that students' thinking and learning could be enhanced through analysis of the structural elements of disciplines that appear distinct on the surface but that are conceptually and logically similar at deep structural levels.

I conclude this chapter as I began it: with a word of caution. Although this area of study certainly seems worthy of further investigation in educational settings, we must be careful when applying the findings of music transfer to educational practice. Indeed, this research represents an excellent example of what has become known as a 'design experiment'. Design experiments are described as educational research experiments carried out in a complex learning context to determine how an innovation affects student learning and educational practice (Cobb *et al.* 2003). Real-life educational contexts are, in turn, excellent settings for experimental tests of an intervention. I believe such experiments represent a crucial research approach within the broader context of partnerships involving teachers, educational researchers, and scientists. I do not, however, advocate teaching music to students in order to improve their visuospatial or mathematical skills. The research base on studies showing enhancement of cognitive function following music instruction is still in its infancy, and there is certainly more to learn. The studies presented here are of scientific importance because they suggest that music and other areas of intelligence share common elements and may be psychologically and neurologically related. I believe researchers should continue to search for links between music instruction and cognitive performance, but that these studies should not be placed at the top of the advocacy agenda. In a recent *Boston Globe* article on arts education, Winner and Hetland (2007) state that

> We don't need the arts in our schools to raise mathematical and verbal skills—we already target these in maths and language arts. We need the arts because in addition to introducing students to aesthetic appreciation, they teach other modes of thinking we value.
>
> (2007, p. E1)

Music education should not have to prove its value by showing that it has non-musical outcomes.

PART 6

Learning musical skills

Edited by Susan Hallam

CHAPTER 24

Musical potential

Gary McPherson and Susan Hallam

Introduction

There is general agreement that music is a universal trait of humankind (Blacking 1995), that *Homo sapiens* as a species has the propensity for musical development, and that musical potential is as universal as linguistic ability (Wallin *et al.* 2000). An ongoing controversy persists however, concerning the extent of individual variability in musical potential and the extent to which observable differences in acquiring musical skills result from social contexts that facilitate learning, genetic factors, or interactions between the two. This chapter outlines key elements of these debates and also considers how 'musical potential' has been assessed.

The nature–nurture debate

Francis Galton (1876) pioneered the study of genetic influences on learning and development using evidence from twin studies to argue that traits leading to eminence were largely inherited. However, recent research suggests that there are complex interactions between the environment and genetic factors which influence observable behaviour, with genetic factors having a closer association with physical attributes than psychological factors, and that many dimensions of an individual's development, such as memory, language development and intelligence, can be enhanced through systematic practice and learning (Gross 2005). Research attempting to establish the extent of the heritability of musical potential has reached similar conclusions with no decisive evidence showing that it is directly dependent on aural acuity, intelligence, or other types of artistic ability (for reviews see Hodges 1996; Shuter-Dyson 1999). A more plausible explanation is that musical development is the result of a range of gene combinations interacting with environmental stimulation in an interactive rather than additive manner (Ceci 1990). Evidence that the cerebral cortex has an amazing ability to self-organize in response to stimuli such as music supports this view (Rauschecker 2003). Cortical activation during music processing reflects personal musical experiences accumulated over time including listening to music, learning to play an instrument, formal instruction, and professional training resulting in multiple mental representations of music that are, in part, interchangeable and rapidly adaptive (Altenmuller 2003). While self-selection for musicianship by individuals with innate functional and structural brain differences cannot be completely ruled out, the evidence indicates that it is musical training that leads to changes in brain function and structure (Schlaug 2003). As genetic inheritance can clearly be enhanced by a musically enriched social context, considerable research is now focused on identifying the environmental factors that facilitate or impede musical development.

Musical savants and Williams syndrome

The most difficult phenomena to explain without resorting to some notion of inherited differences in musical potential are children at the extremes of neurodevelopment, for instance, musical savants, children with Williams syndrome, and child prodigies.

Savants have generally low cognitive functioning but are able to achieve at normal levels in some activities, especially those related to 'non-symbolic, artistic, visual and motor abilities'

such as 'music, art, maths and various forms of calculating (such as calendar-counting)' (Gross 2005, p. 685). Many musical savants exhibit absolute pitch (Miller 1989) enabling them to make confident, rapid judgements about individual pitches and complex chords. They are also sensitive to rules reflecting harmonic relationships and the structure of musical compositions (Young and Nettelback 1995; Sloboda *et al.* 1985). Explaining these skills without resorting to genetic explanations is difficult. However, environmental influences should not be underestimated. Many savants have limited sight and language disorders, which may lead to increased development of auditory processing skills and the use of music as a means of communication. They also spend considerable time practising their skills.

Individuals with Williams syndrome have low measured intelligence and difficulties with mathematical and spatial reasoning but are more adept than might be expected in language and music, the development of the latter depending on access to appropriate musical opportunities. Levitin and colleagues (Levitin and Bellugi 1998; Levitin *et al.* 2003, 2007) have shown that these children are typically as musically accomplished, engaged and interested as ordinary children but display greater emotional responses to music, become interested at a younger age, spend more time listening to music, instinctively experience music much more fully than others, and possess a highly sensitive emotional attachment to music.

Musical prodigies

Prodigies are children who, from an early age, display exceptional talent. Famous examples include Mozart, Bach, Beethoven and Mendelssohn whose significant success in later life depended on having undertaken considerable focused and well-directed effort during their early years (McPherson and Williamon 2006). Ruthsatz and Detterman (2003) identified a recent example of a prodigy, a 6-year-old who despite having had no formal tuition acquired considerable musical skill by imitating other performers and improvising his own musical pieces. He could sing in two languages, had taught himself to play numerous instruments, had an Intelligence Quotient (IQ) of 132, an extraordinary memory, and attained a high score on Gordon's (1982) music aptitude measure. His exceptional musical behaviours were self-motivated and spontaneous and he particularly liked entertaining people. His musical abilities were closely aligned with his extraordinary memory and high IQ, more so than with the time or type of practice he undertook. As we will see below, such early, specific situational behaviours that spark changes in cognitive development to allow a child to be able to direct extremely high levels of attention toward music are becoming of great interest to researchers.

The overt musical behaviours of savants and Williams syndrome individuals share some similarities with the behaviour of prodigies, even though their neurodevelopmental trajectories differ. Neuroconstructivists suggest that typical and atypical development can be viewed as different trajectories in a continuum of possibilities. An atypically developing trajectory affects the interactions of others with the child and the kind of experiences that the child seeks out, which further impact on the trajectory (Mareschal *et al.* 2007). For example, when parents believe that their child has musical ability, they are more inclined to provide musical resources and reward musical activity, which in turn supports increasing levels of expertise as the child engages more fully with music (McPherson, in press). These social dynamics result in the child developing particular neural structures that make further musical development much easier (Altenmüller and Gruhn 2002; Hodges 2006). Familial responses of this type may occur in relation to savants, Williams syndrome children, and prodigies.

Other research suggests that the typical 'rage to master' which characterizes prodigies can be explained as a result of domain-specific high attentional control that begins in infancy to produce a spontaneous version of deliberate practice (Vandervert and Liu in press). This view suggests that the high attentional control of prodigies originates and then accelerates connections between the cerebral cortex (where mental modelling construction and repetition occur) and the cerebellum (where model formation occurs), such that cerebellar control models feedback to the working memory areas

of the cortex. In this way the child prodigy's working memory becomes faster, more concentrated, and more efficient (Vandervert 2007). This explains the behaviour of these individuals in terms of 'the *reciprocal* learning relationships between the anticipatory, *adaptive* cognitive-affective and attentional modelling functions of the cerebellum and those of the cerebal cortex' (Vandervert and Liu in press).

Shavinina (in press) proposes that extreme levels of giftedness occur as a result of stimulation and activation early in life when the developing child selectively responds in ways that heighten his or her cognitive, emotional, and social sensitivities. Such sensitive periods in these children's early years provide the foundations for giftedness in that they accelerate the gifted child's mental development through the actualization of intellectual potential and cognitive experience (Shavinana 2007). Cognitive experience of this type provides the psychological basis from which highly gifted children are able to develop their creative, metacognitive, and extracognitive (i.e., feelings, beliefs, intellectual values, intuition) abilities.

The above explanations support an interactive, dynamic model of how exceptional achievement in music develops as a result of environmental forces acting together with innate potentials at critical moments in a child's development. The following sections attempt to frame these conceptions within specific areas of musical engagement.

The role of learning in the development of musical expertise

Research undertaken within the expertise paradigm has also challenged previously accepted notions that high-level achievement depends exclusively on inherited ability. The basic premise of this theory is that time spent on 'deliberate practice' underpins the development of high-quality expert performance. For instance, it has been established that classical Western musicians need to have accrued up to 16 years of practice to achieve levels that will lead to international standing in playing an instrument. Such individuals usually begin playing at a very early age and over succeeding years increase the amount of practice undertaken, sometimes up to as much as 50 hours a week by adolescence (Sosniak 1985).

Ericsson and colleagues (1993) have suggested a monotonic relationship between 'deliberate practice' (which they define as goal-oriented, structured and effortful practice that is influenced by motivation, resources and attention) and an individual's acquired performance (for review see Chapter 25 this volume, Lehmann and Gruber 2006). This is supported by evidence that musicians with the highest levels of expertise accumulate considerably more hours of practice than their less successful peers, although there are substantial individual (Jørgensen 2002; Sloboda *et al.* 1996), instrumental and genre differences (Kopiez 1998; Gruber *et al.* 2004; Jørgensen 2002).

While researchers agree that practice is important in facilitating the development of expertise, several studies question the simplicity of a monotonic relationship. Sloboda and Howe (1991) found that students identified as having greater ability by their teachers had spread their practice across each of their instruments and therefore undertaken less practice on their main instrument. Wagner (1975) found that increased practice did not lead to any greater improvement in performance over an eight-week period, and Zurcher (1972) found no relationship between total practice time and performance achievement.

Reported correlations between achievement and time spent practising vary between 0.25 (Doan 1973 and 0.67 (Hallam 1998a). In the Hallam study, the correlation rose to 0.84 when years of time learning was correlated with achievement, as opposed to time spent practising. It seems therefore, that the overall length of time over which learning has taken place may be as important as the actual amount of practice in determining level of expertise. This was especially evident in a causal model developed by McPherson *et al.* (1997) which shows a strong association between the length of time learning and taking lessons and high school musicians' ability to sight-read and perform music that they had rehearsed over the previous weeks and months.

Accumulated practice from the time of beginning learning to the present does not seem to

predict the quality of performance at any point in time (Hallam 1998a; Williamon and Valentine 2000). Other factors such as teachers' ratings of musical ability, self-esteem, and involvement in extra-curricular music activities are better predictors of achievement (Hallam 2004). A longitudinal study with beginning instrumentalists also showed that accumulated practice only partly explains children's ability to perform rehearsed music and sight-read and none of their ability to memorize music, play by ear, or improvise. McPherson (2005) showed that accumulated practice explained between 9 and 32 per cent of the variance in the learner's ability to perform rehearsed repertoire over their first three years of learning, and even less for their sight-reading ability. Other skills, such as the sophistication of the mental strategies which the young players adopted to guide their playing, were more important (see also Chapter 25 this volume).

To date, much of the research has failed to take account of the amount of time spent acquiring musical skills through listening to music, engaging in playful musical activity, and participating in group activities where learning and consolidation of skills occurs in an informal learning context (e.g. Kokotsaki and Hallam 2007). In addition, research has neglected those who may have undertaken considerable amounts of practice but have dropped out of music instruction. There are complex relationships between prior knowledge, motivation, effort and perceived efficacy which influence decisions to continue or discontinue learning (Hallam 1998a; Sloboda *et al.* 1996). When a child begins to learn an instrument, prior musical knowledge affects facility of learning and the time needed to achieve mastery. While undertaking additional practice may compensate for a lack of prior knowledge, this has a time cost and requires perseverance. If a task proves too challenging, then a child may perceive that the effort required to succeed is too great and may give up learning altogether (Hurley 1995). Difficulties may also be evident when a child perceives that he or she does not have sufficient ability. Such perceptions often lead to a loss of self-esteem, loss of motivation, less practice, and a downward spiral leading to the termination of lessons (Austin *et al.* 2006; Chandler *et al.* 1987).

Another way to understanding individual differences is to focus on the personal beliefs held by learners and their parents. Parental and child ability conceptions are recognized as having a major impact on motivation and the desire of children to continue learning, especially when faced with obstacles (Austin *et al.* 2006). Indeed, McPherson's (in press) review of literature on mother–child interactions shows that parental ability conceptions can be self-fulfilling. McPherson and Davidson (2002) interviewed mothers before and after their child commenced learning an instrument. Those who held fixed views that their child may not have sufficient ability to succeed musically tended to provide less support for practice than mothers whose view was more malleable. They were also more likely to encourage their child to pursue other activities when they came to believe that their child was not coping. These fixed views of musical potential explained why some of the unsuccessful learners came to feel that they did not have sufficient ability to cope with learning music. Some mothers actually gave up on their child as a potential musician much sooner than the child.

The development of general musical skills

The impact of parents and the home environment is of profound importance in the development of children's musical potential (McPherson, in press). The general milieu of the environment to which a child is exposed and the opportunities parents and significant others provide are among the most critical factors for realizing children's musical potential (McPherson and Williamon 2006)(see also Chapter 28 this volume).

The seeds of musical potential are sown early because the human auditory system is functional 3–4 months before birth. After 28 to 30 weeks of gestation, foetuses can reliably react to external sounds, such that their heart rates vary as a result of exposure to music (Parncutt 2006). The process of musical enculturation therefore begins from the point at which brain development starts to become influenced by auditory stimulation. These processes gain momentum in the minutes after birth when a mother and infant will imitate each other's vocalizations in

ways that show a shared emotional experience that some believe is the very basis of musicality (Trevarthen and Malloch 2002).

In the immediate months after an infant is born, the complex skills required for understanding and analysing music within any particular culture start to develop as a result of ongoing exposure to music. Even though each infant will experience many different levels of exposure, the perceptual and motor control needed to sing an intended pitch and the self-monitoring necessary to notice pitch or rhythmic differences can be accelerated by training (Trehub 2006). Wide individual differences exist regarding the extent to which preschool children engage in singing. For some, it is a part of almost all activities, while others sing only occasionally (Sundin 1997). Even though their exposure to music will have been markedly different, all children will have typically developed a surprising array of internal schemata for particular types of music long before they reach school or begin formal music instruction.

Measuring musical potential

Historically, the developers of musical aptitude tests have held varying views regarding the heritability of musical ability. Seashore (1938a, Seashore *et al.* 1938) believed that musical ability was a set of loosely related basic aural discrimination skills, which had a genetic basis and did not change over time. Wing (1981), Drake (1957) and Bentley (1966) shared Seashore's view of musical ability as being inherited, although they differed in their conceptions of the nature of that ability and how it might be assessed.

More recent tests, based on measurements involving tonal (melody, harmony), rhythm (tempo, metre), and preference (phrasing, balance, style) aptitudes, have been devised by Gordon (1965, 1979, 1982). Gordon (2007) suggests that students rarely display high (or low) aptitudes in all seven aptitudes and that all are based on the ability to 'audiate'; a term he has coined to describe how individuals give meaning to music that is heard or imagined.

The rationale underlying all of these approaches is that 'musicality' has its basis in aural perception. However, the predictive reliability of all of these measures is generally low (Hodges and Haack 1996). While alternative, more active measures for selecting pupils for learning to play an instrument have been adopted by teachers, these have tended not to be formalized. Perhaps the most common of these has been selection based on the child's ability to sing. However, the relationship between developmental tonal aptitude and use of the singing voice may also be very small (Rutkowski 1996). Researchers now generally recognize that aural skills alone are insufficient to predict future success across the full range of musical activities, especially those involving motor skills (Gilbert 1981) and creativity (Vaughan 1977; Webster 1988).

Recent conceptions of musical potential

McPherson and Williamon (2006) adapted Gagné's (2003) *differentiated model of giftedness and talent* to music as a means of defining the natural innate abilities, intrapersonal factors, and environmental catalysts that might impact on the development of musical skills. This conception defines *gifts* (e.g., intellectual, creative, socio-affective, sensorimotor) as natural innate potentials to achieve and *talent* as observable skills. The framework proposes that at least eight distinct types of musical talents (performing, improvising, composing, arranging, analysing, appraising, conducting, music teaching) can be developed through systematic practice and training. Moreover, although physical and mental dexterity, musicality, motor memory and auditory memory are all evident in the first few weeks of formal musical training, each needs to be refined and developed further through extensive practice and learning for children to develop their musical talents. Another key element of the theory is that some types of talents can go unnoticed or, as in the case of composing, develop later than others. By including a range of non-performance based outcomes of musical involvement, the model represents a broader conception of musical potential than has been evident in the past.

As an extension, McPherson (1993, 1996) distinguishes between visual (i.e., sight-reading, performing rehearsed music from notation), aural (i.e., playing from memory and by ear)

and creative (i.e., improvising) aspects of music performance. When considering these in relation to groups of children of differing ages and abilities, he found that different musical skills are involved in developing each of these ways of performing music, that there is not an automatic transfer between the three orientations, and that each needs to be developed separately and in combination to maximize potential. This is rarely the case in most formal learning situations, where visual forms of performance often dominate at the expense of other orientations.

From an even wider perspective, Hallam (1998b) suggests that learning to play a musical instrument depends on the development of a wide range of different professional and personal skills. Some of these may be required for all musical activities, and others are applied more selectively to particular tasks (see Table 24.1). In order to become a successful musician, individuals need to develop social skills (being able to work with other musicians, promoters, the public); planning and organizational skills (planning practice schedules, programmes, travel

Table 24.1 Musical skills

Aural skills required for:	Developing rhythmic accuracy and a sense of pulse;
	Good intonation;
	The facility to know how music will sound without having to play it;
	Improvisational skills.
Cognitive skills required in the processes of:	Reading music;
	Transposition;
	Understanding keys;
	Understanding harmony;
	Understanding the structure of music;
	The memorization of music;
	Composing;
	Understanding different musical styles and their cultural and historic contexts.
Technical skills required for developing:	Instrument specific skills;
	Technical agility;
	Articulation;
	Expressive tone quality.
Musicianship skills are concerned with:	Being able to play expressively;
	Being able to project sound;
	Developing control;
	Conveying meaning.
Performance skills include:	Being able to communicate with an audience;
	Communicating with other performers;
	Being able to coordinate a group;
	Presenting to an audience.
Learning skills are concerned with:	Being able to learn, monitor and evaluate progress independently.

arrangements); and time management skills (being punctual, meeting deadlines). These are clearly required for developing expertise in a range of professions and while necessary are not exclusively 'musical'.

Actualization of musical potential

In the modern world, children have greater access to music through the media and are able to learn music in a multitude of different ways from the past. Technological developments have resulted in changes to the way music is perceived and valued within society, such that mere aural perception is no longer regarded as the defining aspect of musical ability.

Haroutounian (2000), in analysing the level of importance attached to particular criteria in identifying musically able children, suggests that the general behaviours of 'sustained interest' and 'self-discipline' are more important than music-specific characteristics which are normally regarded as indicative of musical ability. Similarly, Hallam and Prince (2003) asked a sample of musicians, student musicians, educators, and the general public to define musical ability. They reported that 71 per cent of the respondents viewed musical ability as being able to play a musical instrument or sing. This finding suggests that musical ability is often identified on the basis of developing practical skills. Overall, 28 per cent of the sample mentioned aural skills as indicative of musical ability, 32 per cent included listening and understanding, 24 per cent having an appreciation of music, and 15 per cent being responsive to music. The integration of a range of skills was cited by only 9 per cent of respondents. Personal qualities including motivation, personal expression, immersion in music, total commitment, and metacognition (being able to learn how to learn) were cited most often by musicians. Unsurprisingly, the musicians gave more complex responses, with many more elements in their explanations.

Further work by Hallam and Shaw (2003) using rating scales to illicit responses to a set of statements about musical ability showed that it was conceptualized in relation to rhythmic ability, organization of sound, communication, motivation, personal characteristics, the integration of a range of complex skills, and performing in a group. Having a musical ear ranked lower in responses than might have been expected given its prominent position with regard to musical ability historically. The high ratings given to motivation and personal commitment demonstrate their importance in developing high-level skills. Overall, the conceptions of musical ability generated by the research were complex and multifaceted, and they reflected the wide range of expert achievement that occurs in the music professions of the developed world.

Conclusions

The extent to which genetic endowment underpins or limits all subsequent musical development has and continues to be fiercely debated (see Hallam 2006; McPherson and Williamon 2006; *High Ability Studies* Volume 18; *Behavioral and Brain Sciences* Volume 21), although there is general consensus that human beings as a species are pre-programmed to acquire a wide range of musical skills. We argue that what children are born with *enables* rather than *constrains* what they will eventually be able to achieve. While a range of generalized abilities may come into play when learning music, a host of environmental and personal catalysts work in combination with teaching and learning processes to develop particular types of talent. These talents form the basis of the many varied ongoing professional, amateur, and informal forms of meaningful engagement that individuals can have with music.

In developed countries, where formal schooling has taken over some of the traditional roles of the family, tests of musical aptitude have been devised to facilitate the identification of children who might benefit from music instruction, or to provide a base line for catering for individual differences after instruction has commenced. In our view, the rationale that underpins approaches based exclusively on aural acuity is questionable, especially given current methodologies and technologies which do not enable us to state with any certainty whether observed differences in musical ability in children are the result of genetic inheritance or learning.

As noted by Kemp and Mills (2002), musical potential is a complex phenomenon that involves many factors. While aural abilities are undeniably important, they do not provide the basis from which to accurately assess a child's current or future musical potential. Instead, musical potential is best thought of as malleable and ever-changing, and a dimension of human experience that takes many forms and occurs at many different levels. As a species-specific behaviour, music is inextricably linked to our basic human design (Welch and Adams 2003), therefore all children are inherently musical and deserve access to the types of informal and formal experiences that will maximize their own, individual musical potential.

CHAPTER 25

Practising

Harald Jørgensen and Susan Hallam

Introduction

Practice is central to the development of all aspects of musical expertise. The musician not only needs to consider the development of technical skills but must also develop musical interpretation, may have to play or sing from memory, rehearse and perform in cooperation with other musicians, improvise, and contend with stage fright. These elements require aural, technical, cognitive, communication, performance and learning skills. These complex skills cannot be acquired, improved and maintained by simple repetitious practice.

Effective practice has been defined by Hallam (1997c) as 'that which achieves the desired end-product, in as short a time as possible, without interfering negatively with longer-term goals' (p. 181). This definition assumes that effective practice might take many forms and implies that the musician requires considerable metacognitive skills to facilitate the completion of task requirements or, in the case of the novice, appropriate support. Practising may be addressed from a psychological viewpoint as an act of learning, where theories of psychomotor learning and motor programmes are relevant, and it may also be viewed as 'self-teaching' (Jørgensen 2004). The multifaceted nature of practice has been encapsulated in models which provide a framework for understanding its relationships with creativity and performance (see Hallam 1997c; Chaffin and Lemieux 2004).

Empirical research on practice has a history that dates back to the beginning of the twentieth century, although the majority of research has been undertaken in the last 25 years. Its focus has been almost exclusively in relation to the training of classical musicians and the individual practitioner.

The quantity of practice

Practitioners and researchers agree that there are two important variables relating to practice that determine progress and attainment: the *quality* and *quantity* of practice in interaction with prior knowledge and skills. In the following section we will concentrate on the quantity of practice, returning to quality issues in the section on practice strategies.

Time spent practising

Research on time spent practising has addressed three different aspects: the initial starting age; the accumulated amount of practice from initial starting age to the present; and the amount of practice at one particular time or during a limited period of time. A major challenge to this type of research is the difficulty in obtaining reliable and valid measures of the amount of practice undertaken (Madsen 2005).

Despite these difficulties some broad trends have emerged. First, most of those who reach a high level of expertise on an instrument have made an *early start*, on either their major instrument or another instrument. This phenomenon has been demonstrated on a broad range of instruments (Jørgensen 2001; Sosniak 1985). Pianists and violinists tend to be particularly early starters, aged from 3–8 years old, while brass and woodwind performers start a little later with their major instrument (Jørgensen 2001). Starting to play at an early age, when physically the body is more flexible, may be important. Certainly, Wagner (1988) has demonstrated that pianists' hands can change physically if they begin playing when very young.

Another trend is that time spent in practice usually increases as age and expertise develops,

with most young people practising almost every day (Sloboda *et al.* 1996). There is evidence that the increase in practice time is greater for those who go on to become professional rather than amateur musicians. However, after entrance to the profession, duration of regular practice time is observed to decrease as pressures of rehearsals and public performance increase (Krampe 1994).

Since many students start early and gradually increase the amount of time that they practise, it follows that many of them have *accumulated a large amount of practice time* by their late teens, and that expert performers have invested several thousand hours of practice over a period of 15–16 years before reaching a high performance level in their twenties (Sosniak 1985). Accumulated practice time has also been found to relate to the performance of rehearsed music in novice players aged 7–9 years, although use of specific strategies seems to be more important when children engage in sight-reading, playing from memory, playing by ear, or improvising (McPherson 2005).

Most research on the amount of practice has not differentiated between instruments or has focused on only one instrument. An exception to this is a study by Jørgensen (1997). He found that the keyboard students in a conservatoire invested most time in practice, 25–30 hours a week, followed by strings, woodwind, brass and voice. There were also differences between specific instruments within these groups. Violinists, for instance, tended to practise more than double bass players, and trumpet players practised more than tuba players. Lammers and Kruger (2006), in a study of American and Japanese students, reported similar results. Physiological restrictions related to the instrument's physical and technical demands (Jørgensen 1997) and the nature and extent of the repertoire are probably important factors determining amount of practice.

Assessment, whether formal in examinations, or informal in a lesson, has an impact on practice time. Hallam (2001) reported that 95 per cent of the novices and advanced students in her study increased their practice time in weeks preceding examinations. Practice activity increases as the number of lessons received increases (Sloboda *et al.* 1996), and there is an increase in practice time the day after a weekly lesson (Lehmann and Ericsson 1998). Not surprisingly the quantity of practice decreases during holidays, even for students in a specialized music school (Sloboda *et al.* 1996).

Research on the relationship between *amount of practice at a particular time and general achievement level* at this time has considered a range of different instruments and age groups with varying outcomes (see Chapter 24 this volume and Jørgensen and Hallam in preparation). The different age groups and levels of expertise, lengths of time period studied, as well as the variety of instruments included in the studies may partly explain why the results are different from study to study. All of the studies have found a positive correlation between amount of practice at a particular point of time and general achievement, although Ericsson *et al.* (1993) found no difference in length of weekly practice between the 'best' and the 'good' violin students. The difference between the 'best' and 'good' violinists was in amount of accumulated practice.

Ericsson and colleagues (1993) suggested a monotonic relationship between 'deliberate practice' and an individual's acquired performance. Similarly, Sloboda *et al.* (1996, p. 308) stated that 'We believe that we have established, beyond any reasonable doubt, that amount of relevant practice is a key variable in determination of music performance expertise.' However, there are substantial individual differences in the relationship between the quantity of practice and attainment (Ericsson *et al.* 1993; Sloboda *et al.* 1996; Jørgensen 2002), suggesting that attainment is not exclusively a question of quantity of practice, but also of quality, which is a result of individual engagement with and knowledge of practice strategies.

Two studies have related amount of current practice to more specific areas of achievement, with conflicting results. Williamon and Valentine (2000) looked at practice and performance among piano students from under 11 to more than 24 years in four levels of skill on one composition, and found that pianists at higher levels of expertise spent more time in each practice session, but that quantity of practice was not significantly related to quality of performance as rated by experienced teachers. Wagner (1975), with college students, assessed performance on 'a selection which best represented their

level of musicianship at that time', and found a positive relationship between amount of practice and 'level of musicianship'.

A specific issue is the time spent practising a single composition. To date, research has focused on the memorization of piano music by professional musicians, students with high levels of expertise (Chaffin and Imreh 1997), or pianists with a broad range of skill levels (Williamon and Valentine 2000). The findings illustrate how time-consuming the memorization process can be, depending on the complexity of the piece. Lehmann and Ericsson (1998) studied a university student preparing for her degree recital, memorizing eight unfamiliar pieces by Haydn, Prokofiev and Debussy. She spent a total of 531 hours practising to prepare for a concert with a total playing time of 37 minutes.

Motivation and drop out

Evidence from students who have dropped out suggests that there are complex relationships between time spent practising, prior knowledge, motivation, and perceived efficacy (Hurley 1995). The amount of practice undertaken predicts whether students will drop out (Sloboda *et al.* 1996; Hallam 1998), although other factors such as socio-economic status, self-concept in music, reading achievement, scholastic ability, measured musical ability, maths achievement, and motivation are also predictors (McCarthy 1980; Klinedinst 1991; Hallam 1998).

McPherson and McCormick (2006) found that self-efficacy was the best predictor of performance. The role of psychological characteristics (rather than musical talent or expertise) was also observed by McNamara *et al.* (2006) in their study of a group of internationally renowned musicians. They found that some characteristics were generic (e.g. dedication, planning and commitment), while others were particularly evident at transition points in their career, i.e. perseverance and adaptability in the transition from study to entry into the music profession.

The quality of practice

Quality is an elusive matter. The concept of 'deliberate practice' defined as goal-oriented, structured, and effortful, was introduced by Ericsson and colleagues (1993) to address the issue of quality. They also outlined constraints which might determine the quantity and quality of practice—motivation, resources, attention. Much of the research exploring issues relating to the quality of practice has focused on the strategies that musicians adopt when practising. Jørgensen (2004) has proposed four strategy types, i.e. planning strategies; strategies for the conduct (execution) of practice; strategies to evaluate practice; and meta-strategies. A similar conception is that of practice as self-regulated learning (McPherson and Zimmerman 2002), where the practitioner is recommended to engage in forethought, performance/volitional control, and self reflection.

Planning strategies

The organization of practice

Instrumentalists and singers are expected to *practise regularly*. Several management strategies have been observed in relation to this. Some students in higher music education practise at the same time every day (Duke *et al.* 1997), while others integrate practice into a daily or weekly plan (Jørgensen 1997). Most students, however, try to fit in practice sessions between other activities without any preconceived plan. The morning may be the best time for high levels of concentration (Lehmann and Ericsson 1998). Ericsson and colleagues (1993) found that conservatoire students at the highest levels of expertise practised in the morning, took naps in the afternoon, and then put in more practice in the evening. For novice students the regularity of practice may be more related to one specific day a week (Hallam 2001), or a specific period of the day, i.e. 'before bedtime' (Pitts *et al.* 2000b). Sloboda *et al.* (1996) showed that the students in a selective specialist music school distributed their repertory practice evenly to morning, afternoon and evening sessions.

Practice may be most effective when it is organized in sequential and logical manner (Barry 1992). At the start of practice sessions many musicians use warm-up exercises, although there is considerable individual variation in the extent to which these are perceived to be necessary (Hallam 1995a). Technical exercises

often follow with repertory work left until last (Duke *et al.* 1997). Sloboda *et al.* (1996) showed that the students in a selective specialist music school practised more than 40 per cent of their scales in the morning session. For conservatoire students, there are pronounced differences between instruments in the relative amount of warming up exercises, technical work, and repertory practice (Jørgensen 1998).

Setting goals and adopting appropriate approaches for particular tasks

Ericsson *et al.* (1993) concluded that a well-defined task was one of four requirements for effective learning through practice, although the evidence suggests that novices and more accomplished students often fail to formulate goals for practice activities and mastering specific tasks (Jørgensen 1998). The nature of particular learning tasks inevitably affects the goals set and the ways in which they are undertaken. McPherson (2005) stressed the importance of helping students to develop task-appropriate strategies for such diverse tasks as practising notated repertoire, playing from memory, sight-reading, playing by ear, and improvising.

Musicians seem to approach practising particular repertoire in different ways. Miklaszewski (1995) observed that professional musicians spent a much shorter time learning a late romantic miniature than three contemporary variations. Lehmann and Ericsson (1995) suggest that the increasing technical demands of twentieth-century music have influenced the nature of practice. Research on sight-reading and improvisation suggests that time spent engaged in these activities is the key element in their development to expert levels (see Chapter 32 this volume).

Developing interpretation

A specific task in formulating goals is the 'performance plan', and the way interpretation is planned and developed through practice sessions. Some musicians plan interpretation at the outset, based on a study of the score or from ideas gleaned from listening to a wide range of music and different interpretations of the same piece (Hallam 1995b; Lisboa *et al.* 2005); primarily letting the expressive ideas guide the technical work (Chaffin *et al.* 2003). A second approach is to develop a performance plan after mastering most of the technical challenges (Nielsen 2001). Experienced performers also report taking the audience perspective into account when developing expressive ideas (Oura and Hatano 2001).

Strategies for the conduct of practice

Variable practice

Schema theory suggests that motor programmes, including those required for playing a musical instrument, are strengthened by increased variability in practice (for instance, practising a passage with different articulations, at different tempos, or a technique using different examples), rather than repetition of the same actions. This facilitates transfer to other tasks (Schmidt 1976). The evidence for the effectiveness of this is mixed (see Hallam 1997c for a review).

Part–whole strategies

Particularly relevant to the acquisition of musical skill is the question of *part–whole transfer* of training. Given a reasonably short piece of music to practise, observational studies have shown that many novice pupils play through the music without stopping to focus on difficult sections, and usually repeat the whole piece several times (see Hallam 1997b; Renwick and McPherson 2002). Some novice and advanced students use a combined approach, starting with the whole and stopping to practise difficult sections en route (Hallam 1997b; Miklaszewski 1989). This gives the performer an overview of the music, and the opportunity to identify and select parts which require more intense work while relating the parts to longer sections or the whole (Chaffin and Imreh 1997; Nielsen 1997). Sections for concentrated work are selected on the basis of a range of criteria including those relating to the formal structure and motor aspects of the performance (Miklaszewski and Sawicki 1992); new or related elements (Nielsen 1999), and the visual layout of the music and its harmonic progression (Williamon and Valentine 2000). As practice progresses and the music is increasingly mastered technically, the sections worked on become longer (Chaffin and Imreh 1997; Nielsen 1999), although attention to detail and work on small sections may continue throughout practice sessions. It is clear from these examples

that the relationship between practising a piece in its entirety, focusing on parts, and mastery is complex. For different tasks whole or part strategies may be more appropriate.

Transfer of learning

Exercises are sometimes used to address *specific challenges* within a given composition (Hallam 1995; Nielsen 1999), but the alternative and more common solution is to practise difficult sections within the music being learnt. Transfer of learning in music needs to be considered in relation to particular tasks and different timescales. In the short term, practice seems to be most effective when it relates specifically to the task being undertaken, with the conditions for learning and performance being as similar as possible.

Strategies for increasing tempo

When passages need to be played at speed, Drake and Palmer (2000) observed three approaches adopted by students at different levels of expertise. Beginners tended to stick to one tempo throughout practice sessions, novices increased tempo gradually until they reached a limit, while the most accomplished students gradually increased tempo over each practice session. Research on the efficiency of these approaches has been equivocal probably due to the ambiguity of concepts such as 'slow', 'fast', and 'in performance tempo'; differences between beginners and experts; the way strategies relating to tempo are often combined with other strategies; and the length and complexity of music involved. Since the adoption of these strategies involves motor and muscular considerations, the observation by Winold *et al.* (1994), that fast and slow speeds of movement seem to be controlled in different ways is important.

Mental practice

Mental practice, where the learner thinks through the procedures without actually playing, has been compared with playing practice in several studies, with conflicting results (Kopiez 1990; Ross 1985). This is hardly surprising, taking into account that:

- the studies differ in the length, familiarity and complexity of the music used;
- 'mental strategy' has been operationalized differently;
- the length of time using the strategies has differed; and
- familiarity with the use of mental strategies has varied between those taking part in the studies.The conclusion by Ross (1985), that a combination of mental and physical practice is most effective because mental practice allows concentration on the cognitive aspects of music performance without the distractions of exercising motor control, is probably sound.

Strategies for preparing for performance

Even if the music is well prepared, performance anxiety may jeopardize all prior efforts, particularly where the performer has to play from memory. The most common strategy for overcoming performance nerves is to be well-prepared and over-learn, investing more time than is required for basic mastery (Lehman and Ericsson 1998) (see Chapters 31, 33 and 36 this volume for issues relating to planning, memorization and anxiety).

Strategies to evaluate practice

Monitoring the effectiveness of practice

To monitor the effectiveness of practice it is particularly important that appropriate schema against which to evaluate progress are developed. Hallam (1997a) found that 60 per cent of beginners, novices and advanced students when learning a new piece left errors uncorrected. She observed that errors once made tended to become permanent and were left uncorrected. Only when students had considerable expertise and had well-developed schema were errors consistently corrected. Whitaker (1996), studying performers, arrangers, conductors and composers also established the necessity of possessing a mental template that served as the focus for all learning and performance activities. In contrast to professionals, many students have been found to be unable to generate auditory schemata from written notation (Grøndahl 1987). These skills need to be developed until at expert level current information about progress can be utilized to develop more sophisticated mental representations. Several external remedies and techniques have been used in the process of

developing schemata. Some studies have reported that to use a tape with a recording of the music is an efficient strategy (Puopolo 1971; Zurcher 1975), although others have found no effect of a recorded model (Anderson 1981; Linklater 1997).

Meta-strategies

Metacognitive strategies are concerned with the planning, monitoring and evaluation of learning. There are considerable differences between beginners, novices and experts in their knowledge and deployment of different practising and self-regulating strategies (Hallam 1997b; Pitts *et al.* 2000a, b) as well as individual differences among musicians and novices at the same level of competence (Nielsen 1997, 1999, 2001; Austin and Berg 2006). Hallam (1997b) demonstrated that professional musicians had well-developed metacognitive skills, including self-awareness of strengths and weaknesses, extensive knowledge regarding the nature of different tasks and what would be required to complete them satisfactorily, and strategies which could be adopted in response to perceived needs. This not only encompassed technical matters, interpretation and performance but also issues relating to learning itself, concentration, planning, monitoring and evaluation. Novices demonstrated less metacognitive awareness, the amount and structure of their practice tending to be determined by external commitments, e.g. examinations. There are differences in students' practising strategies and metacognitive skills, the former being inextricably intertwined with the acquisition of expertise. Skilled musicians are more likely to monitor and control their playing by focusing their attention on what they are practising and how it can be improved.

Among monitoring strategies, the monitoring of concentration is regarded by many music students as crucial to practice. Attempting to improve undergraduate students' concentration, Madsen and Geringer (1981) required them to keep a record of their practice, rate each practice session for productivity over an 8-week period and complete a distraction index. This increased observed attentiveness and performance although the index was time-consuming to complete. Nielsen (2001) suggests that students can enhance self-guidance by covertly or overtly describing how to proceed, giving comments on progress, noting concentration lapses and changes in motivation. Focus is crucial to avoid mindless repetition. The regulation of strategies requires deliberate effort, task selection, speed and intensity.

Rehearsing in small groups

Research on rehearsals in small groups has shown that there is no single best strategy for rehearsing repertoire (Davidson and King 2004). Individual ensembles find their own best ways of working. Berg (2000) found that high school student ensembles adopted four main activities, initiating, performing, orienting and assisted learning. Professional groups usually have a draft plan of the material to be covered across a series of rehearsals with room for extra sessions should they be needed (Goodman 2000). Group cohesiveness centres around the music (Davidson and Good 2002) but trust and respect are crucial for the functioning of groups working together continuously over long periods of time, e.g. string quartets (Young and Colman 1979). To be successful in the long term rehearsals have to be underpinned by strong social frameworks (for a full review see Davidson and King 2004).

The role of the learning environment in practice

The impact that institutional learning environments have on practice has been little studied, although research at conservatoire level in Norway (Jørgensen 1997) reported that music education students and church music students practiced more than expected, probably due to the predominant performance values in a conservatoire.

Instrumental teachers are an important influence on practice. Research on the way that they teach about practising has had mixed results. Jørgensen (2000), in research with beginning conservatoire students in Norway, reported that 40 per cent indicated that their previous teachers had invested 'little' or 'no' effort in teaching them how to practise. However, in the USA, teachers have reported that they always or

almost always include instructions about practice in their lessons (Barry and McArthur 1994). Students do seem to be able to learn how to use expert practising strategies (Barry 1992) and having done so report more positive attitudes towards practising, are more likely to engage in practice planning and problem identification, are better able to select appropriate performance goals, and are able to formulate more cognitively complex goals (Kenny 1992). This suggests that there can be benefits in teaching about practice.

Conclusions

Over the last 25 years our understanding of the nature of practice and its importance in the development of expertise has increased enormously. We know that both the quantity and quality of practice contribute to the level of expertise attained, and that the individual's ability to adopt more effective practising strategies is inextricably linked with their level of expertise. There has also been a recognition that musicians exhibit considerable diversity in the ways that they practise and that these can lead to equally successful outcomes. Despite the considerable progress made there are still areas where we know little. In relation to the quantity of practice there is a need for more studies that address the interaction between instrument, age, level of expertise and amount of practice within a range of different contexts. In relation to the quality of practice there is a need for studies exploring:

- how practice plans and goals are formulated and the way that these influence practice and subsequently performance;
- skill transfer between warming up exercises, technical studies, and repertory practice and the impact of these on performance;
- the effectiveness of aural models of what is to be learned and other types of feedback;
- concentration in practice, and how self-regulating techniques and meta-cognitive skills can be developed;
- the relationships between learning approaches, motivation and practice efficiency;
- how best to teach practice strategies at all levels of expertise;
- the way that social interaction in groups, including non-verbal communication, affects performance;
- the ways in which practice is undertaken on a variety of different tasks, e.g. sight reading, improvisation and in different genres, e.g. popular music, jazz, and world musics.

Such research will not only increase our understanding but also contribute towards enhancing learning and teaching.

CHAPTER 26

Individuality in the learning of musical skills

Helena Gaunt and Susan Hallam

Introduction

Historically, research concerned with individual differences in music has tended to focus on how musicians as a group differ from non-musicians, and the key characteristics which differentiate between musicians. This chapter outlines what we know about the way that individual characteristics including sex differences, physiological characteristics, age, personality, and cognitive and learning styles impact on engagement with and approaches to learning music. Issues relating to musical ability are explored in Chapter 24. The way that elements of the musical and wider environment influence the nature of engagement with music are also considered, excepting the role of the family, which is the focus of Chapter 28, and the school, which is the focus of Chapter 22. This chapter concludes by presenting theoretical frameworks which may serve to guide future research in elucidating the way that different environments interact in a reiterative manner with the individual leading, to different musical engagement outcomes.

Individual characteristics

Sex differences

In the past women have adopted roles in music which have been subservient to those of men, despite the fact that no reliable sex differences have been found in a range of measures of musical ability (Shuter-Dyson and Gabriel 1981; Hallam 2004), that girls tend to perform better in school music examinations (DES 1991; Agak 2002), and that girls report more positive attitudes towards music and musical activities (Crowther and Durkin 1982), and more positive competence beliefs and values for instrumental music than boys (Eccles *et al.* 1993).

Paradoxically, despite the dominance of men in the music professions music is regarded as a 'feminine' subject (Colley *et al.* 1994), although boys are more interested in and confident about music when it is linked to technology (Hanley 1998; Ho 2001) or when musical instruments depend on technology (Hallam *et al.* 2006). Girls are perceived to be interested and successful in singing, playing classical music and in dealing with notation while boys are perceived to have greater confidence in improvisation and composition. Girls are also perceived to be more persistent and more successful with instrumental study, have a broader listening repertoire, and are open to a wider range of musical styles (Green 1997; Hargreaves *et al.* 1995). Singing, in particular, is designated as a feminine activity (Green 1997; Hanley 1998) and although the proportions vary across studies and cultures, in most countries girls are more likely to learn to play a musical instrument than boys (Sheldon and Price 2005; Hallam *et al.* 2006). There are also gender differences in the particular instruments that boys and girls play. Early studies in Western cultures revealed that drums, trombone

and trumpet tended to be played more by boys, while flute, violin and clarinet have tended to be played by girls (Abeles and Porter 1978). Despite the increasing equality of women in Western cultures, stereotypical choice of instruments continues (Sinsel *et al.* 1997; Sheldon and Price 2005; Hallam *et al.* 2006) and exists in non-Western cultures (Ho 2001), although girls are selecting a wider variety of instruments to play along the feminine–masculine continuum than boys (Zervoudakes and Tanur 1994). These gender instrumental stereotypes are shared by parents (Abeles and Porter 1978; Delzell and Leppla 1992).

Presenting instruments to children aurally and visually without players can encourage boys to select more feminine instruments (Abeles and Porter 1978) as can changing the sex-role model playing the instrument (Bruce and Kemp 1993). However, where children choose to play an instrument which is considered inappropriate for their gender they may experience bullying or loss of popularity in school (Howe and Sloboda 1992). Children have clear ideas about which instruments are likely to lead to bullying if they are played (O'Neill and Boulton 1995).

Gendered engagement with different music genres changes over the lifespan. McKeage (2004) found that more girls participated in playing jazz in high school than in college. The women's decisions to discontinue were affected by primary instrument selection, institutional obstacles that narrowed participation options, feeling more comfortable in traditional ensembles, and an inability to connect jazz participation to career options.

Physiological demands of different instruments

Physiology plays an important role in the nature of individual engagement with music. For instance, there are considerable differences in relation to the human voice (Thurman and Welch 2000; Harris *et al.* 1998). The pitch range of a human voice varies with sex and age, the voice tending to become stronger and less agile somewhere in the third decade of life, as the laryngeal cartilages start to ossify (Welch and Sundberg 2002). Different instruments also make different physiological demands both in terms of how a basic sound is produced and the coordination required to play patterns of notes. For instance, singers and wind players rely to a considerable extent on refined muscular control of the respiratory system to make and vary the dynamic and timbre of the sound they make, while string players use both arms and hands for independent tasks which then have to be coordinated to control pitch, articulation and the quality of sound. These physiological requirements may inhibit the take up of some instruments by some individuals and also have implications for the stage of physical development at which learning them can begin.

Whilst instruments are versatile in their potential for musical expression, some within particular genres take on specific roles which impact on the individual player's experience of the music and participation. For example, in jazz, the role of rhythm section players is considered substantially different from 'front line' players who take the lead and play solos, but are not taking the 'whole tune' (MacDonald and Wilson 2005).

Age

Age affects the development of musical skills in a number of ways, through physical development, levels of cognitive skill and approaches to learning, and changing musical taste and motivation. Gembris and Davidson (2002) suggested that between the ages of 0 and 10, musical development in instrumental lessons may be limited by general sensorimotor as well as mental and emotional developmental processes. This is less the case with singing, which plays an almost universal role in childhood and is closely linked to the acquisition of language (Davidson 1994), although a fully professional singing voice in the Western classical tradition develops more slowly than proficiency in instrumental disciplines, and is rarely mature before the age of 30.

Sensorimotor abilities peak in adolescence and early adulthood, but then start to decrease, making facility harder to maintain as an instrumentalist. A crucial period of development amongst professional musicians (other than singers) has been identified as between 12 and 16 years. Sensorimotor ability is high, and cognitive skills are sufficiently developed to enable

independent practice to be increased significantly (Ericsson *et al.* 1993). Taking up a complex instrument as an adult is more difficult physically and tends not to yield the same results in terms of dexterity and instrumental control. On the other hand, knowledge and experience of music continue to grow throughout life, and professional classical musicians have articulated how they have used this resource to compensate for reduced technical facility as the speed of cognitive processing and kinaesthetic response decrease (Coffman 2002). The ability to use and manipulate musical symbols also changes over time, gradually becoming more sophisticated (Davidson and Scripp 1992; Gembris 2002). Coffmann (2002) outlines the different learning strategies adopted at different ages, with adult learners often showing particularly high levels of motivation including personal motivations (self-expression, recreation, self-improvement, use of leisure time), musical motivations (professed love of music, performing for one's self and others, learning more about music) and social motivations (meeting new people, being with friends, having a sense of belonging). Adopting an alternative classification, Gates defines adult learners as dabblers, recreationists, hobbyists, amateurs, apprentices, and professionals (Gates 1991).

Adult beginners may have higher expectations of themselves than children, and experience greater disappointment if they do not achieve their aspirations (Cope 2002). Some prefer informal and self-directed, critically reflective and collaborative modes of learning (Brookfield 1983, 1987), although in formal lessons they may rely on the teacher's expertise and analysis of their playing (Chen 1996). These differences seem to depend on the particular context of learning and may not be related to age per se.

The culture of our childhood determines the types of musical traditions with which we engage and as a result the specific musical schemata which develop and are reinforced over time. Those brought up within a Western culture may be able to distinguish fine pitch differences in Western tonality but be unable to distinguish similar pitch differences within the Javanese pelog scale (Lynch *et al.* 1990). Similarly, children exposed to Western music show no preference for consonance over dissonance up to the age of five, but by the age of nine or ten have developed this (Zenatti 1993).

Personality

The musical temperament of Western classical musicians has been reported to be dominated by introversion, independence, sensitivity and anxiety. Kemp (1996) describes the professional musician as a bold introvert who directs energy inwards and appears outwardly reserved. The nature of solitary practice encourages autonomy, and independence of thought, although introversion while supporting the long hours of practice required may also induce anxiety. High levels of imagination, sensitivity and intuition are reflected in high levels of pathemia (extreme sensitivity) (Kemp 1996) while the presence of suspiciousness and low self-sentiment have been reported as potential contributing factors for the increase of anxiety. Kemp (1996) has suggested that musicians become so committed to music that many fail to separate their personal identities from their identity as musicians. Student performers tend to relate their self-esteem to how they perform (Dews and Williams 1989; Tobacyk and Downs 1986) and in musicians it is difficult to discriminate between self-esteem and self-efficacy (Smith *et al.* 2000). Kemp (1996) has argued that identification of musical achievement with personal value results in either 'prima donna' behaviour observed in high self-esteem performers that perceive themselves to be successful, or negative self-perceptions in performers with low self-esteem who have heightened apprehension, self-criticism and perceptions of incompetence. The competitive nature of the classical music profession provides a context which may encourage these trends. However, the personal characteristics of non-Western musicians in non-competitive environments have not been studied making it impossible to draw conclusions about causality, although comparisons have been made between those engaged in different aspects of Western music.

Research has been undertaken in relation to orchestral players, keyboard players, composers and singers (Davies 1978; Wilson 1984) as well as popular musicians (Wills and Cooper 1988). The findings suggest that string players are introverted, imaginative and radical, while brass

players are more extraverted and have lower levels of self-discipline and intelligence in comparison to other performing groups. Percussionists also tend towards extroversion. These findings suggest that the extent of practice required for these different instruments (typically more for string players) and their role in the orchestra (more prominent for brass, wind and percussion players) either attracts people with personality characteristics suited to these roles or that these characteristics develop in response to the particular demands being made of them by their chosen roles in the music profession. Similar issues are raised with regard to keyboard players who have been described as extroverted, warm-hearted, group-dependent, highly conscientious and self-sentimental, conservative and low in anxiety, and singers who are generally considered as extraverted, independent and sensitive (Kemp 1996).

There may also be complex relationships between personality, practising and performance. Kemp (1996) suggested that the relatively high levels of introversion exhibited by musicians in comparison with the general population might assist them in undertaking repetitive practice, while Hallam (2001a) observed that there appeared to be a relationship between concentration in practice and arousal levels in performance in professional musicians. Those who described themselves as effective, focused learners experienced higher arousal levels in performance which were often problematic.

Cognitive and learning styles, and approaches to learning

In adult learners it has generally been accepted that some individual characteristics are more stable than others. Personality and cognitive styles are perceived as more consistent over time, while learning styles and approaches to learning have tended to be perceived as more responsive to particular learning contexts (Curry 1987). The relationships between these have been relatively little researched in music. Such research as there is has tended to explore whether there are differences between musicians in the way that they learn, with a particular focus on practice and interpretation. Differences have been found in learning styles, conceptions of and approaches to practice, and the length of time taken by professional musicians to learn repertoire.

Two main approaches to interpretation have been identified: analytic holist (taking a wide view of what is to be learned, considering the connections between disparate ideas, making wide use of analogy and illustration, developing ideas from listening extensively to music, planning interpretation in advance of learning) and intuitive serialist (developing interpretation as music is learned, using intuition rather than analysis, avoiding extensive listening to minimize undue influence on ideas), with versatile learners adopting either serialist or analytic strategies as necessary (Hallam 1995a). Musicians also adopt differential approaches to practising, adopting either technical, musical or mixed approaches, the latter depending on the nature of the specific task. Approaches to practising relate to some extent to the styles of interpretation described above. No musicians adopting an analytic holist approach adopted a technical approach to practice, and no musicians adopting an intuitive serialist approach adopted a musical approach to practice. Versatile learners tended to adopt a mixed approach (Hallam 1995b).

Changes in approach have also been identified as expertise develops. Reid (2001) identified five conceptions of learning amongst students learning to play an instrument or sing in a higher education context. At level 1 (instruments) the students focused their attention on the technical aspects of learning and learned by copying their teachers. At level 2 (elements) the students shared similar concerns with those at level 1 but also focused on some musical elements. Students whose conceptions were at the level of musical meaning (level 3) focused on the meaning found in the music and learned by reflecting and adapting their teacher's advice. At level 4 (communicating) the focus of learning shifted to learning to communicate musical meaning and the students learned by experimenting with different styles of playing music using the teacher as only one source. At the final level (express meaning) students focused on expressing personal meanings through the music. These findings reflect those of Hallam (1995a) who identified nine levels of intellectual development in relation to the development of interpretation.

Some of the research has suggested that the adoption of particular approaches to learning leads to particular learning outcomes, while other findings suggest that similarly high-quality performing standards can be attained regardless of the approach adopted (Hallam 1995a, b; Miklaszewski 1995). These differences may depend on the context of performance.

Environmental influences on individuality

Characteristics of musical cultures

Historically, ethnicity determined the nature of the cultural background within which the individual grew up, although with increasing globalization this is now less the case. The impact of ethnicity on the nature of musical participation is determined by the complex interactions between the particular ethnic group to which the individual belongs and the extent to which its cultural traditions have remained intact, adapted, or been superseded by those of the wider global culture. Differences between musical cultures are evident in three ways, each of which can impact on the differences between musicians. These differences concern the music itself including genre, the kinds of behavior associated with making, teaching and listening to the music (the use of notation, aural traditions, relationship between composition and performance, the role of improvisation, formal or informal learning and teaching, group versus individual tuition) and ideas about music and its place in society (Lundquist 2002). Within each musical culture these dimensions form a dynamic system.

Different genres of music are associated with different expectations of performance. In some genres participation in performance is regarded as normal for all players, and the performance context is often dynamic and unpredictable (Cope 2002). In classical Western music the ultimate goal of learning to play an instrument has been viewed as being able to perform in public, although this can be interpreted in many ways from playing in a school concert to performing as an international soloist. Few players achieve the latter (Cope and Smith 1997). Within this tradition technical competence is highly prized, whereas in folk cultures, musicians can regard themselves as competent to play within their chosen musical and social context with relatively little technical expertise (Cope 2002). In popular music, the use of regular recording and listening back to it as a means of reflecting on and evaluating progress and the musical product is increasingly used, and a relationship between this and the development of critical reflection and self-evaluation of musical skills has been suggested (Boespflug 1999; Lebler 2006). This contrasts with the process of exchange between teacher and student which dominates apprenticeship in Western and Indian classical music.

In musical cultures where participation in music-making through singing, playing and dance is integral to social participation, the nature of the support provided for learning in music is a normal part of daily life, embedded in the community, and resulting in young and old alike acquiring an extensive repertoire and often able to play several instruments (see Blacking 1967; Walker 2006). Within the Western classical tradition, where an individual typically spends more time in isolated practice of an instrument, support for learning tends to be more dependent on individual family members, teachers and particular contexts of music-making. In this environment, lifelong commitment to music (involving intrinsic motivation) in adults has been shown to depend on childhood conditions which were supportive of music (see Chapter 28).

Within Western, post-industrial societies, the role of music has changed dramatically in the last 150 years as a result of changing patterns in work, leisure and social interaction; the development of technology, the recording industry and mass media; and improvements in the standard of living. In the UK, for example, many opportunities for music-making in community centres and within family settings have been replaced by a more solitary consumption of recorded music (Zillmann and Gan 1997), although alongside this there are often more opportunities for engagement with music within education (Hallam *et al.* 2005).

Socio-economic status

Socio-economic status is an important determinant of the type of music with which individuals

engage (North and Hargreaves 2007) and plays a key role in musical enculturation. It also impacts on the extent of active engagement in music (Brandstrom 2000) and dropout from instrumental music lessons (McCarthy 1980; Klinedinst 1991). This may be due in part to financial considerations as it can be expensive to provide instruments, pay for tuition, support concert attendance, and create appropriate facilities for practice. Children from middle class backgrounds are more likely to engage with classical music than those from poorer backgrounds.

The way forward: theoretical approaches conceptualizing interactions between the individual and the environment

Research to date exploring individuality in relation to engagement with and learning in music has tended to neglect consideration of the complex interactions which occur between the individual and their environment. Key to developing understanding of these interactions are biosocial models and systems theory. Below we describe two such models: an ecological systems approach to human development and a biosocial model of interaction.

An ecological systems model of human development

Bronfenbrenner (1979) proposed an ecological model of human development, in which the notion of situations or environments is conceptualized as a series of nested structures, each structure itself being a system interacting with other systems (see Figure 26.1). At the centre Bronfenbrenner conceptualized a micro-system consisting of an individual in their immediate environment. For a teenager teaching himself the guitar informally in a pop group the micro-system might include the teenager, the group, and those family members having a direct impact on the individual's musical development. The meso-system refers to the individual's interactions in a wider group of settings.

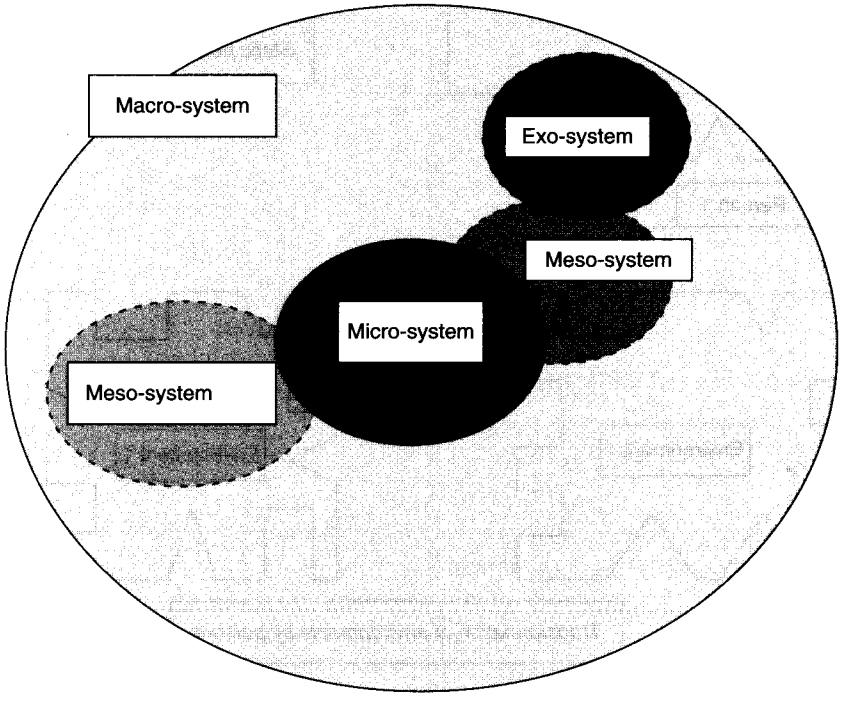

Fig. 26.1 Bronfenbrenner's nested systems.

engage (North and Hargreaves 2007) and plays a key role in musical enculturation. It also impacts on the extent of active engagement in music (Brandstrom 2000) and dropout from instrumental music lessons (McCarthy 1980; Klinedinst 1991). This may be due in part to financial considerations as it can be expensive to provide instruments, pay for tuition, support concert attendance, and create appropriate facilities for practice. Children from middle class backgrounds are more likely to engage with classical music than those from poorer backgrounds.

The way forward: theoretical approaches conceptualizing interactions between the individual and the environment

Research to date exploring individuality in relation to engagement with and learning in music has tended to neglect consideration of the complex interactions which occur between the individual and their environment. Key to developing understanding of these interactions are biosocial models and systems theory. Below we describe two such models: an ecological systems approach to human development and a biosocial model of interaction.

An ecological systems model of human development

Bronfenbrenner (1979) proposed an ecological model of human development, in which the notion of situations or environments is conceptualized as a series of nested structures, each structure itself being a system interacting with other systems (see Figure 26.1). At the centre Bronfenbrenner conceptualized a micro-system consisting of an individual in their immediate environment. For a teenager teaching himself the guitar informally in a pop group the micro-system might include the teenager, the group, and those family members having a direct impact on the individual's musical development. The meso-system refers to the individual's interactions in a wider group of settings.

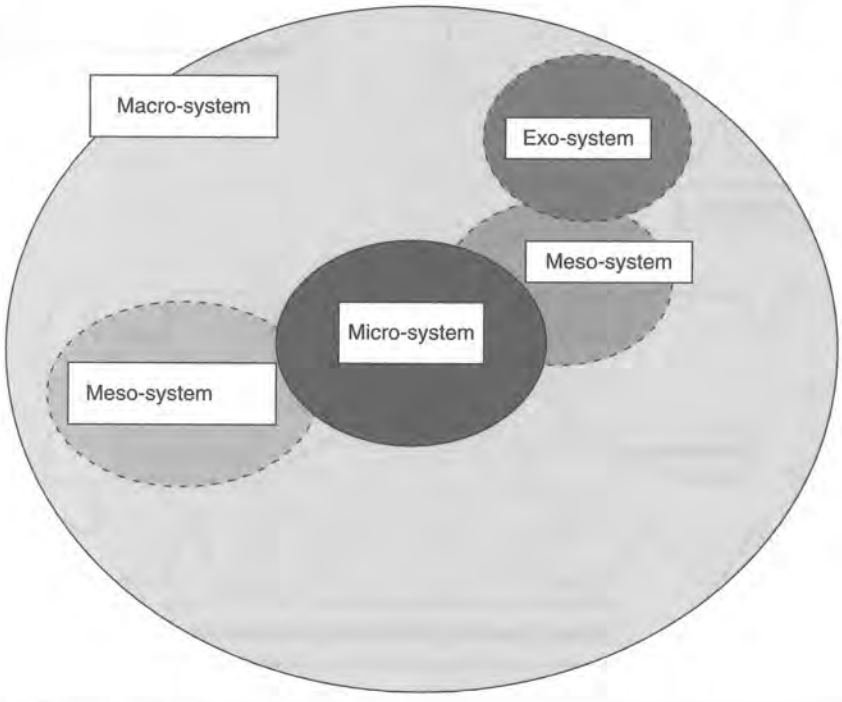

Fig. 26.1 Bronfenbrenner's nested systems.

In the example described above, a meso-system could consist of the teenager's experiences relating to extra-curricular activities at school or through participation in a youth group which facilitated musical activities. Bronfenbrenner also suggests that the individual might be influenced by activity in what he termed an exo-system, a system in which the individual does not interact with others directly but in which another person close to the individual interacts. In the example above, this might be the influence of a parent's working life on a child. For instance, a parent working long hours in an entrepreneurial role might stimulate the teenager to become more committed to the pop group because it offered the potential for commercial success, while also providing an activity in the parent's absence. Finally, all three systems are nested within a macro-system defined as a particular subculture in which particular beliefs, values and ideologies of the lower order systems will be embodied, for instance, a Western culture. An important characteristic of the ecological model is the premise that the interconnections between the different systems within the model are critical to individual development and as important as events taking place within any one system.

A biosocial model of interaction

Adopting a different perspective, Hettema and Kenrick (1992) outline six categories of interaction: static person–environment mesh (the individual is situated in an unchanging environment); choice of environments by persons (the individual selects new environments which meet their needs); choice of persons by environments (typified by a variety of selection processes, for instance in education and the work place);

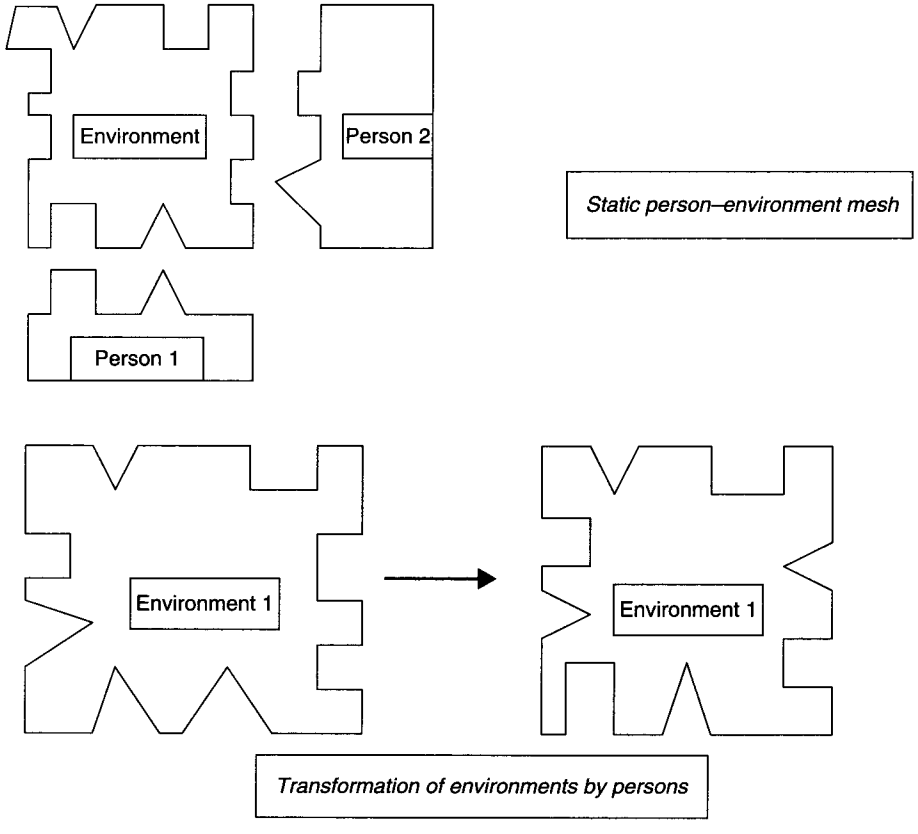

Fig. 26.2 A static person–environment mesh and transformation of environment by person mesh (adapted from Hettema and Kenrick 1992).

transformation of environments by persons (individuals through their actions change environments, for instance, through leadership or disruption); transformation of persons by environments (individuals are socialized into new environments); and person–environment transactions or mutual transactions in which both persons and environments change over time (Hettema and Kenrick 1992). Each category represents different degrees of fit between the individual and the environment. Two examples are given in Figure 26.2. Such interactions influence the development of individuals and the environments within which they find themselves.

A combined model

An example of how the two models may operate simultaneously is shown in Figure 26.3. The presented scenario is based on a teenager teaching themselves the guitar in a pop group formed with a group of friends. Combining the two models highlights the dynamic relationships between the individual and the environment, and suggests the need for research approaches which attempt to develop a framework for understanding the multilayered factors involved in the acquisition of musical skills and the complex relationships between them.

Conclusions

Much of the research exploring individuality has neglected consideration of the dynamic interactions between the individual and their environment which determine the nature of particular behaviours. To increase our understanding of musical learning studies need to take account of the interactions between different elements, map the relationships between micro-, meso-, exo- and macro-systems, and explore the ways that individuals negotiate their relationships with the musical environments to which they have access. Ideally, this would be through longitudinal research which documented individuals' engagement with music through the lifecourse in different learning and performance

cultures and contexts. However, findings drawn from small-scale cross-sectional studies could be drawn together to map the impact of a range of factors contributing to our understanding of commonality and difference in the way that systems influence learning and development.

Research also needs to contextualize findings within recent global changes. The rapid development of technology and sound recording, and the expansion of the mass media have created a huge increase in music consumption, and have dictated standards of production and of 'performance' which make no allowances for the errors which may occur in 'live' performance. There has also been increased recognition of the value of active engagement with music to the individual's intellectual functioning and well-being (see Chapters 23 and 44). As a result, in the developed world, through educational and community initiatives, there has been an emphasis on music for all rather than a select few. In the longer term this will provide greater research opportunities to explore systemic interactions and their influence on a range of learning outcomes.

CHAPTER 27

Motivation to learn

Susan Hallam

The historical perspective

Human motivation is extremely complex. Historically, numerous theories have developed in attempts to explain it. These, to varying degrees, emphasize motivation as deriving from within the individual, within the environment, or as a complex interaction between the two mediated by cognition. The most recent theories emphasize the way that our perceptions of events are determined by our construction of them, these interpretations subsequently influencing our self-esteem, self-efficacy and motivation. They acknowledge the capacity of individuals to determine their own behaviour, whilst also recognizing the role of the environment in rewarding or punishing particular behaviours influencing subsequent cognitions and later actions. There has also been increasing recognition that motivation operates at different levels and across different timescales (for more detail of generic theories of motivation and earlier reviews of motivation in relation to music see Asmus 1994; O'Neill and McPherson 2002; Hallam 2002; Austin *et al.* 2006).

Much of the early research on motivation in music was not embedded within any specific motivational research paradigm or theoretical position, although expectancy-value models which have been proposed to explain motivation for particular tasks in education (e.g., Eccles 1983) have provided a framework for some recent work. The research has also focused almost exclusively on motivation to learn and continue to play an instrument. There has been little interest in motivation to listen to music, compose, or engage in other musical activities.

A framework for understanding motivation in music

In this chapter, I set out a model which attempts to integrate the various theoretical approaches to understanding motivation, embedded within a broadly systemic approach as proposed by Bronfenbrenner (1979), which suggests that the process of human development depends on mutual accommodation which occurs throughout the life-course between an individual and the various systems which they or others close to them encounter in their environment (see Chapter 26 for details).

Figure 27.1 sets out a framework which illustrates the complex interactions which occur over time in relation to motivation. Certain aspects of our individuality are predetermined, for instance, our biological temperament, our sex, and our age. These are shaped through interaction with the environment to develop our personality, gender identity, cognitive processes, and our self-perceptions. We are motivated because we desire social approval, particularly from those we admire and respect. Such praise from others is internalized, raises self-esteem, and enhances confidence. Some environmental influences are internalized to such an extent that they come to affect the individual's functioning over time in a fairly consistent way. Individuals set themselves goals, which determine their behaviour. These goals are influenced by individual and self-perception characteristics as well as environmental factors. Where the environment satisfies individual needs and

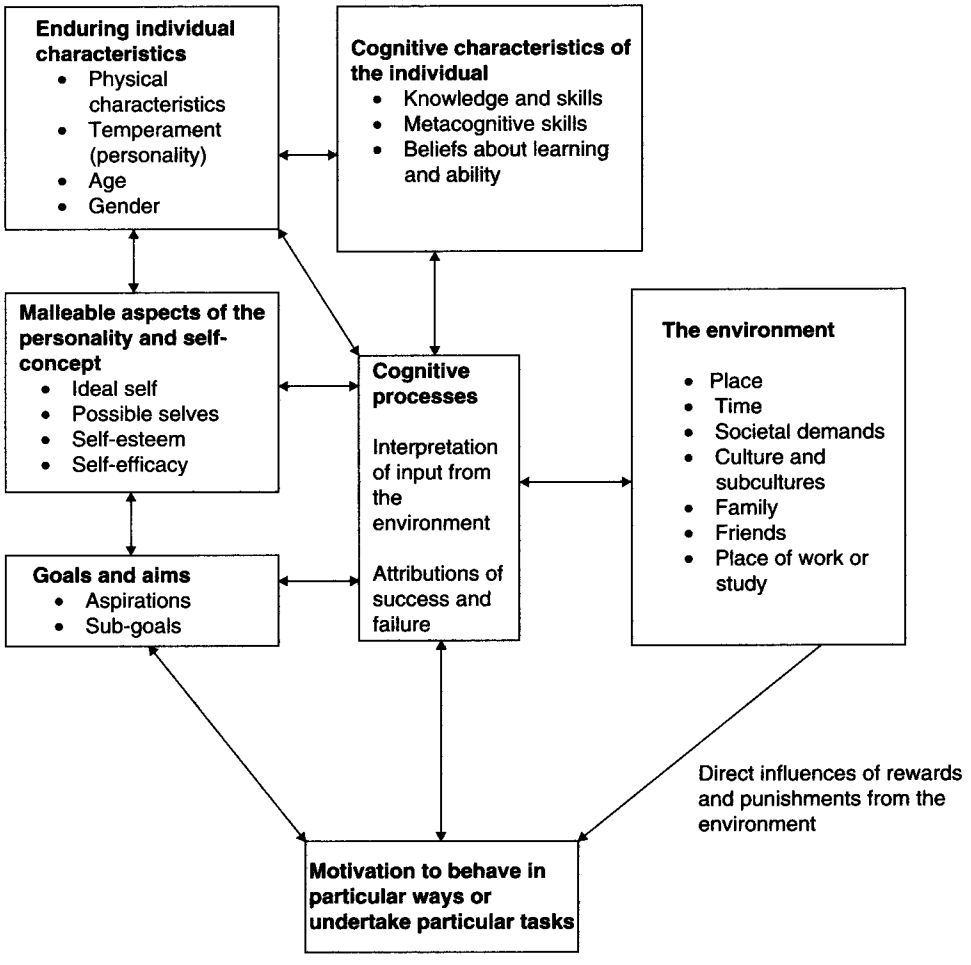

Fig. 27.1 Interactions between individual and environmental factors in determining motivation.

facilitates personal goals motivation is likely to be enhanced. Where the environment presents obstacles, the individual may give up or be spurred on to greater efforts to overcome them, perhaps by finding a more conducive environment. Behaviour is the end link in the chain, but at the time of enactment it too can be influenced and changed by environmental factors. There is interaction between the environment and the individual at every level and in the long and short term. Individuals can act upon the environment to change it, or seek out new environments more conducive to their needs (Hettema and Kenrick 1992). The model recognizes the importance of cognitive factors and self-determination in behaviour. While we have needs and desires we are aware that we need to consider the consequences of our actions before we attempt to satisfy them. Cognition plays a role in the ways in which we attempt to enhance our self-esteem, leading us to attribute our success or failure to causes which will allow us to maintain a consistent view of ourselves. When a learner has completed a learning task successfully this will have an impact on self-esteem and motivation which will be carried forward to subsequent learning tasks. Conversely, when learning outcomes are negative, motivation may be impaired. In the following sections I provide a more detailed account of what we know about each of the elements

outlined in the model as they relate to motivation in music.

Individual characteristics

Enduring individual characteristics: physical, gender and personality factors

Chapter 26 considers many elements of individuality which may influence the nature of engagement with music including physical, gender, and personality characteristics. These are not discussed further here. The focus in this section is the complex and multifaceted nature of motivation to become actively involved in music-making, which includes the way that it intrinsically acts to meet needs which vary between individuals in relation to their personality characteristics. For instance, Motte-Haber (1984) has suggested a range of internal motives including the desire for achievement, curiosity, and self-actualization, while Nagel (1987) stressed the need for personal fulfilment met by the emotion-inducing quality of music, satisfaction of a positive social response within performance settings, exploration of aggressive drives through the exploitation of the motor skills entailed in musical performance, and some voyeuristic and exhibitionist desires. Persson (1993; Persson *et al.*1996) studying pianists also emphasized the importance of hedonic drive, while acknowledging the role of social and achievement motives. Gellrich and colleagues (1986) identified three achievement-related motives: a general achievement motivation; a specifically music-oriented achievement orientation; and a sensual–aesthetic motive, the pleasure and joy of playing certain pieces of music. Musicians it seems derive considerable personal fulfilment from the act of making music, in addition to the social rewards that it offers. The balance between these motives may change over time as individuals progress through their musical careers (Sosniak 1985; Harnischmacher 1997; Manturzewska 1990) and may contribute to determining individual career trajectories.

The diversity of individual motivation has been explored in relation to amateur musicians in addition to professionals. Some amateurs view music as personal amusement, while for others it constitutes serious leisure only distinguishable from the work of professionals because it is not their livelihood (Gates 1991). For some music is a key element of their identity (Pitts 2005) and they invest huge energy and creativity in it (Finnegan 1997). Their amateur status suggests that they find their musical activities intrinsically motivating, although social interaction can also be an important motivator.

Malleable aspects of the personality and self-concept

An individual's identity or self-concept represents the way they thinks about themself and their relationships with others (Rogers 1961) (see Chapter 43) and plays a crucial role in motivation. Behaviour is influenced by the individual's interpretation of situations and events; their expectations; and the goals that they have set for themselves related to their identity. Music self-concept has been shown to be linked to motivation, interest, and participation in school and out of school musical activities (Austin 1991) and develops early as quite young children are able to assess how well they can complete particular musical tasks (Greenberg 1970). However, being good at something does not necessarily transfer to interest in it. Asmus and Harrison (1990) working with non-music major college students found no relationship between music motivation and aptitude. They argued that the drive for music stems from love of music.

Children's self-concept in relation to music at school and the value that they place on music appear to decline as they get older, the latter more than for reading and mathematics (Wigfield *et al.* 1997; Mota 1999). However, those adolescents who are actively engaged in music-making through playing an instrument favour this activity over almost all others. Being a musician becomes an important element of their identity. As children progress through school they become increasingly aware of their own capabilities through making comparisons and receiving feedback from others. Where comparisons are made with high-attaining others self-concept is likely to be deflated. This process is influenced by the context of learning, whether it is supportive or critical.

Self-efficacy beliefs based on our evaluation of the likelihood of our success in relation to

particular tasks or areas of work also play a part in determining whether particular goals will be pursued and subsequently achieved (Bandura 1982). McPherson and McCormick (1999, 2006) studied 190 pianists aged 9–18 before taking an examination and found that self-efficacy prior to entering the examination predicted their examination result more strongly than any other factors. Bandura (1989) suggested that motivation for an activity is at its peak when strong self-efficacy beliefs are combined with some moderate uncertainty about the outcome, i.e. when a person feels competent but challenged. However, for intrinsic motivation to flourish, feelings of self-determination are also necessary. So even if an activity is challenging and a person feels themself to be highly competent, they will not display high levels of intrinsic motivation unless the activity is perceived as self-determined (Ryan and Deci 2000). Evidence of the links between intrinsic motivation, self-determination, and the use of self-regulating practising strategies support this (Austin *et al.* 2006). Renwick and McPherson (2002) demonstrated how a 12-year-old practised with heightened attention, persistence and enhanced strategy use when working on a piece which she had chosen herself as opposed to one chosen by the teacher. The extent to which learners value what they are doing predicts engagement across many different facets of musical practice (O'Neill 1999) and contributes to prediction of examination results more strongly than weekly practice or anxiety (McPherson and McCormick 2000).

Goals and aims

The goals and aims that individuals strive to attain are related to their identity, self-concept, self-efficacy and what they believe is possible for them. These take account of both context and cognition. If an individual perceives themself as successful and attributes this success to high ability they may come to include in their self-concept a 'positive possible future self in that domain' (Markus and Ruvolo 1989). Possible selves can be powerful motivators, providing long-term goals and encouraging the setting up of interim goals which need to be achieved en route. If an individual does not have a positive possible self as a musician (professional, amateur or listener) in the long, medium, or short term they are unlikely to maintain their interest in music. This is illustrated by McPherson and McCormick (2000) who found that for many children playing an instrument was no different from participating in a team sport, taking up a hobby, or pursuing other interests. Very few saw it as something that could possibly lead to a future career. MacNamara and colleagues (2006) also showed that career planning was in evidence in the very earliest stages of learning for nine professional musicians along with dedication, commitment, determination and a willingness to make sacrifices. Self-belief became increasingly important as they encountered more critical appraisal and greater competition as they progressed (MacNamara *et al.* 2006). However, goals can sometimes conflict with each other and their fulfilment can be disrupted by others (Harnischmacher 1995). Individuals may have to make trade-offs between goals at different levels and undertake some activities to attain a particular goal which they may not find particularly enjoyable. For instance, young people wishing to become professional musicians do not always enjoy practising alone and may require parental support and encouragement to do so (Howe and Sloboda 1991).

Cognition: individual characteristics and processes

All modern theories of motivation take account of cognition—an acceptance that much of our behaviour is mediated by our thoughts about and perceptions of events (Kelly 1955). This process is influenced, in part, by locus of control, the extent to which individuals perceive that they have control over situations (Rotter 1966). While prior knowledge and skills in a domain are powerful determinants of performance in that domain, our beliefs about our current capabilities also play a part. Also important are our beliefs about the nature of learning. In mainstream education a distinction has been made between performance and learning goals (Elliott and Dweck 1988), the former concerned with gaining positive judgements of competence as compared with others and avoiding negative ones,

the latter with increasing mastery, reflecting the desire to learn new skills, master new tasks or understand new things.

In learning in music, the relationship between these goals is complex. For instance, in studies of band students, Austin (1988, 1991) found that those assigned to a competitive condition exhibited levels of motivation and performance achievement comparable to those in a non-competitive condition, while Schmidt (2005) reported that instrumental students defined their success in relation to mastery and cooperative orientations, placing less emphasis on competitive and ego orientations. The context of active participation in music seems to influence the goals adopted, some contexts supporting the development of both types of goals. Sandene (1998) found that students' goal orientations were related to the perceived motivational climate in the classroom with overt teacher behaviours, in particular the ratio of positive to negative feedback, being particularly important.

To succeed in music clearly requires mastery behaviour to sustain the motivation for many hours of practice. For instance, O'Neill (1997), studying beginner instrumentalists, found that children who experienced mastery-oriented behaviour after experiencing failure on a problem-solving task made more progress on their instrument than children who initially displayed helpless behaviour. Research from other domains has shown a relationship between students' theories of intelligence and their goal choices. Where students hold an entity theory of intelligence (fixed and immutable) they are more likely to adopt performance goals, while those holding an incremental view of intelligence are more likely to choose a learning goal (Dweck and Leggett 1988). There is potential for exploring these relationships in novice, expert, amateur and professional musicians (see also Austin *et al.* 2006).

Individuals are motivated to establish, maintain and promote a consistent and usually positive self-image, so they develop a variety of coping strategies to maintain self-worth, some of which may be self-defeating, for instance, reducing effort (Covington 1984). How individuals attribute successes and failures is important in maintaining self-esteem (Weiner 1986). The causes of success or failure can be seen as stable or unstable; controllable or uncontrollable and internal or external. Overall, five major attribution categories have been found in music: effort, musical background, classroom environment, musical ability, and affect for music (Asmus 1986a), although findings specifically related to performance in an examination also included effort in preparation, effort in the examination, nervousness, luck, and task difficulty (McPherson and McCormick 2000). Musical ability and effort are the most frequently cited attributions by music students (Austin and Vispoel 1998). Highly motivated music students tend to make effort attributions, while students with low motivation cite ability (e.g. Austin and Vispoel 1998). These findings seem to be broadly consistent across grade levels (Asmus 1986b; McPherson and McCormick 2000), school settings, and music populations, although there is some evidence that ability attributions become more frequent as children get older (Arnold 1997; Asmus 1986b). Harter (1985) proposes that what is important in maintaining self-esteem and motivation is beneffectance. This involves attributing successful outcomes to internal causes and unsuccessful outcomes to external ones. This is likely to be important in sustaining motivation in musical activities. Considering the effect of attributing success or failure to the use of particular learning strategies, Vispoel and Austin (1993) found that explaining failure in terms of the adoption of less than optimal learning strategies was effective in improving these and increasing effort.

Metacognition (the term given to our knowledge of our own learning) is relevant for motivation insofar as it indicates our awareness of our own strengths and weaknesses and the ways in which we learn best, and may be implicated in the way that we manage our attributions. Metacognitive strategies are concerned with the planning, monitoring and evaluation of learning and performance. For most musicians life is dominated by public performance and preparation for it. As practice is not always intrinsically motivating, developing strategies for managing motivation is crucial. Preparing for public performance necessitates giving priority to practice (Manturzewska 1969), mobilizing arousal specifically for performance (Bochkaryov 1975) and managing anxiety (Hamann 1982). These all

depend on the development of appropriate metacognitive skills.

The environment

The environment is crucial in determining the opportunities that individuals have to engage with music and the extent to which they will be supported while doing so. Music is not valued equally in all cultures. In some it is viewed as decadent and is forbidden. In others it is highly valued and those involved in its composition or execution are highly revered members of society. Economic, demographic and political factors can have a major impact on the opportunities that may be available for musical engagement (Simonton 1997). Over time the value placed on music can change, and within any particular culture different types of music may be valued by specific subgroups. We know very little about how these cultural and societal factors mediate motivation to engage with music or the type of activity selected. In the Western world some individuals learn to play an instrument because it is expected by their family or school. Others start by chance because tuition is on offer in school or their friends have decided to play.

Although most individuals are involved in full time education when they take up a musical instrument, there has been almost no research on the relationship between the institutional learning environment and motivation to engage with music. There is some evidence that in a conservatoire environment there are relationships between institutional and departmental expectations and the amount of time spent practising which are mediated by the dominating value system (Jorgensen 1997), and that in mainstream education support within schools from generalist classroom teachers and the senior management team impacts on the extent to which instrumental teaching is effective (Hallam and Prince 2000). Teachers play an important role in motivating students and can contribute towards pupils' attitudes and subsequent attainment (Szubertowska 2005). Where teachers motivate pupils to engage with music, identities as musicians develop leading to more positive attitudes towards school music and teachers (Lamont 2002). In adolescence the peer group is very powerful and can bring negative pressure to bear in relation to engagement with some types of music (Finnas 1987; 1989). To withstand this musical identities need to be well developed. The influence of early teachers who are viewed as warm and sympathetic seems to be particularly important in this respect (Sosniak 1985; Sloboda and Howe 1991). Relatively uncritical encouragement in the early stages of engagement with music encourages the development of a positive musical identity. Once this is established later teachers provide high-status role models with whom the young musician can identify and emulate (Manturzewska 1990).

There is considerable evidence that parents have a vital influence on children's motivation for involvement with music and the acquisition of musical skill (see Chapter 28). In the early years the family are likely to be the main source of musical stimulation and may be key to engendering future interest in music. The age at which children first sing is related to the number of musical behaviours initiated by the parents (Howe *et al.* 1995) and the development of perfect pitch seems to occur with particularly systematic exposure to music in early childhood (Sergeant 1969). The influence of parents can also contribute to the choice of instrument to be played (Fortney *et al.* 1993) and their ongoing support plays a crucial role in whether children persist and commit to musical engagement in the long term. While the literature as a whole indicates that having a highly supportive and encouraging home background is important, it is clearly not essential. Highly effective individuals in a range of domains have been found to have histories marked by severe frustration, deprivation and traumatic experiences (MacKinnon 1965). Another important contributor to motivation is the relationship between teachers, parents and learners (see Chapter 28). The most motivated students are those who work in harmony with their teachers and parents.

Direct influences of rewards and punishments from the environment

Intrinsic motivation is a crucial aspect of developing self-identity as a musician. This may take

several forms, but one key element is enjoyment of the experience of engagement with music. Tasks that are intrinsically motivating share certain structural and emotional characteristics (Csikszentmihalyi 1990), offering a level of challenge that is in balance with a person's current skills (Good and Brophy 1991). When this occurs an individual derives pleasure from the work and tends to continue with it. This is known as a state of flow. If the task is too easy the person becomes bored. If the work demands skills beyond the capabilities of the individual anxiety is created. Csikszentmihalyi and colleagues (1993) have shown that students experience a state of flow most often when participating in chosen activities such as music as opposed to academic-oriented activities or when interacting with peers. Custodero (1999) observed 4- and 5-year-old children in a music classroom over 8 weeks and flow experience was associated with high self-concept or skill, perceived challenge, and active engagement.

Not all musical activities are intrinsically motivating for all people. For instance, novice and professional musicians exhibit diversity in motivation to practise. Many students require parental encouragement to practise (Howe and Sloboda 1991) or other rewards including playing favourite pieces of music or pleasing teachers. Practising for love of the instrument is rare (Harnischmacher 1995). A study of the motivation of beginner instrumentalists found that where the children remained enthusiastic about continuing to play their involvement centred around the instrument itself and the repertoire that they were learning, with less motivated children referring to participation in a band, or the opinions of their parents and friends as shaping their own attitudes (Pitts *et al.* 2000).

Lack of motivation

For a full understanding of musical motivation, the study of drop-outs is important. Those ceasing to play tend to do less practice, have attained less (Sloboda *et al.* 1996; Hallam 1998) and perceive themselves as less musically able, receiving less family encouragement and having greater strengths in other recreational activities (Frakes 1984). The time costs of playing an instrument are too great in relation to the rewards that they receive (Hurley 1995). Overall, no single explanatory factor emerges in explaining drop-out but several have been identified including lower socio-economic status, poor ability to understand instructions, and poor self-concept in relation to reading music, maths, reading achievement, and general scholastic attainment (Klinedinst 1991; Hallam 1998). Research to date has tended to focus on participation in formal music tuition in the Western classical tradition. Different factors may apply to those dropping out of other musical activities.

Future research directions

The evidence presented above suggests that motivation to be involved in active music-making is determined by complex interactions between the individual and the environment within which they find themselves. Some of the environmental effects, in particular those relating to early musical experiences, learning outcomes, self-efficacy and subsequently self-esteem are internalized by the individual in such a way that they become part of that individual's characteristics, rendering it both impossible and pointless to disentangle them. Once internalized they impact on motivation to continue to be involved in music. The individual's commitment to and involvement in music-making can also affect their environment and the people in it. Families may make changes to support their musical offspring, friends may be influenced to participate in making music. The transaction is bidirectional. The nature of the music profession, which is extremely competitive, means that only the highly motivated will have sufficient determination to succeed, although many more may become highly skilled amateurs.

The research to date has mainly, although not exclusively, related to school-aged students and the types of tuition on offer in those contexts. There is a need for research exploring issues of motivation in different learning contexts, informal and formal, and for learners of different ages and across different types of music. Related to this is the question of drop-out at higher levels of expertise than have so far been considered, for instance, those who study music in higher education, who do not then go on to make their living from musical activities, or indeed those

who become professional musicians and then leave the profession early. In addition, most of the research has focused on motivation to become a musician. Listening to music plays an important part in the daily lives of most people in the Western world but there is little research relating to those individuals for whom listening to music is a passion, who have extensive collections of recorded music and are extremely knowledgeable about music without necessarily actively participating in making it. There is also a need to explore why music plays little part in the lives of some people.

CHAPTER 28

The role of the family in supporting learning

Andrea Creech

Introduction

Powerful images of musicians' parents have been immortalized in accounts of the lives of many iconic figures in Western music. Parents have been depicted as exerting enormous influence on their children's musical development, as in the cases of Mozart (Solomon 1994), Clara Schumann (Galloway 2002), and more recently, Yehudi Menuhin (Menuhin 1977) and Jacqueline du Pré (Easton 1989), to name but a few. At the other end of the spectrum are exceptional accounts of musicians who attained high levels of expertise and musical intelligence without parental support, as in the case of Louis Armstrong (Collier 1983). Kyle Pruett (2003, p. 154) invites us to conjure up our 'most enduring stereotype of the musician's parent. Then consider the opposite pole. Next, reflect on the intermediaries.' This chapter will attempt to respond to Pruett's challenge by considering these 'intermediaries' and suggesting the ways in which parents may most constructively support their children's musical development.

Years of educational research, theory and wisdom sustain the view that parents play a key role in their children's academic achievement, educational aspirations, well-being and motivation (Baker 1997; Grolnick *et al.* 2002; Gonzalez De Hass *et al.* 2005). Researchers have concluded that young children and adolescents alike experience improved student outcomes when their parents are actively involved at home and in the school context (Henderson and Berla 1994).

In the domain of music, and specifically relating to the acquisition of expertise on musical instruments, the question of how families can best support their children's interest has been a preoccupation of many researchers. Positive relationships between musical home environments and the musical responsiveness of children from these homes have been reported (Kirkpatrick 1962; Shelton 1965; Wermuth 1971), and these findings have been elucidated by more recent research that has found children's musical development to be influenced by parental musical background (Bloom and Sosniak 1981; Klinedinst 1991), socio-economic background (Klinedinst 1991), parent support for practice and lessons (Doan 1973; Brokaw 1982; Sloboda and Howe 1991; Zdzinski 1992; Davidson *et al.* 1995), parental goals, aspirations and values (Sosniak 1985; Addison 1990; Davidson and Scott 1999), parental self-efficacy (Creech 2001), family interaction patterns (Davidson and Borthwick 2002), and parent–teacher–pupil relationships (Manturzewska 1990; Creech 2006; Hallam 1998). It has been acknowledged that the conditions which facilitate the development of musical gifts and talents involve considerable investment of time and financial resources as well as parental belief and philosophical commitment (Chadwick 1996). The process of facilitating developing talents is seen by Feldhusen (2001) as a long-range one in which parents work together with pupils and teachers. This growing body of research suggests that the ways parents might support their children in persisting with learning musical instruments and developing musical expertise are diverse and complex.

The advent of the Japanese Suzuki method of violin teaching, which came to the West during

the 1960s holding as a central tenet the importance of the parent as 'home teacher', played a powerful role in highlighting the issue of parent participation in the realm of children's instrumental learning. The Suzuki method, however, cannot claim sole ownership of the concept of parent–teacher–pupil partnership in instrumental learning; it has been demonstrated through biographical evidence (Lochner 1950; Weschler-Vered 1986; Milstein and Volkov 1990; Lewis and Staryk 2000; Stern and Potok 1999; Menuhin 1977) that parents, across cultures and historical time frames, have chosen to involve themselves integrally in the process of their children's acquisition of musical expertise. Empirical studies into the role of parents in instrumental learning (Doan 1973; Brokaw 1982; Sosniak 1985; Sloboda and Howe 1992; Davidson *et al.* 1996; Creech 2001, 2006; McPherson and Renwick 2001; Welch *et al.* 2006) have indicated that parental involvement in their children's musical development is not unusual; parents from diverse backgrounds and with children learning by a range of teaching methods and representing a number of instruments and musical genres, have supported their children in pursuit of musical excellence.

Parent involvement has been defined as 'the dedication of resources by the parent to the child within a given domain' (Grolnick 1997, p. 538). Grolnick conceptualizes parent involvement as comprising behavioural support, cognitive/intellectual support, and personal support. This chapter will begin with a brief discussion of the ways in which these three types of parental support have been found to influence children's musical development, with an emphasis given to the latter category of personal support, an area of parental involvement that has been shown in the domain of music to have far-reaching consequences for pupils, parents and teachers alike (Pruett 2003; Creech 2006). A discussion of whether interpersonal relating styles determine the extent to which parents engage in various types of involvement will follow, paying particular attention to the findings of a recent investigation into the influence of interpersonal relationships on learning outcomes (Creech 2006). Based on these findings a typological approach will be taken, with parental support of their children's musical development discussed within the framework of six distinct types of parent–pupil–teacher partnerships in instrumental learning.

Behavioural support

Overt manifestations of parental support, including participatory activities and modelling the importance of the subject area, are included under the umbrella of *behavioural support* (Grolnick 1994). Parent participation in school activities has been found to be a positive predictor of primary school-aged children's school engagement (Izzo *et al.* 1999), and helping with homework is one of a number of parent practices that has been found to have a positive relationship with secondary students' academic engagement (Steinberg *et al.* 1992).

In the domain of instrumental learning parents may offer behavioural support in the form of monitoring and participating in practice, attending lessons and adopting the role of home teacher. In an experimental study involving beginning band students (aged 11–12) Brokaw (1982) found that

> while it was not surprising to discover a strong relationship between the amount of time a student spends practising and the student's achievement in performance ... the amount of time spent by parents in supervising home practice is even a better predictor of successful achievement in the initial stages of development.
>
> (1982, p. 97)

Previously, Doan (1973) had produced similar results, in his study of 11-and 12-year-old violin students. Amongst a number of factors, parental supervision of practice and parent attendance at the child's concerts were identified by Doan as being significantly correlated to student achievement on the violin (1973, p. 79).

Other research has helped to elucidate Doan and Brokaw's findings. In a study of American concert pianists, Sosniak (1985) found that although many of the parents of her cohort had little musical background, their role of stimulating and supporting practice had been vital in sustaining their children's growth in musical competence throughout a first phase of early formal instruction and second phase of systematic

acquisition of knowledge and skills. Sloboda and Howe (1991) concurred with Sosniak when they found that high-achieving 8–18-year-old students in a specialist music school had benefited from the support and encouragement of parents who, with little formal knowledge of music, took responsibility for helping with home practice and for encouraging their children to gain and maintain good practice habits. Beginning band pupils, aged 7–9, were found by McPherson and Renwick (2001) to be helped by parents in developing self-regulated learning, particularly during the first year of learning. Davidson *et al.* (1995) demonstrated that parental commitment to assisting, encouraging and supporting the child in the early stages of learning was a more important predictor of successful musical outcomes than any specialist knowledge on the part of the parent. 'Without the positive involvement of the parent in the process, the highest levels of achievement are likely to remain unattainable' (1995, p. 44).

Zdzinski (1992), in a study involving teenage woodwind players, demonstrated that the effects of behavioural support upon musical achievement may differ with student age. This view was supported by the findings from a more recent study involving 337 violin pupils and their parents (Creech 2006) where a considerable drop in monitoring and assisting with practicing, providing feedback during practice sessions and attending instrumental lessons was found amongst the parents of 13–14-year-olds, as compared to those with children up to the age of 12. Furthermore, when parents were grouped according to levels of behavioural support it was evident that high levels of participatory activities during adolescent years was significantly associated with inhibited pupil–teacher accord and with limitations on the child's autonomous learning. These findings support the evidence reported by Ginsburg *et al.* (1993) who found decreased pupil autonomy amongst early adolescents whose parents operated a regime of homework surveillance.

The ages of 12–18 have been described as the mid-life crisis of young musicians, when the need to acquire or disown the interest in music becomes paramount (Bamberger 1987). This is the point at which behavioural support may become less helpful, while an increasing emphasis on cognitive/intellectual support and personal support may become more valuable to the developing musician.

Parents who have engaged in considerable behavioural support during the early years of their children learning musical instruments face a special challenge of managing the transition to pupil–parent independence, in relation to the instrumental learning. Creech (2006) reported that this transition to independent pupil learning and the shift of emphasis from behavioural support to cognitive/intellectual and personal support sometimes involved the difficult risk that their child would make the choice to discontinue, a choice that carried implications of rejection of parental values. In addition, for many parents this shift entailed the loss of a role they had constructed for themselves, and despite being supportive of their children becoming independent learners many reluctantly surrendered their participation in practice and lessons. Teenage children often took the lead, 'encouraging' parents to relinquish their home teacher role by making it clear that this type of parental input was not welcome. Teachers too sometimes took the initiative, asking parents to cease attending lessons in order to allow a more independent relationship to flourish between pupil and teacher. The most successful transitions were experienced by parents whose children had established strong and positive relationships with their teachers, remaining receptive to parental interest yet taking responsibility for learning without external motivation provided by parents.

Cognitive/intellectual support

Exposing the child to cognitively stimulating activities and materials and engaging in intellectually domain-specific activities in the home have been found to comprise an important area of parental support (Grolnick 1994). Kulieke and Olszewski-Kubilius (1989) demonstrated that families of gifted children engaged in this form of support by espousing values relating to persistence and achievement in the subject area and by facilitating the progress of their children along particular domain-specific paths. Some evidence suggests that children internalize their parents' values and educational aspirations;

Marchant (2001) reported that the perceptions held by early adolescents of their parents' values had a strong association with motivation and attainment. Whether adolescents are likely to incorporate the parents' orientation and persevere on these paths has been found by Smith (1991) to be dependent on parent–adolescent communication regarding educational aims, together with perceived agreement between the two parents.

According to Csikszentmihalyi *et al.* (1993, p. 174) high levels of cognitive/intellectual support and challenge have a positive effect on teenagers across all talent areas. Parents of these accomplished children typically:

- Devote great amounts of time and energy to meeting the needs of their children
- Set high standards
- Encourage productive use of time
- Provide challenging opportunities
- Make sure lessons and materials are available
- Set aside areas of the home where child can work privately.

In the context of instrumental learning, parents offering this type of support provide the opportunities and materials that will assist the development of their children's musical intelligence, including arranging instrumental lessons, attending professional concerts with their children, listening to and discussing music in the home, encouraging participation in extra-curricular musical activities, and providing a quality instrument.

Evidence from a study investigating parental influence on the musical development of musically involved young Australians (Chadwick 1996) suggests that parents who perceived their children to be exhibiting characteristics of musical giftedness provided high levels of cognitive support for home-based musical activities. It has been suggested that children flourish when parents follow their lead and provide the wherewithal for in-depth exploration of their particular interests (Silverman 1992). Chadwick (2000) elucidates this view, suggesting that opportunities to engage in challenging and rigorous musical activities from an early age enhance normative musical development and provide a foundation for the development of musical expertise.

Creech (2006) reported that parents of violin pupils aged 13–18 who had persisted with learning for seven or more years and had attained relatively high levels of expertise on their instruments (beyond grade five, practising six or more hours per week) engaged in higher levels of music-specific cognitive/intellectual support than those with children below the age of 13 and in the beginning stages of playing. In the same study, when 337 parent–pupil pairs were grouped according to parent scores for cognitive/intellectual support, increased pupil enjoyment and parent satisfaction were found in the groups where the parents offered the greatest amount of this type of support. Cognitive/intellectual support was also found to be associated with increased professional satisfaction on the part of the teachers and with pupil–teacher influence, whereby pupils demonstrated independent learning, contributing to setting goals and effecting changes in the learning agenda.

Personal support

A growing body of evidence demonstrates that high levels of personal support represents a key area of parent involvement associated with sustaining a child's musical well-being (Pruett 2003; Creech 2006).

Education researchers have found that children in all age groups, including secondary school students, value their parents' help, interest and support, and that parental influence on children's behaviour remains extensive in adolescence (Brown *et al.* 1993; Crozier 1999). However, Crozier emphasizes the need for pupils to have some control over parents' involvement, highlighting the importance of negotiation rather than imposition of psychological control characterized by intrusive or manipulative controlling/surveillance measures (Crozier 1999; Baumrind 2005). Crozier here touches on the issue, so stark in adolescence, of the delicate balance between dimensions of 'agency' (the drive for independence) and 'communion' (the need to be engaged with others), which has been identified both in the literature relating to parenting style (Baumrind 1989; Brown *et al.* 1993; Noack 1998) and that concerned with interpersonal style (Van Tartwijk *et al.* 1998) and relationships (Birtchnell 1993; Tubbs 1984; Noller *et al.* 2001).

Steinberg *et al.* (1992) demonstrated that teenage students were most likely to benefit from parental involvement activities that included attending school programmes and extra-curricular activities and maintaining an interest in student progress when these forms of parental support were offered within a parenting style characterized by acceptance, warmth, democracy, and some degree of student autonomy. While Ginsburg and Bronstein (1993) found that behavioural support in the form of surveillance and monitoring of homework was associated with an extrinsically motivated orientation on the part of their children, they also noted that when parents provided encouragement and praise the children were more likely to demonstrate curiosity and an intrinsic interest in challenging learning tasks. It has been suggested that emotional support offered by parents in the form of interest and enthusiasm for their children's learning establishes 'a foundation for socializing children's motivation to learn' (Gonzalez-DeHass *et al.* 2005, p. 111). Furthermore, there is strong evidence that regardless of social class parental involvement in the form of home interest, support and discussion has a major impact on educational outcomes (Sui-Chu and Willms 1996; McNeal 2001).

Researchers and theorists argue that 'people function most cohesively and confidently in contexts in which they experience significant others as being both caring and autonomy-supportive' (Noack 1998, p. 227) and achieving a successful balance in this respect is a key factor in providing personal support for children's musical development.

In a musical context, biographical evidence gathered from finalists in the German 'Jugend Musiziert' music competition demonstrated that these young expert musicians had typically benefited from supportive and motivating relationships with their mothers (Bastian 1989). More recently, personal support was found to be associated with persistence with learning and musical attainment as well as with increasing pupil enjoyment of music and motivation (Creech 2006). Those parents with the highest scores for personal support were interested in understanding their child's point of view and prepared to compromise when their personal goals or expectations conflicted with those of the child, subscribing to the stated aim of supporting the child in whatever course of action was chosen (i.e. to continue or not with musical studies). These parents were deeply interested in their children's learning, and were involved with their child learning an instrument to the extent that they considered this endeavour to have been a life-changing experience for themselves. A predominant view amongst these parents was that their children should develop independent learning skills and yet continue to feel supported by their parents. Strong pupil–teacher rapport was valued and this together with admiration of the teacher appeared to make it relatively easy for parents to become progressively less directly involved in the learning partnership (Creech 2006).

The potential for conflict

Considering the potential for conflict amongst those involved with musical instrument learning, particularly over practice, musical preferences, and time commitment expectations, it is perhaps rather surprising that little research to date has been directly concerned with this issue.

The emotional demands made on parents by their musical children can be considerable. The parent–child relationship is particularly vulnerable when adolescents reach the aforementioned musical mid-life crisis (Bamberger 1987) and as young musicians become increasingly susceptible to performance anxiety and the fear of negative judgement (Robson 1987). Clearly it is important for children to sustain a sense of being emotionally supported by their parents even in the face of disagreements. Research with gifted children and their families advocates family meetings as a forum where conflicts and power struggles may be resolved via shared responsibility and negotiation (Silverman 1992).

While parents of young musicians have been found to make frequent references to reluctant practising and to parent–pupil conflict these issues did not, as many parents fear, inevitably diminish either their children's persistence with learning or their own personal satisfaction (Creech 2006). Strategies that parents have identified as being successful in dealing with this potential battleground include simply leaving the room, discussions at times other than practice

time, lowering expectations of daily practice, challenging the child, and offering praise as a reward. Parents did not acknowledge that material rewards would be a useful strategy to resolve conflict over practice, and considered the most successful strategy to have been allowing the child to choose when and how much to practise, within parameters negotiated with the teacher (Creech 2006).

Pruett identifies transcultural qualities of 'good enough parenting' (Pruett 2003, p. 155), amongst which the challenges of personal support are encapsulated. Included on his list are sensitivity to children and their ever-changing needs, the ability to make children feel loved, adored and enjoyed, devotion to sustaining strong values, affirmation of the child's uniqueness while expecting competence, and sustaining an abiding presence through thick and thin. Research in the domain of music supports the enduring importance of these qualities, suggesting that pupils function best when they perceive the adults as both caring and supportive of autonomy and when they are able to engage in ongoing mutual interaction with adults who continue to have a stake in their development and to act as their advocate (Noack 1998; Manturzewska 1990; Creech 2006).

Parent–pupil–teacher interaction: a typological approach

Any discussion of the parental role in children's musical development must take into account the interpersonal context. Systems theory provides a framework in which this context, comprising parents, teachers and pupils, may be conceptualized as a micro-system characterized by *holism*, whereby a human system is understood as the sum of its individual members, and *exchange*, whereby any change in one member of the system produces change throughout the system (Becvar and Becvar 1996). O'Neill (1996) argues that the parent–pupil–teacher relationship in the context of musical instrument learning can justifiably be conceptualized as a micro-system because all three participants experience new patterns of action and communication as a direct result of their interaction, and because many motivational issues can be understood and possibly resolved when considered as a function of the micro-system. From this perspective parental support may be seen as part of the functioning of the parent–teacher–pupil system, influenced by the parent's position on a *control–responsiveness* axis, in relation to teacher and pupil.

Control and responsiveness

Baumrind (2005) suggests that the extent to which parents engage in supportive behaviour is associated with interpersonal qualities she labels as responsiveness and demandingness (interpreted here as *control*). A study by Marchant (2001) involving 230 early adolescents measured parental style using these two dimensions and provided evidence that children's school achievement is indeed influenced by interpersonal relationships amongst teachers, parents and pupils. Trusty and Lampe (1997) investigated the dimension of parent control and suggest that this interpersonal dynamic, when manifested in the context of relationships where parents offer cognitive and personal support in the form of discussing school, current events or troubling issues with their teenagers, is associated with an internal locus of control on the part of the young people whereby they experience pride and satisfaction for their successes. However, Ginsburg and Bronstein (1993) investigated the impact of behavioural support on student motivation and found that when parents monitored, enforced or helped with homework in a controlling fashion their early adolescent children showed less autonomy, satisfaction, persistence and intrinsic motivation related to their schoolwork. Garland (2005) discuss control as a dimension that varies from controlling to autonomy-supportive behaviour, and puts forth the view that while the former encourages children's obedience and compliance the latter promotes choice, self-reliance and participation in decision-making.

Baumrind's model of demandingness—responsiveness interpersonal relating style is reflected in Birtchnell's relating theory (2001) whereby interaction is conceptualized on a horizontal closeness–distance axis intersecting with a vertical upperness–lowerness axis. Birtchnell does not

priviledge different positions on his interpersonal model, pointing out that while closesness holds people together, distance provides the space to become autonomous, and while upperness allows the opportunity for people to exert influence on others, lowerness enables individuals to benefit from the care and leadership of others.

Categories of parent–teacher–pupil interaction

The models proposed by Baumrind and Birtchnell resemble Leary's model for interpersonal interaction (1957) that served as the basis for the examination of parent control and responsiveness in the context of their relationships with their children who were learning the violin and with their children's instrumental teachers (Creech 2006). Parent control, on the vertical axis, was found to comprise underlying dimensions that were (1) perceived teacher leadership, (2) parent–teacher communication, (3) parent isolation within the learning partnership, (4) parent ambition and (5) parent preponderance. Responsiveness, on the horizontal axis, comprised (1) perceived teacher approachability, (2) teacher–parent intimidation, (3) parent–pupil reciprocity and (4) parent–teacher acquiescence.

Six distinct clusters of parent–teacher–pupil interaction types, determined by dimensions of control and responsiveness, were found amongst the parent–teacher–pupil trios. A model (Figure 28.1) representing these six types of learning partnerships demonstrates that clusters one, two and three may be conceptualized as primary dyad plus a third party, while cluster four is represented as two primary dyads connected by one common member. Cluster five is characterized by very little communication between any two of the three individuals, while cluster six is characterized by reciprocity amongst all three participants.

Differences amongst the clusters of parent–teacher–pupil interaction types

Parent support

Significant differences were found between the parents of each cluster with respect to the types

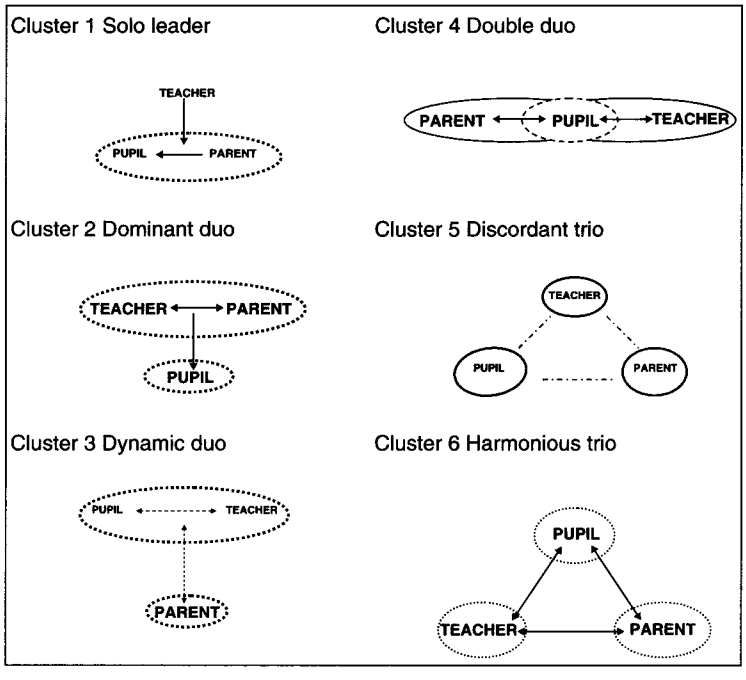

Fig. 28.1 Parent–teacher–pupil interaction types.

of support they were most likely to engage in. Parents in the *dynamic duo* and *discordant trio* clusters, characterized by a distant and powerless parent–teacher relation, offered the least amount of support, overall. Those occupying the *solo leader* cluster, where the parent took responsibility for ensuring that parent and pupil together followed the directive teacher, were found to offer the most behavioural support. The highest levels of cognitive/intellectual support were offered by parents occupying the *dominant duo* cluster, characterized by parents who adopted a predominant and controlling role in relation to both pupil and teacher. The *harmonious trio* cluster, where parents balanced ambitions for their children with responsiveness in relation to both teacher and pupil, had parents who engaged in the most personal support (Figure 28.2).

Pupil age

As pupils matured parent–pupil–teacher trios tended to gravitate towards the *dynamic duo* (pupil–teacher relationship becoming the primary dyad and parents becoming less influential), adding to the body of evidence showing that while parent–child relationships are typically hierarchical, family relationships undergo transformations towards more egalitarian patterns during adolescence (Noack 1998). While younger pupils were more likely to occupy the categories of *solo leader* and *dominant duo* where the basis for teacher–parent cooperation was the perceived dependency of the child, during the adolescent years pupils ceased to be dependent on the parent for motivation and structure (Johnson 1991). It was evident that some parents became isolated third parties (*dynamic duo*) while others shifted from an emphasis on behavioural

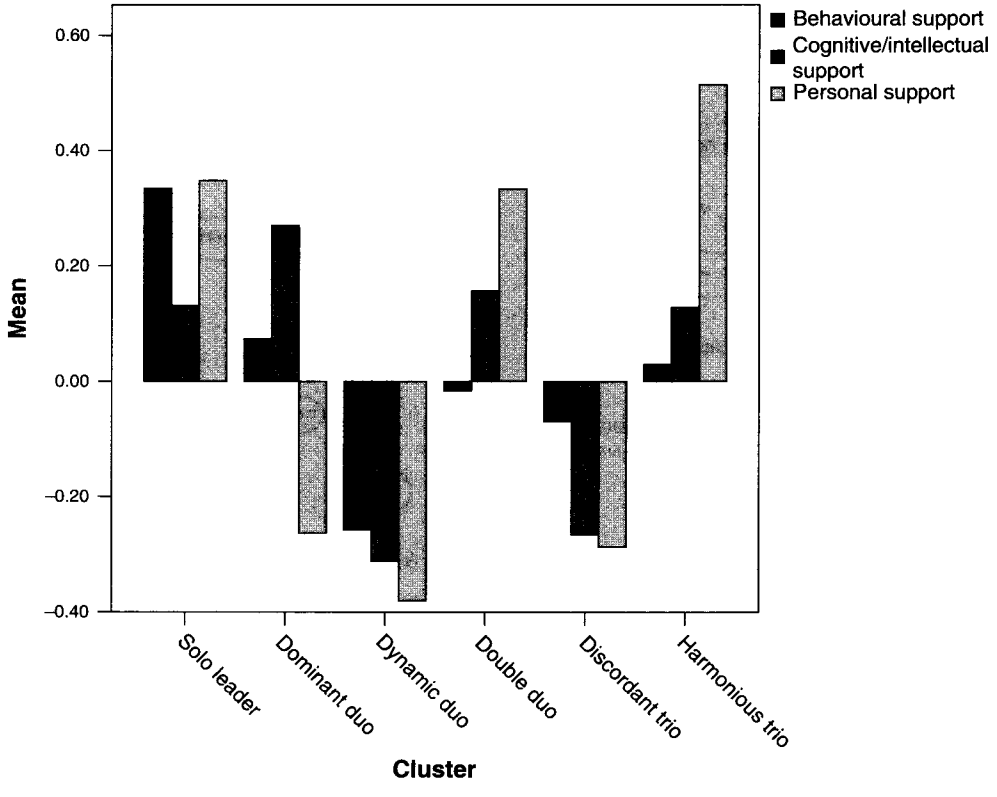

Fig. 28.2 Parent support according to parent–teacher–pupil interaction type (standardized scores).

of support they were most likely to engage in. Parents in the *dynamic duo* and *discordant trio* clusters, characterized by a distant and powerless parent–teacher relation, offered the least amount of support, overall. Those occupying the *solo leader* cluster, where the parent took responsibility for ensuring that parent and pupil together followed the directive teacher, were found to offer the most behavioural support. The highest levels of cognitive/intellectual support were offered by parents occupying the *dominant duo* cluster, characterized by parents who adopted a predominant and controlling role in relation to both pupil and teacher. The *harmonious trio* cluster, where parents balanced ambitions for their children with responsiveness in relation to both teacher and pupil, had parents who engaged in the most personal support (Figure 28.2).

Pupil age

As pupils matured parent–pupil–teacher trios tended to gravitate towards the *dynamic duo* (pupil–teacher relationship becoming the primary dyad and parents becoming less influential), adding to the body of evidence showing that while parent–child relationships are typically hierarchical, family relationships undergo transformations towards more egalitarian patterns during adolescence (Noack 1998). While younger pupils were more likely to occupy the categories of *solo leader* and *dominant duo* where the basis for teacher–parent cooperation was the perceived dependency of the child, during the adolescent years pupils ceased to be dependent on the parent for motivation and structure (Johnson 1991). It was evident that some parents became isolated third parties (*dynamic duo*) while others shifted from an emphasis on behavioural

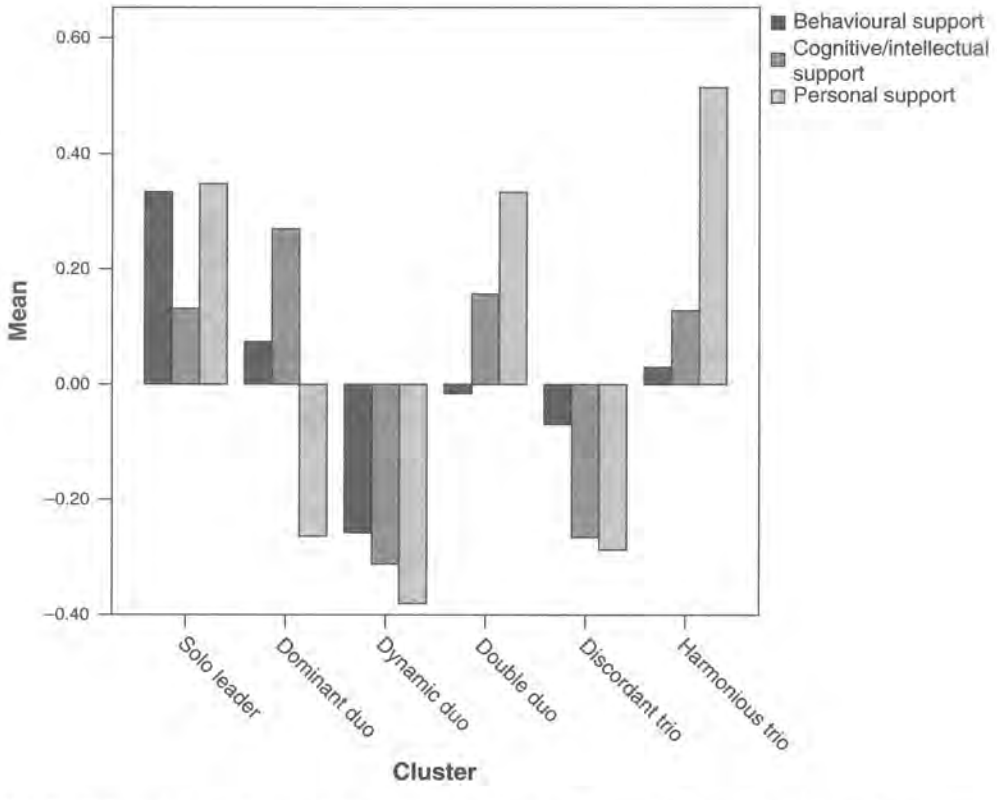

Fig. 28.2 Parent support according to parent–teacher–pupil interaction type (standardized scores).

support to personal and cognitive/intellectual support, continuing to support their children at home but becoming remote from the teacher (*double duo*). Still others (likely to be found in the *harmonious trio*) achieved a balance of agency and communion with their children and teachers within a relationship characterized by continued moderate behavioural support together with an emphasis on both cognitive/intellectual and personal support.

Persistence with learning

Numbers occupying the *discordant trio* category decreased sharply after three years of study, suggesting that characteristics of this type may have led to pupil drop-out, or alternatively to changes to other teachers. Conversely, there was a large increase in numbers occupying *harmonious trios*, after three years of study. The numbers in the *dynamic duo* category remained stable and were not sensitive to years of study, while numbers occupying *dominant duo* and *double duo* categories declined after six years of study. Thus it would seem that the balance of parent support achieved by those in *harmonious trios*, which included moderate behavioural support, higher levels of cognitive/intellectual support and a great deal of personal support, may be associated with their children's perseverance on the instrument.

Few pupils occupying the *discordant trio* cluster progressed beyond grade five, while the *dominant duo* and *harmonious trio* clusters contained greater proportions of pupils who had attained a minimum of grade four. Parents occupying these two clusters, while differing in respect of personal support, were similar in that they demonstrated high parent–teacher acquiescence and perceptions of strong teacher leadership but low teacher–parent intimidation and isolation.

The *harmonious trio* and the *solo leader* were the clusters where the greatest proportion of pupils did in excess of three hours practice per week. Parents in these two clusters were most similar in that they perceived strong leadership on the part of the teachers and also offered a great deal of personal support to their children. Again, parental perception of teacher leadership seems to be a key factor in sustaining persistence with learning.

Pupil learning outcomes

Differences amongst the clusters of interaction types were evident in respect of pupil learning outcomes including enjoyment of music, personal satisfaction, motivation, self-efficacy and self-esteem. Overall the *discordant trio* produced the least positive outcomes while the *harmonious trio* produced the most consistently positive outcomes for pupils. With reference to the former this finding adds to earlier research that suggests where parents place a low value on the subject matter, have low expectations of success, do not have the wherewithal to help their children at home and/or are intimidated by teachers the result can be a downward spiral of mutual distrust, lack of communication and absence of shared purpose amongst parents, teachers and pupils alike (Bandura 1997; Hurley 1995). In contrast, the findings in respect of the latter elucidate earlier research that has proposed a model of parent–professional–child partnership whereby parents lie at the heart of a system which advances the child's development while professionals take primary responsibility for advancement of knowledge and skills (Henry 1996). Furthermore, these findings support the view that pupils function best when they perceive the adults as both caring and supportive of autonomy and when they are able to engage in ongoing mutual interaction with adults who continue to have a stake in their development and to act as their advocate (Noack 1998; Manturzewska 1990).

Summary: the versatile parent

Effective and supportive parental involvement in instrumental learning requires parents to be versatile, adept at moving between the close and distant positions on the responsiveness axis and between directive and acquiescent positions on the control axis of the model for interpersonal dimensions. This involves providing much practical assistance and personal support during the early years of learning yet seeking and following the teacher's advice in musical matters and allowing the child and teacher the space to develop an autonomous relationship. It also involves remaining resilient in the face of reluctant practising while remaining as the child's interested and supportive advocate, long after

practical help has ceased to be appropriate or welcomed by the teacher and pupil. Most importantly, parents should not become uninvolved in their children's learning in the name of agency, nor disempower their children in the name of communion. Specifically, positive outcomes may be achieved when parents (a) elicit their children's views regarding appropriate parental involvement, (b) negotiate with their children over practising issues, within parameters set by the teacher, (c) provide a structured home environment for practice, (d) take an interest in promoting good teacher-pupil rapport, (e) communicate with the teacher in relation to the child's progress, and (f) remain as a supremely interested audience.

Returning to the systems framework, the versatile parent may be conceptualized as one part of a dynamic interpersonal system, influenced by and having a reciprocal influence on the characteristics of both teacher and pupil. There is much scope for future research in relation to this point, particularly concerning (a) how parent–teacher–pupil systems evolve over time and (b) the processes by which these interpersonal systems may underpin teaching and learning outcomes.

For each musical listening function, the presence of a circle indicates that at least 50% of studies reviewed involved damage to the corresponding brain region. The size of the circle scales with the proportion of studies in which such a link was evident. See Chapter 17, p 186, for further details. Key: amyg, amygdala; aSTG, anterior superior temporal gyrus; bg, basal ganglia; cc, corpus callosum; fr, frontal; hc hippocampus; HG, Heschl's gyrus; i, inferior; ic, inferior colliculi; ins, insula; l, lateral; m, medial; PT, planum temporale; TG, temporal gyrus

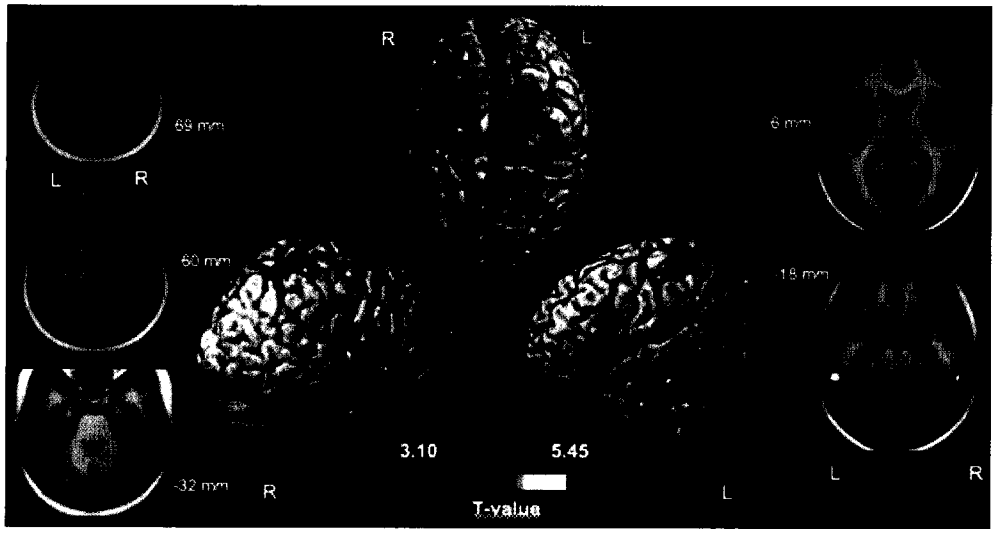

Plate 3 A voxel-based morphometric study showing grey matter volume differences between three groups. Only voxels exhibiting a significant positive correlation between musician status (professional musician > amateur musician > non-musician) and increased grey matter volume are shown here, and those have been overlaid on the rendered cortical surface of a single subject. (This figure was adapted from Figure 1 in Gaser and Schlaug [2003]). See Chapter 18, p 199, for further details.

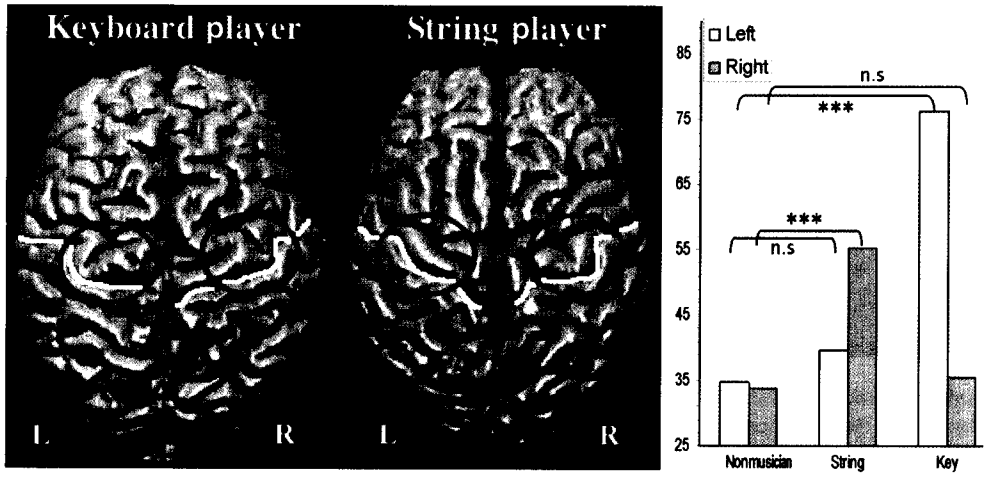

Plate 4 Brain surface renderings of one typical keyboard and one typical string player. The central sulcus is marked with a white line. The portion of the precentral gyrus containing the configuration similar to that of the inverted Greek letter 'Omega' is found within the red circles. In the two examples, a prominent omega sign can be seen on the left more than the right in the keyboard player, and only on the right in the string player. See Chapter 18, p 200, for further details.

See Chapter 18, p 200, for further details.

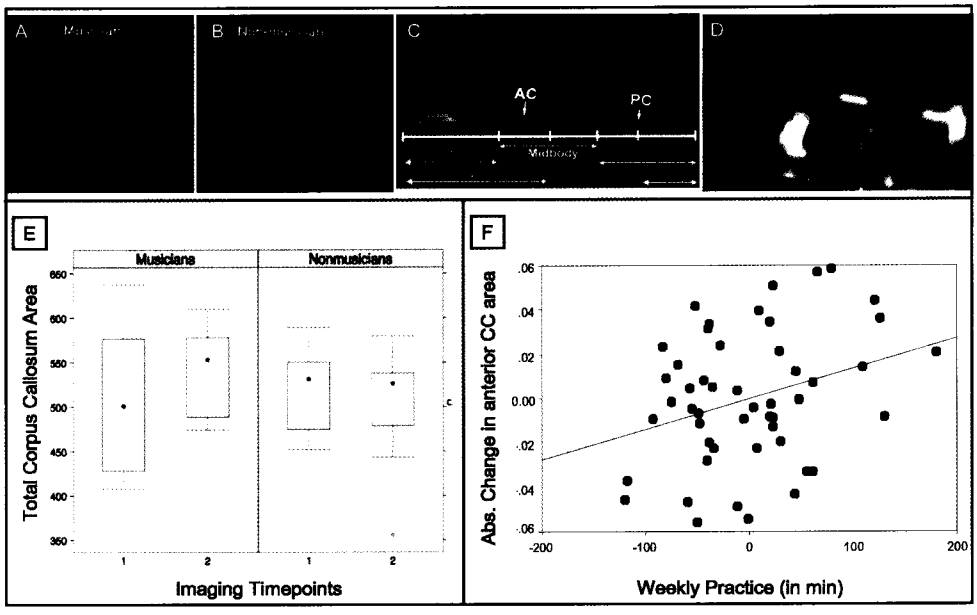

Plate 5 Corpus callosum differences in adults (musicians vs non-musicians) and changes over time in children. (A) and (B) show the midsagittal slice of an adult musician (A) and non-musician (B) showing a difference in the size of the anterior and midbody of the corpus callosum. (C) and (D) show the major subdivisions of the corpus callosum and locations of the interhemispheric fibers connecting the motor hand regions on the right and left hemisphere through the corpus callosum.
(E) and (F) show the mean (dot inside box plots) midsagittal corpus callosum size of the 5–7-year-old children at baseline (time point 1) and after 15 months of musical training (time point 2) shows slightly opposite trends with the instrumental group showing an increase in the midsagittal corpus callosum area. The anterior portion of the corpus callosum (segments 1–4, see Fig. 18.3c) showed a significant correlation with the amount of weekly practice ($p = 0.034$; partial $r2 = 0.094$). See Chapter 18, p 202, for further details.

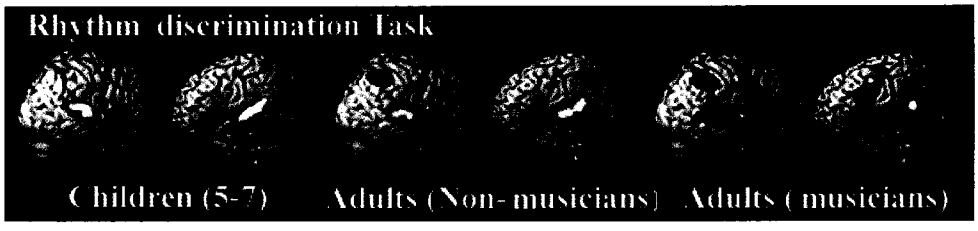

Plate 6 Cerebral activation pattern of a rhythm discrimination task – modulated by maturity and experience. Statistical parametric images superimposed onto a surface rendering of a standardized anatomical brain depict significant activations during a rhythmic discrimination task in a group of 5–7-year-old, musically naive children, adult non-musicians, and adult musicians. The children showed prominent superior temporal gyrus activation on both sides. The adult groups show an extended pattern of activation involving polar and posterior planar regions of the superior temporal lobe as well as the parietal lobe, parts of the frontal lobe, and the cerebellum. Adult musicians differ from adult non-musicians by having less activation of the primary auditory cortex, but more activation of frontal regions bilaterally, particularly in the inferior frontal gyrus. See Chapter 18, p 204, for further details.

CHAPTER 29

The role of the institution and teachers in supporting learning

Graham Welch and Adam Ockelford

Introduction

Musical behaviour and development are natural by-products of the interface between intrapersonal maturational processes and an individual's enculturation into locally dominant sound worlds (e.g. Hallam and Lamont 2004; Welch 2006a) and are basic to human design. They are not dependent on the input of an institution or a 'teacher' as such, but are related to the evolution of generative skills in a sonic environment—our natural propensity to 'continually create, recreate and develop new ideas and materials' (Hallam and Lamont 2004, p. 243). Within such environments, there are various 'institutions' (including cultural settings as well as educational establishments) and 'teachers', i.e. people who have a role in musical learning, with both exemplified in the peer-to-peer popular music skill development of musicians and adolescents (Green 2001; Tarrant *et al.* 2002). Other examples are found in the interweaving of indigenous musics with the rituals of daily life, such as in the *iorram* or rowing songs of the Isle of Mull (Macnab 1970) and as practised by the Northern Ewe children of Eastern Ghana (Agawu 1995).

> *6.00 a.m.* The day's work has begun in earnest. In one home, girls are pounding dried cassava in a mortar to make *kokonte*. In another, they are pounding recently harvested rice in order to remove the husks. As with other forms of daily pounding ... the work ... is made a little less routine by incorporating some rhythmic interest. In place of a regularly spaced alternation between two pounders ... a variant may be introduced. Pounder 1 keeps a steady pace while Pounder 2 pushes her strokes closer to Pounder 1's. Here as elsewhere in Northern Ewe culture, work merges into play and reemerges into work.
>
> Agawu (1995, p. 12)

Contemporary explanations for the mechanism for the process of learning in social and cultural settings often draw on the work of Vygotsky, Luria and Leont'ev in the first half of the twentieth century (cf. Bannon 1997; Cole 1999), as well as being related to systems theory—the interlinking of relationships within some form of organization—(von Bertalanffy 1968), and social ecology theory—the nurturing of development within social contexts (Bronfenbrenner 1979). The early Russian investigators and those who developed their work subsequently (such as the Finnish researcher Engeström) explored how learning and development are the product of inter- and intrapersonal behaviours that are shaped by cultural artefacts (e.g., literature), alongside tools (including psychological tools, e.g., language and other symbol systems), expectations, 'rules'/conventions and norms. The internalization of artefacts is also seen to facilitate the agency of the individual, such that the artefacts themselves are modified through personal use, enabling the possibility of consequent change within the culture. Thus there is an

ongoing mediation process in how individuals interact with the world around them and make sense of their reality.

A key concept in this view of culturally based learning is 'activity', which has been defined as 'the engagement of a subject toward a certain goal or objective' (Ryder 2005). One widely cited model of activity within a system is provided by Engeström (1999, 2001) (see Figure 29.1). In his interrelated system of elements as applied to education, the 'subject' (the learner) is supported in reaching the 'object' (the intended learning outcome) through interaction with various 'mediating artifacts' (such as language and other symbol systems) (a conceptualization strongly associated with the work of Vygotsky). This process is seen as being embedded in a social context that provides support for the activity through the subject and intended outcome being located within a 'community' that has 'rules' (expectations for behaviour) and also the likelihood of a 'division of labour' (diversity of effort). Because of the possibility of tensions within the activity system, it may be that the actual outcome is at variance with the intended object (i.e. that there are unintended outcomes—as explored below).

If the activity system is seen in relation to learning within an institution (such as a school or social collective, for example, the family) in which certain people either adopt or are expected to have, roles as 'teachers', then it is possible to envisage how the theorized activity system might be able to support the intended learning in music (or fail to). The world of music has certain characteristics:

- There are many different musical genres and subgenres;
- Each has its own customary view of what counts as musical learning, or at least the outcomes of musical learning in relation to performance, as well as the traditions (custom and practice) in how learning is usually fostered in relation to the genre's characteristic features, as exemplified in the 'institutions' of India, for example the tradition of musical households or *Gharanas* (Farrell 2001) and Japan, for example the culture schools managed by major business and voluntary organizations (Murao and Wilkins 2001);
- In many diverse musics, there is evidence of the high status accorded to the accomplished expert who demonstrates solo mastery over the sonic material;
- Certain cultures, such as China, Afghanistan and India, continue to have strong traditional music genres. These are characterized by expertise transmission within families across several (or many) generations (Jones 1995; Doubleday and Baily 1995; Farrell 1997). In such traditional cultures, the 'teacher' is in

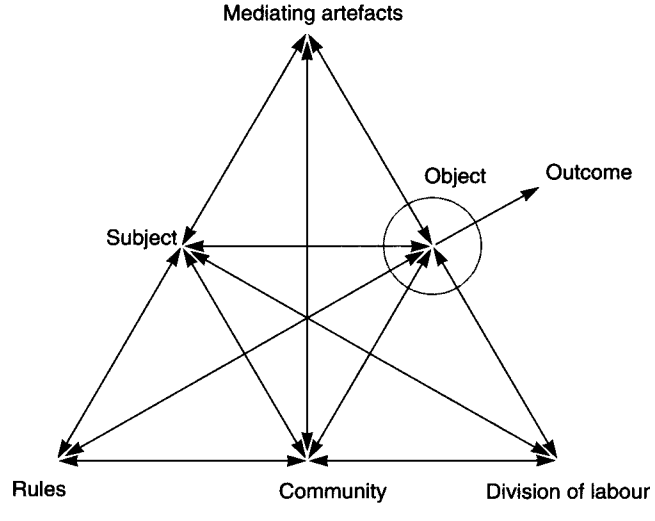

Fig. 29.1 The structure of a human activity system (Engeström 2001b, p. 136).

a master/apprentice relationship with the 'pupil' within a strong local community, often fostered by pupils playing for each other in the presence of the master.

Aspects of the role of institutions and teachers in the process by which musical expertise is learned and demonstrated are illustrated in the four examples that follow (see below). The first relates to musical development in a special education context, the second to advanced music learning in higher education, the third to the relatively new music education world of the female cathedral chorister and the fourth to pupils' experiences of lower secondary school classrooms in England. In the first three cases, the intention is to suggest how the teacher and institution support the activity of learning within a social context, whilst the last demonstrates that not all music learning in within an institution is necessarily positive or as intended.

The role of institutions and teachers in supporting musical learning: four examples

Example one: supporting musical learning in a young prodigious musical savant

Derek Paravicini is a musical savant, now in his late twenties, who is well known to the public through success on the concert platform as a jazz and popular pianist on both sides of the Atlantic. His early life was very difficult, and the initial development of his musical expertise was highly unconventional (Ockelford 2007).

Derek was born premature at 26 weeks, weighing a little over 700 g. In the fight for survival that followed, he lost his sight through retinopathy of prematurity, and developed unspecified neurological impairments that meant he grew up with severe learning difficulties. His family were upper-class and employed the services of an experienced Nanny to care for him and to oversee his upbringing. Neither she, nor anyone else, expected Derek to develop musically in a way that was at all out of the ordinary (there was no history of exceptional musical development in the family). However, following the diagnosis of Derek's blindness a few weeks after returning home from hospital, Nanny decided that sound was likely to play an important part in his life. So she sang to him constantly and surrounded him with sound-making toys. Just like any other baby's, Derek's environment was also perfused with music from the TV, radio and other incidental sources.

Derek was attracted to music as a potential source of stimulation and order in the world around him, and unbeknown to Nanny or his family, his ability to process musical sounds developed rapidly and precociously. Desperate to find an activity that would keep the 1-year-old Derek gainfully occupied, Nanny gave him his grandfather's little electric keyboard to play with. From the start, Derek loved the sounds that it produced and discovered that he could imitate some of the musical sounds that he had came into contact with. With no intervention on the part of Nanny or his family, and with no visual model to guide him, Derek taught himself how to get his hands and fingers in the right places at the right times to recreate some of the snatches of melody and harmony that were familiar to him. This situation—Stage 1 in the journey of Derek's musical learning—is summarized in terms of Engeström's model in Figure 29.2.

One day, after about six months of self-directed exploration at the keyboard, Nanny heard Derek play a version of 'Cockles and Mussels'—using both hands, with a tune and rudimentary accompaniment. His repertoire soon widened, and Derek's relationship with Nanny, his extended family and friends took a new course with the addition of this unexpected but welcome dimension. Still there was no *formal* intervention or guidance, though, from those around Derek in terms of supporting his learning. In the months and years that followed, Derek continued to chart his own, unique, autodidactic course (Stage 2: Figure 29.3).

At the age of five, Derek came to the attention of the second author (AO), who was then teaching in a school for the blind in south-west London. Derek's raw talent was evident, as were his technical eccentricities—including the use of his knuckles, hands and even the occasional

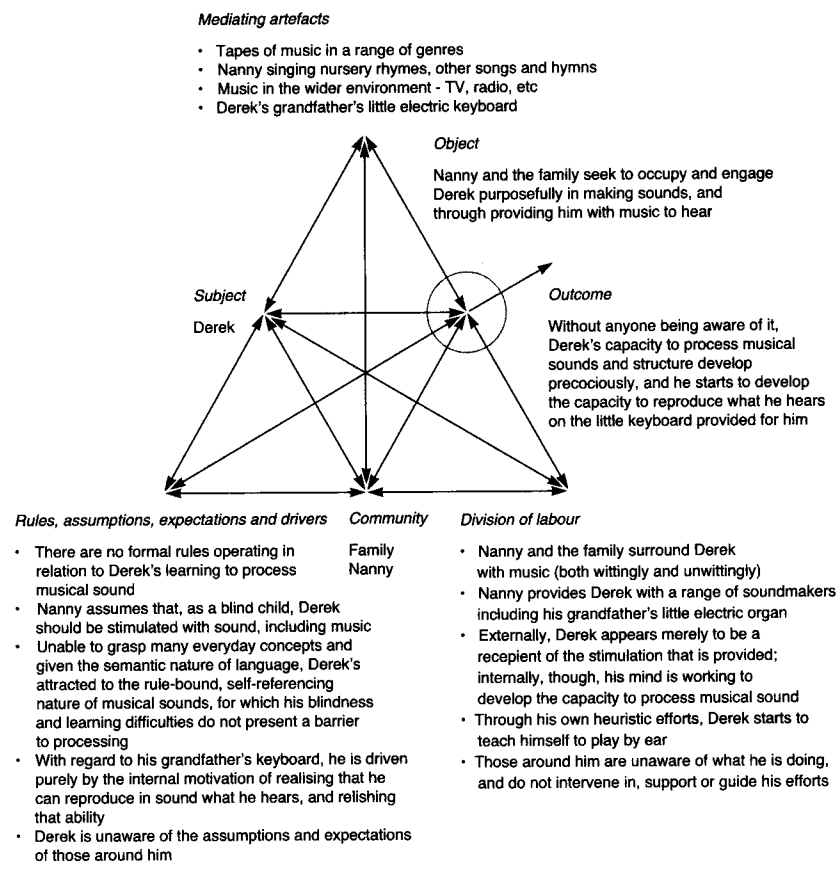

Fig. 29.2 Stage 1, 0–21 months.

judicious dip of his nose which enabled him to reproduce sonorities that were beyond the reach of his limited span (around a fifth on the standard-sized keyboard). In AO's view, while Derek's achievements up to that point were remarkable, particularly given his blindness and severe developmental delay, it was essential that he should come to accept the intervention of another, to guide his further musical development and realize his creative intent. However, Derek had never experienced anything approaching a conventional 'teacher–pupil' relationship, and he was not remotely inclined even to share *his* piano with anyone else, let alone engage in a structured learner–teacher dyad. Hence, a large part of AO's effort for the first six months of working with Derek was directed towards showing him that interaction through music could be productive and, above all, enjoyable. Gradually, involving an initial degree of physical intervention, Derek did come to appreciate that discourse through the medium of musical improvisation was possible and could indeed be a source of great pleasure.

Engaging in social discourse through sound could not alone solve Derek's technical challenges, however, and a final stage in AO's early relationship with him was necessary, whereby Derek would allow AO to show him—physically—how to hold his hands and use his fingers in conventional patterns that would facilitate his technical development. Clearly, Derek had no concept of the goals that AO was pursuing, so it was critical that he enjoyed being guided

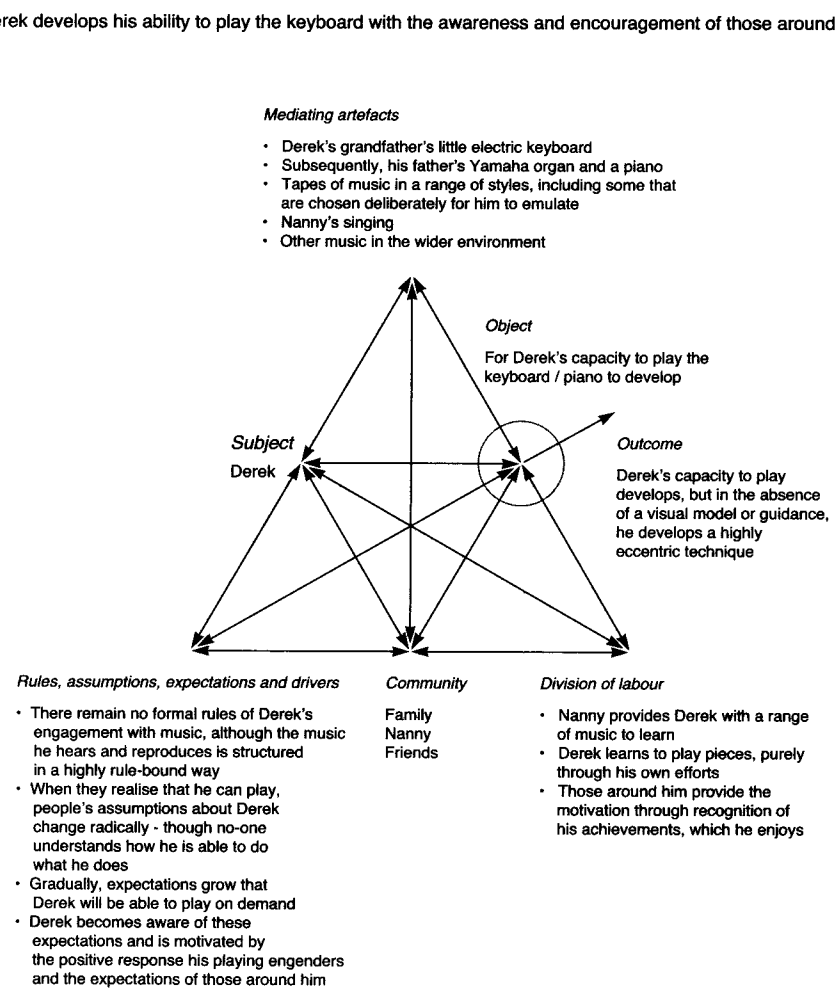

Fig. 29.3 Stage 2, 21–66 months.

through the daily ritual of technical exercises, scales and arpeggios that AO devised for him. Luckily, Derek relished the one-to-one attention and the orderliness of his practice routine, and the pattern of highly formalized intervention with AO continued throughout his childhood on a daily basis (Stage 3; Figure 29.4).

There is much to learn from Derek's story: most obviously, the fact that an individual can be motivated to pursue musical learning to a highly advanced level at an early age with no direct intervention or encouragement on the part of others, and with no global sense of moving towards the goal of becoming a competent performer (see also Ockelford 2008, Ockelford *et al.* 2006). Beyond this, however, it is also the case that Derek, as someone with severe learning difficulties, could, initially through a discourse comprising nothing but musical sounds, develop a relatively conventional teacher–pupil relationship, that eventually enabled him as an adult to have a career as an internationally recognized musician.

Example two: supporting musical learning in higher education

Higher education (HE), on the other hand, is a relatively (often highly) selective educational environment that seeks to advance already competent

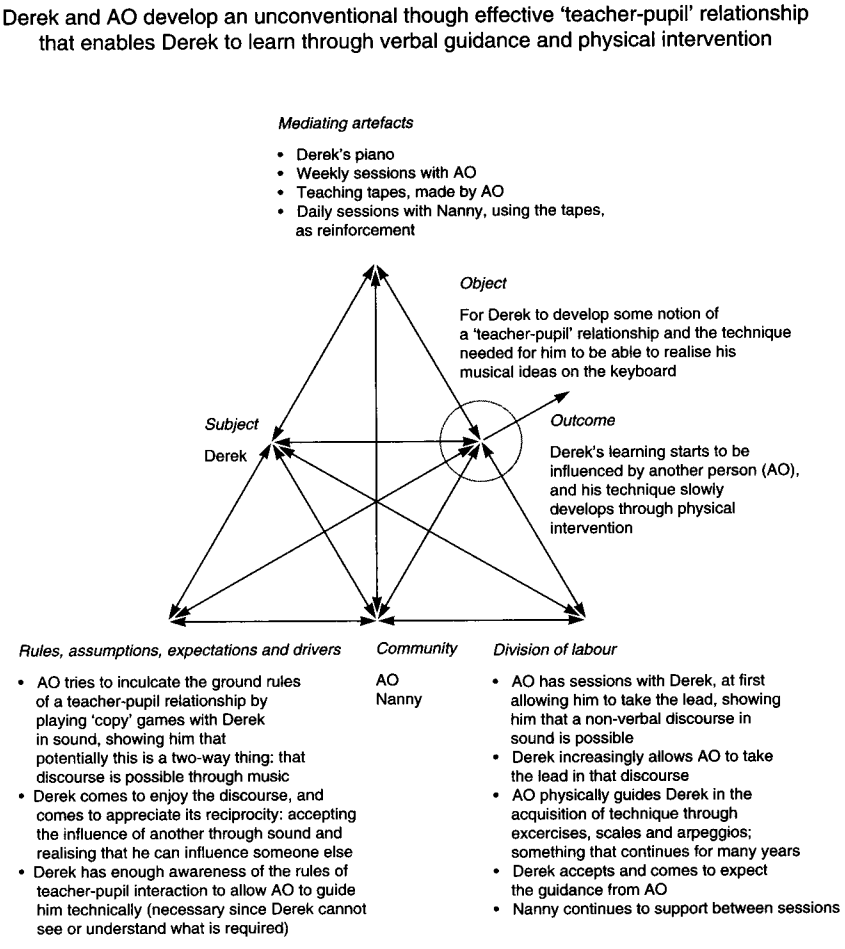

Fig. 29.4 Stage 3, from 66 months.

musical skill levels in young people who normally exhibit (or report) little or no disability (though see for example Lerner and Straus 2006).

Within the spectrum of HE in music, there are observable similarities and differences in the way that the activity of music learning is processed. These are particularly related to context, such as the age and gender of performers, their principal musical genre and the particular HE location. For example, an ongoing study of advanced music learning and teaching in four UK higher education institutions (HEIs) is investigating how classical, popular, jazz and Scottish traditional musicians deepen and develop their learning about performance in undergraduate, postgraduate and wider music community contexts (Welch *et al.* 2006). In the first year of the study, a specially designed, web-based questionnaire was used to survey 244 musicians across the four HEIs. In addition to demographic information, participants provided self-reports about their earliest engagement with music (including first instrumental or vocal lessons), secondary and tertiary education, as well as significant musical experiences and influences. The participants were questioned about the perceived relevance of a range of musical skills and activities, experience of performance and general life anxiety, how they spent their time in an average week, the pleasure that they derived from engagement in musical activities, various self-views (musical self-efficacy, self-esteem,

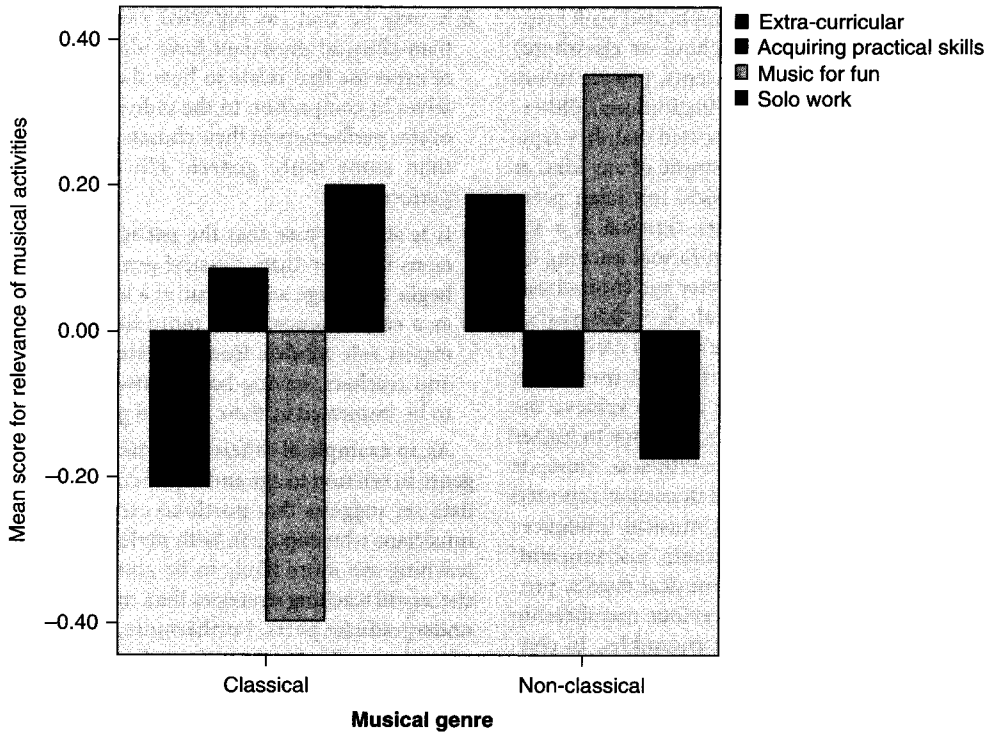

Fig. 29.5 Classical and other-than-classical-musicians' mean scores for categories of musical activities (*extra-curricular*: listening to music from own and outside of own genre, acquiring general musical knowledge, engaging in professional conversations, networking; *acquiring practical skills*: practising alone, practising with others, taking lessons, solo and group performance, listening to music from own genre; *music for fun*: playing for fun alone or with other; *solo work*: mental rehearsal, giving lessons, solo performance). (Creech *et al.* 2008, p223)

self-regulation), group membership and their beliefs about the nature of expertise in musical performance and teaching.

The resultant data analyses suggest that all musicians attached great importance to achieving a high overall standard of performance, although they had different perspectives on the processes by which this might be achieved (Creech *et al.* 2008). For example, in terms of the performance expectations of their particular musical 'community' and its requisite 'tools' and 'rules' (*pace* Engeström), classical musicians ranked the ability to improvise as the least important musical skill, but perceived sight-reading to be very important. In contrast, in relation to the performance expectations of *their* particular communities, the other-than-classical musicians (jazz, popular, Scottish traditional) tended to assign the least importance to the ability to sight-read, but placed greater emphasis on playing from memory and improvisation. Although all musicians recognized the value of practice, the community of classical musicians tended to place greater emphasis on practising alone, whereas other-than-classical musicians attached greater relevance to making music for fun, networking and extra-curricular activities such as listening to a diverse range of musics and engaging in professional conversations with peers (see Figure 29.5). Nevertheless, both classical and other-than-classical groups considered musical expertise to involve the possession of global musical skills that could be transferred to other musical genres (Papageorgi *et al.* in press).

An exploration of underlying processes that might explain the similarities and differences

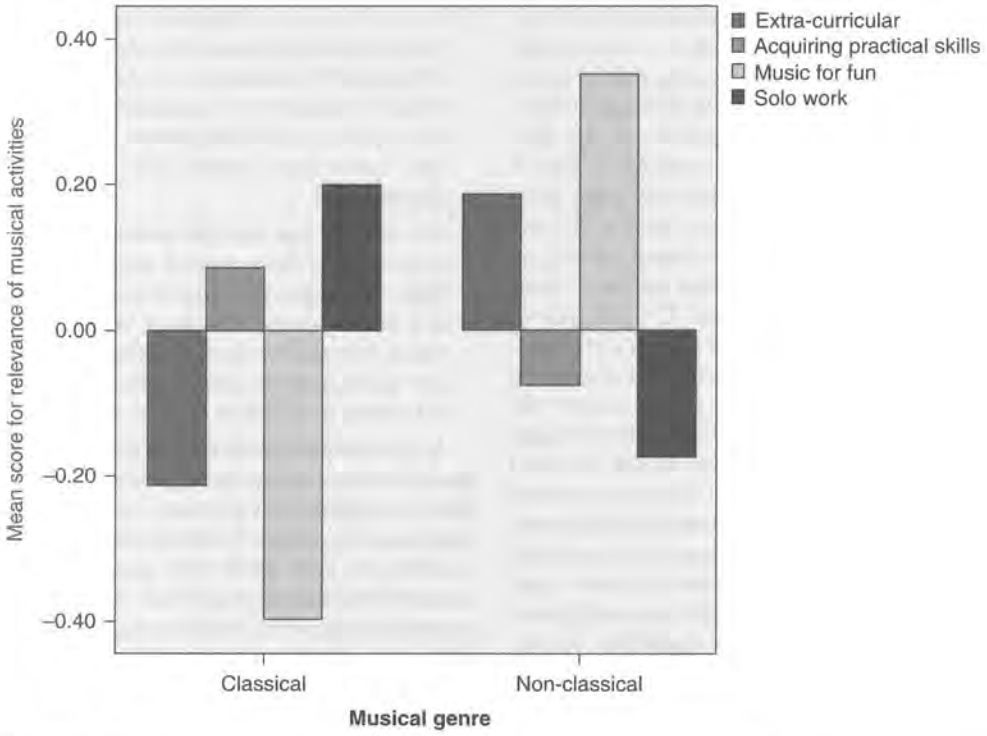

Fig. 29.5 Classical and other-than-classical-musicians' mean scores for categories of musical activities (*extra-curricular*: listening to music from own and outside of own genre, acquiring general musical knowledge, engaging in professional conversations, networking; *acquiring practical skills*: practising alone, practising with others, taking lessons, solo and group performance, listening to music from own genre; *music for fun*: playing for fun alone or with other; *solo work*: mental rehearsal, giving lessons, solo performance). self-regulation), group membership and their beliefs about the nature of expertise in musical performance and teaching.

The resultant data analyses suggest that all musicians attached great importance to achieving a high overall standard of performance, although they had different perspectives on the processes by which this might be achieved (Creech *et al.* 2008). For example, in terms of the performance expectations of their particular musical 'community' and its requisite 'tools' and 'rules' (*pace* Engeström), classical musicians ranked the ability to improvise as the least important musical skill, but perceived sight-reading to be very important. In contrast, in relation to the performance expectations of *their* particular communities, the other-than-classical musicians (jazz, popular, Scottish traditional) tended to assign the least importance to the ability to sight-read, but placed greater emphasis on playing from memory and improvisation. Although all musicians recognized the value of practice, the community of classical musicians tended to place greater emphasis on practising alone, whereas other-than-classical musicians attached greater relevance to making music for fun, networking and extra-curricular activities such as listening to a diverse range of musics and engaging in professional conversations with peers (see Figure 29.5). Nevertheless, both classical and other-than-classical groups considered musical expertise to involve the possession of global musical skills that could be transferred to other musical genres (Papageorgi *et al.* in press).

An exploration of underlying processes that might explain the similarities and differences

between these two groups implicated both institutions (whether home, school or elsewhere) and teachers (including parents, private tutors and teachers in educational institutions). Other-than-classical musicians reported that they typically began to engage with music of any kind at a later age than their classical musician peers (non-classical: $\bar{X}$ = 8.4 years, classical: $\bar{X}$ = 6.6 years). Similarly, they began formal learning on their first instrument at a later age (non-classical: $\bar{X}$ = 12 years, classical: $\bar{X}$ = 8.8 years). Notwithstanding the nature of their early musical experiences, all the participant musicians, irrespective of genre, were able to achieve the requisite baseline skill levels for entry to higher education and beyond. Nevertheless, contexts were not identical. Classical musicians reported that their most important musical influences (past and present) were parents, instrumental/vocal teachers, significant musical events, professional colleagues and previous membership of county (regional) music ensembles. In contrast, other-than-classical musicians claimed to be particularly influenced by well-known performers, as well as university or college lecturers and informal groups of friends (Creech *et al.* 2007). Across all musicians, irrespective of genre, higher education tutors, whether lecturers in particular aspects of music or specialist solo instrumental and vocal teachers, were reported to be significant agents in a communal process of advanced music learning.

Overall, participant classical musicians rated themselves higher in terms of perceived musical expertise. The basis for this difference is likely to relate to (1) the comparative longevity of classical musical cultures in HE, (2) other aspects of participants' group-based self-views and (3) differences in participants' cumulative years of study. For example, interviews with senior academics in the participant HEIs revealed that:

1 Classical music had been established for much longer in their academic programmes compared to the three selected other-than-classical genres (jazz, popular and Scottish traditional). Concomitantly, classical music teaching and learning and assessment practices were reported to be more firmly embedded, rehearsed, formalized and understood within their particular communities;
2 It may be that (as reported earlier) other-than-classical musicians have idealized views of expertise that relate to how they see themselves in comparison to the individual quality of star performers in their chosen genre rather than some more generic HE measure of performance;
3 It is also the case that the participant musicians in other-than-classical genres typically begin to engage with music at a later age and, as a consequence, were more likely to have expert role models from outside their peers and teachers, having had relatively less time to be immersed in their musical genre.

As an example of differences *within* a musical genre in relation to age and experience, the same data set suggests that portfolio career classical musicians who engage in both performance and teaching are more likely to be able to identify successful teaching strategies than their younger, undergraduate peers. Furthermore, the activity of teaching, allied to extensive solo performance experiences, are likely to reduce levels of performance anxiety.

Example three: supporting female music learning in a UK cathedral setting

Male choristers have participated in UK cathedrals since their inception in 597AD at Canterbury. In comparison, it was not until 1991 that Salisbury became the first old cathedral foundation to admit girls on the same basis as boys. The political impact and success of their initiative (although foreshadowed by other religious institutions earlier in the twentieth century but without the same publicity) has led to a growing (sometimes grudging) acceptance of female choristers within the previously all-male culture. By 2006, a majority of cathedrals had choristers of both sexes for the first time in their long history, even though it continues to be relatively rare for the two sexes to sing together, other than at special festival events (Welch 2007).

One of the cited reasons for the longevity of the all-male cathedral music tradition was that young females were regarded as being unable to sing with the same 'pure' quality of vocal timbre demonstrated by the young male voice in the

performance of the cathedral sacred music repertoire. This belief does have some basis in the physical realities of child voice acoustics, even though research has demonstrated its fallibility. First, there are slight differences in the relative sizes of girls' and boys' vocal anatomy, the male being slightly larger throughout childhood and into adolescence (cf. Welch and Howard 2002) and these could be expected to generate perceptible disparities in acoustic outputs. Secondly, with regard to untrained children's voices, there is increasingly perceptible psycho-acoustic differentiation between the sexes as they progress through childhood (Sergeant *et al.* 2005; Sergeant and Welch in press), with observable gender-related differences in their sung spectra. However, the power of the musical activity system in the cathedral is such that formal induction of girls into its performance expectations can generate changes in their basic vocal behaviour such that any gender differences are reduced significantly and often become imperceptible. A series of perceptual studies from the mid 1990s onwards has demonstrated that membership of a cathedral choir can allow girls to be trained to produce sounds that are 'boy-like' in character in order to match the customary, male-biased, performance expectations of the musical repertoire (Sergeant and Welch 1997; Howard and Welch 2002; Welch 2006; Welch and Howard 2002).

Detailed longitudinal case study data from one cathedral suggests that the activity of becoming a female chorister is closely linked to the customary tripartite relationship in music (Small 1999) between the physical setting, people (performers and listeners) and the way that the musical soundscape constrains the variety

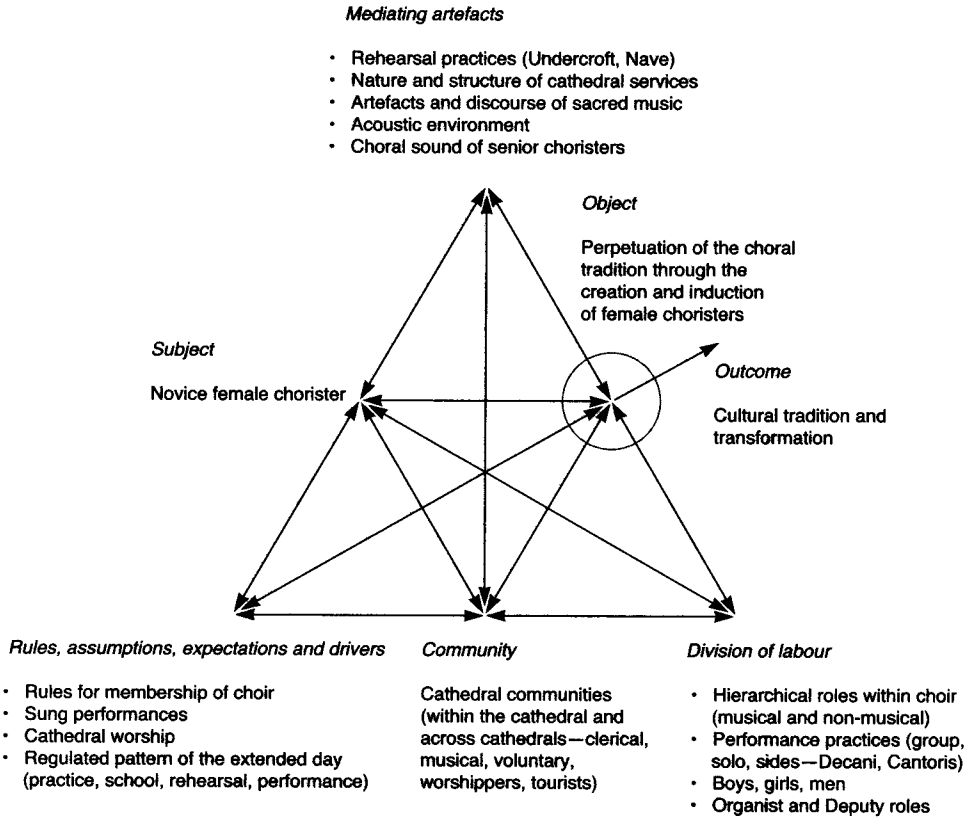

Fig. 29.6 An example of the activity system that frames the development of the novice (female) cathedral chorister (Welch 2007, p. 29).

of possible musical outcomes. The induction process for both young males and females involves the novice chorister (probationer) being required to learn, practise, rehearse and perform music systematically many times each week across the school and ecclesiastical year, whilst standing between and listening to the vocal models of established senior performers (head chorister, deputy head chorister, senior corner girls), supported by group-based (communal) teaching by a highly experienced church musician (organist and choir director or deputy), in order to master a ritualized repertoire (such as the *Introit, Psalms, Response Settings* and *Anthem* for Evensong) that involves both choral and solo performance: see Figure 29.6 for how this experience can be framed within an activity system (Welch 2007).

The acoustic features of the rehearsal and performance spaces within the chancel and choir of the cathedral also shape the learning experience, with features of the choristers' sound amplified by the high stone vaulting of the nave and adjacent spaces and fed back to the performers. The collective and ritual nature of the performance is reinforced by the addition of adult male voices (for most services) and the organ. It is not surprising, therefore, that females are able to perform the established religious repertoire in customary fashion, given the interrelated expectations of the musical learning process and the longevity of the performance practices within the culture that are handed down across generations of cathedral musicians (and where it is extremely rare for a new director to be appointed from outside the tradition).

Example four: supporting music learning in the lower secondary school

In contrast to the above, it is possible that institutions and teachers can also hinder as well as support learning in music. For example, notwithstanding recent improvements in the quality of music education across all four curriculum 'stages' in English schools, embracing the ages 5–16 (Welch 2006b), there is often a particular disparity in the individual experiences of pupils in the lower secondary school (ages 12–14). Although the independent school inspection body, OfSTED,[1] has reported a steady improvement in lower secondary school music teaching since 2001, the overall quality in the other school age phases (both older and younger) has often been reported as higher. The reasons for these systematic differences are likely to relate to:

1 The organization of the timetable in primary schools where one class teacher tends to take all curriculum subjects and, therefore, is in a better position to know each individual child across a school year and to match music teaching to individual need,
2 English National Curriculum music learning expectations of primary school children are lower (in terms of the complexity of musical behaviours) than in secondary schools; this may encourage more positive judgements from school inspectors (who are themselves unlikely to be primary music specialists);
3 Upper secondary school music (ages 14–16) is optional, catering for a small minority of pupils (between 7–9 per cent) who have opted to study music for a further two years to examination at age 16; and
4 Lower secondary school music is compulsory for all pupils—a period of intense personal development in their musical identity (Tarrant *et al.* 2002).

Nevertheless, some secondary schools have been able to counter this trend, even in contexts where 'success' in school examinations may not be the norm. For example, a recent analysis of data from secondary schools in one part of inner London with a high Black African-Caribbean (BAC) population found that up to 62% of such pupils were opting to study music (with an average across schools of 24%). This was much higher than the non-BAC groups in the same schools (average 8%) (Spence 2006). Furthermore, these pupils went on to achieve higher grades in their 16+ examinations for music than in their other

[1] The Office for Standards in Education (OfSTED) assesses the quality of music teaching on behalf of the Government. This is a non-ministerial Government department that reports directly to the UK Parliament. OfSTED is headed by a senior civil servant and is required to inspect and report on the quality of education in schools and in initial teacher education.

subjects, such as English, mathematics and science. A recurrent theme from interviews with these young people was that lesson content had greater enjoyment when it drew on music that they knew, liked and/or could play. They also reported greater liking of teachers who showed respect for them and their music. Such positive emotional engagement appears to be reflected in their relative success in school music.

Further insights in why some young people are 'successful' at school music and some are not are reported in a study of lower secondary school music (Saunders 2006). Pupils in the final year of compulsory music education in England (Year 9, age 13+) have to make a decision about whether or not to continue their school music studies. Coding and analyses of the transcripts of interviews with 44 pupils in one school revealed that pupils tended to see themselves in one of five categories (see Table 29.1).

Only one of the five groups is fully engaged with school music (termed the 'traditional Western musician'), in part because of their formal instrumental performance skills and an ability to identify successfully with the content of the school music curriculum. However, four other groups of pupils have alternative, less positive perspectives. Some see themselves as non-musicians; some have self-taught instrumental skills, but do not identify with school music, even though they are accomplished musicians ('alternative Western musician'); some are accomplished musicians in a traditional sense, but believe that school music is irrelevant and a possible threat to their musician status ('disengaged traditional Western musician'); and some find that the mismatch between their musical skills and the skills needed for the school curriculum is intimidating to their self-concept as a musician ('disengaged alternative Western

Table 29.1 Pupils' self-identified grouping related to classroom music in Year 9 (age 13+) of lower secondary school

Pupil identity related to school music	Example key characteristics
Traditional Western musician	Strong engagement with all music; good family support
	Successful experience of formal learning of an instrument
	Peer group status as a 'musician'
Western non-musician	Strong engagement with music outside school; limited family support
	Limited instrumental skill; immediate peer group do not identify with school music; peer group recognition as a 'non' musician
Alternative Western musician	Strong engagement with all music; family support
	Informally/self-taught instrumental skills; school music seen as irrelevant; peer group status as a 'musician'
Disengaged traditional Western musician	Strong engagement with music outside school
	Formally taught instrumental skills, family support variable
	Peer group do not identify with school music
	Music curriculum seen as a 'threat' to musician status within peer group
Disengaged alternative Western musician	Strong engagement with music outside school
	Informally or self-taught instrumental skills; family support limited
	Peer group share counter culture of musical identity
	'Musician' status threatened by lack of success

musician'). When interviewed, a significant number of young people consider themselves (wrongly) to be unsuitable for continuing music studies. Yet virtually all connect successfully with music outside school, as consumers, listeners, and/or practitioners. Unless pupils identify and find success with school music (e.g. Spence 2006), they are likely to disengage. Subsequent research and analyses of pupil interviews in three other schools has confirmed these findings (Saunders 2008). Comments from individual pupils demonstrate the kinds of diversity in their experiences of music in school:

> It's my favourite lesson of the whole week and well, I wish we could do a bit more of it really.

> I think the stuff at lunchtimes and for the shows is really good, but that lessons aren't anywhere near as exciting as that. I suppose that's because we can't all sing and play like them though.

> Music at school is pants; it's just not any good. It's all duff music. I mean, who listens to this stuff?

> I'm learning from my brother and his mate taught him, so when we get together, it's a bit scrappy, but we're getting better. I don't do it that much in class cos Miss wants us working on the keyboards and I'm not great at that.

Collectively, these comments illustrate the underlying positive connection that these young people have with music, although not necessarily the kinds of music (and musical practices) found in school. Adolescence is a period characterized by the emergence of strong musical identities (Zillman and Gan 1997), often with a clear perception of boundaries between different musics as young people use music to negotiate positions for themselves within their group identities (O'Neill and Green 2001). It is not surprising, therefore, that school music has such a mixed reception during this age phase.

Conclusion

Overall, the various examples cited above are an indication of how learning and teaching in music are shaped by processes outside the individual, not least because of the influences of group membership (allied to age and gender), performance expectations and practices, and professional and institutional cultures. The process of individual induction into the characteristics of a particular musical culture by teachers and institutions influences the formation of identities in music (cf. MacDonald *et al.* 2002), for better or for worse, at least in terms of dominant models within the culture. Indeed, the development of music teachers themselves can be seen within an activity system, i.e. the teacher's understanding of their role is developed both by informal personal reflection of the experience of performance and their own learning and, more systematically, through their own induction process by attendance at a specialist pedagogically focused institution.

PART 7

Musical performance

Edited by Richard Parncutt

CHAPTER 30

Measurement and models of performance

W. Luke Windsor

Introduction

Rationale and overview

This chapter describes and evaluates the ways in which both the measurement and modelling of performances have contributed to the emerging discipline of music psychology. What is intended is a tutorial guide covering major issues, techniques and findings in this area, along with enough context and exemplification to meet this end. Therefore, only a representative sample of references to the literature will be made, and although it is hoped that the chapter might serve as a bibliographical starting point for the researcher, apologies are made in advance for any omissions of literature that might have been central to another's view of this field. Moreover, although the discriminability of measured changes in expressive parameters is an important issue for music psychology this chapter must restrict itself to consideration of measurements themselves, and direct comparisons between such measurements and the predictions made by models.

Measuring performance

Hardware for measuring performances

Mechanical devices for measurement

It is not until the invention of the Piano Camera and its application to a psychology of performance by Seashore and colleagues (see Seashore 1938) that an accurate manner of registering the action of piano keys and pedals in relation to both timing and velocity was obtained. Shaffer, who published a number of studies of music performance in the early 1980s (see e.g., Shaffer 1981, 1984; Shaffer *et al.* 1985), used a modified grand piano using photo-electric cells to register the movement of the hammers. The development of a number of commercial MIDI compatible grand and upright pianos which also utilize photocells has meant that specialist instrumentation is no longer needed for such research. Although the only study (Goebl and Bresin 2003) which addresses recording accuracy on recent Yamaha and Bosendorfer pianos finds considerable evidence for timing errors (especially for the Yamaha instrument) many of the errors are smaller than the errors associated with MIDI itself. However, if exceptionally fine-grained timing microstructure in performance is an issue for the researcher care must be taken to ensure that such recording inaccuracy is not, for example, mistaken for performance variance: some of the errors measured by Goebl and Bresin were five times larger than the errors one might expect from MIDI transmission of data.

Movement and physiological transduction

Recent published work on body movement in performance (and its control) has begun to demand and apply sophisticated techniques that measure and analyse bodily or instrumental movement (see e.g., Askenfelt 1986; Clarke and Davidson 1998; Wanderley and Vines 2006), muscular activity (see e.g. Fjellman-Wiklund *et al.* 2004a, b), or even electrical activity in the

central or peripheral nervous system (see e.g., Kelso *et al.* 1992).

Acoustic instrumentation

Hardware for the acquisition and digitization of sound is available within most computer architectures, either off the shelf, or using third-party solutions. Given that analysing representations of the acoustic wave form of sounds allows for the analysis of timing, intensity, frequency and derivatives of these parameters (such as spectral envelope) is potentially of interest to anyone researching the psychology of performance who wishes to eschew keyboard instruments as data sources, and for the analysis of acoustic recordings of historical interest, such hardware is a vital resource. Moreover, although it may create other measurement issues, it avoids the potentially distorting influence of mechanical measurement.

Software and techniques for measuring and analysing performances

The main purposes of computer software in this context are to (1) transform and record measurements into a particular numerical form, (2) convert between different data formats, (3) apply mathematical functions to deliver visual, numerical or statistical analyses of a data set. To illustrate different software solutions (and demonstrate how they are designed to integrate with hardware choices and particular research questions) two examples will be offered. Whilst not intended as comprehensive, these will give some indications of the range of issues faced when choosing measurement and analysis software.

The first example measures timing and dynamics in commercial recordings of piano performance (Repp 1998, 1999). The main research questions addressed here are what features of inter-onset timing and dynamic variation are shared between performances of the same piece, and how these vary between individual performers, groups of performers and whether sociocultural factors account for this variance. Repp's measurement approach here is fairly direct: the timing of onsets was obtained through the 'visual and auditory cues' provided by a commercial wave form editor. Where there were performance asynchronies (as in chordal events) the onset of the highest pitch was chosen (Repp 1998). Although a partly perceptual measure, this is in direct contrast to some musicological studies of tempo variability (such as Bowen 1996) which involve analysis of the researcher's finger taps at the beat or bar level (indeed there are no psychological studies which use this approach, perhaps because it may suffer from any number of known of unknown perceptuomotor biases or inaccuracies). Neither does Repp utilize automated or semi-automated onset detection software such as that developed by Moelants and Rampazzo (1997) or Dixon (2001), which other researchers have found useful when analysing timing in audio recordings (see e.g., Moelants 2000). For dynamics, measurements of peak sound level in dB were obtained using the automatic peak-picking function in the Signalyze program, using the prior analysis of timing as a guide. Repp then uses a combination of general spreadsheet and statistical software to organize, display and analyse these measurements, converting onset times into inter-onset intervals, and applying standard statistical techniques such as principle components analysis (to identify a small number of common traits), and correlation or analysis of variance (to test whether these vary with the chosen sociocultural variables).

The second example (Windsor *et al.* 2006) analyses inter-onset timing in a dataset of MIDI encoded piano performances, provided at a single sitting by an expert pianist. Here, the extraction of onset timings was achieved by a Yamaha Disklavier, which was connected to a computer running a commercial sequencer package. These MIDI files were converted into a textual format with time expressed in seconds, and were annotated with structural information (such as the beginnings and endings of bars and phrases at different hierarchical levels) in order that the onset timing could be modelled, using the POCO performance research environment (see Honing 1990). Statistical techniques were applied to fit the timing data optimally to the musical structure using a third-party add-on to POCO (SAPA) which shared the same LISP programming environment, and a commercial statistics package was used to display the results in tabular and graphical form.

Future developments in analysis techniques in the form of functional data analysis of time-varying parameters, which might include measurements of body movement and tempo, might offer useful opportunities to relate such continuous time-varying measures to each other (see e.g., Vines *et al.* 2005, 2006). Such techniques can be applied where sampling rates in the two domains to be compared are unrelated, or where one wishes to compare measurements taken from performances with different global tempi.

Analytical methods and discoveries

Psychological studies of performance that derive from measurements exhibit a strong bias towards the measurement and analysis of onset timing. Dynamic variation has also been studied fairly extensively, but perhaps because of the relative ease with which onset times can be derived from performances, most studies are happy to focus on one or more aspects of timing. It is also the case that despite some attempts to model the relationship between parameters such as timing and dynamics (see e.g., Todd 1992) the relationship between the different variables that make up a performance is still little understood (although see Sloboda 1983; Drake and Palmer 1993).

Contributions of measurement to a psychology of performance

Motor programming

Music provides a rich context for studying the control of timing: the performer must often follow instructions from a score or match their movements to a co-performer (or ensemble), and the timing of their actions must be rhythmically organized to reflect the musical structure. The main observation in relation to timing control in music performance is that a serial timekeeper mechanism controls the production of fine-grained units in performance, whereas the timing of larger hierarchical units may be continuously modulated by a rate parameter (Shaffer *et al.* 1985; Vorberg and Wing 1996). These directly controlled units are often argued to be at the beat level in the metrical hierarchy: Shaffer (e.g. 1981, 1984) applied covariance analysis at different hierarchical levels (note, beat, bar) to attempt to identify negatively covarying intervals. Although such analyses normally rely on stationary time-series and may be distorted by drift or systematic tempo changes—which is often removed (Vorberg and Wing 1996, pp. 197–199) which are present in musical performances of this kind, Palmer (1997, p. 130) concludes that such results 'suggest that temporal precision in performance is influenced by the structure of the sequence—in particular, the salience of the beat level or tactus'.

The next issue that arises from this is how such a timing mechanism interacts with the actual events to be performed. The theory of motor programming (see e.g., Schmidt 1985; Gentner 1987) suggests that in a musical context an individual performance is derived from a mental representation of sequence of actions, often organized hierarchically: if one adds to this (as in Shaffer *et al.* 1985) the concept of a controlling internal timekeeper one has a recipe for generating an infinite number of performances from a single motor programme, with the timing of one hierarchical level directly controlled. Given that it is clear that performances by the same performer are surprisingly consistent in timing microstructure (see e.g., Gabrielsson 1987), even when recorded at different times (see e.g. Shaffer 1984; Clynes and Walker 1986), can show remarkable durational similarity, and that patterns of expressive timing reflect the hierarchical metrical and phrase structure of the music (see e.g. Shaffer 1981; Clarke 1988; Palmer 1989), it has become common to assume that for memorized performance at least, each performance given by an individual is related to a common motor programme, and that such motor programmes are structured in such a way as to reflect musical concerns. One theoretical question this raises is the extent to which such programmes are invariant given different overall rates (or global tempi). Deviations from proportional invariance are widely observed (Clarke 1982; MacKenzie and van Eerd 1990; Desain and Honing 1994; Windsor *et al.* 2001; Timmers *et al.* 2002; Repp *et al.* 2002; Windsor *et al.* 2006), and may reflect changes in perceptual or rhythmic grouping at different tempi or failures to transfer learning across tempi (Palmer 1997).

Coordination: within and between performers

Although there is an unfortunate concentration on solo performance in the music–psychological literature, there is a growing body of empirical data which relates to the psychological processes governing within- and between-performer coordination. Evidence from studies of chord asynchrony (see e.g. Rasch 1988; Shaffer 1984; Palmer 1989) shows that melody lead is widespread, again providing evidence that timing in music performance is governed by structural understanding.

Shaffer (1984) argued that synchronization in expert ensemble performance is not achieved by coordinating actions at the level of individual events or even the lowest level of nominal isochrony (beat) or tactus, but at the level of the bar. His data certainly suggest that timing control, whether in a solo or ensemble situation, is most clearly observable at these intermediate structural levels. He (1984) argues that just as a single pianist may coordinate two separate timekeepers for each hand using a single motor programme, so too may two or more performers integrate their performance using such a shared plan. It is also further evidence that musical structures and expressive strategies are formally linked: being able to predict patterns of timing relies on a shared conception not only of musical structure but on the resulting interpretative decisions.

Rhythm and timing

It has long been observed that musical performances of notated scores do not preserve their canonic durations (Seashore 1938), and there are a number of hypotheses that claim to explain this discrepancy. Some researchers explain such deviations from the metronome as expressive, either of underlying musical structures (Clarke 1988) or of extra-musical content (such as emotion or mood) (see e.g., Palmer 1989; Juslin and Madison 1999). Others attempt to show that many such deviations are the result of compensation for perceptual biases or due to motor noise (Penel and Drake 1998). Even simple rhythmic patterns are not performed metronomically, with adjacent intervals exhibiting assimilation (such that intervals are played more equal than they are notated) or contrast (such that similar intervals are made more different) and also context-dependent effects relative to the position of long and short intervals within a sequence and the number of events to be performed (Gabrielsson 1974; Repp *et al.* 2002). Interestingly, the latter of these two studies (which partly confirms earlier work by Fraisse (1956) shows that in a musical context, three note rhythms are rather unlike two note rhythms in that the patterns of assimilation change with tempo, and these changes bring increasing ratio-simplification of the two long-er intervals (and little change to the shorter interval).

Expression, communication and signification

The deviations from nominal score durations (and from small whole number ratios) evident in measurements of performances, along with patterns of dynamics, timbre and vibrato, have suggested that performers may be using such means to express, communicate or signify either intra-musical or extra-musical content. Such an approach is best exemplified by Palmer (1989) and the work of Shaffer, Clarke and Todd (see above). Within this perspective it is possible to find in the literature copious examples of measurements which suggest rule-following expressive behaviour. Expressive timing and dynamics seem to be linked to phrase and metrical structure in predictable ways: many studies (see Clarke 1988; Palmer 1997; Clarke 1999; Gabrielsson 1999 for reviews) have argued on the basis of empirical evidence that the location, and extent of deviations from metronomic performance can be predicted from analyses of phrase structure, metrical structure and voice prominence: hence, it has become accepted that such features may be generative in nature, mapping structural features through a system of rules onto patterns of articulation, rubato, and the like.

Such a generalizing tendency begs the question of the extent to which performances differ, and the underlying reasons for these differences. It is clear that different structural interpretations or intended moods or emotions leads to different performance outcomes, and this is observed in work on emotion (Juslin 2000) as it

is in work which varies structural interpretation (such as Clarke 1988; Palmer 1989; Clarke and Windsor 2000). This is precisely what a generative rule-based explanation of expression in performance would predict. However, large-scale comparison of multiple performances of the same music (e.g., Repp 1998, 1999) suggests that even where performers may share a structural interpretation (and leaving aside differences in intended characterization) there may be significant differences between performers which are as yet hard to explain in any formal manner. Using principal components analysis, Repp here identifies traits in interpretation that suggest different strategies in relation to the same musical structure. It is clear that here is another way in which performers can choose to differ from one another. Precisely how such choices are made is little understood, although work which looks at the development of performances in a more longitudinal manner (such as Chaffin and Imreh 2002) might help deliver some answers.

Algorithmic and statistical modelling of performance

Hypothesis testing and simulation

Models of performance fall into two main categories by motivation: either they seek to test a hypothesis about behaviour, or they seek to simulate that behaviour. As Desain *et al.* (1998) argue, it is possible to fit the output of models with very different assumptions to the same data, and it may be necessary to pay close attention to the architecture of the individual models to judge whether they can be distinguished in terms of their psychological veracity. Moreover, as Honing (2006) demonstrates persuasively, models that fit data well do not always tell us more about the behaviour modelled: they may fit trivial aspects of the data precisely because they do not account for important features in the data which are hard to model. Honing gives two additional criteria to goodness of fit: *simplicity* and *surprise*, arguing that whereas some models will over-generalize to all sorts of behaviour, some will only fit a narrow range of behaviour and are therefore a priori better as they are more falsifiable.

Data-driven and theory-driven simulation

Whereas Gabrielsson (1999, pp. 550–557) distinguishes between models based on measurements and models based in intuitions, it is perhaps more useful here to propose a methodological distinction between data-driven and theory-driven simulations of human data (or a continuum, given that models nay combine the two approaches). Although the one example he gives of a model based on measurements (Todd 1985, 1989, 1992, 1995; see also Windsor and Clarke 1997; Clarke and Windsor 2000) was partly based on measurements it is more accurate to suggest that this is a theory-driven model which was then compared and refined through comparison with measurements of human performances. The model is actually driven by an extremely rigid application of a generative understanding of music performance. Similarly theoretically driven, although based on a rather loose set of intuitions (based largely on informal empirical investigation characterized as 'analysis by synthesis') is the model developed by Friberg and others (see e.g. Friberg 1991; Sundberg 1988).

The alternative to starting from rule-like algorithmic approaches which are then tested against data is to take measurements and to attempt to fit them to hypotheses using statistical means. This is the approach taken by Palmer (e.g. 1989) where hypotheses about the effects of musical structure and performance intentions on rubato, asynchrony and dynamics are tested using standard linear modelling techniques familiar to experimental psychology. Such approaches (based as they are on small numbers of performers and one or two pieces) may present problems of generalization, and do not require the researcher to make specific predictions about the precise effect that, for example, voicing has on asynchrony.

Performance modelling: psychological relevance

In this final subsection on modelling an attempt will be made to evaluate the extent to which such models not only capture general principles of performance, but also whether their architecture in any way represents psychologically plausible

processes (see Desain *et al.* 1998). To this end, four examples will be reviewed briefly. Unfortunately, space does not allow for detailed consideration of the performance modelling approaches taken by Clynes (Clynes 1983) nor that of Mazzola and colleagues (Mazzola 2002): both share some features with one or more of the approaches described below, and are important contributions in their own right.

The first model considered here is most commonly know as *Director Musices*, and has been described in detail in many publications (see e.g. Sundberg 1988; Friberg 1991). Interestingly, just as Todd's approach (e.g., 1992 and see above) both benefits from and is limited by its theoretical simplicity, its ad hoc construction is probably closer to psychological reality than many more systematic models. It is clear that performers combine many different expressive strategies in a performance (see e.g., Palmer, 1989) and that these are often independent (Repp 1999). Nonetheless, such diverse rules make evaluation of the model as a whole, or its independent parameters, extremely tricky, although it has been fit to real performance data with some success (see e.g. Sundberg *et al.* 2003; Zanon and de Poli 2003a, b; Widmer and Goebl 2004). The recent attempt to complement the generative rules in *Director Musices* with models of various types of noise, emotional intent and physical motion (Juslin *et al.* 2002) may indeed make this problem even more pronounced (Widmer and Goebl 2004, p. 206).

Although there have been some successful attempts to fit the different versions of Todd's generative model to actual data (e.g. Todd 1989), 1992) and other more equivocal results (Windsor and Clarke 1997; Clarke and Windsor 2000; see also Widmer and Goebl 2004), Todd's admission in later work that two different models of tempo change might be required for the model to fit different rubato depths (Todd 1995 rather weakens this model's elegance and explanatory power. The model, especially in its earliest form, is an extremely powerful example of how to translate psychologically plausible theories into a coherent algorithm. This model takes a small number of assumptions (about the representation of musical structure and the mapping of structure to expression) which relate well to empirical and theoretical ideas of the time.

Widmer and Tobudic (2003) combine some aspects of curve-fitting, which are similar to Todd's approach, to machine-learning techniques. Widmer and Goebl (2004) suggest that this is a way of combining 'local timing and dynamic deviations' with tempo and dynamic curves associated with phrasing. Such an approach is elegant and clearly effective in terms of fitting real data, accounting for these different levels and types of expression, and doing so without excessive numbers of parameters. Instead it adapts to a training set of performances using fitting and machine-learning. Both of these features make this questionable as a psychologically plausible model, although the rules that it discovers may reflect or describe the outcomes of underlying psychological processes. Hence, this model reflects its background in artificial intelligence (AI), where the outcomes may offer more in terms of the development of machine simulation than they do to the realm of psychology.

Such potential problems are also evident for the final and most recent model to be considered, described in Windsor *et al.* (2006). However, here it is an analytical bias that is evident. The overall degree of fit achieved is high, but the authors focus on the way in which the fitting technique decomposes a complex time-series into different components, and how this can be used to answer empirical questions related to proportional invariance over tempo. The model itself might have some degree of psychological plausibility, but only if the components have an independence in the motor or memory systems of the performer, and it is not at present clear how this might be assessed. In conclusion, this approach, although it looks on the surface to resemble that of Todd, is much closer to the approaches taken in standard statistical testing in experimental psychology.

Measurement and modelling of performance in context

Psychological work on performance such as that described above has had little impact on research and practice within the field of music. Where measurement of performance is evident there seems to be little interest in or account taken of psychological findings. Repp's work on diversity

and commonality (1998, 1999) is hardly known outside the music–psychological community, despite its potential musicological importance), different measurement techniques are employed (as in Bowen 1996), and modelling of performance often seems irrelevant to either musicological or pedagogical research. In some ways this is unsurprising, as music psychology comes with many concerns foreign to the wider study or practice of music. However, there are some indications that a psychological approach to measuring and modelling performance might offer insights and techniques of wider value.

For example, a number of recent projects involving measurement and or modelling have gained funding or produced results which are relevant to, or aimed at, performance pedagogy. In Uppsala, Juslin and colleagues have attempted to use empirical and modelling techniques as part of a project aiming to develop methods of teaching expressivity (see e.g., Juslin *et al.* 2004). Similarly, Desain and colleagues are currently working on a project which both utilizes existing understanding of expression and real-time visualization techniques for learning expression (Brandmeyer *et al.* 2006). Similar goals underlie work by Goebl and Widmer (2006). In a rather different way, research in the development of expert performance has begun to adopt the empirical measurement techniques described here: for example Chaffin and Imreh (2002) have addressed issues of learning and memory in performance through detailed analysis of recorded performances.

Measurement and modelling have provided the psychology of music with substantial insights into the processes underlying music performance. One can safely assume that these insights will be extended given the attention paid to this area by researchers. However, it is disappointing to note that work on expression in music, and one might take as an example that on tempo rubato, is being simultaneously studied both by musicologists and psychologists, without much reference to each others' work. Although the goals of psychology and musicology may be different, both seek to explain and describe musical behaviours in their different ways, and one might hope for more cross-fertilization of methodologies and knowledge. This might simply extend to seeing more reference to historical and cultural context in work on performance within a psychological context (such as in Repp 1998, 1999; Windsor *et al.* 2001) or more methodological exactitude in work carried out in a musicological context (although see Bowen 1996; Fabian 2003). More than this, however it calls for researcher collaborations between these two disciplines (see e.g., Fabian and Schubert 2003) or indeed researchers that are sufficiently experienced in both fields.

CHAPTER 31

Planning and performance

Eckart Altenmüller and Sabine Schneider

Introduction

Performing music at a professional level is probably the most demanding of human accomplishments. Making music requires the integration of multimodal sensory and motor information and precise monitoring of the performance via auditory feedback. In the context of Western classical music, musicians have to reproduce highly controlled movements almost perfectly with a high reliability. These specialized sensorimotor skills require extensive training periods over many years, starting in early infancy and passing through stages of increasing physical and strategic complexities. The superior skills of musicians are mirrored in plastic adaptations of the brain on different timescales.

In the first section of this chapter we introduce essential general information for musical readers concerning the organization of cortical, subcortical and cerebellar motor systems in the brain. The electrophysiological correlates of motor planning and motor expectation will be briefly mentioned, as they provide a deeper understanding of the time course of anticipation and retrieval of motor programmes in music performance. In the second section, brain processes during acquisition of skilled movements in music-making will be addressed and the dynamics of neuronal networks will be demonstrated. Because these processes rely on plastic adaptations of brain networks and anatomical brain structures, the interplay of increasing precision of movements and plastic changes in the brain will be explained. In the third section, new findings on practice strategies and performance quality will be reported. Brain imaging measures collected during mental practice or listening tasks suggest that both motor and auditory cortical areas are active during musical thought processes. Motor-based brain representations are found in behavioural studies on performers' musical interpretations, transfer of learning from one musical task to another, mental practice effects, and anticipatory movements. Implications from these behavioural tasks suggest that an accurate auditory and motor representation underlies successful performance from memory. In the fourth section, the causes of degradation of skilled movements in professional musicians will be addressed. This disorder, termed focal dystonia, is due to maladaptive brain plasticity with fusion of brain representations of adjacent digits in somatosensory brain regions. Such a fusion and blurring of receptive fields of the digits results in a loss of control, because skilled motor actions are necessarily bound to intact somatosensory feedback input. Prolonged practice and pain syndromes due to overuse can precipitate dystonia, which is developed by about 1 per cent of professional musicians and usually ends their career. Finally, we will end the chapter with an outlook and add some comments concerning the significance of results of brain research in order to improve practice habits and performance in musicians.

Introduction

There can be no doubt that making music is one of the most demanding tasks for the human central nervous system. It involves the precise

execution of very fast and, in many instances, extremely complex physical movements that must be coordinated with continuous auditory feedback. Practice is required to develop these skills and carry out these complex tasks. Perhaps the most important study on practice to emerge during the past couple of decades was undertaken by Ericsson and his colleagues in 1993 with students at the Berlin Academy of Music. Ericsson *et al.* proposed the concept of 'deliberate practice' as a means of studying goal-oriented, structured and effortful facets of practice in which motivation, resources and attention determine the amount and quality of practice undertaken. They argued that a major distinction between professional and amateur musicians (and perhaps successful versus un-successful learners) is the amount of deliberate practice undertaken during the many years required to develop instrumental skills to a high level (Ericsson and Lehmann 1996). They proposed that highly skilled musicians exert a great deal more effort and concentration during their practice than less skilled musicians, and are more likely to plan, image, monitor and control their playing by focusing their attention on what they are practising and how it can be improved.

Motor skills are best acquired by massed practice involving countless repetitions, whereas aural skills are typically refined through a broad variety of listening experiences. Both types of skills are not represented in isolated brain areas however, but rather depend on the multiple connections and interactions established during training within and between the different regions of the brain. The general ability of our central nervous system to adapt to changing environmental conditions and newly imposed tasks during its entire life span is referred to as *plasticity*. In music, planning, learning through experience and training are accompanied by development and changes which not only take place in the brain's neuronal networks as a result of a strengthening of neuronal connections but also in its overall gross structure. Unfortunately, it is still not completely understood how practice habits and sensorimotor maturation influence each other. With respect to brain plasticity it is known that music practice enhances myelination, grey matter growth and fibre formation of brain structures involved in the specific musical task (for a review see Münte *et al.* 2002).

There are two main reasons why researchers believe that these effects on brain plasticity are more pronounced in instrumental music performers than in other skilled activities. First, musical training usually starts very early, sometimes before age six when the adaptability of the central nervous system is highest, and second, musical activities are strongly linked to positive emotions, which are known to enhance plastic adaptations. We would be wise to keep in mind however, that the methodologies currently used in contemporary brain research might produce a bias. As an example, it could be argued that the results demonstrated for group investigations of classical instrumentalists are due to these musicians having a similar acculturation due to the canonical nature of their training. Classical pianists tend to study etudes of Hanon, Czerny and Chopin, and the similarity of their training may produce uniform brain adaptations which in turn then dominate any individual changes. In other pursuits such as the visual arts, creative writing, architecture and composing music, individualized training may produce more diverse effects that may be masked within group statistics.

Neuroanatomy and neurophysiology of motor systems involved in planning and performance

Playing a musical instrument requires highly refined motor skills that are acquired over many years of extensive training, and that have to be stored and maintained as a result of further regular practice. Auditory feedback is needed to improve and perfect performance. Performance-based music-making therefore, relies primarily on a highly developed auditory–motor integration capacity, which can be compared to the phonological loop in speech production. In addition, somatosensory feedback constitutes another basis of high-level performance. Here, the kinaesthetic sense, which allows for control and feedback of muscle- and tendon-tension as well as joint positions which enable continuous monitoring of finger-, hand- or lip-position in

the frames of body and instrument coordinates (e.g., the keyboard, the mouthpiece), is especially important. In a more general context, the motor system of music performance can be understood as a subspecialty of the motor systems for planned and skilled voluntary limb movements.

Planned voluntary skilled limb movements involve four cortical regions in both hemispheres: the *primary motor area* (M1) located in the *precentral gyrus* directly in front of the central sulcus; the *supplementary motor area* (SMA) located anterior to the M1 of the frontal lobe and the inner (medial) side of the cortex; the *cingulate motor area* (CMA) below the SMA and above the corpus callosum on the inner (medial) side of the hemisphere; and the *premotor area* (PMA), which is located adjacent to the lateral aspect of the primary motor area (see Figure 31.1).

SMA, CMA and PMA can be described as *secondary motor areas*, because they are used to process movement patterns rather than simple movements. In addition to the cortical regions, the motor system includes the subcortical structures of the basal ganglia, and the cerebellum. The sensory areas are necessary in order to maintain the control of movements. Their steady kinaesthetic feedback information is required for any guided motor action. The sensory areas are located in the *primary somatosensory area* (S1) behind the central sulcus in the parietal lobe. This lobe is involved in many aspects of movement processing. It is an area where information from multiple sensory regions converges. In the posterior parietal area, the body coordinates in space are monitored and calculated and visual information is transferred into body coordinates. As far as musicians are concerned, this area is prominently activated during tasks involving multisensory integration, for example during sight-reading and the playing of complex pieces of music (Haslinger *et al.* 2005).

The *primary motor area* (M1) represents the movements of body parts in a separate but systematic order. The representation of the leg is located on the top and the inner side of the hemisphere, the arm in the upper portion, and the hand and mouth in the lower portion of M1. This representation of distinct body parts in corresponding brain regions is called *somatotopic* or *homuncular order*. Just as the *motor homunculus* is represented upside down, so too is the *sensory homunculus* on the other side of the central sulcus. The proportions of both—the motor

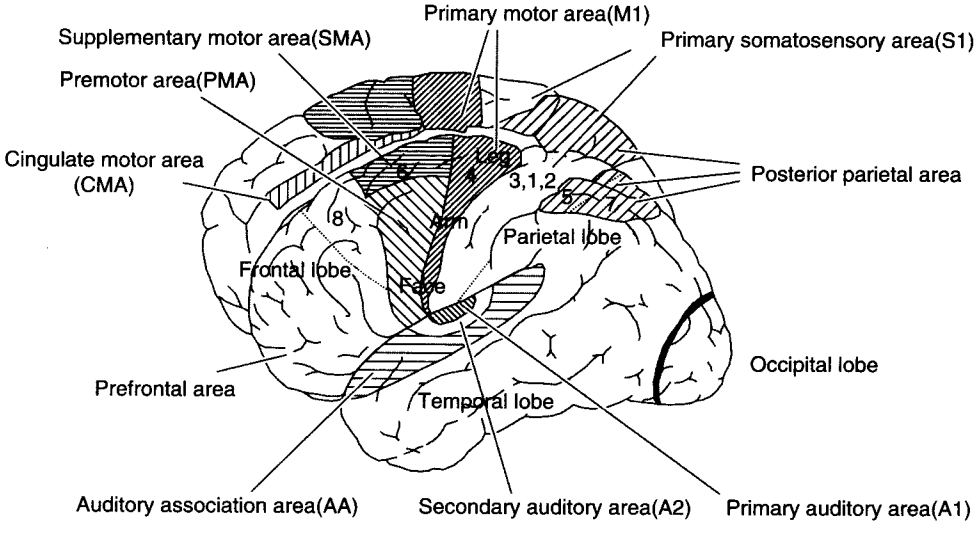

Fig. 31.1 Brain regions involved in sensory and motor music processing. The left hemisphere is shown in the forground (lower right); the right hemisphere in the background (upper left). The numbers relate to the respective Brodmann's areas, a labelling of the cortical areas according to the fine structure of the nervous tissue.

and the sensory homunculus—are markedly distorted because they are determined by the density of motor and sensory innervations of the respective body parts. For example, control of fine movements of the tongue requires many more nerve fibres transmitting the information to this muscle as compared to the muscles in the back. Therefore, the hand, the lips and the tongue require almost two-thirds of the neurons in this area. However, as further explained below, the representation of the body parts may be modified by usage. Moreover, the primary motor area does not simply represent individual muscles: multiple muscular representations are arranged in a complex way so as to allow the execution of simple types of movements rather than the activation of a specific muscle. This is a consequence of the fact that a two-dimensional array of neurons in M1 has to code for three-dimensional movements in space (Gentner and Classen 2006). Put more simply, our brain does not represent muscles but rather movements.

The *supplementary motor area* (SMA) is mainly involved in the coordination of the two hands, in the sequencing of complex movements and in the triggering of movements based on internal cues. It is particularly engaged when the execution of a sequential movement depends on internally stored and memorized information. The SMA can be subdivided into two distinct functional areas. In the anterior SMA, it would seem that the planning of complex movement patterns is processed. The posterior SMA seems to be predominantly engaged in two-handed movements and, in particular, in the synchronization of both hands during complex movement patterns.

The function of the *cingulate motor area* (CMA) is still under debate. Electrical stimulation and brain imaging studies demonstrate its involvement in movement selection in situations when movements are critical to obtain reward or punishment. This points towards close links between the cingulate gyrus and the emotion-processing limbic system. From what we know therefore, it would seem that the CMA plays an important role in mediating cortical cognitive functions and limbic–emotional functions. The *premotor area* (PMA) is primarily engaged when externally stimulated behaviour is being planned and prepared. It is involved in the learning, execution and recognition of limb movements and seems to be particularly concerned with processing of visual information which is necessary for movement planning.

The *basal ganglia*, located deep inside the cerebral hemispheres, are interconnected reciprocally via the thalamus to the motor and sensory cortices, thus constituting a loop of information flow between the cortex and the basal ganglia. They are indispensable for any kind of voluntary actions that are not highly automated. Their special role consists in the control of voluntary action by selecting appropriate motor actions and by comparing the goal and course of those actions with previous experience. In the basal ganglia, the flow of information between the cortex and the limbic emotion system, in particular the amygdala, converges. It is therefore assumed that the basal ganglia process and control the emotional evaluation of motor behaviour in terms of expected rewards or punishment. Finally, the *cerebellum* contributes essentially to the timing and accuracy of fine-tuned movements.

Observing planning in the brain

During the last two decades, knowledge of brain regions involved in complex tasks such as playing a musical instrument has increased enormously. This is mainly due to the development of novel technologies that allow non-invasive assessment of the intact brain's function. A pioneering step was the observation of movement-related brain potentials reflecting planning and movement preparation in the brain. These brain potentials can be extracted from the ongoing electrical activity of neuronal populations in the cerebral cortex using electroencephalography (EEG). The most prominent activation is the so callled Bereitschaftspotential (see Figure 31.2).

The Bereitschaftspotential (BP) is a ramp-like brain activation which precedes any self-paced voluntary motor activity, starting 2000 to 1000 ms prior to movement onset. There is still some debate on the structures in the brain generating the BP. It seems that the first part of the ramp-like shift is produced in the SMA, reflecting the planning of a movement. The subsequent part of the shift is probably generated in the primary

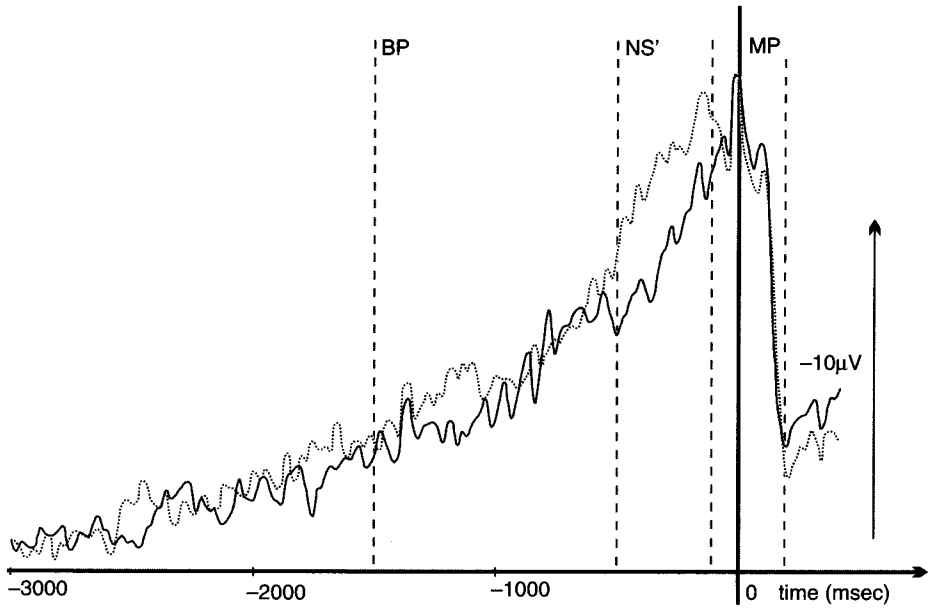

Fig. 31.2 Typical Bereitschaftspotential (BP) in healthy pianists and in pianists suffering from focal dystonia (dotted line) prior to scale playing (Time 0). Brain activation starts about 3 seconds prior to movement onset, reflecting planning and preparation. The proper BP starts 1.5 prior to movement onset and is generated in the supplementary motor cortex. The negative slope (NS') 500 ms prior to movement onset is generated in the anterior part of the primary motor cortex. The motor potential (MP) finally corresponds to activation of the motor neurons in the pyramidal tract. After movement onset, brain activation is reset, yielding a sudden positive shift in brain activation. Note that pianists suffering from pianists' dystonia have larger amplitudes especially in the NS' component of the Bereitschaftspotential (modified from Peschel and Altenmüller 2004).

motor areas, reflecting the activation of motor neurons directly linked to muscles via the spinal cord (for a concise review see Altenmüller *et al.* 2004).

Traditionally, the BP was related to the intentional decision processes of willed action. In intriguing experiments Libet *et al.* (1983) demonstrated that the BP starts about 350 ms prior to conscious awareness of the intention to act. When the subjects 'vetoed' their decision to act, the BP, which had normally developed prior to this 'veto', collapsed and no movement occurred. Libet (1985) concluded that voluntary acts can be initiated by unconscious cerebral processes before conscious intention appears but that conscious control over the actual motor performance of the acts remain possible. This experimental design has had a long and often controversial history. After all, it has remained unclear whether the urge to act, and the action itself, represent actual differences in brain states (Eagleman 2004).

EEG measures such as the BP-recordings have an excellent temporal resolution, reflecting the electrical activity of neurons in the range of milliseconds. Therefore these methods are suitable to investigate the rapid neuronal interactions which constitute the basis of motor planning and performance.

Other imaging tools such as positron emission tomography (PET), and functional magnetic resonance imaging (fMRI) allow the functional assessment and the precise localization of active brain regions. However, these methods have the disadvantage of a relatively poor time resolution, allowing the monitoring of neuronal activation during planning and performance in the range of seconds, but not of milliseconds.

Additionally, new imaging techniques, derived from MRI) technology, demonstrate minute changes in brain structure with precision. Voxel-based morphometry (VBM) for example, provides detailed information of the thickness of the grey matter in the layers of neurons in the cerebral cortex. Using this technique, cross-sectional studies have demonstrated differences in grey matter volume in the range of cubic millimeters as a result of musical training (Gaser and Schlaug 2003). Diffusion tensor imaging (DTI), on the other hand, is a way to assess direction and volume of fibre tracts in the white matter of the brain. In pianists this method has shown changes in myelination of the callosal body which connects the two brain hemispheres (Bengtsson *et al.* 2005).

Learning to plan: the acquisition of fine motor skills

Our knowledge concerning the regions and mechanisms of the brain involved in sensorimotor learning is still incomplete. Overall, musicians appear to process new incoming stimuli more effectively compared to non-musicians. According to newly emerging evidence (for a review see Halsband and Lange 2006) all structures involved in motor control participate in the acquisition of new sensorimotor skills. The cerebellum is involved in the selection, the sequence and the timing of movements and the basal ganglia play a crucial role in procedural learning and automation of movements.

It has been known for some time that the activity in the SMA and in the premotor area of the brain are enhanced as a result of increasing complexity of finger movement sequences (Roland *et al.* 1980). Using fMRI, Karni and colleagues (1995) investigated adult subjects' learning of complex finger sequences which are similar to those necessary for piano playing. After 30 minutes of practice the representation of the fingers in the primary motor cortex increased. However, without further training, this effect diminished after one week with the hand representation returning to its previous size. In contrast, continuous practice resulted in a stable enlargement of the hand area in the primary motor cortex. This effect was specific for the daily trained sequence of complex finger movements, and did not occur when the subjects improvised complex finger movements which were not subsequently repeated. Parallel to the enlargement of the hand area in the primary motor cortex, the size of the cerebellar hand representation diminished, suggesting that the cerebellum plays an important role only in the initial phase of motor learning.

The above mentioned study does not take into account one special quality of musicianship, namely the strong coupling of sensorimotor and auditory processing required for performing music. Practicing an instrument involves assembling, storing, and constantly improving complex sensorimotor programmes through prolonged and repeated execution of motor patterns under the controlled monitoring of the auditory system. In a cross-sectional experiment, strong linkages between auditory and sensorimotor cortical regions as a result of many years of practice have been reported (Bangert *et al.* 2006). Using fMRI, professional pianists were asked to listen to simple piano tunes without moving their fingers or any other body part. Figure 31.3(a) demonstrates the increase in activation of professional pianists in comparison to non-musicians. There is an impressive activation of the motor cortex demonstrating the subconscious or automated auditory–motor co-activation.

Furthermore, in a longitudinal study, it was possible to show that the formation of such neuronal multisensory connections needs less than six weeks of regular piano training (Bangert and Altenmüller 2003). This demonstrates how dynamically brain adaptations accompany musical learning processes.

Activation of motor co-representations can occur in trained pianists not only by listening to piano tunes, but also by observing a pianist's finger movements while watching a video. In Figure 31.3(b) the increases in brain activation of trained pianists are shown whilst they are observing video sequences of a moving hand at the piano as compared to the activation of musically naive subjects (Haslinger *et al.* 2005). Besides the motor hand area in the primary motor cortex, secondary auditory cortices in the temporal lobe and the cerebellum are activated. This neuronal network corresponds to a '*mirror*

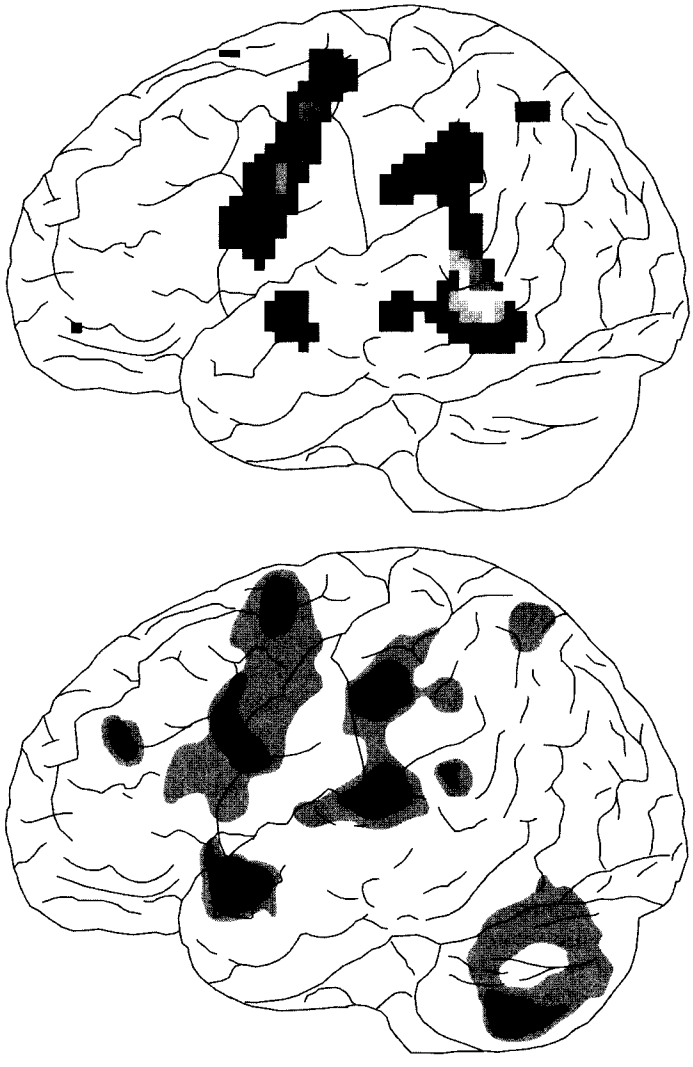

Fig. 31.3 (a) Additional brain activity (grey zones) of skilled pianists compared to non-pianists when listening to piano tunes without moving their fingers. The primary motor cortex of the precentral area and auditory association areas are lighting up, demonstrating an unconscious co-representation of heard tunes as movement patterns (modified from Bangert *et al*. 2006). (b) Additional brain activity (grey zones) of skilled pianists compared to non-pianists when observing pianist movements in a soundless video. Again, the precentral area and auditory association areas are lighting up demonstrating the mirror system: the observed movements are unconsciously activated, albeit the subjects did not move their fingers. Furthermore the auditory areas are activated demonstrating a visual–auditory co-representation of seen movements. This effect demonstrates impressively the powerful human imitation system, and may be utilized by teachers when demonstrating at the instrument (modified from Haslinger *et al*. 2005).

neuron network'. As a consequence of musical practice, it follows that careful demonstration at the instrument may enhance learning. Such a teaching method based on demonstration and imitation is widely used at all levels of musical training, and would appear to be particularly effective in cases where teachers demonstrate an action or series of actions that are carefully and methodically observed by the student.

Practicing through listening and/or observation can be considered as special cases of *mental training*. Narrowly defined, mental training is understood as the vivid imagination of movement sequences without physically performing them. As with observation of actions, principally the same brain regions are active as if the imagined action is performed; that is, the primary motor cortex, the supplementary motor cortex and the cerebellum (Kuhtz-Buschbeck *et al.* 2003). In a study investigating mental training of finger movement sequences of different complexities, brain activation increased along with the degree of difficulty of the imagined motor task. Furthermore, when continuing mental practice over a period of several days, the involved brain regions showed plastic adaptations. Although these adaptations are less dramatic than if the motor tasks were practiced physically, mental training produced a clear improvement in task performance as assessed in finger tapping tests.

Plasticity of sensory motor systems: musicians' brains are different

During the past decade, brain imaging has provided important insights into the enormous capacity of the human brain to adapt to complex demands. These adaptations are referred to as *brain plasticity* and do not only include the connections or firing rates of neurons—the 'software' of our brain—but also the 'hardware', namely the fine structure of nervous tissue and even the visible gross structure of brain anatomy. Brain plasticity is best observed in complex tasks with high behavioural relevance for the individual such that they cause strong emotional and motivational activation. Plastic changes are more pronounced in situations where the task or activity is intense and the earlier in life it has been developed. Obviously, the continued activities of accomplished musicians provide the prerequisites of brain plasticity in an ideal manner. It is therefore not astonishing that the most dramatic brain plasticity effects have been demonstrated in professional musicians (for a review see Münte *et al.* 2002).

Our understanding of the molecular and cellular mechanisms underlying these adaptations is far from complete. Brain plasticity may occur on different time axes. For example, the efficiency and size of synapses may be modified in a time window of seconds to minutes, the growth of new synapses and dendrites may require hours to days. An increase in grey matter density, which mainly reflects an enlargement of neurons, needs at least several weeks. White matter density also increases as a consequence of musical training. This effect is primarily due to an enlargement of myelin cells: the myelin cells, wrapped around the nerve fibres (axons) are contributing essentially to the velocity of the electrical impulses travelling along the nerve fibre tracts. Under conditions requiring rapid information transfer and high temporal precision these myelin cells grow and as a consequence nerve conduction velocity increases. Finally, brain regions involved in specific tasks may also be enlarged after long-term training due to the growth of structures supporting the nervous function, for example, in the blood vessels that are necessary for the oxygen and glucose transportation to sustain nervous function.

Comparison of the brain anatomy of skilled musicians with that of non-musicians shows that prolonged instrumental practice leads to an enlargement of the hand area in the motor cortex (Amunts *et al.* 1997) and to an increase in grey matter density corresponding to more and/or larger neurons in the respective area (Gaser and Schlaug 2003). These adaptations appear to be particularly prominent in all instrumentalists who have started to play prior to the age of ten and correlate positively with cumulative practice time. Furthermore, in professional musicians, the normal anatomical difference between the larger, dominant (mostly right-) hand area and the smaller, non-dominant (left-) hand area is less pronounced when compared to non-musicians. These results suggest that functional adaptation

of the gross structure of the brain occurs during training at an early age.

Similar effects of specialization have been found with respect to the size of the corpus callosum. Professional pianists and violinists tend to have a larger anterior (front) portion of this structure, especially those who have started prior to the age of seven (Schlaug *et al.* 1995). Since this part of the corpus callosum contains fibres from the motor and supplementary motor areas, it seems plausible to assume that the high demands on coordination between the two hands, and the rapid exchange of information may either stimulate the nerve fibre growth—the *myelination* of nerve fibres that determines the velocity of nerve conduction—or prevent the physiological loss of nerve tissue during ageing.

In summary, when training starts at an early age (before about seven years), these plastic adaptations of the nervous system affect brain anatomy by enlarging the brain structures that are involved in different types of musical skills. When training starts later, it modifies brain organization by rewiring neuronal webs and involving adjacent nerve cells to contribute to the required tasks. These changes result in enlarged cortical representations of, for example, specific fingers or sounds within existing brain structures. In the following section, the behavioural correlates of the maladaptive plastic changes, leading to a loss of motor control of highly skilled movements, will be focused on.

Focal dystonia: when planning goes wrong

Approximately 1 in 100 professional musicians suffer from a loss of voluntary control of their extensively trained, refined, and complex sensorimotor skills—a condition generally referred to as focal dystonia, violinist's cramp, or pianist's cramp. In most cases, focal dystonia is so disabling that it prematurely ends the artist's professional career (Altenmüller 2003). Subtle loss of control in fast passages, finger curling (cf. Figure 31.4), lack of precision in forked fingerings in woodwind players, irregularity of trills, sticking fingers on the keys, involuntary flexion of the bowing thumb in strings, impairment of control of the embouchure in woodwind and brass players in certain registers, are the various symptoms that can mark the beginning of the disorder. At this stage, most musicians believe that the reduced precision of their movements is due to a technical problem. As a consequence, they intensify their efforts, but this often only exacerbates the problem.

Males, classical musicians of a younger age and instrumentalists such as guitarists, pianists and woodwind players are among the most commonly affected by focal dystonia. The majority of patients have solo positions and often they have a perfectionist, control-type personality. About 20 per cent of such patients report a history of chronic pain syndromes or over-use injury. Preventing these musicians from developing chronic over-use and tendinitis will most probably prevent them from developing focal dystonia (Jabusch and Altenmüller 2006). However, once focal dystonia is established, the cure of the pain syndrome will generally not eliminate the pathological movement pattern.

Thus far the aetiology of focal hand dystonia is not completely understood, but is probably multifactorial. Without going into the details, most studies of focal dystonia reveal abnormalities in three main areas: (a) reduced inhibition in the motor system at cortical, subcortical and spinal levels (b) reduced sensory perception and integration; and (3) impaired sensorimotor integration. The latter changes are mainly believed to originate from dysfunctional brain plasticity. There is growing evidence for an abnormal cortical processing of sensory information as well as degraded representation of motor functions in patients with focal dystonia. A study with trained monkeys demonstrated that chronic over-use and repetitive strain injury in highly stereotyped movements can actively degrade the cortical representation of the somatosensory information that guides the fine motor hand movements in primates (Byl *et al.* 1996). A similar degradation of sensory feedback information and concurrent fusion of the digital representations in the somatosensory cortex was confirmed in a brain activation study conducted in musicians with focal dystonia, although these musicians had no history of chronic pain (Elbert *et al.* 1998). Therefore, additional factors such as a genetic predisposition and certain susceptibility appear to play an

Fig. 31.4 Typical patterns of dystonic posture in a pianist, a violinist, a flutist and a trombone player.

important role in the development of focal dystonia (Schmidt *et al.* 2006). Interestingly, in musicians suffering from focal dystonia the BP is markedly larger as compared to healthy musicians (see Figure 31.2). This 'overshoot' in brain activation prior to movement execution seems to be linked to the core deficit in focal dystonia, the defective inhibition of motor output.

Unfortunately, there is no simple cure for the condition. Retraining may be successful in a minority of cases, but usually requires several years to succeed. Symptomatic treatment with temporary weakening of the cramping muscles by injecting Botulinum-toxin has proven to be helpful in other cases; however, since the injections need to be applied regularly every three to five months during the professional career, it presents no solution for young patients. Thus, the challenge is to prevent young musicians from such a disorder. Reasonable practice schedules, economic technique, prevention of over-use and pain, mental practice, avoidance of exaggerated perfectionism and psychological support with respect to self-confidence are the components of such a prevention programme.

Conclusions: some implications for practice

In the preceding paragraphs we have demonstrated the neurobiological foundations of planning, motor learning and practice. Here we will summarize the data in order to formulate some practical rules which might be useful for the daily work of instrumentalists.

As with all skilled human motor activities, effective planning, movement preparation and practising are largely based on procedural knowledge. How to practice and when to stop practising is best learned by experience. Practising can be considered as a self-organizing process, which frequently starts with uneconomical activation of large neuronal pools in the sensorimotor brain regions. Optimizing the movement patterns occurs under continuous sensory feedback from the ears, the eyes, the muscles, tendons, joints, and from the skin. The integration of this information into movement patterns is the most important step in procedural learning. It is mainly based on the formation of neuronal networks; for example, the connections between

Fig. 31.4 Typical patterns of dystonic posture in a pianist, a violinist, a flutist and a trombone player.

important role in the development of focal dystonia (Schmidt *et al.* 2006). Interestingly, in musicians suffering from focal dystonia the BP is markedly larger as compared to healthy musicians (see Figure 31.2). This 'overshoot' in brain activation prior to movement execution seems to be linked to the core deficit in focal dystonia, the defective inhibition of motor output.

Unfortunately, there is no simple cure for the condition. Retraining may be successful in a minority of cases, but usually requires several years to succeed. Symptomatic treatment with temporary weakening of the cramping muscles by injecting Botulinum-toxin has proven to be helpful in other cases; however, since the injections need to be applied regularly every three to five months during the professional career, it presents no solution for young patients. Thus, the challenge is to prevent young musicians from such a disorder. Reasonable practice schedules, economic technique, prevention of over-use and pain, mental practice, avoidance of exaggerated perfectionism and psychological support with respect to self-confidence are the components of such a prevention programme.

Conclusions: some implications for practice

In the preceding paragraphs we have demonstrated the neurobiological foundations of planning, motor learning and practice. Here we will summarize the data in order to formulate some practical rules which might be useful for the daily work of instrumentalists.

As with all skilled human motor activities, effective planning, movement preparation and practising are largely based on procedural knowledge. How to practice and when to stop practising is best learned by experience. Practising can be considered as a self-organizing process, which frequently starts with uneconomical activation of large neuronal pools in the sensorimotor brain regions. Optimizing the movement patterns occurs under continuous sensory feedback from the ears, the eyes, the muscles, tendons, joints, and from the skin. The integration of this information into movement patterns is the most important step in procedural learning. It is mainly based on the formation of neuronal networks; for example, the connections between

auditory and motor areas and in a step-wise reduction of cortical activity and augmentation of subcortical activity in the basal ganglia and the cerebellum.

When playing a musical instrument, the central nervous system is mainly involved in processing a huge amount of incoming information from the ears and eyes, and from the sensory organs in muscles, tendons, joints, and skin. The consolidation of the networks necessary for programming movement sequences occurs mainly in the breaks after playing and during sleep. As a consequence, the more complex a task is, the shorter the practice time that should be scheduled in one session and the longer the breaks should be planned. Sleep is another factor supporting procedural memory formation. Therefore, sufficient sleep should be encouraged, especially when an instrumentalist of any ability level is working hard to master new repertoire.

Generally, a practice session should be terminated when signs of fatigue appear. It is important to consider that over-practice (practice into bodily or mental fatigue) not only leads to no improvement, but to an active worsening of motor programmes. This is due to a blurring of central nervous system sensorimotor representations, when muscular fatigue appears. Furthermore, a lack of attention causes a higher probability of uneconomical movements or production of false notes which, as a consequence, are stored in the procedural memory.

The human mirror system is a powerful tool to facilitate skill learning. Auditory and visual cues presented to students activate their sensorimotor representations and can lead directly to the formation of motor programmes. This is the basis of imitation learning. On the other hand, sloppy and careless demonstrations may produce a negative effect for students, decreasing their sensorimotor programmes as they adopt bad habits modelled by their teacher. Teachers should therefore demonstrate skills in a variety of ways in order to ensure that their students are able to comprehend the difference between effective and ineffective performance techniques.

We would like to conclude our chapter with a general remark: processes involved with instrumental musical training are probably the most complex of all human activities. Importantly, these are not restricted to the sensorimotor brain circuits but also involve emotion, memory and imagination. The best trained musicians with the best working sensorimotor networks will not move their listeners if imagination, colour, fantasy and emotion are not a part of their artistic expression. These qualities are often not trained solely within a practice studio, but depend on and are possible linked to experiences from daily life, to human relationships, to a rich artistic environment and to empathy and emotional depth. These factors, which profoundly influence the aesthetic quality of a music performance, are at present far from being accessible to any neuroscientific research.

CHAPTER 32

Sight-reading

Andreas C. Lehmann and Reinhard Kopiez

Introduction

Anyone who wants to perform the works of traditional Western music, and approach other musical styles using a similar performance practice, will most likely have to master music notation. Many musical cultures rely on a system of symbols to store and teach complex musical styles that are not, or only partly, grounded in improvisation. While the beginning music reader has to overcome the same problems as all readers do when learning to read other texts, namely going from a tedious matching of symbols to sounds to meaning, the expert reader has automatized the process of encoding and transforming the signs into embodied action.

For our purposes, we will call sight-reading the execution—vocal or instrumental—of longer stretches of non- or under-rehearsed music at an acceptable pace and with adequate expression. Some people also label this 'playing by sight' or 'prima vista'. Another related set of activities might be called music or note reading: for example, the following of a score with the aim of studying a piece while the music is playing, or the studying of a new piece of music away from the instrument prior to physically practising it. Both activities may even be accompanied by the sounding out of some notes on an instrument. However, the characteristic goal of sight-reading is the authentic performance, or as Mozart once phrased it, 'to play the piece . . . so as to make believe that it had been composed by the one who plays it' (letter from 1778 cited in Crofton and Fraser 1985, p. 111). Similar to improvisation, sight-reading requires the instant adaptation to new constraints, which places it among those that motor scientists refer to as open skills (as opposed to closed skills that require reproduction of well-rehearsed motions, such as swimming, figure skating or playing a well-rehearsed piece of music). Today, studio musicians and accompanists must be able to sight-read, and many orchestra musicians have done it on a regular basis for centuries. It is this kind of un- or under-rehearsed performance that we are concerned with because it forms a well-defined and discrete skill comparable to that of playing by ear or improvising.

When and under what conditions does sight-reading emerge as a skill in a culture? Music archaeology tells us about some forms of notation from ancient Egypt and Greece and other cultures which have developed coding systems for music that mainly serve mnemonic purposes (e.g. Bent *et al.* 2008). The Western model of notation started to develop in the ninth century in order to code multivoice vocal and later instrumental music. In a musical culture (regardless of geographical place and historical time) in which music is solely improvised, sight-reading is not necessary, yet music reading skills may still be used for learning to play an instrument (e.g. in India). When composers and performers assume specialized roles and performers are expected to perform a fixed repertoire, then sight-reading may be required to limit rehearsal times or if the repertoire changes frequently (e.g. in the Baroque era). While the nineteenth century still saw renowned performers play other composers' pieces from the score, canonization of the repertoire, the developing art of interpretation, and rising audience expectations has since then led to a performance practice based on memorized performance by solo performers of the piano and violin. Our modern performance traditions have come to favour

polished performances and relegated sight-reading to a useful craft, generally not worthy of public notice or competition (we know only of the Karl Bergemann sight-reading competition, Hanover, Germany).

Obviously, most orchestral, chamber, and studio musicians play from the score and so do many performers of contemporary art music. There are a few known solo pianists who have used scores even for standard repertoire. It is unclear whether musicians perform better with or without the score, but the audience is likely to expect memorized performances. Also, using the score requires page-turning or the presence of a music stand which may be disturbing for the audience and the performer and might detract from the sounding music. A music stand may obstruct the view and hinder gestural freedom and the positive influence of expression that is conveyed through the body (cf. Lehmann *et al.* 2007, pp. 173–174).

In marked contrast to the public neglect and low prestige of sight-reading among performers stands the steady interest of music psychologists and pedagogues in this skill (for reviews see Sloboda 1984; Lehmann and McArthur 2002; Lehmann *et al.* 2007, Chapter 6). Starting with the early music psychology experiments of the 1920s (published in Jacobsen 1941) and the development of sight-reading tests (Watkins 1942, and the Watkins–Farnum Performance Scale), all aspects of skills relating to sight-reading attracted renewed interest in the 1970s (e.g. Sloboda 1974, 1976, 1977) and have continued to do so (cf. Lehmann and Ericsson 1993, 1996; Kopiez and Lee 2006, 2008 for the acquisition of sight-reading skills) up until recent psychophysiological studies (e.g. Schon and Besson 2005; Yumoto *et al.* 2005). It is important for research that we measure individuals' ability to perform at first sight under standardized conditions. Optimally, those conditions should mirror real-life conditions encountered by expert sight-readers (Lehmann and Ericsson 1993).

In this chapter we will briefly look at how notation is perceived and then move on to the structure of sight-reading while taking into account the real-time conditions under which it takes place. This will include a discussion of perceptual and problem-solving issues. Finally we will outline the course of skill acquisition with its characteristic differences between novices and experts, and present a model of sight-reading performance.

Perception of music notation and sight-reading

To begin, we have to understand how the eye operates when we try to acquire information in everyday life. Contrary to what most people believe, the eye does not function like a movie camera. Rather, its operation can be likened to that of a flashlight in the dark being turned on and off at short intervals. Roughly four to five times a second the eye moves around the visual field in discrete jumps (saccades) with short resting points (fixations). The saccades take about 15–50 msecs, the fixations about 150–200 msecs. At this point it becomes clear that a conscious attending to every eighth note in a piece at MM = 120 would be almost impossible. During each fixation, the external image is projected on the retina at the back of the eye. Wile the retina is comparably large, we are able to receive a sharp image only from a narrow part in the middle. This round central part is called the fovea centralis, and whatever surrounds it will produce the somewhat blurry parafoveal image. Hence, the field of vision that will be perceived in great clarity only averages 0.5–2°, which corresponds to the size of an inch at a reading distance of about 30 inches (75 cm), or the area covered by a pointed-up thumb with extended arm. The parafoveal vision includes 10° of the field of vision (e.g. Rayner and Pollatsek 1989). The role of preview benefits and parafoveal-on-foveal effects are currently a hot topic in word-reading research. It is from such individual snapshots that our brain fashions what we experience as a large and steady picture of the outside world. Unfortunately, the eye movements cannot be allocated wilfully but are in fact guided by preconscious processes and drawn by outside stimuli. For example, movements and boundaries in the visual field attract attention, just as do human faces, but our cognition also guides the eye movements. For example, when a car disappears behind another we are likely to scan the plausible location of its

reappearance, and we search the face of a person for cues to his or her mood. Today, we know that information gathered from one or several fixations is integrated in meaningful units or chunks of information which are the basis for further processing. Since the location and duration of fixations is indicative of the processing underlying music reading, eye movements offer important insights into the workings of the musical mind. To explain the structure of sight-reading, we have to account for how much and which information is retrieved from the page and how it is assembled into meaningful units that are sequentially programmed and executed.

The problem in surveying the results of eye movement in sight-reading is that the research methodologies are not standardized with regard to complexity of stimulus, tempo of performance, and so forth. Unlike in text-reading research where many studies appear within a few years using the same paradigm, the time lag between publications on sight-reading is large and findings are often difficult to integrate. By and large, the earliest studies (Jacobsen 1941) established what subsequent studies have confirmed, namely that eye movement patterns are dependent on the level of expertise: beginners had many fixations, long pauses during fixations, and unsystematic reading of note combinations; intermediate musicians had about as many fixations as there were notes, and they read chords in systematic fashion from bottom to top; experts showed fewer fixations than notes and also systematic reading of chords (from top to bottom). Saccades can point forward in reading direction but also backwards (regressively)—for example to the current point of performance. This is most likely done to double-check things that have been read already or result from attention being detracted to performance errors (not a very efficient strategy). With increasing experience, the sight-reader experiences a reduction in the number of regressive fixations. Kinsler and Carpenter (1995), who strangely claimed that 'a thorough search of the literature failed to find any account whatsoever of the eye movements used to read music' (p. 12), studied eye movements during performance of notated rhythms. Their results showed that slower tempi lead to more and shorter fixations. One problem in research with self-selected performance tempo is that slower tempi necessarily result in more fixations. Lannert and Ullman (1945) found a 0.45 correlation between tempo and accuracy, and we can never be sure if participants have traded off faster tempi for more fixations and thus ensure a more accurate performance. Equal speeds can only be achieved by using a pacing-voice methodology (Lehmann and Ericsson 1993).

That notational input has an influence on the eye movements was mentioned previously (cf. systematic vertical reading of chords). Notational variants (e. g., eighth notes with or without connecting bars) resulted in person-specific eye movements, and eighth notes (with connecting bars) tended to be looked at in pairs while quarter notes were attended to individually (Kinsler and Carpenter 1995). Truitt *et al.* (1997, also Goolsby 1994) questioned why fixations often landed between notes, and we suggest that readers tend to construct intervals rather than reading every note. Weaver (1943) found that polyphonically structured music was read in horizontal zigzagging patterns that tended to follow melodic lines in the different voices, whereas homophonic music resulted in zigzagging up and down motions. However, a critical look at his stimuli unveils that notation and structure were hopelessly confounded, e.g. no attempt was made to notate polyphonic stimuli in alternative (more homophonic looking) ways. none of the stimuli was polyphonic, yet it notated as if homophonically structured. Regardless of the shortcomings, we can say that experience and structure of input modify viewing patterns.

Once the information has been retrieved during one or several fixations, it is stored and assembled in meaningful units in anticipation of the motor performance. Here also it was found that experience allowed for larger temporal range of planning (Drake and Palmer 2000). The extent and nature of the buffering of information is part of the memory system to be discussed in the next section.

Memory processes

The amount of information stored temporarily from a particular sequence of fixations or during a certain timespan can be assessed by experiments that allow sight-readers only limited visual

access to the score by either very brief (tachistoscopic) display, by limiting the period of time during which the score is visible, or by using a computer that follows the fixations with a 'moving window' technique that permits variable preview. By this we can measure aspects of memory, namely the perceptual and the eye–hand span. The perceptual span denotes the distance between the current point of performance and the farthest distance the person is looking ahead. Using a moving window technique, Truitt *et al.* (1997) found that a preview of two beats leads to a slower tempo, larger variability in note durations, and errors. Subjects performed better with previews between two and four beats or, ideally, with previews to the end of the next bar. Furneaux and Land (1999) found the number of notes to be about four for experts and two for novices. Unlike Truitt *et al.* (1997) who found the time between fixation and performance to stand at 0.5 secs, Furneaux and Land (1999) documented between 0.7–1.3 seconds, dependent on the tempo. Similar results have been found in studies on typewriting (Gentner 1988). This narrow preview is at odds with the phenomenological experience of sight-readers who claim a much larger preview. With multiple fixations that can go anywhere in the piece, musicians construct motor programmes that rely on more than mere visual input of the foveal area (see below for further details). This leads to the larger eye–hand spans that can be measured when withdrawing the notation unexpectedly (Sloboda 1977). Sloboda found that meaningful musico-structural units influenced the length of the eye–hand span. For example, a larger distance from the next phrase boundary tended to stretch the eye–hand span; a shorter caused it to shrink. Hiding a longer piece of music at arbitrary points might still allow for cumulative effects of the previously sight-read material, whereas the method of briefly displaying disjointed snippets of information for several hundred milliseconds does not. We know that the reading context influences patterns of fixation (Bekkering and Neggers 2002). If we consider that repeated trials lead to better sight-reading accuracy and that better sight-readers have a better recall for material after a single trial (Lehmann and Ericsson 1993), we have to consider the effects of long-term working memory typically found among experts (Ericsson and Kintsch 1995). This privileged access to long-term memory allows expert readers to store briefly presented material in long-term memory without extensive rehearsal.

Inner hearing

Some authors have claimed that inner hearing and audiation processes may be important in sight-reading, and independent tests of audiation, imagery, and pattern matching are positively associated with sight-reading ability (e.g. Kornicke 1995; Waters *et al.* 1998; Kopiez and Lee 2006). These processes would suggest that the mental representation of music notation involves the building of melodic and other expectancies by the performer. Recent electrophysiological studies have confirmed this point. In studies in which listeners followed a visually presented score that was accompanied by the corresponding sounds, discrepancies between the printed score and auditory events resulted in a recorded mismatch negativity about 150 msec after the dissociation in the vicinity of Heschl's gyrus, where auditory pitch detection is located (Schon and Besson 2005; Yumoto *et al.* 2005). This means that performers are likely able to know if their sounds match the score or not. Whether or not auditory images are used for planning of movements may depend on the musician. For example, Banton (1995) found that sight-reading without auditory feedback led to only slightly more mistakes than normal feedback; however, omitting visual access to the keys resulted in markedly poorer performance. A classic experiment by Allport *et al.* (1972) revealed that pianists could repeat words that were presented while sight-reading at the piano, which suggests that auditory feedback is not necessary. However, it may be used to create expectations.

Sight-reading as problem-solving

We already mentioned that not all notes can be focused on and that problem-solving processes will have to complement the incomplete visual input. In fact, everyday experiences teach us that some pieces are able to be sight-read more easily

than others, which suggests that those processes may be more or less easily accomplished. Ortmann in 1934 (cited in Clifton 1986) showed with brief presentation times of stimuli, 400 msec and 2 sec, respectively, that diatonically organized music, smaller intervals, and sequences that were congruent with tonal expectations were more easily read than others. This suggests—and this conclusion is backed by much research in other domains—that we tend to form meaningful units that are influenced by our previous knowledge, and hence, expectations. Kinsler and Carpenter (1995) found that repeated renditions of the same piece were accompanied by a reduced amount of ocular movements. Presumably, larger chunks were formed, more previous knowledge was brought to the task, and the visual input functioned as a retrieval cue to a known motor programme (just like playing well-rehearsed music from notation).

What happens when our expectations are not met by the printed score? In a clever study (Sloboda 1976), pianists performed a classically sounding piece of music in which several notes had been altered by a half or whole step to violate tonal expectations. These violations were either introduced in the beginning, middle or the end of a phrase, and they were evenly distributed across the left- and right-hand part. Participants were asked to play exactly what was written. As the researcher expected, many of the artificial alterations were erroneously corrected to sound tonal again, middle positions being more likely corrected, and a repeated trial led to even more such corrections. These alterations may be termed proof-reader's errors. Sloboda (1974) asked music experts to judge mistakes made by sight-readers with regard to their musical adequacy. In keeping with our expectations, the errors were plausible alternatives to or reductions of the written music. Expectations are powerful: one can ask pianists to fill in blanks in an unfamiliar piece while sight-reading it, and they will generate successful inferences (i.e. improvise) based solely on the context of the piece, their stored knowledge, and current expectations (Lehmann and Ericsson 1996). Fine *et al.* (2006) showed that singers also made more mistakes when sight-reading tonally modified Bach chorals compared to unmodified ones and that they were also hindered by modified notes in other voices' parts.

Sight-reading is more than pressing the right notes at the right time; it also involves adding musical expression. Although no specific studies have been done so far, we suggest that expression is added algorithmically according to a likely grammar of musical expression (e.g. Friberg *et al.* 2006). Most interestingly, merely counting up the number of correct notes in a sight-reading task correlates highly with expert ratings of the same performance (Lehmann and Ericsson 1993), suggesting that better sight-readers integrate musical expression and correct notes on the fly. This may be due to a larger temporal range of planning. Only when the performer knows what is ahead can meaningful musical expression be added (e.g. slowing at the end of a phrase).

In essence, problem-solving or reconstructive processes during sight-reading are considerable if we consider how few fixations are available and how much material needs to be covered. Obviously, those processes function more effectively in better sight-readers. While plausible expectations are constantly being constructed and will usually facilitate performance, in rare instances they may lead the sight-reader astray and cause errors that unveil the underlying mediating processes.

Acquiring the skill

Sight-reading is such a specialized skill that it is futile to look for specific inborn traits that may cause individual differences in sight-reading skill. Among musicians observable individual differences in sight-reading ability are great and need to be explicated. Several variables have attracted the interest of researchers: all sorts of training variables, intelligence, other musical skills, musical ability, general indicators of memory, and reading performance.

The most promising predictors so far have been training variables. Kornicke (1995) and Banton (1995) found that higher self-rated experience as an accompanist or more regular sight-reading practice was related to more accurate sight-reading in the authors' studies. In Kornicke's study, a cumulative index of experience from several scales correlated reliably ($r = 0.4$) with sight-reading achievement. In a regression analysis the best predictor was the estimated number of pieces sight-read. Lehmann and Ericsson

(1996) assessed first, the size of repertoire that pianists possessed to accompany soloists and ensembles and second, accumulated duration of accompanying experience. Both indicators accounted independently for individual differences in sight-reading: a larger accompanying repertoire and more accompanying experience led to better sight-reading performance under standardized conditions. One could conclude from this that experience with the representative situation (real-time demands, short or no preparation time, etc.) as well as the knowledge base acquired through the performance of many pieces facilitates future performance. In general, among the participants of the study the experience as accompanist started a few years after the onset of piano training. They reported playing progressively more difficult accompanying piano parts, commensurate with their parallel increase in pianistic skills. Counter to many musicians' intuitions, this explains nicely why positive correlations are found between general instrumental skills and sight-reading at pre-professional levels (McPherson 1995, 2005).

A similar study on the acquisition of sight-reading skills included different levels of musical complexity (Kopiez and Lee 2006, 2008). In their experiment, subjects sight-read pieces of five levels of difficulty. Sight-reading performance was assessed along with indicators of psychomotor speed (tapping speed, trill speed), elementary cognitive skills (reaction time, speed of information processing [number connection test]), general cognitive skills (tests of short-term and working memory and general mental capacity), and expertise-related indicators (inner hearing, practice times for piano alone and accompanying, starting ages). The best single predictors for the overall score across all five levels of difficulty were trill speed between the third and fourth fingers, sight-reading experience up to age 15, scores on the number connection test, and inner hearing (Kopiez and Lee 2008). While those results emphasize the impact of experience and efficient perceptual encoding, they also suggest that pianistic abilities play a role. The authors also analysed their results separately for the individual levels of complexity (Kopiez and Lee 2006, see Figure 32.1) and showed convincingly that performance at different levels of difficulty was mediated by different combinations of predictors. Hence, those factors that contribute to better performance at lower levels of difficulty may not be the same as those which mediate superior performance at higher levels.

Many educational studies and reviews have offered suggestions on how to improve sight-reading (e.g. Lehmann and McArthur 2002, pp. 147–148; McPherson 2005) and insightful teachers have developed graded material to train sight-reading systematically. However, some advice might be more useful than other: for example, training eye movements by rolling your eyes or similar exercises are certainly futile—you would simply get better at rolling your eyes. Rather, young performers should get accustomed to playing their instrument without constantly looking at it (e.g. piano) to free up their vision to look at the score while still finding their way on the instrument. Performing under real-time conditions also precludes stuttering, i.e. stopping at every mistake and correcting it, but rather 'faking' one's way through the score, i.e. trying to infer plausible content. This can only be done if the student has ample experience with a certain style of music and can build up suitable expectations about how the music might continue. It is here also that knowledge of music theory can be applied. One has to acknowledge that a stable and deliberate interpretation may not be possible at first sight but that attending to dynamic and articulatory signs along with applying simple rules of expression (e.g. creating phrase arches of tempo and loudness) will generate a musically sounding first impression.

Summary

Sight-reading provides a complex problem-solving situation with an intricate interplay of bottom-up mechanisms (driven by the input stimulus of the score and auditory feedback) and top-down processes (driven by expectations and cognitions). It is conceivable that limitations on the general playing of an instrument or a lack of technical proficiency exist that may consequentially impact the ability to sight-read: One can never sight-read beyond the level of rehearsed performance, but how close to it one sight-reads seems to be very much a matter of training. Sight-reading ability at lower skill levels may partly emerge from general instrumental skill

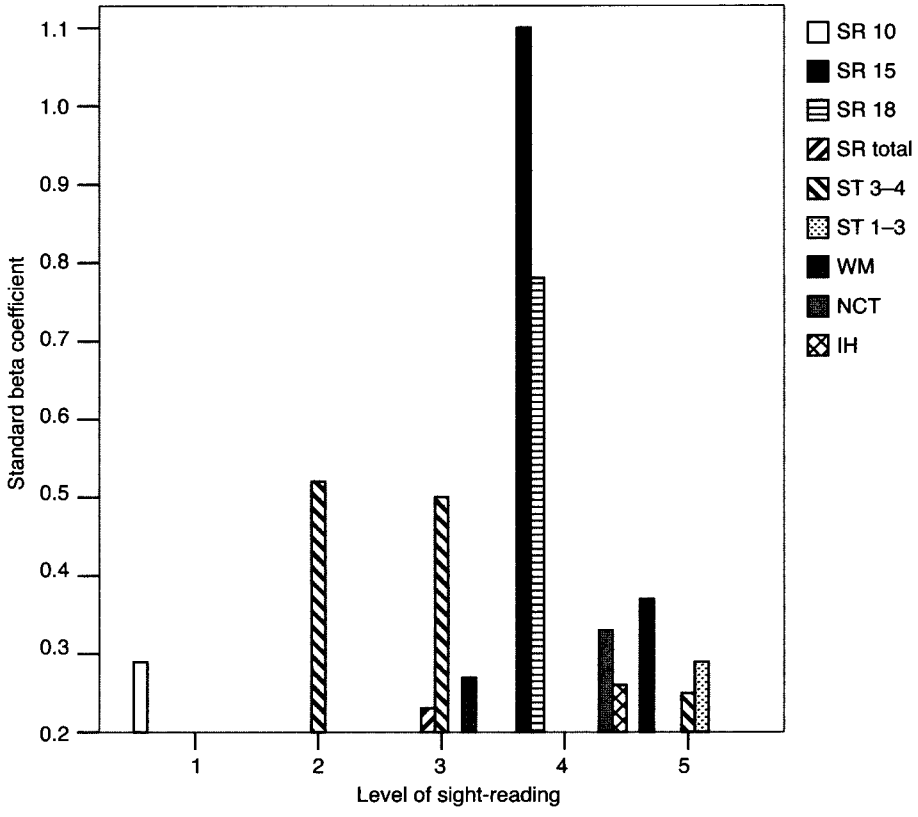

Fig. 32.1 Significant predictors of sight-reading performance, separate for five levels of stimulus difficulty 1=easy, 5=difficult (data from Kopiez and Lee 2006). Predictors: SR, sight-reading experience up to age 10, 15, 18 or total up to the time of the experiment; ST, speed trilling between fingers 1–3 or 3–4 of right hand; WM, working memory in a number task; NCT, speeded number connection test; IH, inner hearing using an embedded melody paradigm.

increase whereas expert sight-reading necessitates extensive deliberate efforts to improve performance. By engaging in many hours of related experience, for example as an accompanist (in the case of pianists), sight-readers develop particular cognitive adaptations, such as efficient encoding, building of expectations and plausible inferencing, and memory skills. These help them cope with the real-time demands of reconstructing on the fly the score along with a preliminary expressive interpretation.

CHAPTER 33

Performing from memory

Roger Chaffin, Topher R. Logan and Kristen T. Begosh

WHAT is the difference between 'learning' a new piece of music and 'memorizing' it? Both involve memory, but of different kinds. The memories that develop spontaneously while learning a new piece take the form of *associative chains* in which each passage cues the memory of what comes next. Deliberate memorization transforms the motor and auditory chains, making them *content addressable*. A memory is content addressable if you can ask yourself, e.g., 'How does the third repetition of the main theme go?', and the music comes to mind. Associative chains have a major weakness: to reach any link in the chain you have to start at the beginning. For a musician, this becomes a problem when something goes wrong in performance. Besides the embarrassment of starting over, there is the agony of wondering whether memory will fail again in the same place. Content-addressable memories avoid this problem. They can be located directly by thinking of the relevant location in the piece. In a memorized performance, content-addressable memory provides a safety net that permits recovery in case the associative chain breaks and the performance is disrupted.

Associative chains and content-addressable memories are learned in different ways and have different properties. Content-addressable memories are more likely to be explicit (conscious) and to involve declarative (language-based) knowledge *that* such-and-such is the case, whereas associative chains are more likely to be implicit (unconscious) and to involve procedural (motor-based) knowledge of *how* to do something. To memorize a piece of music for performance, the musician must smoothly integrate the two kinds of memory.

English has only the one term 'memory' to refer to these two very different mental processes. In everyday talk, musicians make the distinction by referring to 'learning' and 'memorizing'. There is the potential for confusion here. For example, how should we understand musicians who say that they do not memorize, for whom memorization is 'something that just happens' (André-Michel Schub), 'a subconscious process' (Harold Bauer), that is 'very simple' (Walter Gieseking), 'like breathing' (Jorge Bolet); how should we understand Jorge Bolet, when he says that he memorized Liszt's *Mephisto Waltz* in 75 minutes (Chaffin *et al.* 2002, Chapter 3)?

For the musician, the relevant question is whether memory will be reliable on stage. Jorge Bolet probably did not mean that he was ready to go on stage and perform. Professional performers may sometimes find themselves in the position of having to perform at short notice, but they do not normally choose to. It is risky. What happens if something goes wrong? If the memory is in the form of an associative chain, then the only recourse is to start again at the beginning of the chain. This kind of catastrophic memory failure is an unfortunate staple of student recitals. Students often make the mistake of assuming that because they can get through a piece without the score in the studio, they can do the same in live performance. They do not appreciate that the associative chain is just the first step; much more work is

needed to create a reliable, content-addressable memory.

Experienced performers know better; they give themselves a safety net. Memory failures are inevitable in live performance. A performer may go for years without a problem but, with enough performances, eventually it will happen. The important thing is to recover gracefully. Experienced performers do not stop and go back to the beginning. They go on. They have a mental map of the piece that allows them to keep track of where they are as the performance unfolds. The map provides landmarks where they can restart the performance if necessary (Chaffin *et al.* 2002, Chapter 9). When something goes wrong, the expert jumps to the next landmark and the performance continues. Most of the time, the audience is not even aware that anything went wrong. Memorization is the creation of this safety net.

Our account of memory for performance builds on the standard view of memory described by Bob Snyder in Chapter 10 of this volume (also Ginsborg 2004). We focus on the role of serial chaining and content addressability. Two areas of the episodic memory literature are particularly relevant to our discussion: oral traditions and expert memory. In oral traditions, materials such as children's rhymes and folk songs are handed down from one generation to another without the benefit of written records, often for hundreds of years. We will draw on David Rubin's (1995, 2006) analysis of this phenomenon and on his *basic system theory of episodic memory* to describe the role of different types of memory (auditory, motor, visual, emotional, structural, and linguistic) in associative chaining.

The second area of psychological research that we will draw on is the study of expert memory. The history of music is filled with examples of extraordinary feats of memory and these are often exhibited as evidence that the musician in question possessed some special gift or talent. For example, the young Mozart's writing out of Allegri's *Miserere* from memory was seen, at the time and ever since, as evidence of his genius (Chaffin *et al.* 2002, p. 66). The conclusion of careful study by psychologists is that such feats are *not* the product of a special talent for memorization but are the entirely predictable result of years of training and the effective use of retrieval schemes (Ericsson and Charness 1994). Expert memorists develop retrieval strategies to make their memories content addressable so that they can find the information they need when they need it (Ericsson and Kintsch 1995). We will use Anders Ericsson's theory of expert memory to explain how experienced performers memorize, as opposed to simply learn, a new piece.

Associative chaining

Music performance relies heavily on associative chaining: what you are playing reminds you of what comes next. In this respect, memory for music is similar to memory for rhymes, songs, and poems. In each case, the task of memorization is made easier by the fact that what comes next is heavily constrained by what precedes it (Rubin 1995, 2006). For example:

There was a young man of Japan,

Whose limericks never would ____.

The possibilities for the next word in this little verse are constrained by syntax to verbs, by semantics to verbs that can take 'limericks' as agent, and by rhyme to words that end in '__an'. These multiple constraints narrow the possibilities. One does not have to have heard this limerick before to know that the missing word is 'scan'.

The role of schemas[1]

How do we know that the second line must rhyme with the first? We recognize it as a limerick. Even if the word 'limerick' were not explicitly mentioned in the second line, we would recognize the characteristic formulaic opening and 'Te dee-ya, te dee-ya, te-dum' rhythm. Rapid recognition of this sort is a normal feature of memory: it is the same when we recognize a strawberry, a rain storm, or a birthday party. Information in long-term memory is represented in the form of *schemas* that summarize our previous experience and tell us what to expect. The schema for

[1] The Latin root of 'schema' dictates a plural form 'schema' or 'schemata'. We prefer the more regular, colloquial form 'schemas'. All three forms are in common use in the psychological literature.

limericks tells us that the second line will rhyme with the first. Similarly, schemas tell us to eat strawberries, use umbrellas when it rains, and give presents at birthday parties.

Contrary to popular belief, memory is not a vast storehouse containing exact records of a myriad of original events (Mandler 1984). Memories for specific events (episodic memories) are *reconstructed* at each remembering on the basis of schematic (semantic) knowledge representing generic memories. Schemas allow us to economically recall our past in enormous detail, but this ability has a price. When we take the trouble to check, many of the details turn out to be wrong. The same schematic frameworks that allow us to remember are also a source of distortion. We remember the gist, and fill in the details, systematically misremembering in the process.

Given the general fallibility of memory, musicians' routine reliance on rote memory seems remarkable. How is accurate recall possible, if memory for a piece must be reconstructed from generic musical schemas each time it is played? We would expect performances to be full of mistakes as the musician replaces the exact notes provided by the composer with the musical gist based on generic knowledge of harmonic, melodic, metric, and rhythmic patterns.

The answer comes from studies of how memory functions in oral traditions (Rubin 1995, 2006). In non-literate cultures, oral traditions such as ballads, epic poems, and religious enactments often remain stable across centuries, indicating that memories for their performance have been transmitted, more or less verbatim, from one generation to the next across many years. How is this done? Like everyone else, the memories of bards, minstrels, and storytellers are reconstructed at each performance (Rubin 1995, 2006). Their performances *do* vary, but they are sufficiently consistent that the distortion is minimal, even across generations. This surprising level of accuracy is a product of *multiple constraints*. In every oral tradition studied, the material follows strict formal constraints on rhyme, rhythm, and alliteration. Our example of the limerick illustrates how these constraints operate. The multiple constraints of grammar, meaning, metre and rhyme reduce the possibilities available.

In music, similar constraints are provided by melody, harmony, metre, and rhythm. In addition, repetition is normally much more pronounced in music than in language and provides additional local constraints (Huron 2006, p. 229–231). All of these constraints combine to make the task of memory reconstruction easier. Knowing how different composers use the various conventions of each musical genre makes constraints more specific, and so memorization is easier for experts than for novices (Williamon and Valentine 2002). In song, the constraints of the musical and literary forms combine, making memorization easier when words or music are learned together rather than separately (Ginsborg and Sloboda 2007).

Multiple memory systems

Another feature that music shares with the materials transmitted in oral traditions is that it is recalled as part of a *performance*. Performance calls on the many different cognitive and bodily systems involved in action, each of which lays down its own memory traces, subject to its own schemas. These provide multiple retrieval cues, making memory for performance more robust than memory for text (Rubin 1995, 2006). On the basis of cognitive and neurological evidence, Rubin (2006) has proposed a model of memory in which multiple memory systems contribute to episodic memories. We will restrict our description to those systems most relevant to musical performance: auditory, motor, visual, emotional, narrative, and linguistic memory. A memorized performance is generated through the interaction of the information available in each system. For example, musicians find it easier to play a piece of music they have memorized than to write it out because playing provides memory cues from the motor system that are absent when writing out the score (Chaffin and Logan 2006). Just as in the limerick example, the multiple retrieval cues from the different systems interact to reduce the range of possibilities.

Auditory memory

The history of Western music is replete with stories of musicians who were able to hear entire works in their heads (Deutsch and Pierce 1992). Psychological studies confirm this ability in people with or without musical training, and

have begun to specify the form in which the auditory information is stored (Halpern 1992). These studies confirm that people can 'hear' a melody in their heads, usually without accompanying imagery from other modalities, suggesting that the ability is based on an independent auditory memory (Reisberg 2001, Chapter 11). Neuropsychological studies provide further confirmation of the existence of a separate auditory subsystem (e.g. Fornazzari *et al.* 2006). In performance, auditory memory tells the musician what comes next, providing cues to elicit the music from memory, while also letting the musician know that things are on track (Finney and Palmer 2003).

We demonstrated one important way that auditory memory helps constrain recall when we showed how the rhythmic and rhyming schema for limericks narrow the range of possibilities for recall. In a similar vein, Rubin (2006) argued that the organization of ballads into stanzas with invariant metric and rhyming schemas has been largely responsible for the preservation of an oral tradition in North Carolina that is directly traceable to European ballads of the Middle Ages. In similar ways, schemas for standard rhythmic, melodic and harmonic patterns allow musicians to remember music better than non-musicians (Halpern and Bower 1982). Auditory memory appears to contain information about both pitch contour (relative pitch) as well as pitch category (absolute pitch), since people can sometimes recall music in the same key as the original (Dowling 1978; Halpern 1989).[2]

Motor memory

Motor memory allows actions to be executed automatically by providing kinaesthetic memory of the sensory feedback from joints, muscles, and touch receptors. Although motor skills have been studied since the earliest days of experimental psychology (Adams 1987), the contribution of the motor system to memory was neglected by early cognitive theories of memory, entering mainstream cognitive theorizing only with the distinction between procedural (motor) and declarative (conceptual) memory (Anderson 1978; Squire 1987). More recently, the discovery of 'mirror neurons' in the motor system that respond to seeing the corresponding action performed by another (Rizzolatti and Craighero 2004) has reaffirmed earlier claims that the motor and sensory systems are intimately linked (Liberman and Mattingly 1985). The motor system is still largely treated as a completely separate system (Rosenbaum 2005), however, and the study of its contribution to memory is still in its infancy, under the rubric of 'embodied cognition' (Glenberg 1997).

Musicians talk about motor memory as being 'in the hands'. Perhaps the most important feature of motor memory for musicians is that it is implicit (unconscious). Musicians know *that* they can play a particular piece (declarative knowledge), but the knowledge of *how* to play can only be exhibited by actually playing (procedural knowledge). This is a source of anxiety, and may lead to over-practice. Playing seems to be the only way to reassure oneself that memory for a piece is intact. Mental practice provides an alternative but requires explicit memory. To make motor memory explicit, actions must be recoded in propositional form so that they can be rehearsed in working memory as a thought of the general form, 'Next, do this'. This kind mental instruction is a form of *linguistic memory*, discussed below.

Motor memory provides the clearest examples of associative chaining in memory; each action in the series cues the next. This is what makes motor memories implicit: to be accessed, they must be performed. Actions can, of course, be cued in other ways. People stand up for national anthems, shake hands when introduced, and remember to stop at the grocery store on the way home from work. This last example is different from the others, because the action is directed by a cue that we provide for ourselves. The cue is a thought in working memory, e.g., 'Take this exit'. This is the same kind of self-cuing that makes mental rehearsal possible. Chaffin, Imreh & Crawford (2002) introduced the term *performance cues* to refer to the use of this kind of cue in music performance. Setting up performance cues is the main work involved in memorizing for performance and is described below in the sections on *expert memory* and *performance cues.*

[2] Remembering pitch contour requires the use of spatial imagery which Rubin (2006) identifies as a separate basic system.

Visual memory

Visual memory of the score is used mainly in the early stages of memorizing, while visual memory of the hands on the instrument becomes more important in the later stages. The role of visual memory for the score is evident in the difficulty that some musicians experience when working with a different edition of a score from the one they used to initially learn a piece (e.g. Chaffin *et al.* 2002, p. 37). A new score is difficult to work with because the visual information it provides is different from the musician's visual memory. It is common to remember the location of a passage on the page, a form of spatial imagery. Student musicians frequently use the spatial organization of music by pages rather than the formal structure of the piece to organize their practice (Williamon and Valentine 2000).

As in the general population, there are large individual differences between musicians in their subjective experience of visual memory. Some musicians report having 'photographic' memories, while others say that their visual memories are poor or unhelpful. For example, Myra Hess described how she could 'see' and 'read' the printed page when playing from memory, whereas Alfred Brendel reported that his memory was 'not visual at all' (Chaffin *et al.* 2002, pp. 37–41). These reports probably reflect real differences in the detailed information available in visual memory (Reisberg 2001, Chapter 11). Reports of visual images are misleading, however, in two ways. First, mental images are *not* pictures. Images are not neutral, objective depictions of reality but are organized interpretations that reflect the way that the original was understood. To discover whether you misread a note you cannot inspect your mental image of the score, you have to go back and look at the real thing. Second, people who report having no visual memory still have spatial memories which are stored in a separate system. While spatial memory does not provide a vivid subjective experience, it does provide information about the location of notes on the page.[3] So a person could experience no visual imagery but still be disrupted by using a different edition of a score.

Emotional memory

Memories for emotional events are formed more easily and are less likely to be forgotten than non-emotional memories (Bower 1981; Talmi *et al.* 2007). This is as true for music as any other material (Schulkind *et al.* 1999). The positive effects of emotion on memory are disrupted by damage to neural areas involved in emotion (Greenberg and Rubin 2003). Together, these findings are the basis for identifying emotional memory as a separate system.[4] It seems clear that the performer's visceral response to the music contributes to musical memory. We have observed that musicians find it difficult to play from memory when asked to perform without expression and surmise that playing without expression eliminates emotional cues that normally contribute to the retrieval of the music from memory.

Structural memory

We suggest that structural memory is the musical equivalent of Rubin's *narrative memory*: memory for the overall sequential organization and goal structure of a story or biography. Memories for events are organized by schemas that connect temporal series of discrete actions through narrative structures based on the goals of the actors involved (Mandler 1984). Although often expressed in language, narrative structure can be expressed in a variety of forms including pictures, cartoons, silent films, dreams, dance, and mime (Rubin 2006). In the Western classical tradition, the same kind of narrative structure is responsible for the hierarchical organization of a piece into sections and subsections based on melodic, harmonic, and metrical structures. In preparing a piece of music, experienced musicians analyse these structural properties and use them to organize both their practice and their memories (Chaffin and Imreh 1997,

[3] We have not followed Rubin (2006) in singling out spatial imagery as a separate form of memory because in music performance it appears to operate across modalities, binding together representations in the auditory, motor, and visual systems

[4] This is an oversimplification since emotion is a complex and varied phenomenon that draws on multiple neural systems (Rubin 2006).

2002; Chaffin *et al.* 2002; Hallam 1995; Williamon and Valentine 2002).

In 'programme' music, narrative organization is explicitly applied to music. Despite the resistance of critics to providing a storyline for every piece of music, the ease with which music lends itself to this kind of treatment suggests that musical and narrative structure share common roots. We suggest that they stem from the same cognitive system; musical form and the storyline of a musical programme are both manifestations the underlying ability to identify large-scale structural relations between events.

An important difference between narrative and musical structure is that the former seems to be easier to perceive. Even young children are sensitive to narrative structure (Nelson and Fivush 2004), whereas sensitivity to musical structure develops slowly with musical training (Williamon and Valentine 2002) and is not always found, even with experienced musicians (Chapter 10 this volume, pp 113–115). The difference may be due to the fact that in our culture people generally have a lot more experience telling stories than they do playing music.

Linguistic memory

The mental instructions that experienced performers use to remind themselves what to do at key points in a performance are a form of *linguistic memory* (Chaffin *et al.* 2002).[5] These instructions do not necessarily involve words. They are stored in an abstract 'subject-predicate' (propositional) form that usually points to other modalities (motor, auditory, visual, and emotional memories). However, their propositional form means that they can normally be glossed in words, e.g., 'Hold back' or 'Now, like this' (Englekamp 2001).

An important characteristic of linguistic memories is that they can be rehearsed in working memory, where they can serve to direct other mental processes. When the activity of other cognitive systems is re-described in language, the inner speech that results provides a means of mental control that can be used to implement plans and strategies (Reisberg 1992, p. viii; Rubin 2006).[6] Rehearsing a mental instruction in working memory broadcasts it throughout the nervous system, automatically activating other systems and coordinating their activity (Barrs 1988).[7] As we noted above, this ability can be used for mental rehearsal or to recover if the associative chain of a memorized performance breaks.

Content-addressable memory

Associative chaining works well so long as the chain is intact. If the performance stops, however, the chain is broken, and then memory failure is complete and catastrophic. The performer can only go back to the beginning and start over. To avoid such ignominy, experienced performers prepare a safety net that provides other options; they prepare multiple starting points.

When you want to sing happy birthday, you simply think, 'Happy Birthday', and start singing. The verbal label acts as a retrieval cue for the start of the song and the rest is then cued by associative chaining. Now imagine that you want to start at the last line. Most of us cannot do this immediately. We have to start at the beginning and run through. Once we have the last line in working memory, however, we can easily set up a new starting point by thinking, 'Start of the last line' as we sing. A few repetitions to strengthen the associative link between the new cue and singing the last line and we have a new starting point. Any time we want to start at the last line, we can now simply think, 'Start of the last line' and start singing.

We have set up a new performance cue, making this place in the music content addressable (Chaffin *et al.* 2002). Simply thinking of the cue now activates the memories needed to start singing.

[5] The first author has previously referred to both linguistic and structural memory as 'conceptual' or 'declarative' memory (e.g., Chaffin *et al.* 2002; Chaffin and Imreh, 2002). The present terminology represents a refinement of that classification.

[6] The important role of inner speech in mental control has been noted by many psychologists including Pavlov, Watson, Vygotsky, and Piaget.

[7] The process of directing and monitoring our own mental operations in this way may be responsible for uniquely human qualities of conscious experience (Dennett 1991).

The performance cue lacks the multidimensional richness of the associative chain, where the next link was cued by sound, action, and emotion. What it lacks in richness, it makes up for in flexibility. You can now think of the passage at any time, without running through the whole piece from the beginning.

We will focus on two aspects of this strategy. First, when applied to a long piece of music, the strategy of creating multiple starting points has many similarities with how experts memorize in other domains that have nothing to do with music. We will describe these similarities in the next section. Second, there is a risk involved in setting up additional starting points. Thinking about what you are doing can interfere with skilled performance, a phenomenon known as *choking* (Beilock and Carr 2001). We will describe how experienced musicians avoid this problem in the section on *performance cues.*

Expert memory

Experts in any domain memorize with a facility that seems superhuman (Gobet and Simon 1996). Musicians are no exception; as we have already noted, their biographies are full of tales of amazing memory feats. The abilities of other expert memorists have been attributed to the use of highly practiced retrieval strategies by skilled memory theory (Chase and Ericsson 1982) and its extension, long-term working memory theory (Ericsson and Kintsch 1995). These theories are based on the study of domains such as chess boards (Chase and Simon 1973), digit strings (Thompson *et al.* 1993), and dinner orders (Ericsson and Oliver 1989) that are very different from music performance: structural and linguistic memory are primary and associative chaining of motor and auditory memories play minor roles. Despite the differences, the principles of expert memory established in these domains apply to music performance because experienced musicians also rely on structural and linguistic memory to provide a safety net in case the chain of motor and auditory memories breaks (Chaffin and Logan 2006).

The feats of expert memorists can be explained in terms of three principles: meaningful encoding of novel material, use of a well-learned retrieval structure, and extended practice to decrease the time needed for retrieval from long-term memory (Ericsson and Kintsch 1995). The same three principles apply to expert music performance (Chaffin *et al.* 2002; Krampe and Ericsson 1996). First, experts' knowledge of their domain of expertise allows them to make use of schematic knowledge already stored in memory to organize information into larger chunks (Tulving 1962). For a musician, these include familiar patterns like chords, scales, and arpeggios, whose practice forms an important part of every musician's training (Halpern and Bower 1982). Second, expert memory in any domain requires a retrieval scheme to organize the cues that provide access to the chunks of information in long-term memory (Ericsson and Oliver 1989). For a musician, the formal structure of the music conveniently provides a ready-made hierarchical organization to serve as a retrieval scheme. For example, Figure 33.1 shows how the hierarchical organization of JS Bach's Italian Concerto (Presto) into movements, sections, subsections, and bars was used by a pianist to organize her memory for the piece (Chaffin *et al.* 2002). The third principle of expert memory is that prolonged practice is required to bring the speed of operation of a memory retrieval scheme like the one in Figure 33.1 up to the speed needed to guide behaviour (Ericsson and Kintsch 1995). For the musician, this involves practising memory retrieval until it is rapid and reliable enough to keep pace with the performance.

Rapid memory retrieval is important in music performance to prevent the hands from 'running away' as the retrieval of procedural knowledge by associative chaining outpaces the slower, content-addressable retrieval of declarative knowledge. The smooth integration of the two systems creates 'long-term working memory' (Ericsson and Kintsch 1995). Practice is needed so that the performance cue for what comes next arrives in working memory at just the right moment, before the corresponding motor sequences, but not so far in advance as to distract from the execution of the preceding passage and cause 'choking'.

The interplay of the two retrieval systems is illustrated in Figure 33.2. The figures shows the two routes by which memory for a piece of music

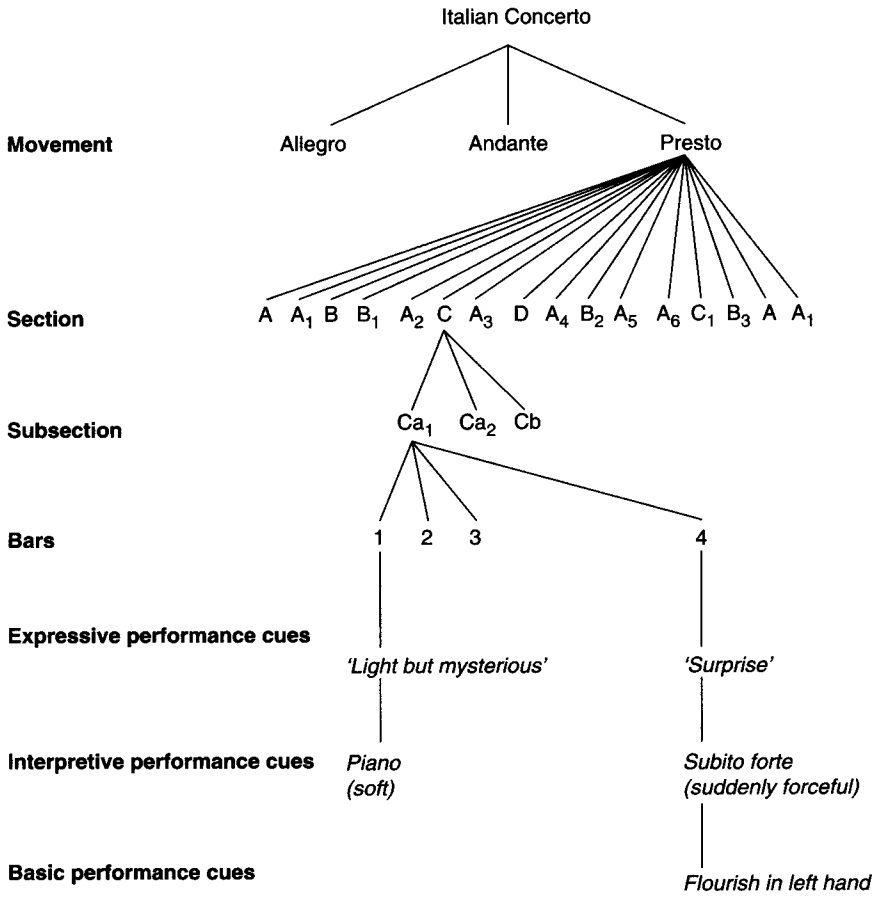

Fig. 33.1 Hypothetical hierarchical retrieval scheme 'unpacked' for Section C of the Presto from the Italian Concerto by JS Bach. Main themes (sections) are represented by capital letters. Section C is 'unpacked' into subsections (Ca1, Ca2, Cb). Subsection Ca1 is further 'unpacked' into its performance cues. (From Chaffin R., Imreh G., & Crawford M. (2002). *Practicing perfection: Memory and piano performance*. Erlbaum, Mahwah NJ, p. 200. Copyright © 2002. Adapted with permission).

can be retrieved. At the bottom of the figure are the serial associations set up while learning to play the piece. These associations, based on schema for rhythm, meter, harmony, and melody, directly link each passage with the next. Each passage is cued only by the preceding passage. Direct, content-addressable access is provided by a second retrieval system, shown at the top of the figure. Here, a hierarchical retrieval organization, similar to that in Figure 33.1, provides direct access to any section of the piece. Performance cues embedded in this organization provide possible 'starting points' in case things go wrong in performance.

Performance cues

One of the main challenges in memorizing for performance is to integrate the two retrieval systems. As one pianist put it in talking about her learning the Italian Concerto (Presto) by JS Bach:

> My fingers were playing the notes just fine. The practice I needed was in my head. I had to learn to keep track of where I was. It was a matter of learning exactly what I needed to be thinking of as I played, and at exactly what point so that as I approached a switching point I would automatically think

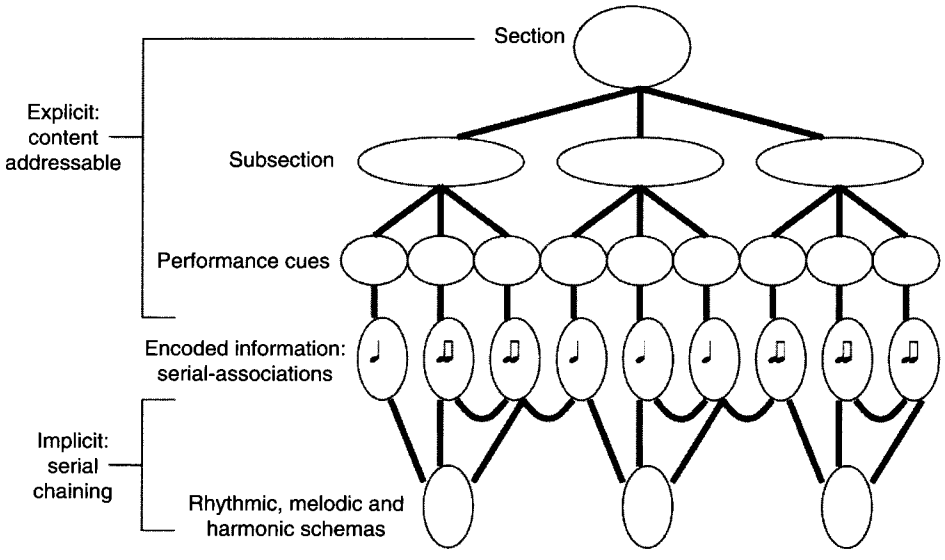

Fig. 33.2 Model of episodic memory for music performance showing separate retrieval organizations for access by content address and by serial associative chaining. (From Ericsson K. A., & Kintsch W., Long-term working memory. Psychological Review, 102, 211–245. Copyright © 1995, The American Psychological Association. Adapted with permission).

about where I was, and which way the switch would go.

Chaffin *et al.* (2002, p. 224)

The musician was talking about the need to practice performance cues. Performance cues are landmarks in the mental map of a piece that an experienced musician maintains in working memory during performance. Because they can be accessed both by serial cuing and directly, by address, they provide a safety net in case serial cuing breaks down. Careful preparation of performance cues makes it possible for soloists to reliably perform challenging works from memory on the concert stage. By repeatedly paying attention to performance cues during practice, the musician ensures that that they become an integral part of the performance, coming to mind effortlessly as the music unfolds. The performer remains mindful of these aspects of the performance while allowing others to be executed automatically. When things go smoothly, performance cues are a source of spontaneity and variation in highly polished performances (Chaffin *et al.* 2007). When things go wrong, they provide places at which the soloist can recover and go on.

Performance cues point to different types of memory according to which aspect of the music they address.[8] *Structural* cues are critical places in the formal structure, such as section boundaries. *Expressive* cues represent musical feelings, e.g., excitement.[9] *Interpretive* cues refer to musical gestures, such as changes of tempo or dynamics. *Basic* cues point to motor memory for critical details of technique, e.g., a fingering that sets the hand up for what follows. Musicians are likely to agree on the musical structure of a piece.[10] They are likely to differ, however, on other cues that are more specific to the performer or instrument. For example, basic performance cues for a cellist include decisions about intonation, bowing, and changing string that are not relevant for a pianist (Chaffin *et al.*

[8] The organization of cues into types here is descriptive and somewhat arbitrary. Other descriptive organizations are possible.

[9] Musical structure and expression are necessarily linked, but expressive cues do not always coincide with structural boundaries (Chaffin *et al.* 2008).

[10] The musical structure of some pieces may, however, be understood in more than one way, e.g., Ginsborg *et al.* (2006).

2008). For solo works, the only performance cues required are those for the individual musician, while for ensemble performance the musicians must also establish shared performance cues to coordinate their actions (Ginsborg *et al.* 2006).

Performance cues are content addressable through their location in the hierarchical organization of the piece (see Figure 33.1). In learning a new piece, the musician moves up and down the hierarchy, attending to each level of organization and each type of cue in turn (Chaffin *et al.* 2006; Williamon *et al.* 2002). Like experts in other fields, who approach a new problem by looking at the 'big picture', experienced musicians approach the task of learning a new piece by getting an overall artistic image of how the music should sound, focusing on structural and expressive cues (Neuhaus 1973; Chaffin *et al.* 2003). Beyond this commonality, the order in which different types of performance cue are practiced appears to depend on the individual, piece, and situation. What all the experienced performers that have been studied to date have in common is that they practice performance cues. This provides them with a safety net for times when associative cuing fails (Chaffin and Logan 2006).

Conclusion

Though it has a long history in Western classical music, playing from memory is often a source of great anxiety for performers. Pianist Janina Fialkowska talked of the 'terror of forgetting'. Lazar Berman reported that, 'Every time I play in front of an audience, it is a very important and difficult affair, both physically and spiritually. I am never sure that it is going to end well' (Chaffin *et al.* 2002, Chapter 3). Anton Rubenstein wrote that fear of memory failure 'inflicted upon me tortures only to be compared with those of the Inquisition' (Rubenstein 1969, p. 18).

Given the costs involved in playing from memory and its long tradition, stretching back 175 years, it might be expected that musicians would have developed a systematic understanding of the problems involved. This has not happened (Aiello and Williamon 2004). Individual musicians know a great deal about strategies for memorization (Hallam 1995, 1997), but this knowledge is conveyed from teacher to student through an apprenticeship system of training that makes it unavailable for systematic analysis. Memorization is viewed as an individual and mysterious process. It is up to each person to find their own method (Ginsborg 2002). This is regrettable and unnecessary. Memory varies no more from one person to another than any other trait or capacity. Beneath a superficial diversity, the cognitive and neurological systems involved in memory are common to all human beings. In this chapter we have described those aspects that are most relevant to performing music from memory.

CHAPTER 34

Movement and collaboration in musical performance

Jane W. Davidson

Introduction

The body has a crucial role in the production and perception of musical performance that has been recognized for centuries. Indeed, the Ancient Greeks recognized the centrality of the body in all artistic performance expression, revealing that there was little to distinguish between the physical coordination required in music and dance. Speaking of all human activity, ethnomusicologist John Blacking (1977) argued in *The Anthropology of the Body* that a detailed understanding of the body set within the individual's cultural context can reveal subtle details about that person and how they interact within society. Increasingly since the 1970s scholarship has paid more attention to the role of the body in artistic activity, providing useful theories relating to how embodied thoughts and actions allow us to know and understand the world we inhabit through artistic performance activities like music and dance. For example, by the 1990s, in the area of critical musicology, Susan McClary's (1991) *Feminine endings* usefully addressed the function of the body through groundbreaking studies of popular artists, especially female artists like Madonna and kd Lang. She illustrated how it was as much our knowledge of these women as pop stars that influenced our experience of them, as it was their physical appearance and stage persona alongside the expressive affect experienced in their musical expressions that contributed to the performance: their bodies were recognized as a very special site of social exchange, thus highlighting the physical, social and cultural nexus.

Research in the field of music psychology on the body has reflected some of the recent social anthropology and critical musicology trends, and so has developed a strand of socially focused enquiry. These ideas have been central to the work of the current author and will be explored in this chapter. Generally, however, the origins of modern psychology of music work on the body has tended to focus more on the bodily control aspects of playing, such as how movements assemble to execute a musical task. Intriguingly, these motor programming studies have been interfaced with some studies on music learning so that evidence for the emergence of these skills has occurred. Further perceptual enquiries and movement tracking studies have explored the body movements used for expressive musical effects. Also, applied research projects for pedagogical results have explored the use of bodily movement and movement metaphors to enhance understanding of musical expressivity for performers, with parallels being drawn between movement effort and flow to depict qualities in the musical semantics. Finally, within the group music context, studies of the identification of types of bodily movement used for interpersonal collaboration, including the coordination of musical and extra-musical material (musical and general social dynamics), and how this information helps to

develop efficient collaborations have been undertaken. Thus, there has been a broad range of investigation, although the overall volume of work to date has been relatively small. In this chapter all the areas of existing enquiry will be explored. Though not comprehensive, the aim of this chapter is to explore the key existing music psychology investigations on this topic. It begins with research on motor programming, moving to more social aspects of performance and bodily movement, and finishing by considering musical collaborations.

Motor programming

We know that the assemblage of all the subcomponent actions required for a musician's movement activity is a highly complex process. Recent writing by Jäncke (2006) explains that the movements musicians use emerge from 'a concatenation of mechanical and neural factors'. Though such movements have been of interest for many decades, understanding how the movement plans are organized has been a challenge to researchers (see Lashley 1951; Bernstein 1967; Wing 2002). There is an underlying 'degrees of freedom' problem that relates to understanding the vast potential array of muscle and nerve impulses that create actions. Since Bernstein (1967) suggested that motor programmes (memory representations) operate for classes of movements rather than individual movements, theories to account for movement systems have ranged from the brain operating as a central executive to control movements, to proposals where movement control arises in an open system where the movements are themselves self-organizing (see Dahl 2004 for a more detailed explanation of these ideas). Ideas have been broad-ranging: for example, it could be that movements trigger one another in a *chain* or a *chain complex* (sequential or in parallel), a *radial net* (this is, where one action may drive several others of equal weighting), a *hierarchy* (here one or more actions trigger more actions at the next level down through the branches of the hierarchy) or a *heterarchy* (multiple feedback loops across the hierarchical structure) (see Wing 2002 for details). The current reality is that we do not have a clear single theory to understand how the movements are organized.

For the musician, an understanding motor programming itself is not essential, however, knowing that the activity of the body involved in playing a piece of music depends on generating and embedding these motor programmes in memory by rehearsal is essential. Indeed, musicians need to rehearse their physical actions until they achieve fluency, or an incompressible minimum time to execute them. We know that it can take years for a professional musician to reach fluency. Sloboda and colleagues (1994) found this to be in the range of 3 hours of practice a day across the 10 childhood years of learning. Intriguingly, and offering support for the positive effects of rehearsal, researchers have revealed that practice results in enlarged representations of somatosenory and auditory cortex (Pantev *et al.* 2001), as well as the motor areas in their brains (Altenmüller and Gruhn 2002). Moreover, since these programmes are established in memory, thought practice can have benefit on physical skill, though it is not as profitable as actual physical practice (Palmer 2006). Additionally, Dalla Bella and Palmer (2004) have shown that pianists move their fingers approximately three to four events ahead of time, suggesting that an early retrieval for action is required, motor activity being an anticipatory and unfurling behaviour in performance.

The development of the motor programmes for economy leads to automaticity. In a complex physical activity like musical performance, automaticity is absolutely necessary because it offers fluency. This automaticity varies from the basic assemblage of the body to execute a single musical note through to rapid sequences of notes, often containing subtle musical effects such as counterpoint or inner voicings to be played out for expressive effects. In essence, the expert's performance movements are seemingly effortless and necessarily effortless: in achieving a high degree of automation (unconscious processing) in the action, the expert performer's conscious thought is relatively 'free' to deal with moment by moment modifications that may be necessary as the music is being performed. The novice, by contrast, requires full conscious attention on the biomechanical activity. Movements often seem cumbersome, the novice not being able to achieve the actions to fluent effect. This means that the

novice is not able to consider other performance-related concerns, for example adapting to new situations such as encountering a piano with a sticking key (see Lehmann and Davidson 2002 for more details).

Of course automaticity is required not only for movement fluency, but for the link between eye and hand if the musician is reading music, or between co-performers and timing, dynamic and overall expressive markings or ideas if the performance is to be coordinated and varying along the same dimensions for all players at all times. Clearly automaticity is a complex and multilayered skill. The layers of complexity were demonstrated in terms of musical timing by Shaffer (1984), who showed that when carrying out an activity like keyboard performance, there are specific timing effects that result as a consequence of the task demand. He noted, for example, that the typing performance by touch typists had specific timing profiles for certain combinations of letters. It is certain that the individual performer's body and instrument itself adds to this situation. For instance, a small pianist will have to develop his or her representations for playing a sequence of loud, large hand-span chords in a manner that will be slightly different from a larger person, even if the technicalities of playing the piano are based on the same principles and similar thought processes. Additionally, the musical systems developed within a specific culture and the types of sonic outputs created (e.g., Indian rag scales or Western tonality) are related to the ergonomics of the musical instrument used (Baily 1985). Wiesendanger *et al.* (2006) have shown that the bowing arm of the string player is highly constrained by the dynamical principles that operate between the bow and string and the arm controlling the bowing action. We can see the interaction of bodily constraints, ergonomics and cultural context within Western art music when a composition is played on different instruments of the same family; for instance, on a harpsichord versus the piano, or even from one piano to another. The differences in the size and shape of the instrument, plus the force required to play it, inevitably shape the physical approach required, and this in turn is influenced by the stylistic requirements of the music to be played—e.g., Baroque versus contemporary.

Shaffer also examined piano keyboard performances, noting that the timing profiles were additionally related to musical structure features, with, for example, a slowing always occurring at phrase boundaries. So, besides the requirements of achieving motor programming automaticity in order to execute sounds on instruments, it has been demonstrated that each music performer does not play in a purely mechanically efficient manner. The performer also has a set of representations that draw on knowledge and experience of musical style. Furthermore, as will be shown in the next section and throughout this chapter, cultural appropriateness also impacts significantly on how the movements are assembled and presented.

Body movements for musically expressive effects

Solo performers

A study by Davidson (1993) demonstrated that when the same piece of music was played with different expressive intentions (deadpan or withheld expression, with usual expression, and with exaggerated expression), the performers moved their bodies in identifiably different ways. Detailed tracking of a pianist's movements (Davidson 1994) showed that although the hands, arms, head and torso followed similar movement contours (those required to execute the music) across performances, there were significant differences in the scale of the movements. This suggested that the more highly expressive the piece, the larger and more ample the movements. The lesser the expressive intention, the smaller the movement. This finding seems to be rather like those seen in the actions of a speaker who frames and articulates speech, where big ideas or highly expressive or emotional states use much larger gestures than more constrained states (Kendon 1980).

From movement tracking data collected, it seems that it was impossible for the performers to use their bodies in a completely 'deadpan' manner. The same was found to be true of the musical sound, with some expressive feature of the music still being articulated, e.g., making slower and more pronounced movements at the boundary points, and surging forwards at a rising crescendo.

Such a finding would correspond with the idea that a musician's body is both generating and reacting to the sounds it is producing.

It is important to note that the performers observed in a series of studies from 1991 to 2007 (see Davidson 1993, 1994, 1995, 1997, 2002, 2006, 2007) demonstrated that the performers bodies moved in a rhythmical pulsing/swaying movement. Sometimes this was more or less apparent, but once movement tracks were made, the swaying could be traced across whatever piece was being played. For pianists, cellists, and tuba players this swaying occurred around the balancing point (fulcrum) of their sitting position; and for instrumentalists who were standing, this swaying was articulated from the balancing position of the weight over the feet, knees, and hips. An explanation for this movement was that the players were pivoting their bodies around a fulcrum through which all expressive information was being articulated. Such conclusions were drawn from extensive observations and detailed analyses of the performance movements generated. Indeed, it was discovered that within the overall swaying there were more local indications of the same sort of action (e.g., a rotating wrist) which conveyed very similar types of information (observers could detect from any single body part the expressive intention). It was concluded, therefore, that a physical centre or fulcrum to express mental representations relating to expressive intention may exist, and that these are then revealed in the body a hierarchical manner: overall movement sway, local body part movement (see in particular, Davidson and Correia 2002; Davidson 2005).

However, in addition to the overall performance movement—which seemed to be a combination of basic biomechanical action integrated with overall information about the music's general expressive intention—it was also discovered that musicians peppered their performances with many specific postures and gestures that had qualities akin to the types of non-verbal communication that accompany speech, e.g., those metaphorical and illustrative features which both generate and react to ideas being expressed (Kendon 1980). For example, head nodding in a series of rapid gestures that seem to mirror the music as it repeats a specific figure or sequence, potentially illustrating the repetition within the musical material. Other gestures seemed to have iconic value, that is, where some feature of the musical action was being described. For example, pianists creating the contour of the music being played by tracing this form in the air with the left hand whilst playing the notes with the right hand. This arguably is done to 'draw out' the smooth legato line that is being attempted in the music.

The specifically identifiable gestures used by individual instrumentalists seems to be rather limited in number, yet what these gestures had the potential to express appeared to be endlessly variable, depending on the context in which they are used. Indeed, Davidson's (2007) assessment of the pianist's movement vocabulary showed that the movements were limited so less than 20 movement types, and these happened to appear across all sorts of musical styles. Indeed, one style of music (Beethoven, for example) an emphatic 'wiggle' of the torso might illustrate an ornament in the music in one context, yet in another context (CPE Bach) this could signal the start of a long legato passage.

These gestures were person-specific, the 'wiggle' being specific to a case study pianist. Some of the other movements seemed more related to illustrative gestural purposes—e.g., nodding for emphasis—and there was a high degree of individual variability in how many of these gestures were used (Davidson 2005).

Since there are some schools of pedagogy which appear to focus only on the efficiency of the action of playing, it might be asked if these postures and gestures are really necessary for the optimal expression of the musical ideas in performance. A study by Davidson and Dawson (1995) requested that pianists should learn an especially composed piece which did not require any range movement as it was constrained to the central two octaves, yet when completely free to move, the pianists made quite extravagant movements in their performances, including both sways and identifiable gestures. Some were asked to learn the piece in a restraining harness to restrict them from moving around, though they were free to reach the keyboard and play all the notes required. In this condition, the performances were never as musically expressive or indeed as visually 'pleasing' as the freely

learned pieces. This indicates that freedom of movement is obviously important in the generation of musical expression.

So far, the indications have been that the gestural and postural movements used help to articulate the musical expression, and that movement gestures have roles of metaphorical function to articulate the musical sounds. It is possible to take these ideas one step further to suggest that musical material itself operates like a virtual person—a social inter-actor—with the performer. So, in a score-indicated fortissimo, a violinist may nod her head as she plays loudly. This action could be an illustration of the force of the movement required, or she may be 'agreeing' with the force of the musical sounds by nodding in 'agreement', as if interacting with another person. These are all speculative ideas, but it is feasible that the music itself operates on the performer like a partner in a conversation, except that in the case of a musical performance the performer both generates and reacts to the musical narrative.

Music pedagogy

It is important to note that the idea of movement and metaphor being crucial to musical meaning is featured in several schools of music pedagogy. Dalcrozian Eurythmics, for example, uses movement coordination such as groups of children bouncing balls in unison as a means of illustrating to them how musical material needs to be coordinationed and musical phrases shaped (see Gell 1997, 2005). Guile (in preparation) has undertaken a Laban technique for dance training and has employed his concepts, such as Effort, into the music learning context. Undertaking extensive training programmes with children, she has found that demonstrating actions with effort characteristics such as 'dabbing' and 'punching', children are able to imbue their musical performance with expressive/emotional characters not otherwise present. At a more advanced level, Pierce (1994) has drawn on movement concepts to assist tertiary level and professional performers to optimize the expressive features of playing.

Thus far, the gestures and movements we have considered all relate to musical material itself, and deal only with the soloist. This ignores the significant influence that co-actors and audience may have on performance movement.

Co-performance

An attempt to understand which postures and gestures are used by co-performers, Davidson and Coulam (2006) studied singers working with an accompanist. It was shown that a co-performing accompanist preferred collaborating with the singers who coordinated musical detail through non-verbal means using the sorts of metaphoric devices mentioned above. However, in addition to these, illustrative gestures such as clicking fingers to set a tempo, and using a series of regulatory head nods and arm gestures to control when and how the players should develop an idea or stop were also used. Such non-verbal means were preferred over talking (Davidson 2005). Indeed, when interviewed after rehearsal and performance activity, the co-performers spoke about 'reading the signs' between them as being crucial to the successful ensemble. Thus, in order to optimize the non-verbal material, gaze and eye contact were very important. Intriguingly, the performers were conscious that they needed to look at one another frequently to make sure that their bodies could coordinate to make the precise musically timed expressive effects.

Durrant (1994) has researched conductors, especially choral conductors, and noted that they use culturally embedded emblems quite extensively, but these are often very elaborate codes (e.g. we need to 'know that a "V" sign with the index and middle finger means "Victory"), and part of the rehearsal period is concerned with choristers learning and then speeding up on decoding what these emblems signify. As the emblems are usually complex signs to short-circuit a lot of spoken instruction, they typically combine technical and expressive instruction. For example, using the hand at the side of the head in a rotational gesture to indicate the notion of creating 'space' for the singing voice to sound and accompanying this with a sharp downward pointed gesture to indicate the vocal attack on the sound. Although there is very limited formal research, Davidson (1997) has hypothesized that the most successful conductors on the international professional circuit

are those who not only focus on non-verbal interaction, but who are also efficient in their use of illustrators and regulators and keep emblems to a minimum, given the time involved in learning their meanings.

Clearly, co-performers need to be able to decipher intention within and between musical parts in order to achieve a fluent performance. Therefore it is necessary to understand the nature of their collaboration and the effect it has on creating a musical performance.

Co-performer collaboration: from rehearsal to performance

Van Knippenberg and Hogg (2003) discuss that any form of group interaction necessarily gives rise to individual as well as group outcomes. It is these outcomes that motivate people to join and continue in groups. Davidson and Good (2002) discovered that collaborative activities between string quartet members depended in almost equal measure upon: first, the dynamics of musical content and its coordination (achieving entrances and exits etc.) in order to get the performance to cohere; and, secondly, those dynamics of a more personal nature (for example, the first violinist making a head nodding gesture of approval to the second violinist after executing a particularly well-accomplished passage) in order to make the social group cohere. In their data, Davidson and Good saw a power struggle emerging in the rehearsal activity observed. This was based principally on sexual politics—one flirtatious male amongst three more or less admiring females—and it was noted that the flirtation was apparent in the use of non-verbal gestures. The male second violinist teased the first violinist about her lack of clarity, imitating in a bold and exaggerated bowing arm the sudden jerkiness of her regulatory gesture to say 'start the music, now!' The example served also to show how multifunctional the role of non-verbal communication can be in the rehearsal. Additionally, the example shows that individual agendas—even if at odds with the musical goals—can still be expressed, and a coherent musical outcome achieved. Indeed, we are all aware of some famous ensembles who do not get along socially, yet are able to rehearse and perform in an excellently coordinated manner by sticking solely to the musical task.

Recalling the string quartet study and the video data obtained, it was intriguing to observe that when there was a lull in the playing activities of the rehearsal, the cellist moved away from the group sitting arrangement to place herself at the edge of the room, away from a flirtatious social interaction between the first and second violinists. The viola player sat in her traditional position but looked away, shifting her body position as if to exclude herself from the interaction. This type of behaviour has been examined within non-verbal communication research and is known as 'proxemics'—the use of personal space.

The field of proxemics was first studied by Hall (1963), and it was soon discovered that humans have a desire to maintain certain spatial 'zones' or safe distances from one another dependent on circumstance, cultural norm and individual variability. At an everyday level, we are all sensitive to someone who stands too close for comfort or is too far away or avoids eye contact. Music-making is no exception. Finding an appropriate place to stand or sit and assessing performance distance seems crucial.

Williamon and Davidson (2002) found that in the collaboration of a piano duo, where the players sit within one another's personal space (the brief overlapping arms are often required), practice brought an increase in the quantity of non-verbal interaction from first meeting through to a performance. The most used movement was a slight head and eye indication for regulation. Also, and again intriguingly, during the course of the rehearsals, the movement styles of the two individuals altered. The player who moved the most moderated his movements by reducing the quantity of his bodily movements somewhat, while the more conservative player produced more movement. It was as if they began to move as one, rather than two individuals, once they were within the same zone. Evidently, the social dimension was found in that they sensed that they were performing this 'together', as one 'unit'.

Davidson and Good (2002) also noticed this movement unifying effect in the string quartet especially when it played Britten's 'Rhapsody'; the players found it much easier to achieve the

canonical musical entries if they were all ebbing and flowing in exactly the same manner, leaning across into one another's movement pathway.

The current author has researched many types of musical interaction and collaboration, and for her one of the most revelatory experiences has been to work with blind musicians. Over a number of years she has run workshops on rehearsal, performance and stage presentation classes in association with the Royal National Institute for Blind People UK (RNIB). In this work, she has become highly sensitive to the importance of proxemics. Clearly, for practical reasons, blind people may need to pace out distances between stage activities, or be advised how best to position themselves in relation to co-players and audience for the advantage of all. These practicalities aside, blind people also demonstrate how important 'safe' distance zones for interactions are for all. As opera singing student Victoria Oruwari comments in a personal communication, blind people can feel 'invaded' as sighted people stand too close for comfort ('they often stand close in attempt to be better understood'). Sighted people also employ a range of non-verbal touching behaviours in their everyday social encounters as they chat (tapping on the shoulder, nudging with the elbow) which are behaviours blind people do not participate in ('Why do they do all that poking and prodding?'). This information has important implications for rehearsal and performance. Achieving a good distance between sighted and blind players for extra-musical feedback, for instance picking up cues from breath and the sounds of movements (shift of foot position, turn of torso *etc.*) all provide information for the blind musician, without engaging in verbal explanation, or worse still uninvited touch. However, the same could be said of any social interaction. These are codes that we need to respect. Keeping a respectful or appropriate distance is essential, just as it is to be sufficiently close to share in musical and necessary social exchange.

Actions including and beyond words

As explored above, movements in musical rehearsal and performance clearly aid in the achievement of musical coherence and can enhance social unity. Studying chamber musicians, Goodman (2002) and Murninghan and Conlon (1991) found that non-verbal communication during rehearsal often solved problems where talk had failed. By simply playing and sorting out coordination 'on the hoof', drawing on non-verbal means of communication, there was often no need to discuss a particular point at all. Or alternatively, when a verbal disagreement about musical interpretation emerged, playing the piece through in several different manners would often lead to a decision being made, again without verbal discussion. These findings are supported in the much larger context of a Western symphony orchestra. It is well-reported that in rehearsals, where there is a conductor, this person leads (Atik 1994). The musical ensemble research indicates that too much talking either from the conductor or in the form of questions from an individual player disrupts the flow of the music in rehearsals (see Weeks 1996; Yarborough 1975; Durrant 1994; Price and Byo 2002). That is, if too much questioning is permitted from one individual, it is likely to lead to interference as other members may become irritated or distracted.

Focusing on the key requisites of ensemble performance, Davidson and Goodman (2004) highlighted that specific moment by moment information needs to be processed and responded to in an ongoing manner, in order to accommodate a co-player's sudden change of tempo or coping with a memory slip. Such a capacity to deal with these matters clearly depends on former exposure to such situations and so also relies on previous knowledge of similar situations. Most powerfully, it depends on an opening of ears and eyes to hear and see cues.

What of these cues? Are they of the form and quantity normally encountered in social conversation? Goodman's work (see Goodman 2002; Davidson and Goodman 2004) has drawn on Bales's (1950, 1999) small group behaviour framework. It shows that in terms of both speech and gesture used in rehearsals of two cello and piano duos, the high amount of agreement indicated in the performers' discourses exceeded a suggested 'normal' social upper limit, suggesting that the performers gave mainly positive socio-emotional reactions (perhaps stronger

than witnessed in other small group scenarios). Indeed, in addition to the illustrative, regulatory and emblematic gestures described above, it has been both observed and discussed (Davidson and Coulam 2006; Davidson 2007) that performers—whether singers or instrumentalists—who make non-verbal signals which revealed unconscious processes of self-stimulation, e.g. rubbing the ear lobe in a gentle manner, or flicking the finger tips in a particularly soft but repetitive manner. These—completely unconsciously produced movements—have been regarded as important factors in determining performance quality, for those performers who were rated highest by their collaborating accompanist used more of these self-stimulating adaptors, the movements seeming to offer knowledge of the performer's 'intimate' socio-emotional states.

Are there elite examples of exceptional performance communication?

In building relations, rehearsing and developing an ensemble, it seems that there are elite profiles. Murninghan and Conlon (1991) studied more or less successful string quartets. They noted that the most successful took account specifically of the opinions and behaviours of the second violinist, who could easily feel like the lesser partner to the first violinist. This finding fits well with group behaviour theory that individuals need to adapt to meet the group demand (see Davidson 1997).

The ensemble achieved between siblings might offer insights or examples of special collaborative and communicative advantage, all members having a deep knowledge of one another in terms of abilities, personalities and movement style (adaptive and personal as well as external and more projected behaviours). Examining the Irish pop band, The Corrs, it was surprising to find that the three sisters who perform in the ensemble were quite idiosyncratic, being influenced by the types of musical instruments, the musical tasks they occupied within the band and their personalities (see Kurosawa and Davidson 2005). For example, Andrea was much more extrovert, and employed many more illustrative and display behaviours. Sharon focused on communicating the narrative of the song, her manner was smaller and less demonstrative than Andrea. Caroline was the most reticent and rather than communicative with her sisters and the audience, most of her movements had a regulatory function. Even when performing the same song, Caroline and Sharon use their bodies differently, with Caroline using more emblematic gestures, gaze and general facial expression, and Sharon using regulators and illustrators.

To try to gain insight into these differences, biographical information was collected. It emerged that Caroline is reported to be the most shy, as well as being the youngest sibling. Also, she plays drums, instruments which fully engage the limbs and which operate within the tight constraint of 'keeping the musical pulse', so she may have developed a general performance style which relies entirely on coordinating and regulating rather than exploring expressive content. By contrast, the violin, played by Sharon, has far more movement possibilities, the arms, hands and fingers arguably being used through their mechanical action through the bow and on the strings to create the musical expression. Finally, Andrea is the most clearly defined as a lead vocalist, and perhaps has more freedom for bodily expression as well as being more used to having attention focused on her. So, according to the case study of The Corrs, it would seem that the observed collaboration and movements of the performers reveal aspects of personality and reflect the type of instrument as well as the hierarchy of prominence of position within their ensemble.

Performers certainly seem to manage multiple social tasks: they have to construct the correct ambience in the rehearsal situation, they have to develop their musical material for the audience: whilst they have to interact with their co-performers to coordinate the performance task, they also have to communicate with and sometimes interact with the audience. Frith (1996) observes that a performance involves thoughts and actions to create the performance which relate to: the occasion itself (e.g., 'star-like' postures and gestures of being the 'stage persona'); the music to be performed (the musical material's narrative content; e.g., 'living' out

the qualities of the character depicted in a song); and the individual performer's true states (current mood, sense of self, etc.). This suggests that there is the potential for a tension between the information contained in the music (its own narrative content), the performer's real state (the individual performers on stage, presenting their own personalities), and behaviours they may engage in to present the music and themselves to their co-performers and audience. It would seem that that performers would need to be efficient at managing these aspects in combination.

Successive studies of popular, jazz, classical and traditional Cantonese opera singers (Davidson 2001, 2002; Davidson and Lai 2007 revealed that above all other musical performers, singers clearly adopt the different roles Frith outlines. The roles were revealed, as indicated with The Corrs, in the very different types of behaviours and communication, much being revealed in bodily movement. For instance, Annie Lennox literally 'showed off' to her audience using provocative sexual body postures. The countertenor Michael Chance created a sense of poise and 'performance occasion' by making a large and slow sweeping forward arm movements over the course of the whole introduction to a Bach solo cantata. The Chinese opera singer Amy Wu held an emblematic stance drawing a focused attention to her raised hand which then flickered, illustrating the 'flame of the red candle' (the title of the song) and presenting the story in a bold and dramatic manner to her audience, yet showed her personal shyness and vulnerability in timid small bows and sideways glances after she had finished performing.

With few existing music research models in this area, it is necessary to turn to another field of psychological research, sports psychology, to pursue the implications of such findings in more detail. There has been some investment of research in sports to understand the personal attributes of elite-level performing athletes (see Vealey *et al.* 1998). Subtle theoretical work by Beauchamp *et al.* (2003) has shown that these performers display an acute understanding of 'self', coupled with the capacity to establish very quickly the patterns of behavioural preference of their collaborators—being highly empathic, they are able to embrace the collaborator's (team member) or audience's perspective in performance. So, working within specific traditions, the 'good' music performer is likely to be someone who can indeed play to the demands of both co-performer and audience. The Jungian concepts of being able to think, feel, sense and intuit are presented by Beauchamp and colleagues as being of central importance to the elite performer, with extraverted attitudes of thought (taking action and seeking order) being associated with feelings of being outgoing, and with sensing preferences for the here and now combining with intuitions including creative work, but also having those reflective, sensitive characteristics apparent. Ronglan (2007), who undertook a season-long in-depth case study of an elite women's handball team to look at the process within the team to build for cooperation and collaboration, showed the same types of characteristics to be crucial to success, with personal enthusiasm, willpower, and persistence being stressed as highly desirable attitudes—but also empathy and patience towards others. In sports, such research has been used to assist in developing suitable training programmes to build performer strategy for collaborative team work and solo excellence. There is, of course, such scope in music though frameworks have not been established to undertake such investigations or training programmes. We can look to extremely successful music performer examples, however, to see whether their case fits the theoretical propositions.

Consider Robbie Williams, arguably one of the most loved performers in the world today. His concerts are hugely popular, and investigating the content of his performer–co-performer and audience exchanges in some detail, it is possible to see that a principal concern for him is to create a coherence between himself and the musicians and to engage the audience actively in the performance. An analysis of Williams' singing the song 'She's the one' at the Knebworth Music Festival in 2004 by Davidson (2006) shows that he gestures warmly to his band, making empathic movements in time with their accompaniment and spends time engaging with them on stage. He also runs to greet his audience on a special performance 'catwalk' which stretches out into the crowd. Crucially, the audience 'know Robbie' through extensive exposure on video. The audience 'knows' how he moves and gestures when he adopts his stage persona.

The crowd even begins to make Robbie's own emblematic gestures ahead of him, anticipating the unfurling narrative of the song he is performing. Despite the thousands in the crowd, they whole audience is found to sway, swirl, dance and sing in perfect unison with their idol. Thus, the pop audience has a special kind of attunement to Robbie's stage persona in the performance. Of course much has been learned in viewing preceding music videos, but it is clear that all of this has been translated into the audience's own expectation and knowledge of Williams' and his stage movements. Yet there is more to Robbie than this the 'cheeky chappy' persona. The crowd also seems to have an empathy with Robbie himself—his authenticity and vulnerability. How is this achieved? Robbie connects with individual members within the whole audience, and without showing self-consciousness, he carries out small personal adjustments behaviours such as fiddling with his earpiece. He also speaks to the audience as it if were a single person. Robbie seems to be the consummate musical communicator.

Of course, each individual performance is a unique confluence of new interactive elements, and familiarity with such experiences prepares co-performers for likely scenarios and outcomes: but does the presence of an audience change the quality of musician behaviour?

Movements for audience effect

We know that physical gestures are not prerequisites to understanding either speech or music, such as in a phone conversation or music played on a CD recording. However, since we make fewer gestures when there is no face-to-face contact in both speech and music, it would seem that whilst some gestures are specifically oriented towards generating the music, a proportion would seem to be used for audience communication effects. Differences between musical and audience concerns are demonstrated in the evidence found in the biography of case the Canadian pianist, Glenn Gould.

Early in his career, Gould performed in all the top classical concert venues including Carnegie Hall. Later in his career, he decided to give up public performance, focusing solely on recording studio performances. Delalande (1990) made a study of Gould's performances taken from rare film footage of both periods. What is striking is that in the recording of the studio playing, Gould's movements are highly repetitive and often quite disturbing to watch. By contrast, those of the public recitals have smooth, flowing movements. Thus, there is some evidence that in the studio case, Gould's concerns were entirely focused on the music, whereas in the public context, he was taking into account the audience's presence.

Not every social tradition permits the same social concerns to develop in collaborative performance, however. In Japanese classical music, for example, performers are not supposed to make any extraneous gestures or facial expressions to detract from the emotional content of the music, thus giving relatively few social cues to the audience or indeed their co-performers about their outer expression (Malm 2000).

Studying Indian classical music, Clayton *et al.* (2004) have shown that performers not only use movement gestures to highlight features of the music in a metaphorical way, but they use gestures that are often almost immediately adopted by both their co-performers and audiences. Fascinatingly, a performer may initiate one gesture, such as a head shaking movement, which is then mirrored by another player in the ensemble, and then passed on to members of the audience. The result is that all participants in the event mutually 'tune-in' to the shared moment. It is as if by collaborating in the production of the gestures they are being active participants in the making of the music itself.

Generally, in Western classical music performance, audiences are far more passive, sitting quietly and acknowledging the performance activity with hand clapping, but never as part of the performance itself. In jazz, audiences do take on more of a performance-focused role, toe-tapping and dancing in response to the music. Similar evidence occurs in other culture—Balinese music drama (e.g., McIntosh 2006a, b). However, as the earlier example of Robbie Williams demonstrated, pop performance offers one of the greatest forums where performer and audience can share in a directed but often mutual 'tuning-in' social interaction. We see in the case of Williams that he offers both the self-stimulating

adaptors—the movements seeming to offer knowledge of the performer's 'intimate' states—alongside the projected 'public' states of 'display' (showing off) and emblematic gesture.

Conclusions

It has been demonstrated throughout this chapter that playing a piece of music requires a high-level interaction of developed cognitive and action processes; thus a range of internal representations in memory are necessary. The ability to use mental representations is determined by knowledge and experience. The capacity to generate representations seems to be limitless, with opportunities for learning permitting refinement, adaptation and addition. It is possible to summarize the key points explored as follows:

For performers:

- The body and bodily movement is inherently bound up with the mental representations required to develop musical performance skills
- Musical performance skills involve the biomechanical aspects of playing the music fluently and also expressively
- Technical achievement and expression combine to produce movements with overall fluency, and also local specifically identifiable gestures which are not necessary for note execution, but are essential for the communicative aspects of performance
- These gestures have functions, a first level being to give the music an immediate and communicative purpose for the performer as they create the music product (generating and responding to the musical sounds in a interactional manner between themselves and the music)
- A second level of function is to provide co-performer cues for regulation of musical content and expression of immediate and perhaps idiosyncratic expressive content
- The movements used to generate these stimuli draw from individual movement repertoires, some of which reveal intimate personal states, others of which are for much more direct communicative ends, e.g., end the phrase *now!*
- The original of these movements is likely to be similar to that of non-verbal communication in speech
- The social and cultural origin of the performance tradition out of which a performance is being produced influences the extent and types of communicative movement produced.

For audiences:

- The movements permit accurate perception of musical intention
- The movements offer possibilities for sharing and participation.

Needless to say, understanding bodily movement is a key area for further enquiry for both performers and audiences. Much research still needs to be done to detail systematically the types and functions of all movement in musical performance. Yet however limited our present knowledge, it is obvious that psychological investigations have given musicians and their audiences insights into how crucial bodily movement is to the execution and interpretation of musical performance, and this research area continues to grow.

CHAPTER 35

Emotion in music performance

Patrik N. Juslin

THERE are several features that we have come to expect from an expert performance: technical mastery, confidence, originality, flexibility, and a true understanding of the musical style. Yet the feature that both performers and listeners appear to regard as the most important is that the performer is expressive. The most loved artists are commonly the ones that are able to express and evoke emotions in listeners.

It should be noted at the outset that there are several ways in which emotion might enter into the performance of music: emotions might influence a performer's motivation, choice of repertoire, interpretation, and concentration, as well as the precise nature of the performance. However, there is little systematic knowledge about most of these processes. Previous studies have mainly concerned how performers express emotions, and this chapter will thus focus on this question, though with brief detours to related topics.

First, I provide working definitions of key concepts (e.g., expression, communication), and consider how performers conceive of these issues. Then I review up-to-date evidence on how performers express emotions. Finally, I propose directions for future research.

Conceptual foundations

Music performance, virtually by definition, requires a performer and a piece of music. The term *interpretation* usually refers to the individualistic shaping of the piece according to the musical ideas of the performer (Palmer 1997). This may or may not involve an intention to 'express' something (e.g., an idea, an emotion) beyond the musical structure, although such expression is usually achieved through the way in which the structure is articulated.

Expression will be used in this chapter to refer to a particular set of perceptual qualities that reflect psychophysical relationships between 'objective' properties of the music (patterns of information) and 'subjective' impressions of the listener (e.g., perceiving certain emotions). Sometimes the perception of an expressive performance evokes an emotion in the listener, but this is not required for the listener to hear the music as expressive. We may be able to perceive that a performer is playing expressively, yet we remain untouched by the performance.

Expression has often been treated as a homogeneous category of which there is more or less (Marchand 1975). However, a careful review of the literature suggests that performance expression is better conceived of as a multidimensional phenomenon that can be decomposed into various subcomponents. Drawing on previous research, I have proposed that performance expression derives from five primary sources, referred to as the GERMS model (Juslin 2003):

- *Generative rules (G)* that mark the structure in a musical manner (Clarke 1988). By means of variations in such parameters as timing, dynamics, and articulation, a performer is able to convey group boundaries, metrical accent, and harmonic structure.
- *Emotional expression (E)* that serves to communicate emotions to listeners (Juslin 1997a).

By manipulating overall features of the performance such as mean tempo, a performer is able to play the same structure with different emotional characters.

- *Random fluctuations (R)* that reflect human limitations in motor precision (Gilden 2001). It has been revealed in several studies that even expert performers who try to play perfectly even time intervals show small, involuntary fluctuations in the timing of their performance.
- *Motion principles (M)* that hold that tempo changes should follow natural patterns of human movement, or biological motion, in order to obtain a pleasing shape (Shove and Repp 1995).
- *Stylistic unexpectedness (S)* that reflects a performer's deliberate attempts to 'deviate' from stylistic expectations concerning performance conventions to add tension and unpredictability to the performance (Meyer 1956, p. 206).

In reality, all components occur together in complex interactions, though for specific purposes (e.g., research, teaching), it can be useful to consider them separately (Juslin 2003).

In this chapter, I will focus on emotional expression (for a working definition of emotion, see Chapter 12 this volume), whilst acknowledging that the other aspects are also important (see Chapters 30–34 this volume). In one sense the term 'emotional expression' is misleading: it is only occasionally that performers are truly expressing their own emotions during the performance—perhaps because optimal performance requires a certain psychological state (e.g., relaxed concentration) that is incompatible with experiencing certain emotions. More typically, what the performer presents in a music performance is not the emotion itself, but rather its expressive form—derived from other forms of non-verbal communication. Still, the term 'emotional expression' is now widely established, and has been used in both cases where the expression is 'spontaneous' (genuinely felt) and where it is 'symbolic' (portrayed). I will therefore retain the term in this chapter.

The notion of expression does not require that there is a correspondence between what a listener perceives in the performance and what the performer intends to express. In contrast, the concept of *communication* requires that there is both a performer's intention to express a specific emotion and recognition of this emotion by a listener. The listener may, additionally, come to experience or feel the emotion in question, but this is not required for it to qualify as a case of communication. For a discussion of emotional reactions to music, see Chapter 12.

Performers' views

Issues concerning expression, communication, and emotions tend to invite controversy. However, while philosophers, musicologists, psychologists, and educators commonly express strong views on these issues, it is surprisingly rare that the performers or listeners themselves are consulted. Thus, before reviewing findings from basic research on these issues, it may be appropriate to consider recent findings on performers' views. Lindström *et al.* (2003) carried out a questionnaire study, featuring 135 expert performers from music conservatoires in three countries (England, Italy, Sweden). Open-ended responses to the question 'In your view, what does it mean to play expressively?' were content-analysed and divided into categories. The results revealed that the musicians (both classical and popular) defined 'playing expressively' largely in terms of 'communicating emotions' (44 per cent) and 'playing with feeling' (16 per cent). The two response categories were not always easy to distinguish, although the first focused more on conveying something to an audience, whereas the second focused more on the performer's own feelings. A third group (34 per cent) provided answers in terms of 'a focus on the music itself' (e.g., 'conveying the structure'). Of particular interest is that 83 per cent of the performers reported that they consciously try to express specific emotions in their music performances 'always' or 'often'.

These results were confirmed and extended by Minassian *et al.* (2003), who conducted a survey study, including 53 expert performers of classical music, in order to explore what factors were associated with an 'optimal' performance. Performances judged as optimal tended to be those where the performer had a clear intention to communicate (usually an emotional 'message'), was emotionally engaged with the music, and believed the message had been received by

the audience. Interview studies have further indicated that performers in pursuit of a professional performing career are more inclined to think of music as a vehicle for communication than performers in pursuit of a non-music career (Burland and Davidson 2004), and that many performers value music as a form of emotional outlet (Gullberg and Brändström 2004).

Research paradigms

There is an immense number of historical treatises that feature very detailed descriptions or prescriptions concerning the performance practices that may be used to enhance emotional expression (Bach 1778/1985; Buelow 1983; Mattheson 1739/1954). Most of these writings, however, are based on speculation, intuition, folk theory, or personal experience –which may or may not be correct.

Systematic attempts to investigate emotional expression—as manifested in performance features (e.g., timing, timbre) rather than features of particular pieces of music (e.g., melody, mode)—developed only in the mid-1990s. Most investigations used the so-called *standard paradigm* (a term borrowed from studies of vocal expression of affect; e.g., Juslin and Scherer 2005): this means that musicians are asked to play brief melodies to express various emotions chosen by the researcher. The resulting performances are first recorded and then evaluated in listening experiments to check whether listeners can recognize the intended expression. Each performance is further analysed to study what acoustic means each performer used to achieve each emotional expression. The basic assumption is that because the melody remains the same in different emotional expressions, whatever effects that are found in listeners' judgements or acoustic measures should mainly be the result of the performer's expressive intention. Having performers play the same piece with different emotional expressions might appear 'unnatural' from a musical point of view. However, this design is necessary to secure the internal validity of the experiments: if different emotions are expressed by different melodies, it is impossible to know whether the obtained effects on listener judgements or performance measures are due to the melody, the performance, or some interaction between the two.

However, there is no denying that this is a fairly artificial set-up, even though musicians sometimes do try alternative interpretations of the same piece (Lindström *et al.* 2003). Hence, it is paramount to try other approaches to investigating emotional expression in performances, such as analysing existing recordings of performances (Siegwart and Scherer 1995), observing a performer from the preparation of a piece to a concert performance (Clarke *et al.* 2005), or investigating listeners' responses to performance in a real concert using questionnaire (Thompson 2006).

Can performers communicate emotions accurately to listeners?

It might appear strange to talk about accuracy of communication in a musical context. However, it is reasonable to assume that most performers are concerned about whether their interpretation is perceived by the audience in the manner that they intended it. The performer may, for instance, wish to highlight an emotional character in the piece. The degree to which performer and listeners 'agree' about the expression of the performance can pragmatically be seen as a measure of the accuracy of the communication. Listeners' judgements can be indexed in terms of adjective ratings (Juslin 1997a), forced choice (Juslin 1997b, Experiment 1), free labelling (Juslin 1997c), or continuous response (Sloboda and Lehmann 2001).

Juslin and Laukka (2003) reviewed 41 studies of emotional expression in performance. The studies covered a wide range of musical styles such as classical music, folk music, Indian ragas, jazz, pop, rock, children's songs, and free improvisations. The most common style was classical music (17 studies = 41 per cent). The number of emotions studied ranged from 3 to 9 (M = 4.98), and typically included happiness, sadness, anger, fear, and tenderness. Twelve musical instruments and twelve nationalities were included. Most studies used professional performers and the performances were mostly monophonic to facilitate acoustic measurements.

Juslin and Laukka conducted a meta-analysis of communication accuracy featuring 29 studies, which indicated that performers are able to

communicate 'basic emotions' (happiness, anger, sadness, fear, and tenderness) to listeners with an accuracy approximately as high as in facial and vocal expression of emotions. Overall decoding accuracy was equivalent to a 'raw' proportion correct of $P_c = 0.70$, in a forced-choice task with five response alternatives. Across studies, sadness and anger were the emotions that were communicated with the highest level of accuracy, and this pattern was found for both music performance and vocal expression. The available evidence suggests that the communication proceeds in terms of fairly broad emotion categories, whereas finer distinctions within these categories are hard to communicate reliably—at least, without some additional context. In general, commonly postulated 'basic' emotions are easier to communicate than 'complex' emotions. For explanations, see p. 385–386.

The accuracy depends on a number of variables (e.g., the piece, the response format, the procedure), yet perception of emotions in music is robust in that listeners' judgements are only marginally influenced by musical training, age, and gender of the listener (see Gabrielsson and Juslin 2003). That musical training is not required to express (Yamasaki 2002) or recognize (Juslin 1997a) emotion in music performance suggests that general mechanisms of perception of emotions are involved—which is supported by the finding that abilities to decode emotions in music performance are correlated with measures of emotional intelligence (e.g., Resnicow *et al.* 2004). Developmental studies of perception of emotions in music have not clearly separated performance features (e.g., tempo, timbre) from compositional features (e.g., melody, harmony), but preliminary evidence from several studies indicates that that children as young as 3 or 4 years old are able to decode 'basic emotions' from music with better than chance accuracy (for a review, see Juslin and Laukka 2003, p. 788). The ability appears to improve with age, but declines again in old adults (Laukka and Juslin 2007).

How are different emotions communicated?

Most of the processes that underlie communication of emotions in music are implicit—which helps to 'mystify' the nature of expression (see Juslin *et al.* 2004). One of the pioneers in research on emotional expression in music more generally (e.g., Chapter 13), Kate Hevner (1935), observed:

> If the great artist could speak to the audience verbally as effectively as he does musically, our efforts would be unnecessary, but seldom he expresses himself except through the medium of his art, and when he does, it is usually not in the terms calculated to be most useful and helpful.
>
> (p. 204)

Hence, psychologists are forced to explore the mechanisms by means of acoustic measurements, commonly carried out using computer software. Table 35.1 presents a summary of the most important acoustic parameters and also explains how they are measured. In the following, I shall refer to these parameters as *cues* (bits of information) that together make up the code used to communicate various emotions. Researchers have recently developed computer algorithms that can help to speed up the otherwise complicated and time-consuming process of manually analysing the cues (Friberg *et al.* 2007).

Code description

Table 35.2 shows a summary of cues that are correlated with specific emotions in musical expression. For completeness, the table includes cues that are commonly part of the musical structure (for further discussion of structural features, see Chapter 13). However, those cues that can usually be controlled or modulated by the performer are set in italics. While Table 35.2 is limited to a few emotion categories (i.e., those that have been explored most frequently in previous research), one can easily imagine how the categories can be combined or 'mixed' in various ways, and also how the expression can be altered during a performance. Some of the cues shown in Table 35.2 may be common knowledge to most performers, whereas other cues are less obvious. The number of cues available depends on the instrument used. Other things being equal, the communication will be more reliable the more cues that are available. The results suggest that tempo, sound level, timbre and

Table 35.1 Definition and measurement of primary acoustic cues in emotional expression in music performance

Acoustic cues	Perceived correlate	Definition and measurement
Pitch		
Fundamental frequency (F0)	Pitch	Acoustically, F0 is defined as the lowest periodic cycle component of the acoustic wave form. One can distinguish between the macro pitch level of particular musical pieces, and the micro intonation of the performance. The former is often given in the unit of the semitone, the latter is given in terms of deviations from the notated macro pitch (e.g., in cents).
F0 contour	Intonation contour	Sequence of F0 values. In music, intonation refers to manner in which the performer approaches and/or maintains the prescribed pitch of notes, in terms of deviations from precise pitch.
Vibrato	Vibrato	Periodic changes in the pitch (or loudness) of a tone. Depth and rate of vibrato can be measured manually from the F0 trace (or amplitude envelope).
Intensity		
Intensity	Loudness	Intensity is a measure of the energy in the acoustic signal. Usually measured from the amplitude of the acoustic wave form. The standard unit used to quantify intensity is a logarithmic transformation of the amplitude called the decibel (dB).
Attack	Rapidity of tone onsets	Attack refers to the rise-time or rate of rise of the amplitude of individual notes. Usually measured from the acoustic wave form.
Temporal features		
Tempo	Velocity of music	The mean tempo of a performance is obtained by dividing the total duration of the performance until the onset of its final note by the number of beats, and then calculating the number of beats per minute (bpm).
Articulation	Proportion of sound to silence in successive notes	The mean articulation of a performance is typically obtained by measuring two durations for each tone—the duration from the onset of a tone until the onset of the next tone (dii), and the duration from the onset of a tone until its offset (dio). These durations are used to calculate the successive dio:dii ratio (the articulation) of each tone. These values are averaged across the performance and expressed as a percentage. A value around 100% refers to legato articulation; a value around 70% or lower refers to staccato articulation.
Timing	Tempo and rhythm variation	Timing variations are usually described as 'deviations' from the nominal values of a musical notation. Overall measures of the amount of deviations in a performance may be obtained by calculating the number of notes whose deviation is less than a given percent of the note value. Another index of timing changes concerns so-called durational contrasts between 'long' and 'short' notes in rhythm patterns. Contrasts may be played with 'sharp' durational contrasts (close to or larger than the nominal ratio) or with 'soft' durational contrasts (a reduced ratio).

Continued

Table 35.1 Definition and measurement of primary acoustic cues in emotional expression in music performance (*continued*)

Acoustic cues	Perceived correlate	Definition and measurement
Timbre		
High-frequency energy	Timbre	Refers to the relative proportion of total acoustic energy above versus below a certain cut-off energy in the frequency spectrum of the sound wave. In music performance, timbre is in part a characteristic of the specific instrument. However, different techniques of playing may also influence the timbre of many instruments, such as the guitar.
The singer's formant	Timbre	The singer's formant refers to a strong resonance around 2500—3000 Hz, and adds brilliance and carrying power to the voice. It is attributed to a lowered larynx and widened pharynx, which forms an additional resonance cavity.

Table 35.2 Summary of cues correlated with specific emotions in musical expression

Emotion	Cues
Happiness	*fast tempo*, *small tempo variability*, major mode, simple and consonant harmony, *medium-high sound level*, *small sound level variability*, high pitch, much pitch variability, wide pitch range, ascending pitch, perfect 4th and 5th intervals, *rising micro intonation*, *raised singer's formant*, *staccato articulation*, *large articulation variability*, smooth and fluent rhythm, *bright timbre*, *fast tone attacks*, *small timing varibility*, *sharp contrasts between 'long' and 'short' notes*, *medium-fast vibrato rate*, *medium vibrato extent*, *micro-structural regularity*
Sadness	*slow tempo*, minor mode, dissonance, *low sound level*, *moderate sound level variability*, low pitch, narrow pitch range, descending pitch, *'flat' (or falling) intonation*, small intervals (e.g., minor 2nd), *lowered singer's formant*, *legato articulation*, *small articulation variability*, *dull timbre*, *slow tone attacks*, *large timing variability* (e.g., rubato), *soft contrasts between 'long' and 'short' notes*, *pauses*, *slow vibrato*, *small vibrato extent*, *ritardando*, *micro-structural irregularity*
Anger	*fast tempo*, *small tempo variability*, minor mode, atonality, dissonance, *high sound level*, *small loudness variability*, high pitch, moderate pitch variability, ascending pitch, major 7th and augmented 4th intervals, *raised singer's formant*, *staccato articulation*, *moderate articulation variability*, complex rhythm, sudden rhythmic changes (e.g., syncopations), *sharp timbre*, *spectral noise*, *fast tone attacks/decays*, *small timing variability*, *accents on tonally unstable notes*, *sharp contrasts between 'long' and 'short' notes*, *accelerando*, *medium-fast vibrato rate*, *large vibrato extent*, *micro-structural irregularity*
Fear	*fast tempo*, *large tempo variability*, minor mode, dissonance, *low sound level*, *large sound level variability*, *rapid changes in sound level*, high pitch, ascending pitch, very wide pitch range, large pitch contrasts, *staccato articulation*, *large articulation variability*, jerky rhythms, *soft timbre*, *very large timing variability*, *pauses*, *soft tone attacks*, *fast vibrato rate*, *small vibrato extent*, *micro-structural irregularity*
Tenderness	*slow tempo*, major mode, consonance, *medium-low sound level*, *small sound level variability*, low pitch, fairly narrow pitch range, *lowered singer's formant*, *legato articulation*, *small articulation variability*, *slow tone attacks*, *soft timbre*, *moderate timing variability*, *soft contrasts between long and short notes*, *accents on tonally stable notes*, *medium-fast vibrato*, *small vibrato extent*, *micro-structural regularity*

pitch are the most powerful cues in terms of their effects on listeners' ratings (see Juslin 1997b; Juslin and Madison 1999; Scherer and Oshinsky 1977). Certain instruments might be more effective in communicating certain emotions than others depending on their specific timbre (Behrens and Green 1993; Bunt and Pavlicevic 2001). The focus on 'basic emotions' is sometimes criticized, though findings from survey studies of both music performers (Lindström *et al.* 2003) and listeners (Juslin and Laukka 2004) suggest that they regard these emotions as the ones that are easiest to express via music, and they thus represent a natural point of departure from which more 'complex' emotions may gradually be investigated. See Juslin *et al.* (2004, Table 13.2) for examples of complex emotions.

Expressive patterns and ornamentation

Most studies in the field so far have focused on cues that are applied in much the same way, and to much the same extent, throughout a piece. Indeed, experiments suggest that 'overall' levels of cues, such as mean tempo, explain considerably more variance in listeners' emotion ratings than does variability (e.g. Madison 2000). However, there exist patterns of changes in tempo and dynamics that are characteristic of particular emotions. Listening tests using systematic manipulations of synthesized (Juslin 1997b) or real performances (Juslin and Madison 1999) indicate that such patterns may be used by a listener to decode the emotional expression. What is it in these patterns that conveys the relevant information? One clue comes from the study by Lindström (1999), who found that performers accentuated different aspects of the melodic structure of a piece depending on the intended expression; thus, for example, if a certain note in the melodic structure was regarded as especially 'happy', then the performers emphasized this note in happiness expressions, but de-emphasized it in sadness expressions.

Another structure-related aspect of emotional expression in performances that has been little investigated is *ornamentation*, the use of expressive features that are not necessary to the melodic or harmonic line, but only serve to decorate that line. Historical performance treatises feature extensive discussions of ornaments, and they may be especially important in Baroque music (e.g. Bach 1778/1985; Neumann 1978). Standard ornaments include the trill (a rapid alternation between two notes), the mordent (a rapid, single alternation between two notes), the glissando (a continuous slide upwards or downwards between two notes), and the appoggiatura (a grace note which delays the next note of the melody, taking half or more of its written time value). A first attempt to investigate the use of ornaments in the expression of specific emotions was made by Timmers and Ashley (2007). They analysed performances of fragments from Handel's G-minor sonata for recorder and basso continuo (HWV 360) by a flutist and a violinist and found that the use of ornaments varied according to the intended expression. Figure 35.1 shows examples of the ornaments use to express the various emotions.

Synthesis of emotional expression

Performance analyses have shown that performers can use a number of cues to express particular emotions. However, these analyses do not prove that listeners actually *use* the same cues in their judgements. To take just one example, the above study of ornaments showed that a performer used ornaments differently to express various emotions, but it did not prove that a listener could actually utilize any of these ornaments to decode the intended expression. Thus, to test the validity of hypotheses about expressive cues derived from performance studies, it is necessary to conduct listening experiments with synthesized performances. Note that there are two different approaches to synthesis of emotional expression in performance that can answer different questions. Based on a distinction introduced by Brunswik (1956), I have called them *representative design* and *systematic design* (Juslin 1997b).

Representative design means that one tries to recreate the emotional expressions of real music performances by programming a computer to perform in accordance with the emotion-specific patterns of acoustic cues obtained in previous studies (Table 35.2). Ideally, the patterns used to synthesize the emotional expression should be 'representative' of real performances in the

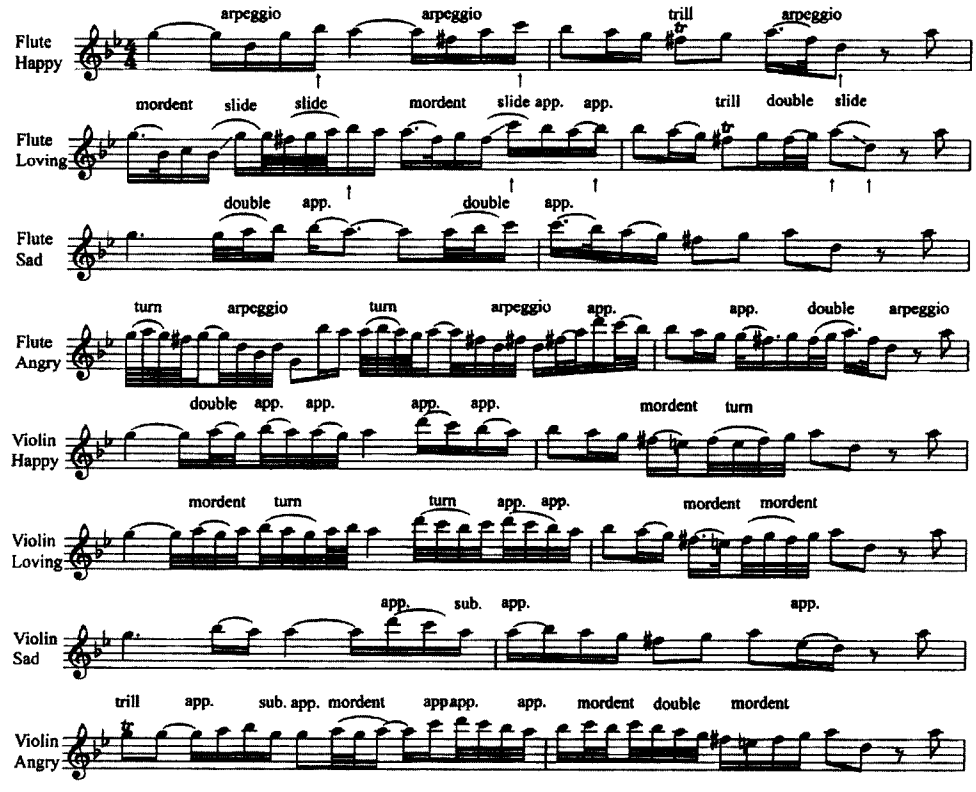

Fig. 35.1 Examples of ornaments used by a flutist and a violinst in music performances intended to express 'basic emotions' (from Timmers and Ashley 2007). Reprinted by permission of the University of California Press.

sense that they display similar statistical characteristics (e.g., cue intercorrelations, means, and standard deviations). Preliminary studies have shown that one can program a computer to communicate emotions with the same level of accuracy as a human performer (Juslin 1997b, Experiment 1; see also Bresin and Friberg 2000). However, such synthesized performances do not sound as musically satisfying as human performances do, perhaps because they lack other expressive features, such as marking of structure, biological motion, and random fluctuations, that are also important (Juslin *et al.* 2002). A representative design is useful when comparing the decoding accuracy of real and synthesized performances, although it cannot prove that the implementation of an individual cue is correct, or even that listeners are using the cue.

To be able to unambiguously attribute variance in a listener's judgements of emotions to individual acoustic cues, one needs to use a systematic design, or more specifically a factorial design. Such a design removes all the intercorrelations among cues, and renders it possible to ascertain the effectiveness of individual cues. Notably, only some of the performance cues in Table 35.2 have been tested in this way (Juslin 1997b, Experiment 2; see also Scherer and Oshinsky 1977). The lack of independent cue manipulation may explain why some early studies of emotional expression in music reported that some cues were associated with opposing emotional expressions.

A theoretical approach

Origin of the code

Juslin (1997a, 2000, 2001) proposed that the acoustic code used in emotional expression in

music performance reflects two primary factors. The first factor is innate patterns for vocal expressions of 'basic emotions'. According to this notion—partly inspired by Herbert Spencer (1857)—the origin of the 'expressive code' is to be found in involuntary and emotion-specific physiological changes associated with emotional reactions, which strongly influence different aspects of voice production (for a review of the relationships among emotion, physiology, and voice, see Juslin and Scherer 2005). This notion was later named 'Spencer's law' by Juslin and Laukka (2003), who also offered strong empirical support from an extensive meta analysis of parallels between vocal and musical expression of emotions. One implication of this finding is that 'basic emotion' categories will be privileged, because of their biological preparedness for effective communication. This is not to deny that more precise emotional contents can also be conveyed under certain circumstances (e.g., through social or musical convention).

The second factor governing emotional expression in performance is social learning of various forms. This is a life-long process, beginning with the early interaction between mother and infant. (In fact, this 'imprinting' process might begin even prior to birth; see Chapter 20.) For example, when mothers talk to their infants, if they want to calm their infant, they reduce the tempo and intensity of their speech, and talk with slowly falling pitch contours, whereas if they want to express disapproval towards some unfavourable activity, they employ brief, sharp, and staccato-like contours (Papoušek 1996). Although the code used by mothers seems to be universal, the expressive style of the mother modulates the expressive style of the infant. This modulation of expressive skills continues throughout life, as one accumulates experience and learns links between cues and extra-musical phenomena, such as movement (see Chapter 34).

Nature of the code: modelling the communicative process

Studies of emotional expression in music performance present some puzzling findings, which can only be explained if the nature of the communication process is explored in greater detail. For instance, how can the communicative process usually be successful despite the fact that different instruments offer different cues, and that there are so wide individual differences among performers in expressive style? One way of capturing the crucial characteristics of the communicative process is to conceptualize it in terms of a variant of Egon Brunswik's (1956) *lens model*, as first suggested and implemented by Juslin (1995, 2000).

The modified lens model (Figure 35.2) captures how a performer 'encodes' (i.e., expresses) emotions by means of a set of acoustic cues (e.g., variations of tempo, sound level, or timbre) that are probabilistic (i.e., uncertain) and partly redundant. The emotions are 'decoded' (i.e., recognized) by listeners, who utilize these same cues to 'infer' the expression. The cues are probabilistic in that they are not perfectly reliable indicators of the intended expression. For example, a fast tempo is not a perfectly reliable indicator of happiness expressions, because a fast tempo occurs also in anger expressions. Thus, relationships among cues and emotions are merely correlational—they do not have a one-to-one mapping. Consequently, performers and listeners have to combine the cues for reliable communication to occur. However, this is not just a matter of pattern matching, because cues contribute in an additive fashion to listeners' judgements—each cue is neither necessary, nor sufficient, but the larger the number of cues used, the more reliable the communication. The redundancy among cues partly reflects how sounds are produced on musical instruments (e.g., a harder string attack produces a tone that is both louder and sharper in timbre). A mathematical formulation of the relationships among the various parts of the lens model, *the lens model equation*, was first formulated by Hursch *et al.* (1964). When applied to music performance (Juslin 2000), it allows one to explain the success (or not) of the communicative process by decomposing it into different components (e.g., the consistency of cue utilization, the degree to which the performer's cue utilization is matched to the listeners' cue utilization). Such a decomposition is highly useful if one wants to improve the communicative process (for evidence, see Juslin *et al.* 2006).

Although the lens model may appear simple, it has a crucial implication for research on

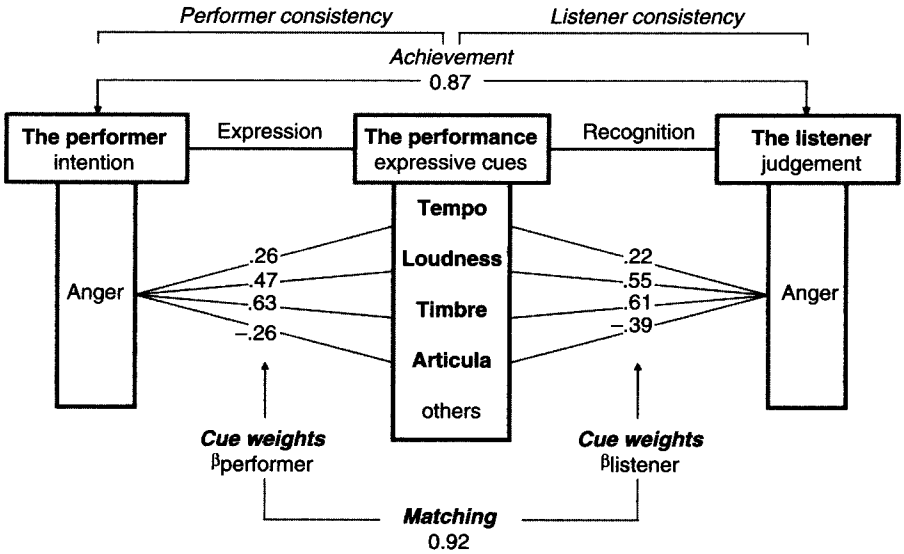

Fig. 35.2 Modified lens model of communication of emotions in music performance (adapted from Juslin 1995). *Achievement* (r_a) refers to the relationship between the performer's intention (e.g., intending to express sadness) and the listener's judgement (e.g., perceiving sadness). It is a measure of how well the performer succeeds in communicating an emotion to listeners. *Cue weight* (β_1, β_2, β_3 ...) refers to the strength of the relationship between a cue (e.g., tempo), on the one hand, and a performer's intentions or listeners' judgements, on the other. *Matching* (G) refers to the degree of similarity between the performer's and the listeners' use of acoustic cues, respectively. *Consistency* (R_e and R_s) refers to the degree of consistency with which the performer and listeners, respectively, are able to use the cues.

communication: if the cues are redundant to some extent, more than one way of using the cues may lead to a similarly high level of decoding accuracy, because different cues may substitute for one another—so-called *vicarious functioning*. Hence, Brunswik's lens model may explain why there is accurate communication of emotions even when the cues are used inconsistently across different performers or pieces of music. Multiple cues that are partly redundant yield a robust communicative system that is forgiving towards deviation from optimal cue utilization. Therefore, researchers should not expect acoustic cues in expressive performances to conform rigidly to the patterns shown in Table 35.2; the communicative system is so robust that perfect consistency is not required. Robustness comes with a price, however. The redundancy of the cues means that the same information is conveyed by many cues. This limits the information capacity, which is another reason why 'basic emotion' categories are the easiest to convey.

The 'original' version of the lens model was limited to performance cues (Juslin 2000), but listeners' perception of emotions may also be affected by interactions between composer and performer cues. Hence, we have suggested an *expanded lens model* (Juslin and Lindström 2003; see Figure 35.3) in which both composer cues and performance cues are included to make it possible to explore their relative contributions. Furthermore, important interactions between performer and composition cues are included as separate predictors in the regression model. An experimental study based on this framework, using synthesized and systematically varied pieces of music, showed that about 75–85 per cent of the variance in listeners' emotion ratings could be explained by a linear combination of the main effects alone. Moreover, results suggested that the interactions between

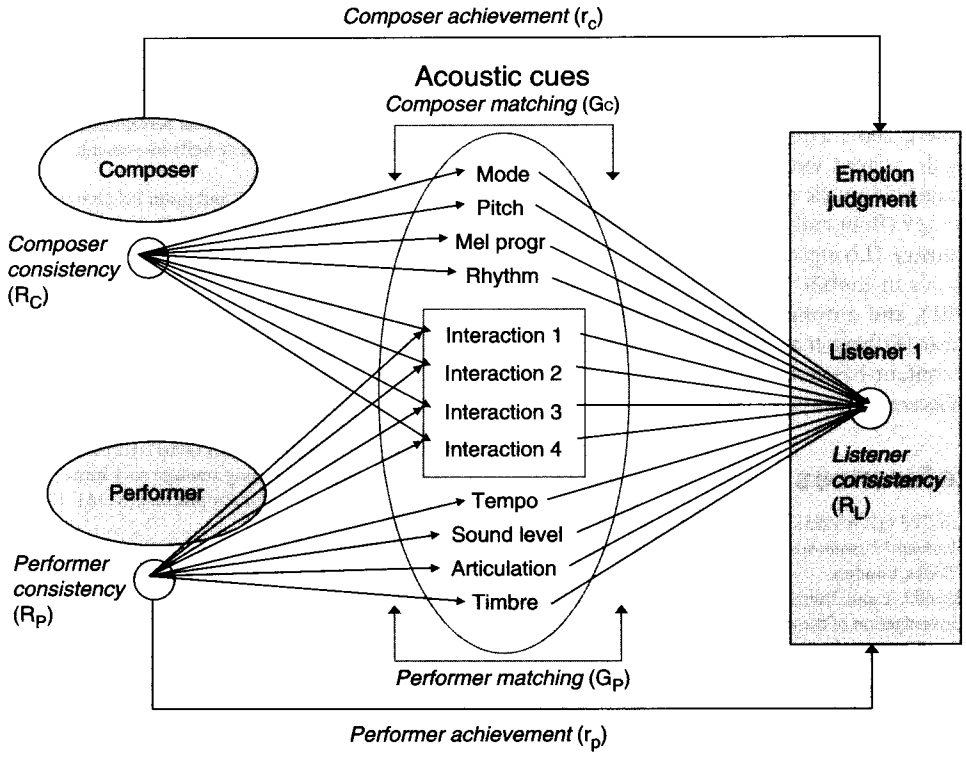

Fig. 35.3 Extended lens model of communication of emotions in music (from Juslin and Lindström 2003).

composer and performer cues made small—although not negligible—contributions to the predictive power. That the cues contribute primarily in an additive fashion to judgements is partly why the communicative process is so robust, because additive cues may compensate for one another in ways that multiplicative cues cannot.

Directions for future research

As revealed by this review, researchers have made much progress in understanding how music performers are able to communicate emotions via music performances. However, there are several limitations that need to be addressed in future research. One limitation is that the studies thus far have focused mainly on Western music (but see Balkwill and Thompson 1999; Clayton 2005). Hence, it remains to be seen how much of the results will generalize to other musical cultures. Even within the current culture, more research is required to examine more subtle, style-specific aspects of expression that contribute to the communicative process (e.g., ornamentation). Another important future direction is to study more closely how the different aspects of expression (e.g., structure marking, emotional expression, motion) interact with one another (Juslin *et al.* 2002). So far, the components have been studied either separately, or as if they all consisted of a homogeneous single entity. Closer collaboration among performance researchers within different subspecialties represents a promising avenue towards a deeper understanding of performance expression in all its complexity. One further topic that currently receives increasing attention is the influence of other perceptual channels. While most studies of expression in music performance have focused

composer and performer cues made small—although not negligible—contributions to the predictive power. That the cues contribute primarily in an additive fashion to judgements is partly why the communicative process is so robust, because additive cues may compensate for one another in ways that multiplicative cues cannot.

Directions for future research

As revealed by this review, researchers have made much progress in understanding how music performers are able to communicate emotions via music performances. However, there are several limitations that need to be addressed in future research. One limitation is that the studies thus far have focused mainly on Western music (but see Balkwill and Thompson 1999; Clayton 2005). Hence, it remains to be seen how much of the results will generalize to other musical cultures. Even within the current culture, more research is required to examine more subtle, style-specific aspects of expression that contribute to the communicative process (e.g., ornamentation). Another important future direction is to study more closely how the different aspects of expression (e.g., structure marking, emotional expression, motion) interact with one another (Juslin *et al.* 2002). So far, the components have been studied either separately, or as if they all consisted of a homogeneous single entity. Closer collaboration among performance researchers within different subspecialties represents a promising avenue towards a deeper understanding of performance expression in all its complexity. One further topic that currently receives increasing attention is the influence of other perceptual channels. While most studies of expression in music performance have focused

only on auditory features, it seems that visual features of the performer can also make important contributions to the perceived expression of the music in live settings (see Dahl and Friberg 2007; Thompson *et al.* 2005). Finally, much current work concerns applications of findings in music education (Juslin *et al.* 2006), therapy (Bunt and Pavlicevic 2001), the gaming industry (Livingstone and Brown 2005), ring signals in mobile phones (Bresin and Friberg 2001), and automatic analysis of emotions in music (Friberg *et al.* 2007) which might be used in content-based music searches at the Internet (Wieczorkowska *et al.* 2005).

CHAPTER 36

Optimizing physical and psychological health in performing musicians

Dianna T. Kenny and Bronwen Ackermann

Introduction

Performing musicians face a number of physical, social and psychological challenges that must be mastered if their musical career is to be both rewarding and sustainable. However, musicians are at high risk of physical and psychological strain and injury in the execution of their art. Physical and psychological stressors exert reciprocal and synergistic effects on the musician, and careful analysis of the intrinsic characteristics of the performer and the extrinsic demands on the musician must be made in order to develop appropriate interventions. In this chapter we provide an overview of the risks and challenges facing musicians with the aim of developing awareness and understanding of how to prevent and manage these challenges. The chapter is divided into two sections: physical challenges and psychological challenges, focusing on music performance anxiety. In each section, we outline the key issues and then provide an overview of evidence-based treatment.

Physical health issues

Musicians are like athletes because both require superior sensorimotor integration (Alternmuller *et al.* 2000), neuro-musculoskeletal skill and many hours of training and practice to achieve mastery (Tubiana 2000). Several large epidemiological studies have shown high physical injury rates among musicians (Manchester 2006). Performer-related risk factors for injury include poor posture, poor physical condition, inadequate instrument set-up, long hours of playing, insufficient rest breaks and inefficient movement patterns (or poor technique) (Ackermann and Adams 2004a).

Although musicians may suffer injury from non-performance related causes such as lifting and carrying awkward or heavy instruments and suitcases (when on tour), demanding work schedules, sitting on poorly designed orchestral chairs, temperature variations (Manchester 2006), demanding repertoire and poor visibility of music scores (Horvath 2002), the majority of musicians' injuries are over-use injuries (Dawson *et al.* 1998) with soft-tissue symptoms predominating (Pascarelli and Hsu 2001).

Musicians of all ages and levels of skill are vulnerable to injury, but the risk increases as hours of playing increases. The neck, upper limbs and lower back (Fjellman-Wiklund *et al.* 2003) are vulnerable with upper limb over-use injuries comprising 75–85 per cent of all injuries (Slade *et al.* 1999). Strains of the muscle–tendon unit predominate, with other common problems including inflammatory disorders such as tenosynovitis, arthritic problems and hypermobility (also called double-jointedness) i.e. joints that stretch more than normal (Dawson 2002). People with hypermobile joints may be more easily injured and may be more at risk of developing problems from muscle over-use, as muscles must work harder to control joint movement.

Injury types vary according to instrument type, gender (Engquist *et al.* 2004), years of performing, repertoire, hours of practice and age (Warrrington *et al.* 2002). Older musicians more typically develop degenerative conditions (i.e. conditions that have a gradual deterioration in the structure of a body part with a consequent loss of the part's ability to function) while younger musicians suffer more from performance-related musculoskeletal pain (Warrington *et al.* 2002).

Effective training for any athletic pursuit, including music performance, involves a fine balance between working hard enough to continually improve performance, while simultaneously resting enough to avoid incurring an over-use injury, a task assisted by specifically designed cross-training programmes (Marieb 2001). Muscle fatigue, which may arise from central (brain) or peripheral (muscle) fatigue (Gandevia 2001) due to over-practising without adequate rest breaks (Ackermann and Adams 2004a) may be a factor in developing altered movement patterns that can be a precursor to injury. Exercise aimed at conditioning muscles may reduce the effect of muscle fatigue by increasing muscle cross-sectional area and creating neural adaptations that lead to an improved ability to recruit motor units (Herbert 1993).

Types of injuries

Muscle/tendon injuries

Muscles are the primary source of force needed for the performance of motor skills such as instrumental playing. An occupational over-use injury may result from insufficient muscle tolerance to cope with the quality, quantity and rate of task demands (Hagberg *et al.* 1997). Dynamic postures are less likely to cause pain than static postures due to the short rests that occur between the bursts of activity of muscles involved in dynamic movements (Vergara and Page 2002). Some strategies for musicians within task-constraints are possible for small-scale movements that can allow these dynamic motions to occur (Rolland 1974). Pablo Casals intentionally practised relaxing between phrases, no matter how difficult the material, to minimize the build up of adverse muscle tension (Ma 1986).

Joint injuries

Joint injuries in musicians are degenerative, likely to be related to repetitive use, but more specifically to regional overload. For example, the right thumb of a clarinettist carries the whole weight of the instrument and shows early degenerative changes (Chesky *et al.* 2000). Ergonomic devices such as a neck strap to carry the weight of the clarinet may effectively reduce strain on the thumb, although long-term effects of transmitting this load through the neck are unclear (Chesky *et al.* 2000).

Nerve compression disorders

Nerve compression syndromes in musicians are related to the demands and nature of musicians' work, such as sustained awkward positions, sustained muscle contraction pressure, or the compression arising from having to support the instrument itself (Spinner and Amadio 2000). Common nerve-entrapment disorders include symptoms from compression of the ulna nerve at the elbow, the median nerve at the wrist, cervical radiculopathies, occasional digital neuropathies and symptomatic thoracic outlet syndrome (Schuele and Lederman 2004).

Central nervous system disorders

The most common performance-related condition of the central nervous system (CNS) affecting musicians is focal dystonia, a movement dysfunction syndrome thought to be due to disruptions between central sensory processing and motor output (Chen and Hallett 1998). Focal dystonias involve abnormal, often twisting movements that tend to affect performers in a similar way, with the left ring finger the main reported site of the dysfunction in violinists (Hochberg and Hochberg 2000). While a definitive cause remains unclear, the amount of movement repetition is a major factor in developing dystonias (Hochberg and Hochberg 2000), and these are potentially more potent if abnormal biomechanical factors are present (Wilson 2000).

Treatment

Treatment, assessment and management procedures are still largely based on clinical experience rather than scientific research (Schuele and Lederman 2004). A primary goal of treatment is

not only relief of symptoms but restoration of function, addressing both local and general effects of an injury (Herring and Kibler 1998). Psychological factors may be involved in the genesis or maintenance of physical problems. Spahn *et al.* (2001) found significant rates (25%) of somatization and somatoform disorders in musicians presenting to hand surgery clinics. Most of their sample (75%) did not attribute their current physical problems to psychosocial factors, even though there was no identified organic cause for their physical problems. The authors concluded that psychosomatic aspects play a decisive role in somatic problems of musicians and that these should be addressed in treatment to avoid unwarranted medical interventions.

Rest and rehabilitation

There is no benefit from prolonged rest for soft tissue injuries in the majority of cases (Nash *et al.* 2004). Scott (1997) defines the term rest for soft tissue injuries with the mnemonic 'Resume Exercise below Soreness Threshold', and emphasizes the importance of continuing to play in a reduced and careful fashion wherever possible without causing aggravation of the injury. Guidelines for rehabilitating sports overuse injuries stress the importance of relative rest, where overall fitness is maintained even in the acute stage of an injury while rehabilitating the injured part back to performance requirements (Herring and Kibler 1998). Relative rest can be achieved if necessary with the assistance of splints or ergonomic aids.

Poor muscle balance around the shoulder girdle is frequently considered to be a cause of upper limb symptoms in the musician, and restoring a good balance of muscle condition as well as strengthening postural muscles in this area is an important part of rehabilitation (Chamagne 2000).

Retraining

Retraining is used for the treatment of both neurological and musculoskeletal conditions occurring in musicians. Some treatment approaches for focal dystonia include splinting with specific exercises (Candia *et al.* 1999), postural and movement retraining strategies (Chamagne 2000), proprioceptive and sensory retraining techniques (Ackermann and Adams 2005), and the slow-down exercise regime involving task-specific music drills (Sakai 2006). Movement patterns can be re-trained by restoring good muscle balance and functioning of the arm as a whole kinetic chain unit to correct any underlying mechanical inefficiencies (Dreyer and Boden 1999).

Manual therapy

Trigger point therapy may be useful for soft tissue problems, particularly when palpation of active trigger points reproduces the musicians' symptoms (Davies 2002). Joint mobilization techniques of the cervical spine, thoracic spine, forearm, wrist and hand are necessary to restore full functional range of movement for musicians following an injury (Kember 1998).

Prevention of playing-related injuries

Prevention is the best form of management for occupational over-use injuries (Melhorn 1998). Key factors in injury prevention include awareness of correct postural requirements, technique and biomechanics involved in playing one's instrument, and maintaining overall good physical condition that is achieved by warming up, stretching (Zaza 1994) and strength and endurance training (Marieb 2001).

Posture

Correct posture minimizes stress applied to each joint. Poor posture, defined as a 'faulty relationship of the various segments of the body, producing increased stress on supporting structures' (Aaras *et al.* 2001), is a major risk for injury because musicians have to maintain awkward, relatively static postures over extended time periods (Brandfonbrener 2000). Musicians must maintain their posture within physiological boundaries, even with asymmetrical instruments such as the violin and flute, with good proximal muscle support and weight balance to avoid injury and to allow optimal fine control of movements during performance (Tubiana *et al.* 1989). The musical instrument should be considered as an extension of the musicians' body (Dommerholt 2000).

Ideal sitting posture alignment occurs with hips and knees at 90° of flexion, with a 10° backward

inclination of a supportive back on the chair (Kendall *et al.* 1993), or a level seat and a backrest set back 20° to minimize lumbar loadings (Bonney and Corlett 2002). Sitting should also be balanced between sides by weight-bearing evenly on both sides, as excessive weight-bearing on one side may lead to lateral stresses on the lumbar discs (Cailliet 1990).

Technique, biomechanics and physical condition

Within a technique or movement pattern on a musical instrument, early more rigid movements are replaced by efficient movements within anatomical and task constraints as the skill is mastered (Sparrow and Newell 1998). Musicians working under pressure may be so focused on achieving a musical goal that a distortion of technique or posture occurs, and these aberrations may then become established in the motor programme, causing a subconscious alteration in technique (Wilson 2000). These physical adaptations do not represent the players' normal technique and may lead to maladaptive changes including muscle misuse or more serious neurological disorders such as focal dystonia (Wilson 2000). Excessive muscle tension also accompanies mechanical inefficiencies in performance (Ma 1986).

Warming up and stretching

Regular stretching improves flexibility (Wilkinson 1992), and musicians benefit from instrument-specific stretching programmes (Markison 1998). Stretching should be performed regularly to maintain adequate range for performance demands (Norris 1993). Stretching prior to performance only may not be sufficient to minimize injury risk (Pope *et al.* 2000). General warming-up and cooling-down routines are recommended (Markison 1998). Players using instrumental warm-up strategies may protect themselves against the development of a playing-related injury (Zaza and Farewell 1997).

Strength or endurance conditioning

Poor physical condition is a predisposing factor to playing-related injuries (Ackermann and Adams 2004a). Instrument-specific strength and endurance training is effective in reducing injury frequency and intensity as well as reducing the perceived exertion associated with practising their instrument (Ackermann *et al.* 2002). In contrast, participating in unsupervised general sports was not found to provide any benefits in terms of injury prevention for musicians (van Hees 1997).

Ergonomic aids and advice

Various ergonomic interventions aimed at reducing physical load include hand splint adaptations for the trombone to assist with reach difficulties (Quarrier and Norris 2001), development of polymer drumsticks with reduced vibration characteristics (Zaza *et al.* 2000), a neck strap to carry the weight of the clarinet and bassoon may effectively reduce strain on the thumb (Chesky *et al.* 2000), and many other designs such as angle-headed flutes, key extensions on wind instruments, and remodelling of viola or guitar bodies (Norris 2000). Instruction on good lifting technique is important for musicians who may injure their lower back as a result of carrying heavy or awkward-shaped instruments (Fjellman-Wiklund *et al.* 2003).

Psychological health issues

Stressors experienced by musicians

Sternbach (1995) described the working conditions of professional musicians as generating a 'total stress quotient' that far exceeds that observed in other professions. Like elite athletes, performing artists must maintain their skills at peak form, endure many hours of solitary, repetitive practice, constantly self-evaluate their performances and subject their public performances to close scrutiny. They are required to work in a pattern akin to shift work, be available to travel to performance venues, leave their families while on tour, adjust to changing time zones, live at close quarters with colleagues and peers, and cope with financial insecurity. For these reasons, it can be difficult to differentiate between the occupational and physical stressors discussed in the previous section and psychological problems that can arise in individual musicians that may require individualized psychological intervention.

Frequently reported psychosocial issues while on tour or working on contract with interstate

and overseas orchestras include loneliness, homesickness, sexual frustration and relationship breakdown. Occupational issues include language barriers, unfamiliar backstage arrangements at concert venues and variable quality of dressing rooms. In addition to these psychological and occupational stressors, there is the physical stress associated with moving instruments and luggage, setting up on different stages, adjusting to differently shaped chairs at every venue, sleeping in different beds with different pillows, coping with jet lag, general fatigue and lack of sleep. New injuries or pains are frequently reported by professional musicians on tour, as a direct result of these factors (Ackermann 2002).

Individuals vary in their capacity to cope with such stressful working conditions. However, since not all performers suffer the same degree of psychological distress or indeed report the same levels of occupational stress, individual differences in a range of psychological characteristics are likely to account for variations in the degree to which musicians experience symptoms. For example, the difficulty in coping may be compounded for those who are also highly anxious, who lack confidence in their abilities and who engage in unhelpful strategies to deal with their anxieties, such as the regular consumption of alcohol, and licit (e.g. beta blockers) or illicit (e.g. marijuana) drugs. Since music performance anxiety is one of the most commonly reported psychological stressors in musicians, the remainder of this chapter will focus on music performance anxiety, its manifestations, consequences and treatment.

Anxiety in public performance

Performance anxiety is a group of disorders that affect individuals in a range of performance settings, such as examinations, competitions and public speaking. Solo and orchestral instrumentalists (van Kemenade *et al.* 1995) and solo and choral vocal artists (Kenny *et al.* 2004) all report experiencing music performance anxiety. Music performance anxiety is also observed in young musicians (Kenny and Osborne 2006), and children and adolescents show a similar constellation of symptoms to college level music students and professional musicians (Osborne *et al.* 2005). Students of classical music report higher levels of performance anxiety than students of Jazz (Kaspersen and Gotestam 2002). Like all performance anxieties, music performance anxiety occurs on a continuum of severity from 'normal everyday healthy aspects of stress and anxiety that are intrinsic to the profession' (Brodsky 1996, p. 91) to the severely debilitating symptoms of stage fright.

The phenomenology and determinants of music performance anxiety

Performance anxiety may occur as an isolated disorder, affecting only one specific part of a person's life, such as public speaking, test-taking or music performance. However, for a significant minority of those suffering performance anxieties, other comorbid disorders may be present, the most common of which is generalized anxiety disorder, which appears to co-occur in about one third of those presenting with severe performance anxiety (Sanderson *et al.* 1990). Generalized anxiety disorder is characterized by excessive, uncontrollable and often irrational worry about everyday concerns and is disproportionate to the actual source of worry. People with generalized anxiety disorder may have a long history of chronic worry and apprehension in most facets of their lives, not just in performance situations (American Psychological Association 2000).

Others may qualify for a diagnosis of social phobia (social anxiety) if the performer demonstrates significant impairment in interactions with others as well as in the performance setting and who otherwise meet the criteria for social phobia presented in DSM-IV-TR (American Psychological Association 2000). About 10–15% of those with a social phobia also meet criteria for clinical depression (Kessler *et al.* 1999). For a subgroup of music performance anxiety sufferers, there may be underlying psychological conflicts that need to be identified and resolved before the symptoms abate (Lazarus and Abramovitz 2004).

Two distinct aspects of performance anxiety have been identified—cognitive anxiety and somatic anxiety (Martens *et al.* 1990). High cognitive anxious individuals generally display a

consistent style of thinking about their performance that includes the following characteristics:

1 stronger negative expectancies before the event
2 stronger negative bias in their retrospective self-evaluations of performance
3 stronger expectation that their performance will be judged negatively by their examiners/audience
4 stronger concerns about the consequences of a poor performance
5 heightened responsiveness to changes in reactions of judges or audience
6 failure to derive comfort from evidence that they have handled the situation skilfully (Wallace and Alden 1997).

Somatic anxiety refers to the experiencing of a cluster of physical symptoms during an anxiety-provoking activity such as performing in front of an audience. It is characterized by muscle tension, agitation, and other phenomena such as trembling, sweating, dry mouth, shallow breathing and 'buttlerflies in the stomach' that are associated with the 'fright–fight–flight' response, first described by Cannon (1915) and subsequently by many researchers (Friedman and Silver 2007). These symptoms occur as a result of arousal of the sympathetic nervous system via the release of the hormone epinephrine (adrenaline) and to a lesser extent norepinephrine from the medulla of the adrenal glands (Gleitman *et al.* 2004).

Music performance anxiety and performance quality

Performance quality is determined by a number of interacting factors, including the ability of the performer and the level of achievement attained as a musician (Fortune 2007), the degree to which the performance repertoire has been mastered (Wilson 2002), the fit between technical ability and task difficulty (Fehm and Schmidt 2006), the circumstances of the performance, for example, whether the performance will be evaluated by expert judges, audience characteristics (Brotons 1994), and the type and severity of anxiety experienced (Wang 2002).

To date, Wilson (2002) has offered the most comprehensive model of music performance anxiety that incorporates the performer's trait anxiety, or their constitutional and learned tendency to become anxious in response to socially stressful situations; the degree of task mastery achieved; and degree of situational stress, such that high anxiety is more likely to be experienced in situations where social or environmental pressures are high. Performance anxiety may exert either an enhancing or detrimental effect on performance depending upon the interaction between these three factors (Fehm and Schmidt 2006). For example, an individual with high trait anxiety will perform best with an easy, well-prepared piece in a relaxed environment, whereas an individual with low trait anxiety will perform better if the piece is challenging and performed in an evaluating environment, such as an exam or competition.

Optimizing music performance

An optimal performance is determined by a complex interaction between person characteristics, task characteristics and performance setting. These include adequate preparation, achievement of task mastery such that the complex motor tasks required to perform the task have been (over) learnt to the point of being automatic (Oliveira and Goodman 2004), familiarization with the performance venue and adequate rehearsal with other performers in the case of ensemble performance. When all of these characteristics occur at an optimal level, the performer is said to be 'in the zone' (Young and Pain 1999) or to have achieved a state of 'flow' (Marr 2000). Another construct to describe peak performance, borrowed from sport psychology, is the 'individualized zone of optimal functioning' (IZO) (Hanin 1986), that is, the performer has achieved the optimal level of pre-performance anxiety that results in a peak performance. 'Optimal' pre-performance anxiety is a good predictor of performance quality (Turner and Raglin 1991).

Although one would expect highly anxious individuals to experience performance breakdown or impaired performance quality more often than low-anxiety performers, this is not usually the case (Strahan and Conger 1998).

Even in situations where the highly anxious do perform less well than the less anxious, social or artistic performance catastrophes are rare. There are a number of possible explanations for this. First, people display highly individual ways of responding to stressful situations. Very small changes in context or task-expectancy can change a person's appraisal of a situation as anxiety-provoking or not (Bandura 1991). Secondly, those situations that could produce a catastrophe are indeed rare, even for highly anxious individuals. Thirdly, highly anxious professional performers are likely to engage in a number of pre-performance compensatory activities, such as over-learning, additional rehearsals, or visiting the venue before the performance to ensure that their performance can withstand the additional anxiety they know they will experience during the performance (Kenny *et al.* 2004).

Treatments for music performance anxiety

Many treatment programmes have been developed to assist the anxious or stressed musician. However, most of the available treatments have not been adequately assessed as to their effectiveness. These include:

1 Prescription pharmacological interventions such as antidepressants, benzodiazepines, beta-adrenergic receptor blockers, and busipone.
2 Meditative interventions (autogenic training, (self-) hypnosis, meditation, yoga)
3 Physiological and physically based interventions (aerobic exercise, Alexander technique, biofeedback, Feldenkrais, massage)
4 Relaxation therapies e.g. progressive muscle relaxation training
5 Cognitive and cognitive behavioural interventions: assertiveness training, attention-focusing techniques, cognitive behaviour therapy (cognitive restructuring), multimodal behavioural therapy, coping skills training, exposure therapy, goal setting, lifestyle changes (e.g. development of non-musical hobbies and interests), imagery (distraction and focused), mental rehearsal, stress inoculation, systematic desensitization and systematic rehearsal
6 Music therapy (music enhanced relaxation techniques; group therapy for musicians)
7 Psychotherapy (Nagel 2004).

Space permits only a brief overview, update and summary of the most commonly used and researched treatments and their effectiveness—the cognitive and behavioural therapies. A detailed review and analysis of other treatments for performance anxiety can be found in Kenny (2005).

Cognitive, behavioural and cognitive behaviour therapies

Behaviour is determined by a combination of thoughts, feelings and past and present behaviours (Turkington *et al.* 2006). Three groups of therapies—behavioural (van de Wiel *et al.* 2007), cognitive (Willner, 2006) and cognitive behavioural (Butler *et al.* 2006)—are all based on the same principles, but use the available therapeutic techniques in different amounts. Behavioural therapies focus primarily on changing the dysfunctional behaviours that arise when people feel anxious. One of the main targets of behavioural therapies for anxiety disorders is excessive muscle tension, which is treated with deep muscle relaxation training (Conrad and Roth 2007) and systematic desensitization (Pagoto *et al.* 2006), a procedure in which the person is encouraged to imagine the feared or anxiety provoking situation in graded steps, called the fear hierarchy, until they can visualize the situation without experiencing the muscle tension that used to accompany the visualizations. Once the fear hierarchy has been mastered in the therapist's office (imaginal desensitization), people are encouraged to apply their new skills in the actual, anxiety-provoking situation (called *in vivo* desensitization) (Choy *et al.* 2007). This allows for behavioural exposure, i.e. repeatedly practising the task in the feared situation until the associated anxiety is reduced to manageable levels. For this to be effective, the task must have been mastered so that the performer can ensure successful performance in the more stressful situation (Rauch and Foa 2006).

Cognitive therapy focuses on mental states such as thoughts, feelings and images (Willner 2006). Dysfunctional cognitions, those that create emotional distress or maladaptive responses,

can be the result of cognitive deficits (i.e. difficulties with problem solving) (van Winkel *et al.* 2006), and/or errors or biases in information processing (Joormann *et al.* 2007). Cognitive therapy changes faulty thinking patterns that give rise to maladaptive behaviours, such as excessive muscle tension, avoidance of the feared situation, or impaired performance. In this therapy, people learn a skill called cognitive restructuring, a process whereby people replace negative, unproductive, catastrophic thinking with more rational, useful ways of understanding their problem situations (Murphy *et al.* 2007). Based on changed thinking patterns, people are often able to reassess or reappraise their feared situations in ways that reduce the perceived threat.

Cognitive behavioural therapy (CBT) is a combination of behavioural and cognitive interventions (Turkington *et al.* 2006). CBT uses educational and psychological interventions that are based on the idea that changing negative thinking patterns and behaviours can have a powerful effect on a person's emotions, which in turn can change behaviour in situations in which the negative emotions arose. Like all new learning, CBT requires commitment, practice and application in situations outside the therapy office (Yovel and Safren 2007). CBT is focused and directive, usually of short duration and is action-oriented,—it relies on the client's record-keeping, active participation, application and evaluation (Rees *et al.* 2005).

A more recent variant of CBT, multimodal behavioural therapy (Lazarus and Abramovitz 2004) proposes a multimodal approach to treatment that involves the assessment and management of any combination of seven components: behaviour, affect, sensations, imagery, cognition, interpersonal relationships, and drugs/biological factors. Research is needed to assess whether this more comprehensive approach will produce better results for the anxious musician.

Prevention of music performance anxiety

Parenting style is important in the prevention of anxiety and depression in children (Barlow 2000). Parents who are responsive, unobtrusive, not overly protective, and who give children age-appropriate opportunities to exercise control over their environment foster a sense of control and mastery in their children that provides protection against the development of anxiety (Gar *et al.* 2005).

Most forms of performance anxiety are difficult to treat and anxiety levels after treatment rarely reduce to those of non-anxious people (Kenny 2005). The best form of treatment is to prevent its occurrence. Sound pedagogy, appropriate parental support and expectations, and the learning of self-management strategies early in one's musical education can help to mitigate the effects of entering a highly stressful profession.

Children should be offered frequent, low-stress opportunities to perform almost from the beginning of their musical training. These performances should be presented in a positive, non-judgemental way, so that young performers can learn that performance is an integral, enjoyable and manageable part of their musical education. Children should not be prematurely thrust into competitive environments whose focus is evaluation (such as auditions or competitions) and when they are, students need to be well prepared for the performance both musically and psychologically. Repertoire should be well within the technical capacity and interpretive abilities of the student and the material should be well-learned. Sensible pre-performance routines should be established that attend to the performer's physical well-being (having adequate diet and sleep), psychological well-being (developing positive self-statements and realistic self-appraisal capacity) and musical demands (adequate practice, appropriate level of complexity, cognitive and physical capacity commensurate with the musical demands). These strategies will enhance the student's sense of competence and control so that when confronted with critical performances, a strong sense of a competent self will guide a self-actualized performance.

PART 8

Composition and improvisation

Edited by Peter Webster

CHAPTER 37

Making a mark

The psychology of composition

Jonathan Impett

Introduction

Given the central place of creativity as a defining component of the self-image of humanity, it is extraordinary how until recently it has received little attention from psychologists (Albert and Runco 1999). Studies have tended to consider the general case of the generation of new ideas or the process of invention within a particular constrained environment. While both biography and analysis can shed light on the process of composition, musicology has generally been more concerned with the context or fruits of the process. Artistic creativity poses considerable challenges to the experimental psychologist—in gaining access to the creative process itself other than through self-reporting, and in evaluating the quality, significance and uniqueness of work. The formulation of questions concerning an activity which is both cultural and personal naturally tends to reflect current modes of explanation.

There is little agreement on the cultural definition of composition, even within the context of contemporary Western culture. In conventional terms, it may be understood to be an activity bounded by the artefact of the musical work and by the persona of the composer. Discussion of the psychology of composition calls into question fundamental assumptions about the nature and role of musical activity and the musical artefact, and such assumptions must be acknowledged in any investigation. Taking Western masterworks as our sole evidence might be equivalent to understanding architecture only on the basis of the pyramids; objects of wonder but perhaps eccentric to any general case of human behaviour. The modern Western composition could be seen as the distillation of a social activity described by Blacking as 'humanly organized sound' (Blacking 1973). In an economic interpretation, Attali suggests that technology might return composition to its socially distributed state (Attali 1985, pp. 133–148). The cultural environment surrounding such works values them as exceptions, works of unique genius, expressions of individuality. As evidence from which to generalize they are thus to some extent self-invalidating. Biography and autobiography are likewise inseparable from context. The romantic, romanticized or modernist artist is inseparable from his work; Berlioz is an often-cited example. From late Bach to Boulez individual works stand as autobiographical statements, acts of musical self-exploring and self-situating. From at least the late sixteenth century, the advancement of the art has been a conscious obligation on most composers, and must therefore be understood as having substantially informed the relevant processes. Schoenberg's writings are perhaps the clearest expression of this awareness (Schoenberg 1975). In other cultural contexts, the role of the musician may be precisely to practice an art such that it may be transmitted without technical corruption or personal intervention. Guercio (2006) investigates the ways in which an awareness of public biography has fed back into artists' practice.

The concept of the work, the object of composition, has come increasingly into question, particularly in terms of its identity, autonomy, and the intentionalities it may be seen to embody. Goehr (1992) presents a case for the

historical contextualizing of the work concept. Davies (2001) proposes a measure of *thickness* of the work to reflect the degree to which its instantiation depends on culturally distributed knowledge. We can identify two characteristics of the activity of composition: a degree of identity between subject and object—composer and composed—and the structuring of music over a temporal scale beyond that of unstructured short-term memory or the doggerel patterning of simple song or dance forms.

Motivation

> I believe that a real composer writes music for no other reason than that it pleases him. Those who compose because they want to please others, and have audiences in mind, are not artists.
>
> Schoenberg (1975, p. 54)

The question of the motivation to compose is likewise beyond the scope of experimental psychology. Where observer, observed and reader inhabit the same cultural milieu this is less problematic; in his view of the artwork as the manifestation of an artist's particular biography and psychological development, Freud is reinforcing the Romantic aesthetic of self-expression native to his own context. He concluded that 'whence it is that the artist derives his creative capacity is not a question for psychology' (Freud 2001a, p. 187). His observations on the relationship between artist, work and public have been more influential. He suggests that the artist is driven to the imagination by dissatisfaction with his reality and returns to reality via the work, which then serves the same function for others (Freud 2001b, p. 224).

Some measure of social empathy is at play, therefore. Heidegger extends the notion of phenomenological reality to one of truth, relating aesthetic success to the ethical behaviour of the artist in respect of his material (Heidegger 1971, pp. 15–86). Badiou's development of this view of artistic behaviour as ethical also in respect of society emphasizes the search for commonality over the assertion of difference, an approach that resonates with theories of creativity discussed below (Badiou 2001). The technical researches of both Schoenberg and Cage could be interpreted in this light; technique mediates between the banality of the imagination and the aspiration of critical reflection. Freud's insistence on the ludic nature of artistic creativity has been enthusiastically taken up by contemporary critical theorists. The concept of *play* is central to Gadamer's explanation of the ontology of art and of aesthetic experience (Gadamer 1989, pp. 102–171). Lacan's related notion of *jouissance* serves as the basis for his distinction between desire and drive. Following the work of Lacan and Foucault, contemporary critical theory is fundamentally informed by psychoanalysis. Its central topics of the relationships between subject and object, desire and drive, bear directly on the metaphysical and psychological relationship between composer and work and the urge to compose.

> Desire is grounded in its constitutive lack, while drive circulates around a hole, a gap in the order of things ... drive is quite literally *the very drive to break the 'all' of continuity in which we are embedded*, to introduce a radical imbalance into it.
>
> Žižek (2006, pp. 61–63)

Psychology and composition

Given the primacy of composition in Western music, the silence of psychology in this respect is deafening. Sloboda (1985, p. 103) observed 'that composition is the least studied and least well understood of all musical processes, and that there is no substantial literature to review'. Brown still notes that 'Although there is growing interest in music cognition, little progress has been made in understanding composition per se' (Brown 2003, p. 2). As psychology has developed through the twentieth century, the authority of earlier psycho-biographical narrative explanations has been called into question. Meanwhile composition has turned consciously to self-reflection as other norms and constraints have dissolved. Already in 1937 Cage suggested that the future principle of the organization of musical sound would be 'man's common ability to think' (Cage 1961, p. 6). In the light of new technologies, Minsky has suggested more recently that art and psychology must inevitably converge (Minsky 1999). Musical expressionism is the stylistic embodiment of unmediated expression

in the romantic sense; the conscious embodiment of psychological states. Adorno saw Schönberg's *Erwartung* as heroically confronting the compositional challenge of the dissolution of tonality—by no coincidence a product of the same milieu as psychoanalysis and phenomenology. Subsequent approaches to post-tonal language included Hindemith's *Unterweisung*, based on perceived intervallic tension in melodic and harmonic space (Hindemith 1942, pp. 56–58). Few have attempted to work through the implications of music psychology to derive a set of aesthetic constraints. A notable exception is Lerdahl (1988), for whom only functional tonality satisfies the requirements. Implicit in Huron's theorizing of musical experience in terms of expectation is an understanding of composition as the prediction, management and thus presumably internal modelling of that expectation (Huron 2006, p. 240).

The incapacitating vertigo of the composer faced with infinite possibility is described by Ferneyhough (1995, p. 22). Sloboda suggests that a new dialogue between psychology and the composer can help in reducing this search space (Sloboda 2005, p. 192). The sonic and music–organizational possibilities of new technologies in the late twentieth century and the perception of composition as a potential research activity together informed the shape of institutions such as IRCAM in Paris, incorporating research into the psychology of music; Born (1995) gives an account of the co-evolution of institution and individual compositional practice. Writers such as Roads (1996) and Cook (2001) acknowledge psychoacoustics as an essential part of the electroacoustic composer's necessary knowledge. The close link between compositional technologies and research into psychoacoustics is a strong indicator of the extent to which conventional modes of music-making embody both innate understanding and cultural experience of music psychology. Technological approaches to composition and music-generation have been based on varying degrees of cognitive verisimilitude in the underlying mechanisms. Rowe (2001) presents a broad range of such research, largely developed in imitation of human compositional abilities. Cope's *Experiments in Musical Intelligence* (Cope 2001) generates new compositions within a given style based on the analysis and recombination of individual compositional *signatures*. Hofstadter points out that irrespective of similarity of psychological process, the inability of a culture to distinguish must lead us to question assumptions and understanding (Cope 2001, pp. 33–82).

Theories of creativity

> Surely it's premature to ask how great composers write great symphonies before we know how ordinary people think of ordinary tunes. I don't believe there is much difference between ordinary and 'creative' thought. Right now, if asked which seems the more mysterious, I'd have to say the ordinary kind.
>
> Minsky (1985, p. 80)

Study of the general case of creativity begins in earnest as a reaction to the twin myths of romantic aesthetics and mid-twentieth-century information theory. Koestler (1964) was among the first to address the human practice of creativity, to demystify the process. Boden (1990) examines the paradoxes and conceptual difficulties in dealing with such a charged cultural concept. The earlier notion of genius as embodying the distance between conventional experience and that of the great artist—somewhat problematic in psychological terms, in that by definition it cannot be more widely understood—has been revisited. Simonton (1999) proposes an evolutionary explanation; that genius typically explores a wide range of potential behaviours, often in parallel, searching for complexity, novelty and emergent structure.

Most theories of creativity acknowledge that the everyday transmission and reception of ideas is in some sense creative. To varying degrees they incorporate the exploration of conceptual or physical spaces, the drawing of new connections between concepts or spaces, the satisfying of rules or constraints and the solving of problems. Holyoak and Thagard (1995) propose a model of creative thought around the drawing of analogy between different mental spaces within interacting constraints of similarity, structure and purpose. Boden (1990) describes the spontaneous reflexive process of the mind's generation of maps of its own conceptual spaces. In the absence of coherent bodies of data,

theories of creativity have been largely informed by the challenges of artificial intelligence. In Copycat, a computational model of analogy-seeking, Hofstader shows how one concept slips into another under different kinds of pressure or attractor, producing the mental fluidity fundamental to creative thought (Hofstadter 1995, pp. 205–267). Gärdenfors' notion of multidimensional *conceptual spaces* avoids the symbolic/connectionist division of computational models (Gärdenfors 2000).

Brown (2003) narrates the composition of Debussy's *Ibéria* as a process of knowledge-based problem-solving. He acknowledges the multidimensionality of the undertaking: 'music historians, music theorists, and cognitive scientists can join forces in trying to understand [how composers make their choices]' (Brown 2003, p. 162). Problem-solving and space-searching models generally rely on some form of heuristic to direct the process. This might be seen as where the craft of composition lies and why it requires such time to develop. Weisberg (1999) examines the relationship between creativity and knowledge through the development of expertise, citing particularly the '10-year rule' proposed by Hayes (1989) following examination of the creative trajectories of 76 composers. Explanations of this kind also assume some definable end-state. The model of composition proposed by Sloboda (1985, p. 118) takes account of the symbiotic evolution of work and work-definition. Brown's amended version incorporates historical context (Brown 2003, p. 9) (Figure 37.1).

Byrne (2005) shows that rational thought and counterfactual imagination are predicated on common cognitive mechanisms. She describes the probing of possible space by the imagining of alternatives to a given reality and how imagination works by exploring the parameters along which it might be otherwise. This seems a useful model for understanding the selecting of musical material according to its potential in context, as well as its subsequent treatment.

A mechanism of 'conceptual blending' is proposed by Fauconnier and Turner, to model the production of analogical links and inference transfers by mappings between mental spaces. 'Blending ... operates on two Input mental spaces to yield a third space, the *blend*. The blend *inherits partial structure* from the input

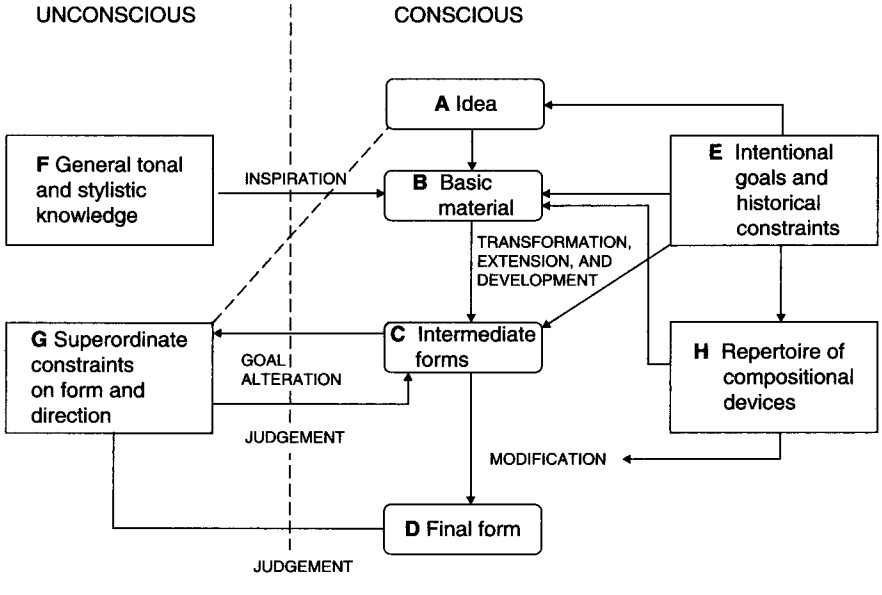

Fig. 37.1 Diagram of typical compositional resources and processes. Brown (2003, p. 9); developed from Sloboda (1985, p. 118).

spaces and *has emergent structure* of its own' (Fauconnier 1997, p. 149). Blending through the multimodality, multiple spaces and scales and potential conflicts of human experience is achieved in *conceptual integration networks* (Fauconnier and Turner 2002, pp. 309–353). Turner describes the integration over time of a vast perceptual diversity, most clearly embodied in the activity of the artist, as *compression* (Turner 206, p. 94). Applying this approach to music, Zbikowski identifies three fundamental cognitive mechanisms: categorization, cross-domain mapping and the use of conceptual models (Zbikowski 2006, p. 116). Complex cultural and contextual factors can thus be incorporated to account for the emergence of meaning: 'Compositional strategies ... assume an alliance between syntax and processes of meaning construction: composers arrange musical materials with relatively specific expressive or communicative goals in mind' (Zbikowski 2002, p. 138). Specific musical detail derives from broader strategies through templates of categories and attribute values (Zbikowski 2002, pp. 149–153).

Metaphors and models

Psychology and aesthetics are interlinked. The possibility of the composer having some responsibility to art, music, truth or any higher authority has material implications for the conceptual model within which composition takes place. The cosmology of Zarlino, Bach's theology or the Romantic aesthetics of Wagner in some respects have equivalent implications. In acknowledging the limits on understanding the creative process from sketches, Nottebohm adduces Goethe's metaphor of a plant, of unity in diversity, that runs through Romantic accounts of art and can be presumed to inform the self-understanding and conceptual models of composers from Beethoven to Webern (Webern 1963, p. 40). As mid-twentieth century composers questioned assumptions about musical language and aesthetics, they sought structuring metaphors in other areas of thought: natural phenomena (Xenakis), science fiction (Ligeti), semiotics (Berio), social theory (Cardew). Lachenmann describes his process explicitly as a sequence of metaphors: reflection, instrument-building and the freeing of imagination (Lachenman 2004, p. 45).

The material role of metaphor in thought has been shown by Lakoff and Johnson:

> Most of our normal conceptual system is metaphorically structured; that is, most concepts are partially understood in terms of other concepts ... The heart of metaphor is inference. Conceptual metaphor allows inferences in sensory-motor domains ... to be used to draw inferences about other domains (e.g., domains of subjective judgement.
>
> Lakoff and Johnson (2003, pp. 56, 244)

They demonstrate how abstract conceptual thought—which might include musical reasoning—is grounded in metaphors derived from human physicality and physical context (Lakoff and Johnson 1999). The reported synesthesia of Scriabin or Messiaen could be such metaphorical transfer; a case in which both spaces map onto physical experience. The range of personal, technical and cultural metaphor used by composers means that their self-reporting requires sensitive interpretation for use as evidence of psychological process. The generality of Bahle's study of 1947, based on the self-reporting of both living and past composers, illustrates the difficulty in drawing conclusions. He lists a range of intra- and extra-musical factors, composing environment, the urge to imitate or explore and artistic compulsion (Cooper 1990, pp. 14–15).

If the ability to model certain aspects of the physical and social world is to some extent innate (Pinker 1999, pp. 316–333), this can interact with cultural experience such that a composer might be able, for example, to model the performer's physicality and audience's impression of a particular violin phrase. The constraints of physical causality are effectively removed in working with new technologies (Lury 1998), and much contemporary technology-based creativity is concerned with the search for structural and conceptual metaphors to focus unconstrained imagination.

Imagining

What we imagine does not necessarily take on a concrete form and may remain in a state of

> virtuality, whereas invention is not conceivable apart from its actual being worked out.
>
> Stravinsky (1942, p. 53)

Composition is an activity simultaneously of aural and aesthetic imagining, in some kind of feedback relationship. Both physical and artistic percepts are generated as hypotheses. The relative roles of emotional and intellectual elements in the latter are a proper topic for aesthetics, although in brain-science terms emotion and subjectivity are both real and rational (Damasio 1999; Thagard 2006). The compositional behaviour of a particular individual may be characterized by the scope, precision, innovation and relationship of aural and aesthetic imagination.

In many art forms, modes of scaling or reduction retain sufficient salient features of the whole such that the reduced form can be meaningfully understood or manipulated. A sketch for a painting may already display essential stylistic or representational properties while affording compositional reflection. A literary narrative can be outlined in the same language as its full version. Music does not afford the same reduction of scale. There is little invariance; material, surface and 'meaning' are lost. Some established schema—sonata form, for example—might allow the composer to concentrate on appropriate material, development and deviations from norms. Sloboda suggests that the modular process of working simultaneously on different levels of detail is akin to that of architecture (Sloboda 2005, pp. 194–195). Ligeti describes the repeated process of such formal macro planning in his Violin Concerto (Steinitz 2003, p. 335); Berg follows a similar procedure (Hall 1996, p. 21). The composition becomes an autonomous artefact as the composer discovers its nature from multiple perspectives.

In an often-quoted (and doubted) passage of reflection on his own process, Mozart describes imagining a composition as a simultaneity. The act of consciously contemplating a unitary concept takes time. Notation is itself a process of reflection and decision-making, and combined with the time of imagining is unlikely to happen in real time or less. The variables at play here seem to be the degrees of consciousness and assimilation of the processes involved. Following examination of Mozart's sketches, Konrad has concluded that he experimented at the piano and on paper, and that 'he prepared himself consciously for a particular compositional task and sought the working environment necessary for its fulfilment' (Konrad 1992, p. 77).

The relationship between imagined time, musical time as the object of reflection and the experiential time of musical performance is therefore critical to the process of composition; it acts on the temporal plane of memory. Berio describes the process of emergence from the interplay of imagining and memory of 'forms which stir and question memory but at the same time deny it' (Berio 2006, p. 41). A memory-based approach to contemporary composition is proposed by Snyder (2000). Kramer suggests that musical time works not only in a uniform speed and direction, but also non-linearly, retrospectively and in multiple layers (Kramer 1988). Some such principle must be fundamental to composition. Its precise nature is a highly individual question, and closely related to a particular composer's modes of experimentation and representation.

Improvisation

Sloboda (1985, pp. 138–150) suggests that studying improvisation might provide insight into composition. Cultural understandings of improvisation vary; absence of fully prescriptive notation and a degree of ephemerality of the phenomenon are common features. Nettl and Melinda bring ethnomusicological perspectives to bear on 'music created in the course of performance' to investigate the musicians' own understanding of their behaviour (Nettl with Melinda 1998, p. 1). Isolating difficult-to-translate metaphorical descriptions can be misleading; many are technique- or theory-specific. Two have particular resonance, however. Sabah Fahkri describes the development of an ecstatic state through a process of feedback: 'I consider the audience to be me and myself to be the audience' (Racy 1998, p. 96). Jnan Prakash Ghosh describes his role in Hindustani music as 'keeping it going' (Slawek 1998, p. 336), implying an acknowledgment of some autonomy of the musical phenomenon and abstraction of its possibility. In contrast, Boulez dismisses improvisation as irrelevant to composition 'instant

imagination misfires more often than it fires; and anyway such freedom has less to do with invention in the proper sense than with the practicalities of invention' (Boulez 1991, p. 32).

Jazz and its successors provide instructive examples of longer-term musical design emerging through the practice of improvisation. Armstrong's *West End Blues* presumably grew out of his own improvisational style, from a continuous, repetitive practice, and having emerged in 1927 remains quite stable through subsequent versions. In Coltrane's solos on *Giant Steps* or *A Love Supreme* we hear the fruit, however spontaneous, of sustained intellectual and technical engagement with his material. Cecil Taylor prefers to communicate his more abstract structures orally: 'That gives the lie to the idea that the only structured music possible is that music which is written. Which is a denial of the whole of human expression' (Spellman 2004, p. 71). The musico-cultural theory and graphical scores of Anthony Braxton demonstrate the role of musical intelligence and imagination in the feedback loop of reflective practice, and the inevitable generation of higher-level structures (Braxton 1985). The technical achievement and musical power of the limit-case work of guitarist Derek Bailey in insisting on an entirely 'non-idiomatic' mode of improvisation is evidence of the irrepressibility of the urge to compose, of the difficulty in suppressing memory, association and imaginative projection (Watson 2004, p. 212). Evan Parker describes his own work as composition through improvisation and points to the impossibility of creativity denying structure, memory and repetition (Parker 1992). As recording technologies evolved from being simply the documentation of a performance, a new situation developed in which compositional exploration may be audibly inscribed. Thus in the recorded activity of composing Miles Davis's *Jack Johnson* or Mick Jagger's *Sympathy for the Devil* we can follow the distribution of musical ideas, the absorption of the input and techniques of others and the pattern of technological intervention (Davis 2005; Godard 2006).

Passages designed to give the impression of successful improvisation are instructive. Presumably improvisation contributed to Beethoven's generation of ideas, for example. His cadenzas to his own piano concertos could be seen as composed illustrations of his own creative process. Consideration of the cognitive mechanisms of improvisation gives some indication of its relationship to composition. Surveying the skills and components of improvisation, Pressing (2001) proposes a feedback and feedforward problem-solving model based on the generation of and selection from arrays of elements having musical, acoustic and motoric features. Sarath points to time as the essential parameter of difference between composition and improvisation (Sarath 1996). He derives a concept of retensive–protensive temporality from Husserl to describe the relationship of the musical thought of the improviser with the continuously moving present.

Traces

Sketches

A composer's sketches provide a trace of his conscious thought processes. While early sketch studies sought to investigate specific genius rather than composition in general, the field has more recently developed methodologies that afford broader interpretation (Kerman 1982; Brown 2003). Deductions can be made about the chronology of composition and possibly the models and constraints they embody and the problems they address. One might observe the 'harried' nature of Beethoven's writing (Hall 1996, p. 9) or the considered recording of musical thoughts in Webern's sketchbooks. The distribution of ideas on the page can itself reveal patterns of thought (Hall 1996, p. 13); Sloboda notes how Stravinsky uses a single simple idea to generate a variety of material (Sloboda 1985, pp. 108–112). Less certain is any induction as to the precise mental processes of which they are a trace. In reconsidering the discipline in 1982, Kerman observed that 'one could go on to study musical creativity in general, at least in theory' (Kerman 1982, p. 177). In an early case study, Nottebohm points out that Beethoven's sketches demonstrate both top-down and bottom-up approaches; sometimes a movement is repeatedly reformed in its entirety, sometimes a piece of thematic material is worked in different directions. Beethoven's comment that he often works on

several compositions simultaneously suggests a mutually reinforcing feedback between projects (Nottebohm 1979, p. 5).

Technology

Modes of representation and the manipulations they afford are essentially a question of technology. So too are issues of dissemination and likely audience; notation, printing and the Internet transform the composer's concepts of self and agency. Banchieri's *Contrapunto alla Mente* (1608) is a parody of the limits of rule-based contrapuntal composition without the use of notation. Luzzaschi and Monteverdi describe the process (Owens 1997, pp. 65–66). The use of the wax tablet to work out points of polyphonic imitation must inform the grain of thought—the relationship between local contrapuntal texture and broader architecture. Changes in paper production through the eighteenth century meant that while we effectively have no sketches by Bach, whose supply of paper had to be approved and accounted for, Beethoven could presume a limitless supply. He could therefore experiment and store freely, reusing, reworking and re-mediating over his whole life—a random access memory allowing the process of composition to be highly distributed through time and contexts. In 1025, Guido d'Arezzo presented his new form of notation as addressing questions of memory. Symbol manipulation lies at the heart of Western composition. The symbolic representation and manipulation afforded by technologies from wax tablet to computer constitute a form of conceptual prosthesis. Virtual, mental quasi-external representations are both more ephemeral and more plastic than their material counterparts. The points at which a current state is externalized constitutes a unique signature in the compositional process. Instruments themselves constitute music computers; the piano is the ideal small-scale calculator for tonal music, with its octave equivalence, registral mapping, unique shapes for keys and scales and consistent but discrete relationships between them.

The multiple and hybrid representational environments of computer-enabled composition generate less transparent traces. Ferneyhough sees the computer as enhancing creative liberty, affording a more immediate and intuitive understanding of a complex compositional situation. 'It can generate a "musical archaeology", accessing and linking vastly different types of material and degrees of evolution from moment to moment' (Ferneyhough 1998). Lyotard describes the conventional modes of memory in the creation of art as *breaching* and *scanning*, to which he adds *anamnesis*—the remembering of the previously unknowable—in the case of technological creativity (Lyotard 1991, p. 48). In his study of digital craft, McCullough (1996, p. 99) describes computational environments as 'dense notational contexts for action'. Technology-informed changes in aesthetic stance also condition the nature of the traces remaining. For some of the late works of Nono, for example, there are copious sketches but no authoritative score. Compositional methodologies as set out in various historical manuals may reflect an understanding of composition which informs any conforming behaviour. They are not identical with an individual's psychological process, however.

Conclusion

Composition is a reflexive, iterative process of inscription. The work, once named as such and externalizable to some degree, passes circularly between inner and outer states. It passes through internal and external representations—mostly partial or compressed, some projected in mental rather than physical space, not all necessary conscious or observable—and phenomenological experience real or imagined. At each state-change the work is re-mediated by the composer, whose decision-making process is conditioned by the full complexity of human experience. This entire activity informs the simultaneous development of the composer's understanding of the particular work in its autonomy, of their own creativity and of music more broadly. Environment (culture, technology) and agents (composer, work) co-evolve at different rates. Important areas of future research include the perception of form, the imagining of music 'off-line' and the process of identifying novelty and potential in that imagining.

Donald (2006) proposes six cognitive principles to art, all fundamental to the activity of composition. They may be paraphrased thus:

1 Composition should be regarded as a specific kind of cognitive engineering, intended to influence the minds of an audience.
2 Composition always takes place in the context of distributed cognition.
3 Composition is constructivist in nature, aimed at the deliberate refinement and elaboration of mental models and world views.
4 Composition is meta-cognitive in nature.
5 Composition is a technology-driven aspect of cognition.
6 The role of the composer, viewed as a component in a distributed cognitive system, is not necessarily fixed.

While the urge to compose—to invent, structure and define sound and musical behaviour—may be to some degree innate, modes of conceiving, representing and realizing are the product of a situated process. Even if some or all of that activity is so well assimilated personally or culturally that it remains hidden from experimental view, it remains a behaviour in respect of an emerging object. That object is an artefact embodying the composer's own simulation of its situated performance. Stravinsky describes the process:

> The very act of putting my work on paper, of, as we say, kneading the dough, is for me inseparable from the pleasure of creation. So far as I am concerned, I cannot separate the spiritual effort from the psychological and physical effort; they confront me on the same level and do not present a hierarchy.
>
> Stravinsky (1942, p. 51)

CHAPTER 38

Musical improvisation

Richard Ashley

Introduction

Musical improvisation is, to many in the Western world, an activity shrouded in mystery. Most listeners are familiar with some genres of music in which improvisation is a commonplace, such as rock and other popular styles, jazz, or perhaps 'ethnic' musics—that is to say, composed or improvised 'traditional' musics falling outside the typical Western canons. Therefore listeners are aware that many musicians can, and routinely do, produce novel musical utterances in real time. The question for most listeners is not 'Can music be improvised?' but rather 'How is improvisation carried out?' With this formulation of the question, musical improvisation becomes a suitable topic for psychological investigation, focusing on cognitive, physical, and interpersonal processes, and on the musical structures on which these processes operate. Viewed in this way, there are parallels that can be seen with regard to processes of verbal production. No one would think it unusual to find native speakers of a language producing new utterances on the spur of the moment; indeed, to find someone without such an ability is the unusual case (as pointed out in Blacking [1976]).

This chapter seeks to bring together the literature on musical improvisation which will be of interest and benefit to those wishing to know more about it from a cognitive perspective. There is currently a modest but growing literature dealing with the psychology of musical improvisation; the curious might compare the number of articles cited herein with those in other chapters of this volume. One major strand of the music–psychological literature will not be dealt with here, namely the use of improvisation in music-therapeutic, clinical, or psychotherapeutic settings. The interested reader is referred to the appropriate sections of this volume for references on those topics.

Constraints on the processes of musical improvisation

Before moving on to a review of some dozens of studies dealing with improvisation, it is helpful to set a minimal theoretical framework for these discussions. The core notion here is that of *constraint*: of the scarcity of resources, in real time, that humans can utilize for making music when they are not following a predetermined plan of action (whether notated or not, as insightfully noted in Baily [1999]). To improvise appropriately in a given musical style—especially if the improviser is concerned with significant, productive interaction with other musicians, and with communicating with an audience—is a kind of tightrope act, where there is always the chance that something will go wrong (the recorded performances of master musicians show that even they make mistakes sometimes). Making music demands considerable resources from people; that is, no doubt, part of why music-making is enjoyable, in that it brings us into some more optimal relationship between our capabilities and our actions, along the lines of Csíkszentmihályi's notion of 'flow' (Csíkszentmihályi 1990, 1996). The use of one's abilities inside the constraints of one's body and its limits in performance, the timing of one's actions with external events, and retrieving and utilizing one's knowledge promptly in improvisation provide a powerful framework for a sense of personal achievement, and is thus a great

proving ground for Csíkszentmihályi's concepts of optimal experience and creativity.

What, more precisely, are significant constraints on musical improvisation? We shall consider three here, not closing the door to others. These are: the limits of the body (physical constraints); the limits of time (temporal constraints); the limits of knowledge (cognitive constraints). From these we shall then move into an examination of the psychological literature regarding improvisation.

Constraint 1: the body

Improvisers work with their hands, feet, and voices to make music in the moment. Unlike a composer, who can consider and reconsider at length the different possibilities which a diverse ensemble might provide for the expression of a given musical idea, the improviser is left with only his or her own physical abilities to make the music when needed. The complex relationship of the human body's abilities to real-time music-making has rarely been explored (but see Eric Clarke's *oeuvre* for a stimulating, Gibsonian approach to the issue). In some ways, this can be seen as comparable to processes of speech production and articulatory phonology (Levelt 1989) in language, but is still more complex, in that these musical utterances must typically be articulated in the context of larger-scale structures, like discourse structure in language, and in tight temporal concert with other performers, unlike speech, where the norm is one speaker at a time.

Constraint 2: real time

The proverb says, 'Time and tide wait for no man' ... and, we might add, time waits for no one improvising music. Sometimes the improvising musician is without any other collaborators (many blues recordings fall into this category), and in that case the improviser is free to alter the timing of their performance as they see fit, having no need to to coordinate with other performers. However, in many other situations, the improviser has other musicians with whom they are interacting in the moment and so very close timing constraints apply. These are often in the range of 1/25th of a second (40 msec or less)—see Iyer (2002, 2004)— and thus are of critical concern, since the margin for error is so slight. Why might this matter? because, as Stravinsky allegedly said, 'Music is the art that defines Man's relationship to Time.' Music provides the fine grid against which our ongoing lives are measured, more finely than with language or with clocks; it is humanity's great measure of time, down to the finest levels we can determine—and our auditory systems can detect the minutest levels of timing, well under 1/1000 of a second.

Constraint 3: limits on what we know

Typically, people can only act on what they know; music is no exception to this rule. For the case of improvisation, the knowledge one uses should be encoded in procedural (know-how-to) rather than declarative (know-about) form. There are several reasons for this, mostly having to do with speed. Declarative knowledge is generally applicable, but slow: it must be interpreted in order to be used. Procedural knowledge, on the other hand, is typically viewed as recoded or 'compiled' into a tighter, more efficient form, from that initially given in its declarative form. Thus, improvisers must have their knowledge encoded in procedural form, to be used quickly enough, but must also make use of the implicit knowledge of musical structure possessed by listeners in order to make their in-the-moment compositions coherent and stylistically appropriate.

Thus, structure, pattern, and bodily engagement emerge as key elements of improvisational technique, and this has been reflected in psychological research into improvisation. This approach attempts to go beyond the limitations of interview and self-report; as Johnson-Laird writes:

> [musicians] can articulate only a limited answer, because the underlying mental processes are largely unconscious. If you ask yourself how you are able to speak a sequence of English sentences that make sense, then you will find that you are consciously aware of only the tip of the process.
>
> Johnson-Laird (2002, p. 417)

making plain why the discipline of psycholinguistics exists as well as the science of music cognition.

Studies on improvisation in jazz

Much of the psychological literature dealing with musical improvisation focuses on jazz improvisation of some kind. The reasons for this are several: some of the researchers involved are themselves jazz musicians; improvisation lies at the heart of jazz, rather than being a more occasional garnishing of precomposed musical structures (as is the case, for example, with guitar solos in many rock songs); and jazz musicians display improvisational skill at a very high level. Since investigations of jazz are centrally placed in psychological studies, we turn now to them.

Where do ideas come from in jazz?

One of the most common popular misconceptions of jazz improvisation is that it involves 'picking notes out of the air' or some similar statement. Jazz musicians themselves know that this is not the case, but have in general done little to explicate the mental and musical processes involved in improvisation. There are notable exceptions, such as Berliner's *Thinking in jazz* (1994), or Monson's *Saying something* (1996), deep ethnomusicological investigations into the workings of jazz improvisation. These studies, which are musicological rather than psychological in nature, provide a rich background for understanding some basics of jazz improvisation. It is a skill which takes thousands of hours of effortful practice to develop; it develops in community rather than with isolated individuals; it is intensely physical in real time; and it involves acquiring and becoming fluent with a kind of musical vocabulary or lexicon of patterns, which form the basis of musical expression the same way words or phrases do in spontaneous production of language.

Improvisation, pitch, and tonality

To many listeners, the facility with which improvising musicians produce the melodies and harmonies they play is something almost magical. How can these notes be found so quickly—and so accurately? Clearly the tones are not selected at random or the results would not be so coherent and compelling. The answers to this question have been sought by researchers in a variety of ways.

The first, and quite well-documented, aspect of pitch organization by improvisers is their use of a set of pre-existing materials which serve as a vocabulary or lexicon from which they can select and on which transformations may be effected. This has long been noted in improvisation outside the Western tradition, for example in Balkan epic song performance (Lord 1960). In the early- to mid-twentieth century, two scholars—Milman Perry and Albert Lord—developed an idea of oral composition in Homeric poetry and in epic bards from the Balkans which has influenced much subsequent thought into the nature of improvisation. This work brought to the fore the notion of formulas as key elements of the oral composer's craft. These formulas can be thought of as recurring turns of phrase, such as 'the rosy fingers of dawn' in the Homeric epics. Researchers into jazz improvisation have adopted this notion using different terms, including 'licks', 'crips', and 'schemas' (Berliner 1994). Building a store of these patterns, which then can be reworked, varied and refined over time, is one of the primary ways in which young improvisers learn their craft and manage the time demands of improvisation.

However, there are deeper organizing principles at work, as well. There is solid evidence that jazz musicians' improvisations obey many of the principles of tonal organization found in the Western art-music tradition, as has been shown in a number of ways. Järvinen (1995) conducted an in-depth analysis of improvised saxophone solos by Charlie Parker. Järvinen's question was: in what ways do 'bebop' jazz improvisations' pitch content reflect the principles of tonal organization that have been found in other, composed repertoires (cf. Krumhansl 1990)? He found that the tonal profile—the prominence of scale degrees relative to the tonic pitch class—of the tones of Parker's solos fit quite well with Krumhansl's results This indicates that the broad statistical properties of tonality serve to guide the improviser at a deep level. This finding

is buttressed by other researchers, such as Larson (2002), whose work has long demonstrated that fundamental aspects of tonal organization as shown in melodic and harmonic teleology are shared between jazz and 'classical' music. Another Finnish researcher, Petri Toiviainen (1995), has used computational models of neural networks as a tool for exploring the tonal and rhythmic organization of improvisations, and has demonstrated ways in which the patterns and techniques, such as the improviser's use of centrally important 'target tones', can be simulated with these models, and also the subtle and powerful interplay between pitch and rhythm in improvisation (Järvinen and Toiviainen 2000).

Improvisation, time, and rhythm

Rhythm in its different aspects is the lifeblood of improvisation (Pressing 2002; Iyer 2002). The improviser must be fully in command of rhythm. With regard to jazz, one recurring question is that of 'swing' or 'groove', at varying tempos, especially the extremely fast ones jazz musicians sometimes use. The literature shows (e.g. Friberg and Sundstrom 2002) that improvisers have a very fine control of timing and great accuracy, within the limits of what the body can do. Hence, at very fast tempi, while maintaining an impressively steady beat, the 'swing ratio' of unequal eighth-notes approaches a 1:1 ratio, perhaps because of physical limitations on moving hands and drumsticks.

However, not all improvisations take place under the kind of high real time demands that fast tempo jazz imposes. Ashley (2002) investigated the more small-scale improvisational aspects of master jazz musicians playing the melodies of ballad. These are slow, commonly played songs, and the variations in performance, which are enormously large relative to those found in the Classical tradition, should be considered acts of improvisation rather than simple re-creation and performance nuance. The primary findings of this study were related to performer's responses to musical structures. First, the performers observe the motivic patterning of the melodies, in that musical passages sharing the same basic figures were altered in similar ways, preserving the categorical nature of the melodies no matter how extreme the differences in timing might be from some original or nominal form of these motives. At a level below this, there were extensive deviations from the nominal rhythms of these materials, either as notated or as performed on prior recordings which served as the model for the improvisers. Above the level of the motive, at the rhythmic level of the phrase, there was a strong tendency for the soloists's expressive deviations to cease at cadence points, thereby anchoring the melody in the larger formal structure through reinforcing cadences. Expressive variation in timing was thus seen as operating on two levels: one structural, where motivic identity is and phrase rhythm is preserved, and one micro-expressive, where individual variation is valued. Microtiming variations are well-documented throughout the literature on jazz performance, as shown in Iyer (2002) and Collier and Collier (2002) from vastly different literatures and points of view.

Improvisation and the body

Unlike musical composition, which can be mostly construed as a more-or-less purely cognitive undertaking, improvisation is an activity deeply steeped in and connected with the human body. To improvise means that one is producing music, audibly and in real time; this necessarily means either playing an instrument or singing. We approach this topic through the work of the psychologist-turned-ethnomusicologist John Baily, noting that imilar issues are raised, for example, by Sudnow (1993) in his narrative of learning to play the piano. Baily was trained as an experimental psychologist in the area of motor behaviour. When he turned to issues of music performance he found a particularly interesting topic in which to work: issues of performance on a kind of long-necked Afghani lute, the dutâr. This instrument underwent significant changes in its form over a relatively short span of years, and the techniques needed for playing it and the kinds of musical figures which were thereby idiomatic on it were necessarily altered. The study of these issues, and others related to them, led Baily (and his associate Blacking) to reconceptualize the relationship between the body and musical structure. In this

'motor grammar' approach, the sequences of sounds which are typically the object of musical study are not seen as abstract structures which performers then recreate, but are instead understood to be deeply informed and shaped by the physiological processes necessary for their performance (Baily and Blacking 1991). The patterns of sound are the result of motor behaviours, and thus bodily movement can be seen as the ultimate source of musical structures. Baily's work, both on the dutâr (Baily 1985) and on the guitar (Baily and Driver 1992), can be seen as having many parallels to articulatory phonology in linguistics, where the way in which language is shaped as a series of sounds is deeply rooted in the dynamic behaviour of the vocal tract (Browman and Goldstein 1989). It is interesting, and gratifying, to consider speech and music—the two main ways in which humans use sound for communication and for pleasure—as fundamentally connected to the embodied nature of human cognition.

Computational and grammatical models of improvisation

Given the complexity of the issues which have been covered so far, it is no surprise that researchers might seek to tie them together in a more unified model. A trio of scientists serve as examples of the approach to understanding improvisation through compuational modelling: Johnson-Laird, Jeff Pressing and Mark Steedman. We consider each briefly in turn.

Philip Johnson-Laird, who is both a psychologist and an improvising musician, has dealt off and on for years with questions of creativity, touching on jazz improvisation more than once. In his 2002 article, he sets out a computational system which can produce some kinds of jazz-based improvisations (walking bass lines) given a chord progression. The program Johnson-Laird outlines attempts to deal with a primary psychological constraint facing jazz improvisers: limited short-term memory, operating in real time. His intriguing solution is to use the constraints occurring in musical structures as ways of limiting the set of options faced by a player at any given instant, so that the loads on memory and decision are lessened considerably. From the choices presented in the set of options yielded by the constraint, quite simple and efficient selection mechanisms suffice. This approach is quite different from those based on over-learned pitch-patterns or formulas, and the dialogue between these two viewpoints continues.

Jeff Pressing (1984, 1988, 1998, 2001), a polymath whose musical focus was improvisation, spent years developing a sophisticated, comprehensive approach to musical improvisation which has as the time of this writing no parallel. Its attempt to draw in physiological, cognitive, cultural, and structural dimensions of improvisation is impressive. In Pressing's model, structural and physical representations of improvisational technique are all represented, and work together to inform the musical result. The physical, embodied considerations in improvisation are fundamental to Pressing's thought: he notes 'the historical fact that music, of all art and sport forms, has developed improvisation to the highest degree', due he thinks to the high time resolution of the auditory and motor systems. Pressing's model of improvisation is based on notions of the interaction between the physicality of performance and the materials being performed, and deals in its own way with the notion of constraints (physical or music–structural) as important elements of a control structure for efficient, real-time improvisational behaviours. The model is explained in significant detail in Pressing (1988) and cannot be adequately described in brief terms, but basically generates novel 'utterances' through the production of musical figures ('event clusters') which may then either be continued based on one or more features of the events currently underway, or may be turned in new directions by a process of interruption. It is in part this duality of control structure, which enables both continuity and surprise, which is responsible for the system's quite impressive performance.

Mark Steedman's work has concerned itself with musical structure and its formal representation since his student days. His work, while not properly speaking a model of improvisation, has been very influential in understanding how improvisers might generate new versions of harmonic progressions from simpler underlying

prototypes. In Steedman (1984) he proposes a grammar of blues chord progressions which involves the use of typical transformation rules or rewrite rules, allowing a simple progression to be elaborated recursively into much more sophisticated, and yet stylistically appropriate, sequences. Since then he has continued to work on how such a grammar might be best constructed, and Steedman (1996) presents a solution which is more elegant in many ways but presents problems for the reader not already familiar with formal grammars. Steedman's work shows how one of the core issues in jazz improvisation, harmony, can be modelled efficiently for inclusion into a comprehensive model of improvisation.

Improvisation, interaction, and identity

To be an improviser is, most often, to be a member of a community of musicians who share a common purpose, set of skills, and musical vocabulary. Different researchers have pursued this matter in a variety of ways. Some, like the musicologist Ingrid Monson (1996), have focused on the processes of interaction between jazz musicians while they are playing together, finding that the interplay between performers is essential to the nature of the art and to the skills and behaviours of individuals as well as groups. Others, like the communication theorist Keith Sawyer (1999, 2003, 2006) have connected musical improvisation with other collaborative activities, notably in the domain of theatre. Sawyer identifies three main elements of importance: improvisation, collaboration, and emergence. Improvisation, of course, refers to the production of new ideas 'on the spot' rather than recreating already composed ones; collaboration locates creativity not in any individual but in the group as a whole; and emergence, the notion that somehow the 'whole is greater than the sum of its parts,' and has dynamic properties which are hard to predict ahead of time. Seddon (2005) identified six modes of communication between student improvisers, both verbal and non-verbal, and proposes the notion of empathetic attunement and creativity as a key element in successful group improvisation. It is clear that group process is one of the areas in improvisation research which is ripe for additional study, and the growing field of dynamic systems and complex organization has much to offer in this regard.

Connected to the idea of group activity are the notions of community and the improviser's identity. This topic has produced a few interesting studies (e.g. Duranti and Burrell 2004) but has been most seriously investigated by a pair of researchers, Raymond MacDonald and Graeme Wilson (MacDonald and Wilson 2005, 2006; Wilson and MacDonald 2005). The focus of their research has been the ways in which membership in a community of improvisers serves to define, for the members, both important aspects of their individual 'identities' or self-understandings, and the very concepts they use in understanding what kind of music they see themselves as playing. MacDonald and Wilson make the case that group interviews, rather than interviews with individuals, are the best method for investigating these matters, as issues of identity and cognitive constructs such as the meaning of 'jazz' are in fact developed and shaped by the social group's interactions, which is most clearly seen in group discussions.

Improvisation, children, and music learning

Since the publication of Hargreaves (1986) there has been a significant growth in the research literature surrounding developmental aspects of improvisation. We can only touch on the matter in this chapter but it is clear that improvisation can be a very significant aspect of childrens' musical development and an important avenue of creativity (cf. Webster 1987, 2002). A number of researchers have investigated ways in which children develop as improvisers. Paananen (2007) demonstrated the steady growth of hierarchic concepts in childrens' improvisations from the age of 6 to 11; these hierarchies were reflected in tonal structures as well as in rhythm, metre, and motivic organization. Brophy (2005) undertook a longitudinal study of children from the age of 7 through to the age of 9, recording their pentatonic improvisations on xylophones. His primary interest was in phrase and motivic

structure and metre; he found that there was increasing use of motive and antecedent-consequent phrase structure in the first two years of his sample, another sign of increasing sophistication at quite an early age. Kratus (1989) showed that children too young to be skillful in more structured composition (those up to the age of 7) could be productive as improvisors, suggesting that improvisation with younger children would be a good path for music learning. Other research (such as Azzara 1993) has demonstrated that using improvisation as a regular aspect of a fifth-year elementary school music learning curriculum had positive significant transfer to other musical activities and abilities.

Other researchers have looked at the influence of context on children's improvisations. Guilbault (2004) found that 5- and 6-year-olds are sensitive to the accompaniments played while they improvise; when a harmonically oriented accompaniment was provided, the children made more use of tonal function and implied harmony in their improvisations. Young (2003) dealt with 3- and 4-year-olds who were improvising together with an adult partner, and identified social interaction in the form of play to be an important source of children's creative behaviours, resulting in an enriched musical output. Finally, Burnard (1999, 2002) has shown that 12-year-olds engage in quite sophisticated group improvisational behaviours, involving interactions between their bodies, movements, and choices of instruments to facilitate improvisation, and valuing group collaboration and interaction in their music-making.

Conclusions

The value of research into improvisation is clearly demonstrated by the studies mentioned here, and many others as well. Improvisation is not an isolated side issue with regard to human music-making; it connects musical structure, our bodies, and our sense of ourselves as individuals and as members of social units in powerful ways. Much work remains to be done but a strong foundation exists at this time.

CHAPTER 39

Children as creative thinkers in music

Focus on composition

Peter R. Webster

THE study of creative thinking in music involves a complex combination of cognitive and affective variables, often executed at the highest levels of human thinking and feeling. This is such a complicated set of long-term engagements (composition, repeated music listening, or decisions about previously composed music in performance) or 'in the moment' engagements (improvisation and one-time listening), that it becomes quickly apparent why this field has not attracted more music researchers and why many feel the topic is hopelessly impregnable.

There are many reasons for optimism, however, as we are starting a new century of scholarship. The changes in education and the role of music in formal learning demands that we address creative thinking as best we can. The serious study of creative thinking from a psychological perspective is helpful to review as well. This chapter is designed to offer some perspective on these matters and to place in context the growing research literature in music completed by musicians. While it is generally acknowledged that children's creative thinking in music occurs as part of many music experiences such as listening, performance, conducting, and improvising (Reimer 2003), the focus here is on composition.

Education context

Since the beginning of the twentieth century in North America, music educators have seen themselves as largely teachers of music performance, especially in the secondary schools where music study becomes centred on the 'talented' few (Mark 1996, p. 11). Many school systems require music instruction in the elementary and middle school grades for the entire school population with the curriculum often centring on singing, movement activities, and some listening. Attempts to include a wider variety of music experiences, including composition and improvisation at all grade levels, are only now beginning, inspired in part by the National Standards (Consortium of National Arts Education 1994) and arguments from music education philosophers and framers of curriculum (Reimer 2003). The situation in other English-speaking countries such as Australia and England has been qualitatively different. For some time, the emphasis in curriculum has slanted more toward compositional experiences or at least a more balanced approach that has addressed composition together with performance.

The English-language research literature on creative thinking in music for children, therefore, has been influenced in large part by these teaching traditions. Music psychologists interested in children's generative behaviour and unfamiliar with developments in music teaching and learning will find it necessary to understand this context.

One particularly powerful view of learning that has influenced the research is constructivism (Kafai and Resnick 1996). Constructionist thinking is not new to educational theory, with roots that can be traced to Dewey, Piaget, and others. This line of thought has been given a fresh perspective in writings on school reform

(Gardner 1999). The basic goals of constructivism are to place emphasis on creativeness and to motivate learning through activity. Learning is seen as more effective when *situated in activity* rather than received passively. In other words, children learn best when actively involved in creating things and not when asked to only memorize facts for later recall. Such memorization is important of course and must not be eliminated; rather, such learning should be partnered with creative activities that allow students to demonstrate command through action. Each child should be allowed to *construct* their own understanding with the expert help of the teacher. At the heart of these ideas is a shift away from thinking about education as being centred solely in the mind of the teacher to more of a partnership between teacher and student, with the teacher as the major architect of learning. Project-centred learning is celebrated with students solving problems.[1]

Bases in psychological literature

J. Paul Guilford's 1950 keynote address to the American Psychological Association (Guilford 1950) is often cited as the commencement of the modern-day study of creativity. In the address, he noted the lack of attention paid to divergent thinking[2] and called for more systematic study. His work would evolve into the formation of a factor-of-intellect model of human intelligence that celebrated the intersection of product, operations and content (Guilford 1967). His subsequent factor analytic studies brought attention in psychology to a multiple intelligence theory that was meaningful. The specific model proposed came under fire by the research community due to the problems inherent in factor analysis as an empirical methodology (Sternberg 1999), but the spirit and logic behind Guilford's work lives on in many guises.

Since that time, the growth of formal study of creativity has been slow, at least until most recently. There are two edited volumes published in the last few years that are excellent compilations on the subject of creativity. The first is by Finke *et al.* (1996). The book has 14 chapters aimed at offering a contemporary view of creativity in a cognition context. Topics such as insight, problem-solving, memory, and incubation are included, as well as an interesting opening chapter by the editors on cognitive processes in creative contexts. Attention is also paid to machine intelligence and on connectionism and neural nets.

A more recent collection of writings was published by Cambridge University Press, edited by Sternberg (1999). This volume is perhaps the most comprehensive and definitive, single volume in the field of general creativity and contains 22 chapters written by many notable scholars in the field today. The book is important because it documents the recent upturn in interest among cognitive psychologists in the study of this difficult topic. Sternberg (2006) has also recently completed a retrospective analysis of his own work on creative thinking and it is highly recommended.

There are now major journals in psychology devoted to the topic of creativeness, including the *Journal of Creative Behavior* and the more recent *Thinking Skills and Creativity*. Two books on adult creativity have been written—one by Gardner (1997) and the other by Csikszentmihalyi (1997)—and each applies recent work to the explanation of genius.

Despite these developments, creativity as a construct (or as a set of complicated constructs) has largely been avoided in modern psychology. Sternberg and Lubart (1999) offer six possible reasons:

1 Mystic and spiritual roots of this topic which tends to put off the more scientific community
2 Its pragmatic, commercial nature exploited by those who offer popular accounts of the creative thinking process which are not based on theory and research

[1] For an extensive treatment of constructivism and its role in music teaching and learning, see Wiggins *et al.* (2006) and the accompanying response by Webster.

[2] The concepts of 'divergent' and 'convergent' thinking are at the heart of much of my writing and thinking about creativeness. Divergent thinking is simply that kind of thinking for which the result has no single goal and a number of products may result—a kind of personal brainstorming. Convergent thinking is work that focuses on a final result. Creative work involves both kinds of thinking many times and in many complex ways.

3 Early work on the subject that was not theoretically or methodologically central to the field of psychology, and, as such, not respected
4 Problems with definition and criteria that 'put off' the researcher who is looking for easier and perhaps more conceptually understood topics for tenure and promotion committees to understand
5 Approaches that have viewed creativity as an extraordinary part of an ordinary thing so as not to really need separate study, and
6 Unidisciplinary approaches to creativity that have tended to view a part of creativity as the whole phenomenon, trivializing or marginalizing the study (Sternberg 1999, p. 4).

Those researchers in general psychology that have been brave or inspired enough to deconstruct the general creative experience through empirical study have taken the following approaches (Mayer 1999):[3]

- *Psychometric.* Assessment work aimed at the creation of tools to measure specific traits or evaluate overall creative ability (Guilford, Torrance, McKinnon)
- *Experimental.* Traditional empirical paradigms designed to seek cause and effect relationships (Sternberg and Davidson, Collins and Amabile)
- *Biographical.* Studies that use historical data to understand the creative process and creative thinking (Wallace and Gruber, Gardner, Simonton)
- *Psychodynamic.* Writings based on clinical evidence and philosophical/psychological speculation about creativeness (Freud, Kris, Kubie)
- *Biological.* Data derived from physiological data (Martindale and Hines, Hudspith)
- *Computational.* Conceptual work based on mathematical and computer-based models and simulations (Boden, Shank)
- *Contextual.* More qualitative work based on the realities of social context (Csikszentmihalyi)

Each approach has strengths and inherent weakness. Selected reading of studies in each approach is highly recommended to gain a sense of the contemporary scene in the general literature before reviewing specific studies in music and music composition with children. In drawing implications for music teaching and learning, this literature helps to bolster the aspects of enabling conditions (both personal and culturally based) and enabling skills (personal competence) that are so critical for creative thought. Much of this literature, too, underscores the vital importance of divergency of thought and imagination in context with more convergent thinking that often involves just plain hard work. The vital role of social context is also apparent from this general literature.

Promising new research for music

When comparing the approaches in the general literature to music, the psychometric, experimental, and contextual approaches from Mayer's listing are noticeable. A more 'descriptive' approach is emerging in music which places emphasis on the content analyses of the creative music experiences themselves. Hickey's review (2002) of creativity research in music and other arts stressed the importance of what she called 'confluence studies' which bring together social/cultural contexts with historical forces, events and trends. These studies, which will be noted below, often focus on the musical decision-making processes and on more personal issues outside of the music itself such as confidence, peer-interaction, and self efficacy.

Over fifteen years ago, I published a review of the literature on creative thinking in music education (Webster 1992). I have continued to maintain an annotated bibliography that attempts to cover the field of music teaching and learning.[4] My organizational model for this

[3] A complete review of each approach is not possible here but see Mayer (1999) for a more detailed description of each approach and for references to the scholar's work whose names appear in this listing.

[4] For the most recent annotated bibliography, consult the following website: http://musicalcreativity.com/?cat=3.

literature includes studies organized in three major categories:

1 *Theoretical*, works based on philosophical or psychological arguments as well as review, standards and historical writings;
2 *Practical Application*, literature designed to inform praxis but not derived fundamentally from empirical evidence; and
3 *Empirical*, work from numerical or observational data.

This empirical category is the most complex, with studies that examine teaching strategies, assessment design, technology, relationship between variables in and outside music, and the actual creative experience. Work on collaboration and social context has gained a great deal of ground in the last few years. Work with technology and teaching strategies is growing quickly as well. The early literature model was based on less than 200 writings. A current review of this literature will reveal nearly three times this amount.

There are a number of trends that can be seen in the literature in the last 15 years. Here is a summary of the major developments noted in this new literature in terms of children's composition. Key references are noted to give the reader a start in exploring the body of work. A brief summary of this work follows.

- Adoption of the postmodern tendency to question the assumptions made by previous generations and to be concerned more completely with social context and more naturalistic settings and qualitative methodologies in studying data (Burnard 2006).
- Empowering children's voices about the composition experience and valuing the meaning that children describe (Barrett 2003; Burnard 2000; Stauffer 2003).
- Heighten interest in the young child's work with invented music notation and the child's discussion of the notation as a window to understanding knowledge (Gromko 1994).
- New approaches to assessment, including consensual techniques and peer assessment (Byrne *et al.* 2003; Hickey 2001; Hickey and Lipscomb 2006).
- Attention to the role of collaboration and group composition (Kaschub 1997; Odam 2000; Miller 2004; Faulkner 2003; Seddon 2006).
- Emergent thinking on the pedagogy of composition teaching (Hewitt 2002; Webster 2003; Stephens 2003; Berkley 2004; Strand 2006; Odena and Welch 2007).
- New speculation on and experimentation with the role of music technology (Hickey 1997; Nilsson and Folkestad 2005; Crow 2006; Ruthman 2007; Pachet 2006; Burnard 2007).
- Models of creative thinking in music from a variety of perspectives (Webster 2002; Burnard and Younker 2002; Hickey 2003; Wiggins 2003; Espeland 2003).

Shift in research paradigm

Burnard (2006) presented an informative retrospective of research approaches as a prelude to a chapter on children's meaning-making as composers. It characterizes a shift from the more 'positivist, large-scale studies aiming to measure creativity in children's composition towards ethnographic, qualitative approaches and to research focusing on the actual site of operations and practice' (p. 111). She argued that, with the development of socially centred theories, the need to study children in more natural settings doing more natural activities is more desirable. She further argued that more attention must be paid to the children's views, perspectives and accounts of process and product. Burnard's accounting of this shift in paradigm is reinforced as one studies many of the most recent research studies on children's composition noted in this chapter; however, it should be noted that more theoretical and positivist approaches continue as researchers seek better answers to assessment, teaching practice, and the description of what children actually produce musically.

Empowering children's voices

A good example of the literature that moves more toward Burnard's characterization is the work honouring the naturally expressed, child perspective on what it means to compose. Barrett (2003) has written eloquently about children's descriptions of composition and the function that it plays in the lives of children.

Of interest is less the musical content itself and more the way children internalize and deal with the request to compose music and the way they make meaning from the experience. It is reasoned that the more we understand this process, the more we understand learning. Burnard (2000) has explored this theme effectively in her examination of how children blend improvisation with composition in the classroom. Stauffer (2003) offered a perspective on identity and voice in her review of several years of compositional data among children using computers to compose music. The accent in her work is on observation of evolving musical thinking with minimal direction from the teacher/researcher.

Invented notation

One window into the minds of children when dealing with music composition is invented notation. Musical drawings offer a means for non-verbal communication of cognitive processing and representation. Gromko (1994) and others such as Barrett (1997) have explored this approach. Typically, children without formal notation understanding are asked to 'notate' their composed work so that others might understand it. After the invented notation is created, children might be asked to tell the researcher what the notation represents. This often leads to a better understanding of what drives or organizes the music composition. Such work leads to a better understanding of how children think in sound and how this changes with age and experience.

New approaches to assessment

Invented notation is one way to deconstruct the complexities of children's composition, but other approaches to assessment of both product and process have been explored. Byrne *et al.* (2003) have reported positive and significant correlations between levels of optimal experience of Csikszentmihalyi's 'flow' levels and quality of group compositions as measured by creativity ratings. Such work is very tentative to be sure and fraught with difficulties, but such experiments are worthy additions to the literature as a partner to more qualitative work.

Hickey (2001) and Hickey and Lipscomb (2006) have reported some success using the consensual assessment technique made famous by Amabile. This approach is based on a theory that creativeness is best measured by experts in the domain of a field using global approaches and that the articulation of specific criteria is less valid.

Collaboration and group composition

One interesting facet of recent study of children's composition is the effectiveness of collaborative and group composition. Kaschub (1997) profiled the processes of two composition projects, one with six sections of sixth-grade general music students and one with a high school choir. In each case, a composer worked with the groups to create a process cooperatively. The article is rich with examples of how children gained a stronger understanding of music. Seddon (2006) reported success in using composition as a group activity with computer-mediated collaboration over a distance. Similarly positive experiences were reported by Faulkner (2003) in working with group composition involving 6–16-year-olds in a rural school in Iceland; however, his study also identified some causes for concern in terms of group work. Odam (2000) published a critical perspective on group composition as it was implemented in certain schools in England and Wales as part of obligatory Key Stage 3 curriculum; he noted that too many teachers used inappropriate methods and much time was wasted. Miller (2004) contributed an action research study that featured group composition in an elementary school. This study is noteworthy because it was based on a careful review of the literature and featured the story of a teacher who was employing compositional experiences for the first time.

Pedagogy of composition

Of interest to those that teach or are planning to teach, this recent development in the literature deserves special attention. Examples include the work by Hewitt (2002) and Odena and Welch (2007) which demonstrated a direct link between success in teaching composition and past experience with music and compositional thinking. Implications for teacher-preparation programmes seem obvious. Berkley (2004) contributed data on approaching the teaching

of composition as a problem-solving activity that should be presented in a positive atmosphere of student autonomy. Stephens (2003) presented several techniques that have been shown to be effective in teaching and stressed the importance of melodic ideas, technique, musical structure, and personal voice. In writing about the judicious use of revision, I have tried to argue for a balance between complete freedom in teacher direction and dominate control (Webster 2003). An extensive survey study by Strand (2006) of music teachers in Indiana revealed no consistent definition of composition and no real consistency in activities that purported to be compositionally based. Much work remains to be done on the preparation of music teachers to lead successful teaching sequences in composition that is inspired by both the more qualitative and quantitative studies described here.

Role of music technology

Advances in music technology have profoundly affected the research and practice of children's compositional engagement. We have already mentioned the work of Seddon and Stauffer in this regard. The case studies by Hickey (1997) of individuals working with computer technology are important models. The work by Nilsson and Folkestad (2005) is yet another example of a set of investigations of how computer-based technology can be used to study the creative process; noteworthy was their desire to study product and process as an organic whole and to do so with a focus on social/process issues together with music content. On the other hand, Crow (2006) provided a more critical perspective on the implementation of certain music technology and fault was found not only with the materials but the techniques that employed them. Ruthman (2006) documented the use of social computing software applications and online collaboration techniques which promise to make a major advancement in music teaching. Pachet (2006) provided a more pessimistic view of common hardware and software applications and favoured interactive, reflexive music systems. One such system, The Continuator-I, developed at the Sony Computer Science Laboratories in France, allows the user to perform gestures on a music keyboard with an answer returned in such a way that a musical dialogue can be established. Implications for this system in encouraging and studying creative thinking in music are great.

One of the most interesting contributions to the literature concerning the nexus of technology and creative thinking in music is from Burnard (2007). She provided a set of theoretical constructs for the consideration of technology as a pedagogic change agent.

Models of creative thinking

Finally, model building related to children's creative thinking in music continues to flourish. My own model (Webster 2002) has been newly revised based on much of the literature cited here. The model argues for a central process of staged thinking with music materials that represent the interplay of divergent and convergent processes—all informed by enabling skills and conditions. The work by Burnard and Younker (2002) on the pathways that children follow in the creative process is supportive of this model and extends it in fascinating ways. Espeland (2003) has contributed a model for compositional process that features personal and compositional actions in the context of school. Hickey (2003) has offered a componential model based in part on the work of Amabile; it stresses the critical role of social and intrinsic motivation and the nature of instructional set. Inspired by her own extensive teaching and the recent socially based literature on learning, Wiggins (2003) has provided a powerful 'frame' for understanding creative process for individuals and groups. Embedded in the frame is a carefully conceived interplay between teacher and student that stresses a safe and rich environment and a shared understanding of culture, curriculum, and compositional problem.

Conclusion

This chapter has taken a decidedly 'teaching and learning' approach in summarizing the many studies on creative thinking in music. This has been purposeful on my part because some of the best work in this field is done by researchers interested in the developing minds of children

and the best way to educate them in this rich and complex century. Chapters such as this are difficult to write as much good work is not mentioned. The hope is that this sampling of recent studies may convince the reader to delve deeper into this topic, design and execute research, and apply the ideas in practice.

PART 9

The role of music in everyday life

Edited by John Sloboda

CHAPTER 40

Choosing to hear music

Motivation, process, and effect

John Sloboda, Alexandra Lamont and Alinka Greasley

Introduction

A substantial amount of music listening in contemporary Western society is deliberately chosen. This chapter reviews what is known about the psychology of self-chosen exposure to musical performances of others (recorded or live).

The cultural contexts studied in this research are characterized by three broad trends. First is the growing prevalence of 'musical consumers' (i.e. people who do not participate in musical events as performers, or rarely do so). Second is the increasing availability of recorded music of all genres and periods (through methods of production, marketing and distribution—especially Internet-based). Finally, the increasing miniaturization, portability, and flexibility of music delivery systems (e.g. iPods) means that the choice to hear specific music can be exercised in more and more situations. This has led to fundamental changes in the ways in which people use music (Liebowitz 2004).

These trends present a paradox. Although musical engagement is increasingly passive, because it is not linked to performance skill or participation, music use has never provided more opportunities for active agency. The choice of what music to listen to, when, and how has proliferated.

We organize the research reviewed here by the functional niche that the music is chosen to be part of. Music often accompanies some non-musical activity, chosen to enhance that activity in some way by affecting a psychological state which impacts on desired outcomes. In these contexts the music may not be the primary focus of attention or concern—the focus is rather on its effects.

Six main niches appear in the literature. These are:

1 travel (e.g. driving a car, walking, using public transport);
2 physical work (everyday routines like washing, cleaning, cooking, and other forms of manual labour);
3 brain work (e.g. private study, reading, writing, and other forms of thinking);
4 body work (e.g. exercise, yoga, relaxation, pain management);
5 emotional work (e.g. mood management, reminiscence, presentation of identity); and
6 attendance at live music performance events as an audience member.

Within these niches, we also identify four recurring functions of self-chosen music use. *Distraction* is a way of engaging unallocated attention and reducing boredom. *Energizing* is a means of maintaining arousal and task attention. In *entrainment*, the task movements are timed to coincide with the rhythmic pulses of the music, giving the task or activity elements of a dance. Finally, *meaning enhancement* is where the music draws out and adds to the significance of the task or activity in some way. Evidence for these comes predominantly from qualitative and ethnographic research, where music listeners are asked to talk or write freely about their music uses (e.g. DeNora 2000; Sloboda 1999; Sloboda *et al.* 2001), but we also present experimental findings as appropriate.

Travel

Most everyday travel is made alone (for instance, to work). Music is chosen to accompany travel more consistently than in almost any other setting. This is made possible through mobile sound delivery systems that can accompany the traveller. Around 90 per cent of travel episodes are accompanied by self-chosen music (North *et al.* 2004; Sloboda *et al.* 2001; Stutts *et al.* 2001).

Driving a car

Driving is a highly skilled task, requiring constant vigilance, which—if not appropriately applied—can result in death or serious injury. Dibben and Williamson (2007) review evidence that in-car music can decrease driving performance through its distracting and masking qualities: music makes it more difficult to attend to the key visual and auditory signals that must be constantly monitored to avoid accidents (e.g. engine noise, external warning signals). An additional accident-related distractor is adjusting controls on in-car audio-systems, thus taking attention off the road (Stutts *et al.* 2001).

Music while driving generally enhances performance through its capacity to assist with achieving or maintaining appropriate levels of arousal and concentration. Long and boring drives (e.g. on rural highways) promote drowsiness. Use of a sound system has been found to reduce accidents in such situations (Cummings *et al.* 2001), although the drowsiness-reducing effect is most marked in the first 30 minutes of driving, and drivers believe that music reduces their drowsiness more than it actually does as measured by EEG (Reyner and Horne 1998).

Some studies have looked at the effects of music on driver behaviour, often in simulated driving environments (e.g. Beh and Hirst 1999; Brodsky 2002; Turner *et al.* 1996). The benefits of music on reaction times and avoidance of hazards are found to depend on the nature, speed, and intensity of the music. Whilst music enhances reaction times to signals in the centre of vision, high levels of music-induced or situation-induced arousal can narrow the field of attention, causing people to drive faster and decreasing their driving safety.

Are drivers aware of the potentially deleterious effects of the music they choose to drive to? A survey of 2473 UK drivers by Dibben and Williamson (2007) showed that most drivers (87 per cent) listen to the same music while driving as at home. When asked about the effect of music in the car, many (62 per cent) cited music's capacity to soothe them, making them calmer and more relaxed. Rather fewer (around 25 per cent) claimed that music helped them concentrate whilst driving. The safest drivers (as indicated by having retained their no-claims insurance discount) were most likely to prefer silence while driving.

In sum, drivers listen to music in their cars for primarily motivational and enjoyment reasons. They do not typically self-consciously design an auditory environment designed to minimize accidents, but rather listen to the music they like in general in the car.

On public transport

Around 60 per cent of journeys on UK public transport involve listening to chosen music via portable sound systems (North *et al.* 2004). Selecting reasons for listening in this context, respondents noted that 85 per cent of music listening episodes 'helped to pass the time', and 73 per cent chose 'I enjoyed it'. However, only 21 per cent of music-listening episodes helped participants concentrate/think. This confirms that, in general, music listening on public transport is used to enhance (or distract from) a routine, even boring, low-demand experience.

One obvious consequence of private music listening via headphones is that the music isolates the listener from other people (Bull 2001). This choice may thus allow music to mask unwanted noise or conversation, or to function as a defence mechanism against the anxiety-provoking elements of being in close proximity with strangers.

Physical work

Domestic chores (such as washing, cooking, cleaning, gardening) are the most prevalent everyday physical tasks. These simple and often-repeated tasks have low interest and attentional demands, and music is a very frequent accompaniment.

'Singing while you work' has been a core activity in cultures over time and space (e.g. Gioia 2006). Music is frequently described as an accompaniment to mundane (mainly solitary and domestic) everyday activities (Sloboda 1999), and North *et al.* (2004) found that self-chosen music accompanied housework on 90 per cent of occasions.

Qualitative ethnographic evidence suggests that all four functions of music use—distracting, energizing, entrainment, and meaning enhancement—arise in relation to this activity (DeNora 2000; Sloboda *et al.* 2001). The following example highlights how music energizes, entrains and adds meaning to the routine of cleaning (from Greasley and Lamont 2006):

> I've got a CD that I **always** clean my house to, which is Swing When You're Winning by Robbie Williams [laughs]... it just kinda makes it a bit easier, a spoonful of sugar I suppose helps the medicine go down, and it's just, it's lively as well, most of it is quite lively and if you're hoovering, it's yeah, you can dance around to it while you're doing it.
>
> (Female 26 years old)

The interviewee later noted that she was 'not a massive Robbie Williams fan'. This exemplifies the functionality of the chosen music. Individuals choose music in conjunction with concurrent tasks and activities to help them achieve goals (see also DeNora 2000; Hargreaves and North 1999; Sloboda 1992, 1999).

Brain work

Desk work in occupational settings

Technological advances mean that individual workers can increasingly make self-directed decisions about whether and how to listen to music. In an office environment, Lesiuk (2005) provided a selection of CDs for individual use via headphones over a 2-week period. Music was found to improve a number of work-related measures, including overall mood: those who listened to music for more time had a more positive mood (see also Oldham *et al.* 1995).

Haake and Dibben (2006) surveyed employees' personal use of music in a variety of office settings. They found a high degree of music listening at work from their volunteers (80 per cent reported listening at work, for an average of 36 per cent of total working time). Respondents tended to listen to music while doing routine solitary tasks, word processing, web-surfing and emailing. They tended not to listen during tasks involving interaction with colleagues. Considering the functions of music listening, respondents cited task-related functions (improving concentration and focus, or blocking out unwanted noise) and more general positive effects (reducing stress, contributing to well-being and improving the perceived quality of the working environment). Some respondents suggested that music stimulated positive social interaction between colleagues by providing a talking point. Finally, particularly for those undertaking low-demand tasks, music was a way of relieving boredom. In common with other studies (e.g. Sloboda 1999) the main disadvantages of music in the workplace related to the involuntary overhearing of music chosen by others. Another problem raised was the difficulty of attracting a colleague's attention when they were wearing headphones.

Private study

Very often children undertake homework in a room where a TV or radio is playing. Pool and colleagues (2003) found that background music from TV or radio had no significant effect on homework performance or duration. In contrast, soap operas caused a significant decline in performance, probably as their explicit narrative and verbal content caused cognitive interference with the task. Beentjes and van der Voort (1997) found 64 per cent of Dutch children claimed to play pop music 'often' or 'always' while doing writing assignments for homework. Most children claimed that this benefited their performance, although these results can imply that if there must be background media, music is less disruptive than spoken media.

Music is frequently used by adults as an accompaniment to private study at home (as recently confirmed for university students by Kotsopoulou and Hallam [2006]). However, there appears to be no systematic published research on the use of music for adult private study.

Body work

Music has the capacity to alter bodily processes, such as physiological states and behavioural movements (see Chapter 11 this volume) and coordination and motivational levels (Chapter 44 this volume), and is used to accompany activities such as exercise, relaxation, and pain management. Below we review studies exploring factors that influence people's choices of music to accompany such activities.

Exercise, yoga and relaxation

The key issue in the choice of music to accompany physical activities such as exercise or relaxation is the appropriateness of the music for the activity, and the functions of energizing and entrainment are central. Most experimental research uses experimenter-selected music (e.g. North and Hargreaves 1996, 2000), although some include a limited choice within this; one recent study surveyed the preferred music of their population before selecting music for use in their experiment (Karageorghis *et al.* 2006). Results indicate that choice and preference is affected by the appropriateness of the arousal potential of the music for the activity. For example, people prefer listening to high arousal music during exercise and low arousal music during relaxation (North and Hargreaves 2000), and faster music is preferred for higher intensity exercise (Karageorghis *et al.* 2006). Studies with restricted music choices also show that the perceived appropriateness of the music for the exercise affects liking (North and Hargreaves 1996), and over the long term this might affect independent choices made in real-life settings.

Belcher and DeNora (1999; see also DeNora 2000) explored the function of entrainment in relation to music and exercise in some detail. Using ethnographical methods (including in-depth interviews, questionnaires, and observation), weekly aerobics sessions were studied over a year. They found that beats per minute was one important feature of music choice for different exercise settings. Successful entrainment was partly influenced by participants' perceptions of the music. Valued sessions had music which varied in rhythm, lyrics, melodies and orchestration, facilitating appropriate levels of energy, motivation and endurance for the aerobics routines. Despite evidence for a consistent relationship between features of music (especially tempo) and exercise settings, there has been virtually no research looking at wholly self-chosen music that accompanies body work activities like exercise and relaxation.

Pain management

As music is held to have active and structuring properties on and for the body (DeNora 2000), it has been explored as a tool for pain management. Studies have examined the effects of music on pain perception and management in both clinical and experimental settings (Good 1996; Mitchell and MacDonald 2006; Mitchell *et al.* 2006). Beneficial effects of repeated music listening over a week have been found for chronic pain sufferers in terms of higher levels of perceived control over the pain and lower levels of reported pain, depression and disability (Siedliecki and Good 2006).

Experimental studies show that choosing from a range of experimenter-selected music is more beneficial than listening to entirely experimenter-chosen music (Siedliecki and Good 2006), but listening to one's own preferred music has the most significant effect on pain (Mitchell and MacDonald 2006; Mitchell *et al.* 2006). Survey research illustrates that chronic pain sufferers regularly listen to music (75 per cent of the sample in Mitchell *et al.* 2007) and are also aware of music's potential for attention diversion and relaxation. Music which is entirely under the listener's control can thus be a very effective tool in pain management for a number of different reasons, including attention diversion and perceived control over the situation (Mitchell *et al.* 2007).

Emotional work

Having evaluated the use of music in relation to non-musical tasks and goals, we next consider some more intrinsic outcomes of music listening by focusing on the use of music to manage mood, self, and emotions.

Reminiscence

A common function of self-chosen music listening is reminiscence (reminding oneself of past events), which is particularly common in older adults (Juslin and Laukka 2004). Sloboda (1999) found that adult participants who were asked to recall early memories involving music were able to report detailed and highly emotional memories despite the considerable time which had elapsed. Many adults use their musical autobiographies to reconstruct their life story (DeNora 2000; Greasley and Lamont 2006), illustrating that music is intertwined in the construction of autobiographical narrative.

Mood management

Listeners also regularly report mood management as a common function of self-chosen music listening, as indicated from surveys (Laukka 2007; Sloboda 1999) and qualitative studies (DeNora 2000; Greasley and Lamont 2006; Hays and Minichiello 2005). Unsurprisingly, given that people choose to listen to music that they like and that makes them feel good, they predominantly experience positive emotions as a consequence of music listening (Juslin and Laukka 2004). Individuals have considerable awareness of how they can use music for personal functions such as mood management. Batt-Rawden and DeNora (2005) describe this practical knowledge as 'lay' therapeutic practice, which, they note, is often subsumed by other goals or tasks rather than an independent act of behaviour (see earlier sections).

There are some differences in this awareness between individuals. For example, Sloboda (1999) found that women's free responses relating to mood were more detailed and articulate, and North *et al.* (2000) found adolescent girls to be more concerned than boys with how music could aid their emotional needs. Greasley and Lamont (2006) show that less musically engaged listeners seem less aware of the range of emotional functions that music has, while more engaged listeners have this 'lay' practice at their fingertips. For example, one male respondent noted:

> There's a different mood attached to all of them, there's a different feeling attached to all of them, um, I know every single one of them inside out, so I know what I want and where it'll be and I always have a choice.

Research itself can also stimulate the process of self-reflection, making listeners more aware of the emotional potential of music listening in everyday settings. In an innovative participatory study, Batt-Rawden and DeNora (2005) explored links between music listening, well-being and health. Participants reported the process of listening, choosing, and responding to different CDs to be therapeutic in its own right, sometimes heightening awareness of how and what to listen to for purposes of self-care.

Presentation or confirmation of social identity

As well as using music for reminiscence and emotional self-regulation, music can also be used in the presentation or confirmation of identity. Preferences for particular types of music may carry a message to others regarding a range of attitudes and values (Zillmann and Gan 1997; Rentfrow and Gosling 2006; North and Hargreaves 2007). Adolescents' music preferences in particular have been shown to reinforce both how they see themselves and how they are seen by others (Tarrant *et al.* 2001). Listeners are also aware of the messages they may send by expressing particular musical preferences. Finnäs (1989) found marked differences between the music preferences young people stated publicly and those that they privately endorsed. Young adults also believe music preferences reveal information about their personal qualities (Rentfrow and Gosling 2003). In subscribing to a music taste culture, people are often associating with a particular lifestyle and wider set of values (Russell 1997). (For a more detailed account of musical identity, see Chapter 43 this volume).

Attending live events

Despite the technological advancements in availability of recordings and media portability mentioned at the outset, attending live music events is still popular. For example, the Arts Council of England reports that around 10 per cent of the

population attend classical concerts in a year, while 36–39 per cent attend any live musical event (cited in Riley and Laing 2006; see also DCMS 2006). However, despite the sustained popularity of attending live musical events, this facet of everyday musical experience has received very little research attention.

Motivations for attending live musical events

Socio-economic factors have long been recognized as influential in determining patterns of arts attendance. While most people report enjoyment and seeing a specific performer or event as their primary motivations for attending arts events (DCMS 2006; Pitts 2005a), it seems that more people would attend classical concerts if tickets were free of charge (Knight Foundation 2002). Moreover, in the US, only 4 per cent of the population regularly attend live events out of 27 per cent 'potential' classical music consumers (Brown and Bare 2003). This suggests an economic barrier (absolute or perceived) to concert-going amongst the less affluent.

Economic approaches to culture provide complex analyses of how people choose to spend their leisure time. Linder (1970) suggested that economic growth leads to *less* time spent on culture, since the opportunity cost of attending a concert rises alongside wages. However, increased income leads those people who choose to engage in cultural activities to do so through relatively goods-intensive experiences such as CD buying rather than time-intensive experiences such as concert attending (Ekelund and Ritenour 1999). Bourdieu's (1984) sociological concept of cultural capital explains why certain social groups engage in particular kinds of cultural behaviour, relating patterns of cultural consumption to sociological variables such as class and gender. Considering music concert attendance, classical music concert audiences are typically professionals with higher incomes, while folk music attendees are typically middle- and lower-class (DiMaggio and Useem 1978; Pegg 1984).

These large-scale approaches (see also North and Hargreaves 2007) are useful in informing us of high-level social factors influencing patterns of engagement, and powerfully demonstrate that many people decide that classical music in particular is 'not for them'. However, they tell us little from a psychological perspective about motivations for attending live events or the experiences that audiences have at such events, and there has been very little research directly addressing these questions.

In her exploration of audience participation at a chamber music festival, Pitts (2005a) provided some insight into why, having chosen to attend the festival, audiences selected particular concerts within it. Reasons broadly related to musical preferences (for example, avoidance of vocal concerts), the performers, and the audience's familiarity or unfamiliarity with the music (for example, many deliberately chose concerts with some unfamiliar elements). Reasons for not selecting a concert related mainly to musical preference and familiarity, especially relating to over-familiarity with certain works. While Pitts' research emphasizes musical factors that influence participation and attendance at events, non-musical factors like the mood of the listener and the physical environment (e.g. traffic noise, uncomfortable seating) also affect listeners' predicted enjoyment of concerts (Thompson 2007). This might also influence audiences' choice to attend a particular event. The reasons for attending live events are thus complex and extend well beyond the content of the programme or the star performer.

What kinds of experiences do concert-goers have?

The expressive and emotional effects that a performer or group can have on a single listener are now well understood (e.g. Juslin 2001; Davidson 2005), but much less is known about the experiences of a group of listeners at real musical events.

Some research has focused on the retrospective nature of the listener's experience at live events. Gabrielsson and Lindstrom-Wik (2003) found around 75 per cent of strong experiences related to music arose in listening rather than performing situations, and a similar proportion in live rather than recorded experiences. Free written descriptions show that these experiences are diverse in nature, encompassing physical reactions, perception, cognition, feeling and

emotion, existential and transcendental aspects and personal and social aspects. A recent UK study (Lamont, in preparation) indicated that 54 per cent of university students' strongest experiences of music were at pop or rock festivals and concerts and 27 per cent related to live classical events, while less than 20 per cent of the strong experiences resulted from listening to recorded music.

Less research has focused directly on the live performance situation as it occurs. Pitts (2005a) reported informal conversations with audience members at a chamber music festival, although her analysis focused mainly on retrospective accounts provided by audiences through written and interview methods. Using a more structured yet highly ecologically valid method, Thompson (2006) asked a concert audience to rate their experience, enjoyment and emotional response to the performance. Listeners were able to differentiate between the quality of the performance and their own affective responses. Moreover, their enjoyment of the event was better predicted by their own degree of emotional engagement than the perceived quality of the performance, although much variance was left unexplained. Thompson's research highlights some important questions for further research, including the importance of looking at both musical and non-musical factors (see also Thompson 2007).

Is attending a live event different to listening to recorded music?

Little research has directly considered the relationship of live experiences in comparison with listening to recorded music. Gabrielsson and Lindstrom-Wik (2003) did not present analysis of the differences between live and recorded experiences, although Lamont's (in preparation) study highlights some striking differences:

> Listening to them [Radiohead] on CD is one thing, but when thousands of people surround you, singing to every word like you, the atmosphere electric, there's no other feeling as strong, or intense, as that.

Thus concert attending provides a greater sense of community than solitary listening (see also Bogucki *et al.* 2005), and for the popular music audience, concerts complement rather than duplicate the experience of listening to pre-recorded music. Similar responses were found from some classical music festival attendees who suggest that CDs complement the live listening situation (Pitts 2005a). However, other audience members reported avoiding recordings of pieces they had experienced live, noting that 'nothing can replicate what we have experienced this evening' (Pitts 2005b, p. 99). This selective approach to listening to recordings may be more common amongst classical music listeners, although more research is required.

In summary, the live performance situation and the audience's response to it are only beginning to be understood from a psychological perspective. Biographical retrospective data highlights that the live performance situation can have a substantial impact on individuals' lives, and research undertaken closer to the time of experiencing the event emphasizes the importance of emotional engagement with the experience. Future research will need to continue to explore this complex but highly significant aspect of music listening in everyday life.

Conclusions

There is an idealized view of music listening which is implicit in much of the traditional music appreciation literature (see, for instance, Cook 1998). This places 'pure art music' as an object for the reverent attention of the ideal listener, silent, still, totally focused on the music and its aesthetic or spiritual value.

The psychological research presented here paints a much more varied picture, where the surrounding contexts of music not only intrude on the act of hearing, but in many cases shape and control the very purpose, nature, and effect of that hearing. Music may, indeed, be listened to with total silent attentiveness, but for many people this appears to be the exception rather than the norm. Instead, music is more often the chosen accompaniment to all sorts of activities which have no direct connection to music, and could mainly be accomplished without music being present at all. Far from requiring reverent attention, much music experience could be described as background—like the soundtrack of a film, never defining of the focus

of attention, yet psychologically powerful nonetheless.

Two areas of research are ripe for development. One is a fuller characterization of the factors which shift music experiences from the periphery to the centre. Under what conditions does the urge to hear and re-hear specific music become a dominant one, and what kind of changes in thought and feeling come about as one becomes very familiar with a piece of music, through choice? To put it another way, how does music move between 'background' and 'foreground' in a person's everyday life? A second, related question, is the extent to which individuals develop expertise in music choice, in the sense of selecting specific pieces of music with the reliably fulfilled intention of achieving certain psychological outcomes (just as taking an analgesic is done to reliably ease pain). Are some people more expert in their self-chosen administration of musical 'doses' than others, and what makes them more expert? Placing the study of self-chosen music listening within a theoretical framework that acknowledges the high degree of agency involved may well be an important next step in advancing understanding a phenomenon which, despite its ubiquity, still proves elusive to characterize.

CHAPTER 41

Music in performance arts

Film, theatre and dance

Annabel J. Cohen

Introduction

Music in performance arts: music that is not alone

Music is rarely alone (Cook 1998). Throughout civilization, it has typically been performed in conjunction with dance, poetic text, theatre, and, more recently, film and television (Cohen 1999). This chapter considers the psychology of music in the contexts of performance arts, in particular the arts of the moving image, drama, and dance. Research in the psychology of music far exceeds psychological research in any of the other arts. Within music psychology, research on the role of music in film and television constitutes a small but vibrant subdomain (e.g., Cohen 1994; Lipscomb 2008). The growing research on the psychology of film music reveals that the role of music in the context of other performance arts is amenable to psychological investigation. Similar progress can be envisioned for a psychology of music in theatre and dance where foundations are fortunately beginning to emerge (e.g., for dance Grove *et al.* 2005; for opera Boerner 2004). The present chapter may help to further set the stage for such work.

Nomenclature

The psychology of music usually focuses on the listener, but in fact visual and kinaesthetic senses usually play a role, be it watching the motion of the performer, sensing the ambiance of the venue, or tapping one's foot to a beat. Music for film, video, theatre and dance more obviously requires not only a *listener* but also a *viewer*. For participatory dance, a *mover* sensitive to kinaesthetic information, that is bodily motion, must also be considered. In the present chapter, the term *audience* refers to the generic member of an audience. Thus the statement *the mind of the audience* refers to the mind of a typical member of the group attending a performance (notwithstanding individual differences).

Music as part of a multimedia experience

The following section begins with a review of the role of music in film and television, taking a historical approach and considering the recent research in the field of music psychology. Next we will consider the role of music in dramatic contexts and finally dance performance and participatory social dance.

Moving images and the psychology of music

The art of moving images began in the early twentieth century just after the beginnings of experimental psychology which originated only a few decades earlier, and, like film, owed its progress to twentieth century technologies. Hugo Münsterberg of Harvard University was the first psychologist to take film seriously.

As indicated in his book *The Photoplay*, published in 1916, he believed that of all the arts, film was most like music from a structural and psychological standpoint, although theatre and photography more strongly resembled film on the surface than did music. Münsterberg also noted the value of music in film for relieving tension, maintaining interest, providing comfort, reinforcing emotion, and contributing to the aesthetic experience. Of course his views applied only to silent film as he predated the talking film. Although there is no psychological research on the role of music in the original silent film context, the conditions of the silent film (i.e., without dialogue and sound effects) simplify psychological studies of the role of music in film, and several researchers have taken advantage of this to study effects of music on interpretation, beginning with Marshall and Cohen (1988).

Marshall and Cohen (1988) asked whether two contrasting examples of background music would alter observers' attitudes toward characters in a short (2-minute) animation. The animation featured two triangles and a circle and had been used in social psychology research by Heider and Simmel (1944), who showed that typically viewers ascribe personality traits to these geometric 'characters' in systematic ways. For example, the larger triangle was regarded as a bully. Using semantic differential judgements (bipolar adjectives scales such as fast–slow, strong–weak), Marshall and Cohen showed that the ratings of the film overall and of the individual characters differed under the two types of music. For example, the rated activity of the small triangle was greater for one than for the other of the two types of music. Further examples of the role of music on the interpretation of silent film have been shown in studies of sense of closure (Thompson *et al.* 1994), the perceived aggressiveness–friendliness of wolves (Bolivar *et al.* 1994), and realistic clips of ambiguous human interactions (Bullerjahn and Güldenring 1994; Cohen 1993; Shevy 2007; Tan *et al.* 2007).

It was assumed that the advent of the talking film in 1927 would drive music for film into obsolescence. However, surprisingly, films without music were found lacking (Kalinak 1992, p. 45; Kracauer 1960, p. 138), and a new industry for recorded music for the talking film replaced the old industry of live musical accompaniment for the silent film. The movie industry soon recognized the importance of the music soundtrack. Recently, Simonton (2007) analysed the relation between success of over 400 award-winning films (as measured by ticket sales, awards, and critic ratings) and success (as indicated by awards) of film songs and film scores. He sampled data from seven professional organizations which give annual awards for film including film music, either best score or song or both, for example, the Academy of Motion Picture Arts and Sciences (Oscars), the British Academy of Film and TV Arts (BAFTAs), and the Online Film Critics Society. Success of score, but not film song, was positively correlated with receipt of the best picture award. The positive influence of the film score was as high as that for visual effects (e.g., cinematography, costumes, etc.) and for technical aspects, though all of these were less effective than dramatic components (e.g., best actor). Simonton (2007) suggested that a successful score contributes to the film narrative without drawing attention to itself, while a successful song may actually disrupt the narrative.

Tan and colleagues (2008) compared the effects of background and foreground music. In their study, a 1.25 minute action sequence from Spielberg's *Minority Report* (2002) was paired with three soundtracks: (1) the original soundtrack which belonged to the shopping mall environment of the action, (2) the same soundtrack presented as a background score, and (3) a second soundtrack presented as background score. There were 245 participants who completed rating scales following the presentation of each condition. Background music as compared to foreground music in a film led to different interpretations with respect to characters' emotions, relationship between characters, and mood of the scene. The study is the first to show that different specific effects of the music arise depending on whether the music is part of the foreground drama (known as the *diegesis*), or part of the background (*non-diegesis*).

Music in a film is typically non-diegetic, having no basis in the reality of the story (cf. Gorbman 1987). This non-diegetic function of music raises an important question for the psychology of music. How does the audience use this musical information and why does it add value to a film, as suggested by Simonton's (2007) correlational study of award-winning films and

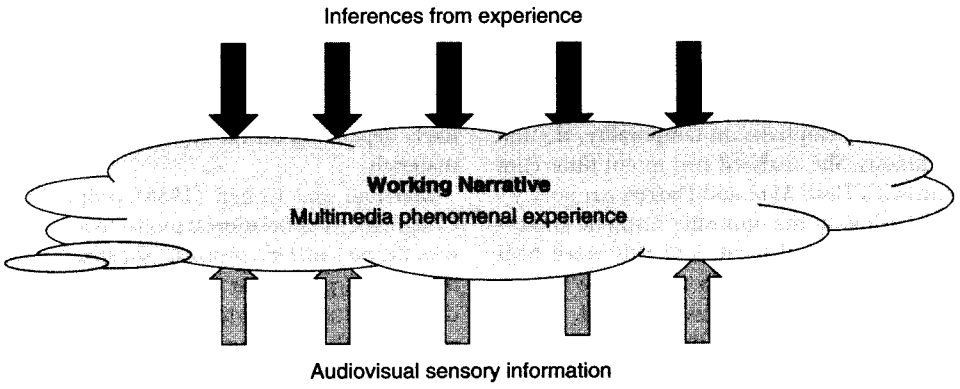

Fig. 41.1 Sensory and cognitive sources of information that contribute to the audience's creation of the experience of an arts performance

as consistent with the experience of most filmgoers? The answer arises by considering that the audience does not aim to record all of the information impinging on the eye and ear. Rather, the audience seeks sufficient information to support engagement and entertainment, making use of two sources of information: sensory information arising from the real world presentation and past experience residing in long-term memory (see Figure 41.1). The audience is constantly synthesizing a story, a working narrative, derived jointly from sensory information and hypotheses or expectations based on long-term memory. According to this model, then, the audience takes what is needed from music and discards or ignores the rest. Given the capacity limitations of the mind (Miller 1956), including in multimedia settings (Fisch 2000; Mayer 2005; Sweller 2005), the audience has really no other choice. This approach is basic to Cohen's Congruence–Association Model of music in multimedia contexts, to be described later.

Film information other than music, such as the film's visual images, speech or sound effects, have been regarded as less effective than music in communicating emotional meaning (cf. discussion of music as the most efficient code for emotional expression in film by film-music theorist Kalinak [1992, p. 87]). The actual sounds of the music used to convey emotion are irrelevant to the story and consequently to the audience. Thus, acoustical information from the music can be discarded as far as engagement in film is considered. The sound of the music may be registered but not as an essential component of the story.

The integration of film and music within the constraints of mental capacity may also be viewed from the perspective of two analytic processes (Cohen 2005; Marshall and Cohen 1988). The first focuses on the *structural* aspects of the media: how patterns of information change in time and space (for example, rhythms of loudness and pitch, visual movement, visual intensity, colour, and contour). Marshall and Cohen (1988) argued that the temporal congruence of musical and visual patterns directed attention to specific elements of animation, and thus visual attention patterns could differ as a function of the particular pattern of music–visual congruency.

Several researchers have explored structural congruency of music and film. Lipscomb (2005) showed influences of temporal audiovisual alignment on judged effectiveness of simple visual animations. Kendall (2005, 2008) defined specific iconic archetypal forms (e.g., arch and ramp) which apply in both musical and spatial domains and has noted that judged congruence of visual and auditory versions of these forms is higher for some forms (e.g. arch) than others. Kim and Iwamiya (2008) examined the effect of formal congruency between sound patterns and animated text (Telops) using materials from television programmes as well as computer synthesis. They distinguished two kinds of formal congruency: similarity in temporal accent pattern and similarity in other changes (e.g., augmentation). In a related follow-up study, Iwamiya (2008) noted that increased formal congruency led to increased subjective congruency and as

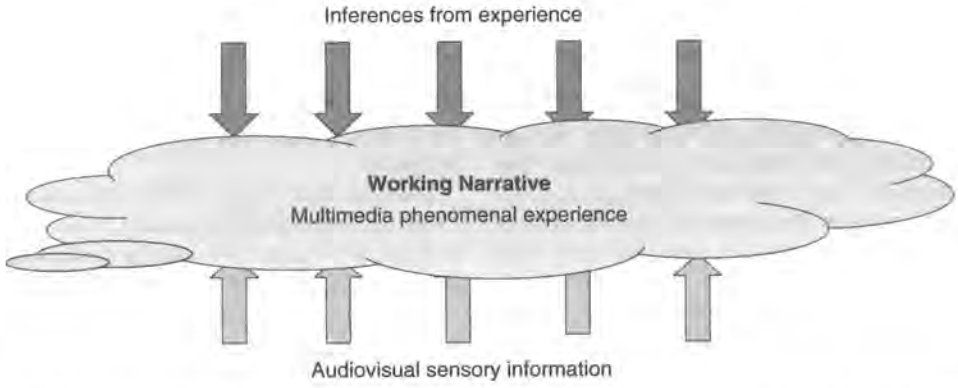

Fig. 41.1 Sensory and cognitive sources of information that contribute to the audience's creation of the experience of an arts performance

as consistent with the experience of most filmgoers? The answer arises by considering that the audience does not aim to record all of the information impinging on the eye and ear. Rather, the audience seeks sufficient information to support engagement and entertainment, making use of two sources of information: sensory information arising from the real world presentation and past experience residing in long-term memory (see Figure 41.1). The audience is constantly synthesizing a story, a working narrative, derived jointly from sensory information and hypotheses or expectations based on long-term memory. According to this model, then, the audience takes what is needed from music and discards or ignores the rest. Given the capacity limitations of the mind (Miller 1956), including in multimedia settings (Fisch 2000; Mayer 2005; Sweller 2005), the audience has really no other choice. This approach is basic to Cohen's Congruence–Association Model of music in multimedia contexts, to be described later.

Film information other than music, such as the film's visual images, speech or sound effects, have been regarded as less effective than music in communicating emotional meaning (cf. discussion of music as the most efficient code for emotional expression in film by film-music theorist Kalinak [1992, p. 87]). The actual sounds of the music used to convey emotion are irrelevant to the story and consequently to the audience. Thus, acoustical information from the music can be discarded as far as engagement in film is considered. The sound of the music may be registered but not as an essential component of the story.

The integration of film and music within the constraints of mental capacity may also be viewed from the perspective of two analytic processes (Cohen 2005; Marshall and Cohen 1988). The first focuses on the *structural* aspects of the media: how patterns of information change in time and space (for example, rhythms of loudness and pitch, visual movement, visual intensity, colour, and contour). Marshall and Cohen (1988) argued that the temporal congruence of musical and visual patterns directed attention to specific elements of animation, and thus visual attention patterns could differ as a function of the particular pattern of music–visual congruency.

Several researchers have explored structural congruency of music and film. Lipscomb (2005) showed influences of temporal audiovisual alignment on judged effectiveness of simple visual animations. Kendall (2005, 2008) defined specific iconic archetypal forms (e.g., arch and ramp) which apply in both musical and spatial domains and has noted that judged congruence of visual and auditory versions of these forms is higher for some forms (e.g. arch) than others. Kim and Iwamiya (2008) examined the effect of formal congruency between sound patterns and animated text (Telops) using materials from television programmes as well as computer synthesis. They distinguished two kinds of formal congruency: similarity in temporal accent pattern and similarity in other changes (e.g., augmentation). In a related follow-up study, Iwamiya (2008) noted that increased formal congruency led to increased subjective congruency and as

well influenced the evaluation (goodness) of the visual form. On a larger scale, musicologist Kulezić-Wilson (2005) has recently explored the notion of the musicality of the structure of film, with specific emphasis on temporality, rhythm and kinesis. She analysed two recent films (Jim Jarmusch's *Dead Man* and Darren Aronofsky's *Pi*) focusing on the opposing aesthetic choices of the shot and the cut, and this work begs for psychological research to test the human sensitivity to the structures described. Cohen (2002) noted the rondo-like structure of *The Red Violin* and suggested comparable music and film research to explore its cognitive and aesthetic effects.

The second aspect of film and music for analysis is *meaning*. Earlier in this section, studies of film music were referred to that showed the effect of music on interpretation of a film, film characters or depicted world. The music can also lead to the feeling of emotions, which is an aspect of meaning that can often be best measured physiologically. Thayer and Levenson (1983) showed that background film scores were successful in both reducing and increasing electrodermal (skin conductance) responses to a stressful film. Baumgartner *et al.* (2006) have shown that classical music (as compared to no music) enhanced the emotional meaning of and physiological response (skin conductance, heart rate, respiration, and EEG) to emotional visual images taken from the International Affective Picture System (IAPS). Related work has been reported by Spreckelmeyer *et al.* (2006) who measured brain evoked potentials (ERP) to brief (350–550 ms) presentations of happy or sad emotional IAPS scenes and happy or sad single tones sung by trained opera singers. Participants focused on either the visual or auditory information and were required to rate the emotional meaning. Influence of integration of the two modalities was seen in ERP waves as early as 150 ms. The brain-wave recordings were more sensitive than were the ratings of the emotional valence. The visual scenes had a greater influence on the judgements while focusing on the audio than did the audio stimuli while focusing on the visual modality. These studies pave the way to research with actual video (as opposed to pictorial) and music materials so as to reveal the underlying music–video integration process. The research suggests that integration occurs quickly and that the brain treats the emotional meaning of visual and auditory material similarly, with sensory (audio or visual) dominance likely depending on the relative salience of the materials.

Marshall and Cohen (1988) proposed the Congruence–Associationist model to accommodate the two analytic processes for structure and meaning, arguing that structural congruencies direct attention to particular elements of a film scene, and that the associations (meaning) from the music are then ascribed to this direction of attention. In light of research on comprehension in other fields (e.g., Kintsch 1998, for text comprehension), Cohen (2001) expanded the model to emphasize the audience's narrative purpose in viewing a media presentation. She proposed that the audience is constantly engaged in generating a *working narrative*, a story of the unfolding drama. The working narrative is the audience's experience of a film. Cues from music as well as from the other sources of information contribute to the working narrative. The second expansion of the model accommodated a notion of the influential French film theorist Christian Metz. Metz gave prominence to music as one of five channels relevant to the experience of film: text, visual scenes, speech, sound effects (noise), and music (described by film theorist Stam 2000). The Congruence–Associationist model thus included these five channels as seen in Figure 41.2.

Marilyn Boltz (2004) conducted research on the role of music in television, and interpreted her results with respect to the Congruence–Associationist Model which she referred to as the C-A Model (to be referred to hereafter as CAM). In Boltz'study, 72 participants were presented with short (approximately 4 min) audiovisual television clips for which the music was presented as either mood congruent or incongruent. They were asked to attend to the audio track, the video track, or to both tracks. Subsequently, they were tested for their memory of the visual film clips and the music excerpts. Performance in the mood-congruent condition was superior to that of the incongruent condition. Performance in the incongruent condition was good for the attended audio or visual medium but did not extend to the unintended

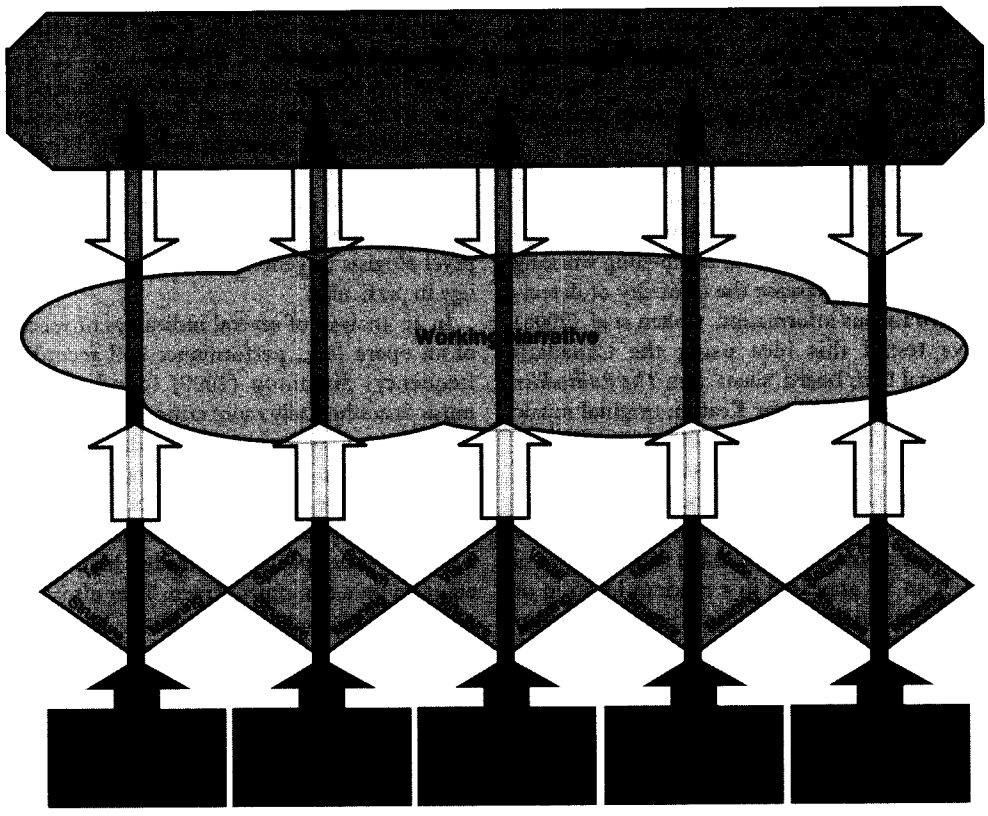

Fig. 41.2 Congruence–Associationist framework for understanding film-music communication (see text for explanation).

medium as it did when the mood of the music and video clip coincided. According to Boltz, congruence in mood of the music and film elicited a search for similar structural properties in the music and film, and the success of the search led to jointly encoding the music and visual material and an integrated music–video memory. Thus, memory for music information would mean memory for the visual information. However, without mood congruencies, attention to the entire music visual complex suffers as the focus is on only one of the modalities (as per instructions in the experiment) and attention is not automatically directed to the other modality which conveys incongruent meaning.

Arguing that an effective working narrative leads to audience absorption or involvement in the film, our laboratory has aimed to determine the role of music in engaging the audience in the film, a phenomenon with which most moviegoers can identify. Two procedures were developed. One is a direct method in which the audience is asked to rate their level of absorption in a film clip presented under different conditions of music. Cohen *et al.* (2005) have shown higher absorption in the presence versus absence of music in short excerpts of several types of genre (e.g., animation, soap opera, drama). As predicted, more realistic genres (such as news) did not show the effect, although the relation between impact of music on absorption and realism of the genre was non-linear, no doubt a result of numerous variables arising from the specific examples chosen. Cohen *et al.* (2006), also explored the relative contributions of the three audio channels–sound effects, dialogue, and music–on self-rated absorption using two contrasting 1-minute clips (from *Witness* and *Day of the Jackal*) presented with only one type

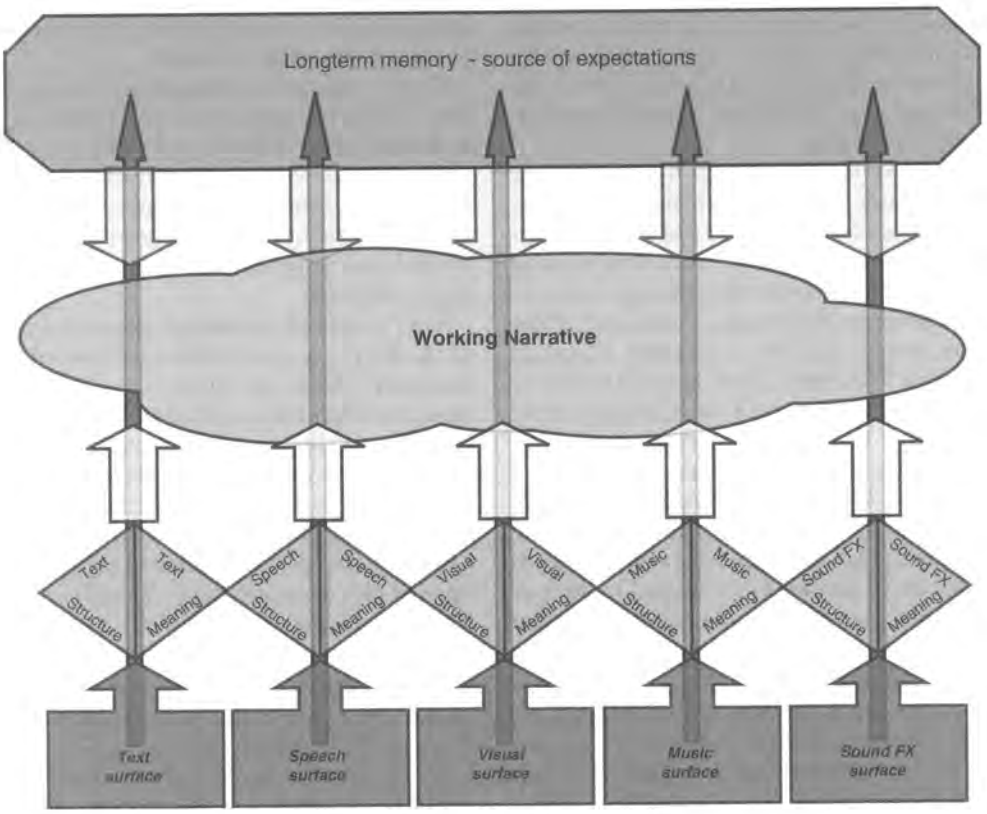

Fig. 41.2 Congruence–Associationist framework for understanding film-music communication (see text for explanation).

medium as it did when the mood of the music and video clip coincided. According to Boltz, congruence in mood of the music and film elicited a search for similar structural properties in the music and film, and the success of the search led to jointly encoding the music and visual material and an integrated music–video memory. Thus, memory for music information would mean memory for the visual information. However, without mood congruencies, attention to the entire music visual complex suffers as the focus is on only one of the modalities (as per instructions in the experiment) and attention is not automatically directed to the other modality which conveys incongruent meaning.

Arguing that an effective working narrative leads to audience absorption or involvement in the film, our laboratory has aimed to determine the role of music in engaging the audience in the film, a phenomenon with which most moviegoers can identify. Two procedures were developed. One is a direct method in which the audience is asked to rate their level of absorption in a film clip presented under different conditions of music. Cohen *et al.* (2005) have shown higher absorption in the presence versus absence of music in short excerpts of several types of genre (e.g., animation, soap opera, drama). As predicted, more realistic genres (such as news) did not show the effect, although the relation between impact of music on absorption and realism of the genre was non-linear, no doubt a result of numerous variables arising from the specific examples chosen. Cohen *et al.* (2006), also explored the relative contributions of the three audio channels–sound effects, dialogue, and music–on self-rated absorption using two contrasting 1-minute clips (from *Witness* and *Day of the Jackal*) presented with only one type

of auditory background. Heightened absorption in the presence of music, as opposed to speech and sound effects, was noted for the *Witness* clip that used music which had originally accompanied it in the film.

The second methodology for studying the role of music on absorption in film is less direct, and is based on the rationale that higher absorption (arising from a more compelling working narrative) will increase the difficulty of detecting extraneous information. Cohen *et al.* (2008) have tested this idea using the Canadian National Film Board 'silent' film *The Railrodder* (1965) (starring Buster Keaton; original music composed by the eminent Eldon Rathburn). There were 72 participants assigned to one of three music background conditions (original, inappropriate, no music). While watching the 20-minute film, they responded with a key-press when an 'X' appeared in a random location of the computer screen on 20 occasions. The film was presented twice. Consistent with the hypothesis, the original music, as compared to no music, led to slower response time. On the second presentation, the original music also led to slower responses than inappropriate music. Individual scores on the Tellegen (1982) Absorption Scale correlated negatively with hit rate, validating the detection task as a measure of absorption.

The paradigms that have been developed for studying music perception and cognition in the context of film have thus begun to reveal the effects of music on meaning, memory, structural judgments, physiological variables, and absorption (involvement). The Congruence–Associationist model has been proposed to accommodate these data and suggest testable hypotheses. All of this may be useful in addressing the role of music in other performance art forms of theatre and dance.

Theatre

The role of music in opera, musical theatre, and other dramatic genres has received little attention from researchers in music psychology, in contrast to that which has focused on film and video. Part of the reason for this arises from the live nature of theatre, which makes replication of experimental conditions difficult. Nevertheless, many questions raised by music in theatrical contexts in fact could be studied.

Opera is among the most ambitious and complex of the performance art forms. It entails an orchestral score, soloists, ensemble, libretto, sets, dance, as well as epic dramatic themes. How the mind integrates and appreciates such rich information should be of great interest to psychologists in general and to music psychology in particular.

In an analysis of several indicators of success of an opera (e.g., performance and recording frequency) Simonton (2000) found that the music is aesthetically more critical to opera than is the libretto. Gregory (1998) conducted a study of opera music in which listeners showed the changes in the strength of their emotional response to a selection of opera arias by moving a mouse whose position indicated high or low emotion on a computer screen. They also completed emotional adjective checklists. Consistency among listeners was shown, and higher emotion was elicited by voice than by the orchestra alone. Similar studies with video recording or in a live situation beg to be conducted.

Boerner (2004) proposed a hierarchical componential framework of performance quality in opera, emphasizing a distinction between the musical and staging aspects. The audience is viewed as judging the congruence of musical and staging dimension, congruence within these separate dimensions (the relation between soloists, choir, and orchestra), congruence within the individual components (relation among soloists). The author admits the concept congruence here, based on Adorno, is vague and in need of operationalism. A questionnaire study of audience assessment of live opera (Verdi's *La forz del destino*) supported Boerner's componential model, but suggested that staging contributed more to the judgments than did the music (Boerner *et al.* 2008). While this seems paradoxical, particularly in the face of Simonton's evidence for the importance of the music in opera, the authors suggest that high quality of the music is assumed by the audience, while the quality and type of staging is more variable and thus gains greater conscious attention. The authors note the importance of further related research that would explore different operas and control for individual differences.

It would also be of interest to apply this methodology to musical theatre, which bears similarities to opera yet has notable differences which might be regarded in terms of reduced cognitive load (e.g., use of popular musical style and native language). Music is also occasionally found in dramatic works. For example, Mendelssohn composed music specifically for Shakespeare's *A Midsummer Night's Dream*. Frankly, however, the psychology of music knows little about the role of music in musical theatre and in drama, and the field is wide open to exploration on the more microanalytic level using paradigms from film-music research or at the level of audience appreciation as recently developed for opera.

Dance

With the advent of film and video recorders, progress in dance research seems more secure than in the past, now that dance performances and choreography can be preserved. Jordan (2000, p. 102) however emphasizes that no single source of information about dance provides an adequate basis for research, as each form of representation highlights some aspects at the expense of others. Notation systems for dance, such as Labanotation and Benesh, have both selective and subjective components.

With few exceptions, classical ballet entails dancing to music. Choreographers have varied in the significance they attach to the structure of the music and the function of ballet in representing this structure. The Russian choreographer Fedor Lopukhov (1886–1973) influenced the development of dance as a non-narrative art form (cf. Jordan 2002) which gave full importance to the structure of music. Lopukhov prescribed matching dance to music on the dimensions of emotional climaxes, curve, colour, and key changes. Major and minor keys were to be treated differently, 'en dehors' and 'en dedans' respectively. Lopukhov was an influence on Ballanchine, who danced in one of Lopukhov's famous works, 'Dance Symphony' (Jordan 2002, p. 3). Contemporaneous with these two eminent choreographers is Jacques-Dalcroze, the Swiss pedagogue who shared the basic principle of the structural similarities of music and human motion. He believed that the best way to understand and learn about music was to experience the elements of music with the body. His curriculum, known as Dalcroze Eurhythmics, has been taught to generations of young people worldwide. Recent attention has been directed to Dalcroze from the perspectives of psychology, developmental education, and African musical pedagogy respectively (Seitz 2005; Juntunen and Hyvönen 2004; Phuthego 2005) supporting the significance of Dalcroze' ideas, and implying the need for empirical research that will validate intuitions about the connections between bodily motion and musical understanding.

A pioneering psychological study of the interaction between music and dance is provided by Krumhansl and Schenk (1997) who used a film of Balanchine's choreography of Mozart's Divertimento No. 15 to test whether dance could represent the structural and expressive qualities of music. Three groups of participants were asked to watch the choreography alone, listen to the music without seeing the dance, or watch the dance and listen to the music simultaneously. All three groups then rated the tension and emotion throughout the piece as well as indicated the beginnings and endings of phrases. Results showed agreement among all three groups and additivity of the information from the separate channels of music and dance: the response in the 'music and dance' condition could be predicted as a combination of the responses to the 'music only' and 'dance only' conditions. The generality of these results to other works of dance would be worth exploring in view of the fact that the particular work chosen by Ballanchine was one in which the choreography was treated with great sensitivity to music-theoretic structural parallels.

Mitchell and Gallaher (2001) examined the ability to detect a 'match' between a piece of music and its intended choreography. The musical pieces were by John Cage, Peter Gabriel, and David Lanz, and the dances were choreographed and performed by a university-level dance educator. Participants were presented with a piece of choreography in silence followed by three selections of music. They were then asked to choose the musical selection that best matched the choreography. The reverse condition, in which the music was presented followed by three examples of dance, was also tested. Participants were also presented with a piece of

choreography paired with a piece of music, either intended or not intended to go with it. In both the sequential and simultaneous test format Mitchell and Gallaher's results show consistently high ratings for perceiving a 'match' between a piece of music and choreography intended to go with it. Participants' answers to a questionnaire indicated that their matches were influenced by similar characteristics perceived in the media, 'including emotion, fluidity, an African or Middle Eastern quality, and temporal characteristics such as rhythm and pace'. The results indicated that memory for dance was sufficient to enable judgements of congruence with musical excerpts presented later, and that the basis for judged music–dance congruence generalized across participants in the study and was multidimensional.

Based on both the work of Mitchell and Gallaher (2001) and that of a dance theorist, Fogelsanger and Afanador (2006) propose four parallels between music and dance that may contribute to a sense of congruency:

1 matching or intertwining pulse or rhythm
2 alignment of coincident structural temporal aspects other than pulse
3 analogous cross-modal qualities
4 complementary referents.

It is notable that the first two items refer to structural characteristics, while the latter refer to associations or meanings, which echoes a distinction made earlier between structure and meaning in the discussion of film and music. Dance can represent structure for its own sake (e.g., choreography of George Ballanchine) and be independent of typical narrative plot but can also tell a story through pantomime and other symbolic movement, such as the story of *Coppelia*, *les Sylphides*, *the Nutcracker*, or a *Midsummers Night's Dream*.

As such the proposal of Folgelsanger and Afanador (2006) fits within the CAM framework and is amenable to psychological test, for example, to determine whether in fact these parallel aspects of music and dance lead to perceived congruency, and whether some dimensions of congruency are more salient than others. While it is appreciated that music–dance structural congruence is hardly a universal choregraphic goal, it is still important to know what congruencies are discernable by an audience and what impact they have on appreciation. In regard to audience appreciation of choreography, Renee Glass completed a doctoral thesis which developed a qualitative and quantitative questionnaire (Audience Response Tool, ART) to determine audience responses to contemporary dance. The dances she examined entailed sound effects but not music in the traditional sense, but the tool in theory could be applied to dances in which music played a role.

Ivar Hagendoorn (2004) has recently proposed that the experience of watching dance creates pleasure for us through the fulfilling and undermining of our expectations. Viewers of a dancer to some extent sense the dancer's movement as if they were doing it themselves. Hagendoorn's proposal of a neurobiological system for a kinaesthetic response to dance aligns with recent evidence for mirror neurons which respond equally to an action carried out by the organism or simply from viewing such action (Rizzolatti and Craighero 2004). However, other research on biological motion detection by Troje (2002) accounts for perception of biological motion without having to call into play mirror neurons. Brown *et al.* (2006) in a unique if not extraordinary positron emission tomography (PET)-scan study of experienced dancers of tango localized a portion of the brain known as the cerebellar vermis that enables entrainment of dance steps to music as opposed to self-paced movement.

Whereas classical ballet and modern dance are performance art for the stage, social dance is an avenue open to and taken by most individuals by their adolescence or early adulthood. In spite of both the prevalence of social dance as an aspect of human behaviour and the reliance on music for this activity, there has been almost no attention of music psychology directed to the social dance situation. Music in the context of social dance in a sense legitimates patterns of human interaction that might seem ridiculous or embarrassing otherwise. Music is at least one of the components in social settings that allows people to behave differently than they otherwise would. The permission-giving power of music may result from effects of music that engage more emotional as opposed to analytic processing

(Niedenthal *et al.* 1999). Cross (2007, p 660) has suggested that

> music's powers of entrainment, together with its 'floating intentionality', fit it for use as a medium for communicative interactions in which meanings are under-determined to the extent that participants are free to develop their own interpretations of the significance of their own, and others', contribution to the collective musical behaviour.

Concluding comments: future research, trans-art congruencies, and lifespan experience

Because music occurs frequently in the context of other arts, a model of music perception and cognition must take these other domains into account. The next decades may well see research programmes on the promising frontiers of the psychology of opera, musical theatre, and dance that will match the recent research activity of the psychology of music and the moving image. The psychology of music and the moving image may also do well to take note of recent research in opera and dance which aims at a global understanding of what the audience appreciates.

For all of the performance contexts for music, a recurrent concept is that of congruence: congruence between music structures and structure within the visual or kinaesthetic dimensions, congruence of meaning, and congruence that refers to the gestalt or sense of the whole. Thus, questions remain about the perceptual and cognitive responses elicited by these similarities between the music, visual, and kinaesthetic domains, and the temporal course of any integration processes.

Yet another aspect that will need attention is that of the role of individual experience of the audience member and when in the life course this experience occurs. A final diagram is therefore offered to reflect both the chronometric and synchronic dimensions of a general model of the audience engaged in music and the performance arts (Figure 41.3). This model, though very abstract, conceptualizes the mind of the audience as actively engaged in performances in

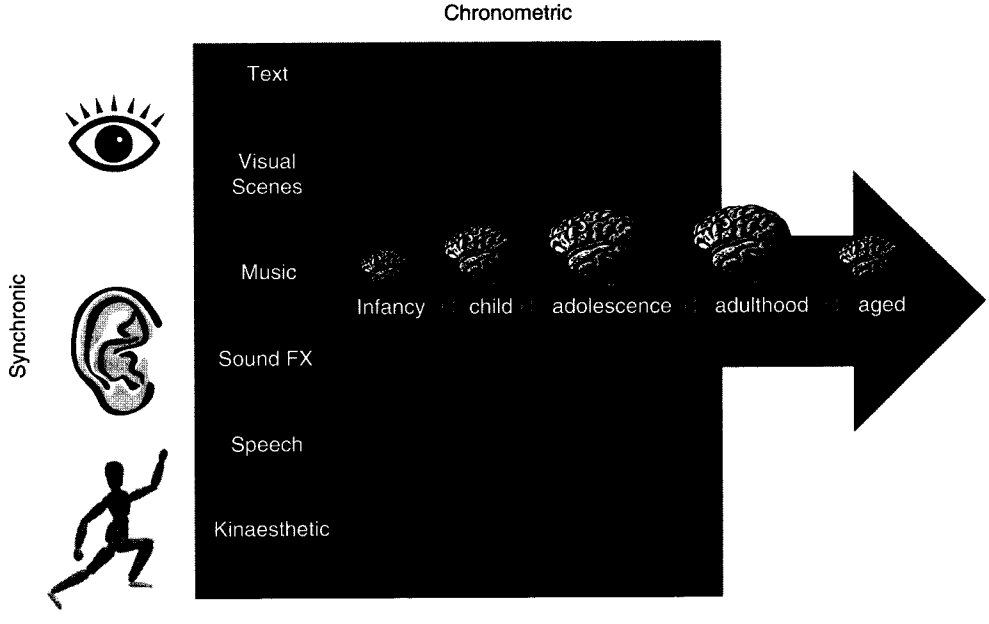

Fig. 41.3 The Congruence–Associationist Model (CAM) in a developmental context. The kinaesthetic sense has been added to accommodate its significance as referred to in the text.

(Niedenthal *et al.* 1999). Cross (2007, p 660) has suggested that

CHAPTER 42

Peak experiences in music

John Whaley, John Sloboda and Alf Gabrielsson

Introduction

Many people experience intensely positive affective states in response to music. The intensity of these experiences often brings about a sense of transcendence and transformation, and their relative rarity makes them greatly prized in the minds and lives of the individuals experiencing them. People tend to retain vivid memories of such experiences many years after they have occurred, and they are often cited as a major reason for continued involvement with music (to increase the chances of such an experience occurring again: see e.g. Sloboda [2005]). Yet these are 'everyday' experiences in the sense that they seem to require no special context in which to occur. They may occur in the home, while travelling, in places of work or study, or in the more specialized contexts of concert hall or place of worship. They may be triggered by any genre of music, and during both listening and performance. Peak experiences also seem to require no specific musical training or expertise; they have been described by young and old, by the learned and the musically unlettered. Moreover, these experiences are not conjured by acts of will or intention—they usually come unannounced and unexpected—and thus cannot be the subject of skill acquisition or pedagogy.

Maslow (1959) was one of the first to formalize the study of what he called Peak Experiences, or 'moments of highest happiness and fulfilment' (1999, p. 85), and 'a spurt in which the powers of the person come together in a particularly efficient and intensely enjoyable way' (1999, p. 106). Maslow spent many years studying peak experiences, and his findings laid the groundwork upon which all peak literature is built. While his investigations were not limited to musical triggers, he discovered very early that 'the two easiest ways of getting peak experiences [are] through music and sex' (1976, p. 169), and it is upon the former that this chapter is based.

What follows highlights research on the peak experience, emphasizing literature focusing on music-specific peaks. After outlining four studies fundamental to the study of peaks in music, a section will discuss precursors to peaks and proposed differences between those who have achieved peaks and those who have not. A section on the cognitive, perceptual, emotional, and physical phenomena associated with peak experiences will then be followed by an investigation on the after-effects of peaks. Next, a section discussing methodologies for the investigation of musical peak experiences highlights the possibilities and difficulties of this work. Finally, a brief section summarizes the contents of the chapter and looks towards the future of research in this field.

Fundamental peak experience in music literature

Four studies represent the empirical backbone of the study of the musical peak experience. As these will be heavily referenced in each subsequent section, a brief description here of their methods and findings is helpful.

Maslow coined the term 'peak experience' after analysing 190 written and 80 oral responses, having asked participants for descriptions of

> the most wonderful experience of your life; happiest moments, ecstatic moments, moments of rapture, perhaps from being in love, or from listening to music, or suddenly 'being hit' by a book or painting, or from some great creative moment.
>
> (1999, p. 83)

The contents of the experiences were individually unique, and in reporting his findings the author 'added together all the partial responses to make a "perfect" composite syndrome' (1999, p. 83). Beyond arguing that music is a reliable trigger of peak experiences, Maslow describes many of the phenomena experienced both during and after the peak, and asserts that: the peak experience is a self-validating, self-justifying moment with its own intrinsic value. It fills an individual with a sense of wonder and awe. Peaks are never negative, unpleasant, or evil, and cause a characteristic disorientation of time and space as well as a loss of fear, anxiety, doubts, and inhibitions. Frequently eliciting sudden feelings of happiness and well-being, peaks also bring about a heightened sense of an individual's physical and 'existential' state of being, a sort of positive hyper self-awareness. After a peak the individual may experience a number of effects, including a more positive view of the self, other people, and the world, various therapeutic effects (both physical and mental), even a sense that life itself is worth living.

In an effort to analyse art-specific peaks, Panzarella (1980) gathered reports of an 'intense joyous experience of listening to music or looking at visual art' (p. 71) from a pool largely composed of musicians and visual artists. Roughly half of responses were music-related. Content analysis revealed 11 response categories that were factored into four major dimensions of the experience: renewal ecstasy, motor-sensory ecstasy, withdrawal ecstasy, and fusion-emotional ecstasy: renewal ecstasy concerned a new or altered perception of the world and a desire to engage further with the artistic medium. Any physical elements like tears, changed heart rhythms, chills, or quasi-physical elements like a floating sensation were categorized as motor-sensory ecstasy. Withdrawal ecstasy involved a perceptual narrowing, during which there was a sense that everything disappeared except the object (i.e. music or art) and that the object was in perfect focus. Finally, fusion-emotion ecstasy referred to a 'fusion' with the medium, like a sense that the music or painting merged and became 'one' with the individual. Panzarella (1980) also argues that the peak experience has three distinct 'temporal stages', beginning with 'cognitive responses and loss of self; climaxing with continued loss of self and motor responses; and subsiding with emotional responses, [and] self-transformations' (p. 69). Various precursors and aftereffects of the 'joyous experience' are also reported.

Ecstasy was also a central theme in an earlier study by Laski (1961), who collected 63 incidents of 'transcendent ecstasy'. Triggers of such experiences included childbirth, sex, art, beauty, science, and religion, though the author concludes that 'of all the more common triggers to ecstasy, music would be the most rewarding to study in any attempt to find a relation between the qualities of the triggers and the effects produced' (p. 190). The contents of these episodes were collapsed into four categories: feelings of loss (e.g. sense of time, space, self, sorrow), feelings of gain (e.g. joy, salvation, perfection, unity with music or mankind, knowledge), feelings of ineffability (the experience eludes description or analysis), and quasi-physical feelings (e.g. peace, pain, light, heat).

To date, the most comprehensive attempt to understand exceptional experiences with music is the Strong Experiences of Music (SEM) project conducted by Gabrielsson and Lindström Wik (1993, 2000, 2003). This project makes use of over 1000 free descriptions of strong experiences in connection with music, collected and content-analysed over more than 10 years. Participants were asked, in as much detail as they could, to describe 'the strongest, most intense experience of music that [they had] ever had' (2003, p. 163). The resulting wealth of data culminated in the Strong Experiences of Music Descriptive System (SEM-DS), which lists the most common attributes of strong experiences in music and includes seven categories: general characteristics, physical reactions, perception, cognition, feeling/emotion, existential/transcendental, and

personal/social. These attributes, which will be further discussed on p. 455–7 of this chapter, provide significant insight into the nature of the strong experience, what occurs *during* the experience. Various other publications using SEM data discuss other aspects of the experience, including therapeutic after-effects (Gabrielsson and Lindström 1995), emotions (Gabrielsson 2001), experiences reported by old people (Gabrielsson 2002), and musical triggers (Gabrielsson 2006).

A note about nomenclature is necessary. Maslow's (1999) peak experience, Laski's (1961) ecstasy, Panzarella's (1980) joyous experience, and Gabrielsson and Lindström-Wik's (2003) strong experience are not identical concepts. For instance, peak experiences are, by definition, positive, whereas some strong experiences are negative. In addition, one could argue for a separation between *exceptional* experiences (like strong, ecstatic, or joyous) and true *peak experiences* which, thanks to Maslow, have a slightly more stringent definition.

Recognizing these inherent problems, we focus this chapter on 'peak experience in music' for two reasons: First, the term peak experience is a recognized term within the broad psychological literature. A term such as joyous experience is not in common use. Second, although there are negative experiences triggered by music, we would argue that positive experience is the most frequent and prototypical case, from which negative experiences may be considered a deviation, or a special case. However, we do not intend to restrict this discussion to any single, strictly defined term. We recognize the overlap amongst these terms, and accept the fact that no single term or definition fully captures the experience discussed here, be it peak, strong, optimal, ecstatic, or otherwise.

Precursors and predictors of the peak experience

Maslow (1976) concluded that 'any experience of real excellence, of real perfection. ... tends to produce a peak experience', but immediately and frustratingly added 'though not always' (p. 17). Peak experience literature is full of such qualifications, and has shown mixed results with regard to the demographic, situational, and musical differences between those who have achieved peaks (henceforth referred to as 'peakers') and those who have not ('non-peakers').

Maslow stated that only the self-actualized, i.e. those who had achieved the highest level of his hierarchy of needs (1943), were capable of enjoying a peak experience, as it was a 'momentary intensification of their general tendency to apprehend reality more directly and clearly' (1999, p. 19). Lacking a strict definition of self-actualization, subsequent research identified some general personality characteristics of peakers which include openness, tender-mindedness, flexibility, an experimental nature, an interest in creative work and a holistic, interpersonal, and emotional approach (Masluk 1999; Mathes 1982; McClain and Andrews 1969; Paffard 1970). Peakers appear to display a general willingness to explore and experience states of consciousness differing from their usual states of being and are 'open' in the broadest sense of the word (Masluk 1999).

Within music-specific peak literature, Panzarella (1980) discovered only minor, insignificant personality differences between peakers and non-peakers and argues that 'peak experiences represent an unusual mode of functioning for the individual rather than an intensification of the person's usual mode of functioning' (p. 85).

Research has also shown mixed results with regard to the predictive power of demographic differences between peakers and non-peakers. Studies comparing the peak reports of various demographic sample groups have shown that despite significant differences between groups' age, gender, education, race, and religion, there are no significant differences observed in their descriptions of peak experiences (Allen *et al.* 1964; Gordon 1985; Yeagle *et al.* 1989; Lanier *et al.* 1996). Nevertheless, some older studies found significant differences in peak descriptions between Caucasians and blacks (Mathis and McClain 1968), non-psychotics and psychotics (Margoshes and Litt 1966), and low and high verbal abilities (McClain and Andrews 1969).

Research on where a musical peak experience is most likely to occur has shown a few tendencies, though the situational unpredictability

remains similar to that of personality and demographic differences. Having collected a sample of experiences with music during childhood, one study found that peak experiences were most likely to occur during relaxed, informal music listening, while surrounded by positive social and environmental factors (like friends and family), and in casual non-evaluative surroundings, like listening to the radio (Sloboda 2005). Although this finding is confirmed by other studies (e.g. Gabrielsson and Lindström Wik 2003), research has yet to systematically examine the peak-inducing power of various settings. With regard to music performance, Gabrielsson and Lindström Wik (2003) found that, despite the large number of musicians in their sample, over 80 per cent of all SEM were in music listening. A survey of performing musicians revealed a wide variety of circumstantial factors in performance-specific peak experiences, including perception and involvement with audience, relationships among band members, and connection with music being performed (Boyd and George-Warren 1992).

With regard to musical genre, Maslow found that classical music, specifically 'the great classics' (1976, p. 170) were the most reliable trigger of peak experiences. Panzarella (1980) and Laski (1961) also list 'serious/classical music' as the primary peak-inducing music in their work, though each include descriptions of experiences induced by rock, folk, jazz, and other previously less well-represented genres. A recent analysis of Gabrielsson's (2006) SEM data produced 15 separate categories/genres, which included all varieties of classical, folk, and popular pieces. This analysis also revealed significant demographic differences between participants and their triggers, where older participants were more likely to list classical music and younger participants more likely to list popular music.

Do peak-producing musical works have structural or sonic features that predict their ability to evoke peaks? Very little research has been undertaken on this topic. In analysing the capacity of music to evoke 'chills' (one physical component of some peak experiences), Sloboda (1991) discovered that certain musical devices were statistically associated with the precise temporal location of a chill. These devices, including appoggiaturas and syncopations, all seem to involve violations of listener expectancy. His findings confirm those of Gabrielsson (2006) in that the responses collected were not specific to any one musical genre, and were found in a wide range of genres.

The nature of the peak experience

> I was filled by a special feeling that the music began to take command of my body. I was charged in a way. A tremendous feeling of harmony which made me really enjoy the music, and I found it difficult to stand still ... the mystery and power really gripped me. I was filled by an enormous warmth and heat. I really swallowed all the notes that were streaming out in the air, not a single note, effect or sequence missed my hungry ears. I was captivated by each of the instruments and what they had to offer me. Nothing else existed!
>
> Gabrielsson and Lindström Wik (2003, p. 166)

The research literature contains much data, exemplified by excerpt above, about the nature of the peak experience drawn from retrospective accounts of how it felt *while* it was happening. Such accounts demonstrate key features of the peak: their positivity, their powerfulness, rarity, non-voluntary nature, and some emotional, physical, perceptual, and cognitive correlates (Gabrielsson and Lindström-Wik 2003; Maslow 1976). In short, the peak is the antithesis of mundane, it goes beyond the everyday, and is not easily forgotten. The peak has even been called indescribable, and many find their expressive palate insufficient to properly elucidate the experience (Thorne 1963; McClain and Andrews 1969). Peaks are somewhat unpredictable; they are non-volitional and cannot be 'generated' (Maslow 1976).

Verbal reports provide insights into the subjective content of a peak experience, what happens during it, and what it feels like. There is no single element a peak experience *must* contain—rather there exists a diverse set of elements, each of which could be said to be indicative or typical. Gabrielsson and Linstrom Wik (2003) categorize

these elements into a three-level hierarchy, the top and most general of which includes seven categories: general characteristics, physical reactions, perceptions, cognitions, feelings/emotions, existential/transcendental and personal/social aspects. These categories are proposed as capturing the most common elements of the experience.

The following excerpt, taken from Gabrielsson and Lindström (1993, p. 123), is from a woman's description of how she experienced Tchaikovsky's Symphony No. 6, *Pathétique*, when she listened to it for the first time. Note the various elements—physical, perceptual, cognitive, emotional, transcendental and personal/social—in her description:

> I have had similar [strong] experiences of other music but none so terribly deep as *Pathétique*. In certain passages it evokes sobs, and I feel totally crushed. My listening is fully concentrated, the rest of the world disappears in a way, and I become merged with the music or the music with me, it fills me completely. I also get physical reactions, wet eyes, a breathing that gets sobbing in certain passages, a feeling of crying in my throat and chest. Trying to find words for the emotion themselves, I would like to use words as crushed, shaken, tragedy, maybe death, absorption, but also tenderness, longing, desire in vain, a will to live, prayer. The whole experience also has the character of a total standstill, a kind of meditative rest, a last definite and absolute end, after which nothing else can follow.
>
> After the experience I am sort of 'gone'—the people in the foyer and their murmur are at a distance, like a stage set rather than something real. I have a hard time trying to talk to them, to 'get started' and to 'return' to the ordinary reality. The most difficult part is to talk about the music experience itself, it is possible only after a while, when it has faded out a little. One of my concert friends is very sensitive to classical music and he too can have wet eyes. It has happened several times that we are just standing there, shaking our heads and looking down on the floor. Nobody finds any words, one cannot add anything to what the music already has told.

Descriptions like these testify to both the uniquely powerful nature of the strong experience and its ability to include many experiential elements in a single moment. This woman's experience is not only physical ('wet eyes ... breathing... . sobbing'), emotional ('tenderness, longing'), or perceptual ('the rest of the world disappears, and I become merged with the music'), but *all* of these, and more. It is these unique but overlapping elements that Gabrielsson and Lindström Wik's (2003) SEM-DS attempts to categorize, and in what follows these categories will be elaborated with reference to other research studies where available.

Physical reactions during the peak experience may include such physiological responses as chills/thrills, tears, changes in breathing, heart rate, and body temperature. Beyond internal physical manifestations, overt actions range from closing of the eyes to singing, shouting, jumping or dancing around. Contrarily, some people experience total physical immobility, or a sudden desire to be alone. Finally, included with physical reactions are a set of quasi-physical reactions, like a sense that the body has been dissolved into the music or merged with it, or that the body has actually transcended time or space, an out-of-body experience.

Some of the physical reactions which typically accompany peaks also occur in the context of emotional reactions to music which are less intense. This is particularly true of chills/thrills (e.g. Konecni *et al.* 2006; Panksepp 1995; Sloboda 1991). These are phenomena such as pilo-erection, 'shivers down the spine', tears and lump in the throat. These phenomena are ubiquitous—in some people they can occur several times a day, or even several times within the same piece of music. On their own they may be of rather little lasting significance, but when accompanied by other psychological experiences may become part of a memorable and significant peak.

Perceptual phenomena during peaks may include auditory, visual, tactile, kinaesthetic, synaesthetic, intensified/multimodal perception, and musical perception–cognition elements. The auditory–musical perception may be accompanied by strong visual impressions, tension or relaxation of the muscles, or simply an intensified sense of perception, among others. Performers, like listeners, frequently

describe a perceptual sense of being 'embedded' in the sound (Boyd and George-Warren 1992).

The cognitive category includes elements like changed attitude, a changed experience of situation, body and mind, time and space, or wholeness, a loss of control, a changed attitude to music, a connection to old associations, memories, and thoughts, cognitive imagery, and musical cognition–emotion. Cognitive elements may relate to some of the more lasting effects of the experience (further discussed in the next section) when, for example, an individual achieves a new understanding of some element in their life, like a relationship or their appreciation of the art.

Emotional elements include strong/intense emotions, both positive and negative emotions, and mixed emotions. Positive emotions predominate, especially joy and happiness, while typical low arousal feelings include a sense of peace and calm, and high arousal feelings include rapture and euphoria. In addition to the prototypical positive emotions, there are examples of negative emotions such as loneliness, sadness, anxiety, or even anger during the experience. Typically such negative feelings are related to various personal and other circumstances rather than to the music itself. Mixed emotions often result from the mix of positive affect and the negative social or personal circumstances, such as hearing music that reminds one of a lost loved one. For the majority of people, however, peaks are accompanied by unusually intense positive emotions.

Existential and transcendental aspects include, among other things, reflections on human life and existence, cosmic experience, experience of other worlds, religious visions, and encounters with the divine. While these items are easily categorized and listed, their experiential impact and post-experience implications can be immense. Many, for example, describe their peak experience as having resulted in a better understanding of the human condition, or offered a glimpse at God, Heaven, or similar 'other worldly' elements.

Finally, personal and social aspects include elements such as feeling liberated, uplifted or cleansed, getting new insights, hope, power and increased self-esteem, and further various therapeutic effects.

Effects of the peak experience

Maslow (1999) likened the peak to a 'personally defined Heaven from which the person then returns to earth. Desirable after-effects of such an experience, some universal and some individual, are ... very probable' (pp. 110–111) and discovered that some 'after-effects may be permanent, [though] the high moment itself is not' (p. 14). His analysis of peak reports revealed seven broad categories of after effects, not all of which result from every experience. These categories are supported by a later peak experience literature (Frick 1982; Lanier *et al.* 1996; Warmoth 1965).

In relation to music, Panzarella (1980) reported that 90 per cent of participants attributed long-lasting, often permanent, effects to their peaks. Through his analysis, he derived a list that closely resembles Maslow's (1999) and includes:

1 General appreciation of music or visual art
2 Altering of self-appreciation
3 Altering of relationships with other people
4 Altering of attitudes toward life or world in general
5 Increased aesthetic sensitivity
6 Enhanced perception of everyday reality
7 Long-lasting mood effects.

The first element, 'general appreciation of music or visual art', is notably absent from previous lists of after-effects, including Maslow's (1999). Participants in this study who achieved joyous experiences through either art or music emerged with a renewed appreciation for the medium. A similar study found that participants reported a desire to continue pursuing music either as a hobby or profession, and a desire to continue listening and engaging with music (Gabrielsson and Lindström Wik 2003).

Gabrielsson and Lindström (1995) document the ability of strong experiences to elicit positive therapeutic effects. Having analysed hundreds of SEM reports, the authors mention therapeutic implications including: relief from physical pain, grief, and depression, a release of personal and social barriers, increased self-confidence and sense of one's ego, even a total reorientation of one's attitude and value system. This report,

the most specific and thorough of its kind, provides substantial music-specific evidence of one of Maslow's original effects.

A final after-effect that warrants discussion is the desire to continue pursuing peaks. Research has shown that peak experiences in music, particularly in early childhood, have long-lasting effects on the likelihood of engagement with music (Sloboda 2005). Having collected descriptions of experiences with music before age ten, Sloboda (2005) found that positive experiences early in life were likely to spur continued involvement in music or, in other words, continued peak-seeking behaviour. Similar behaviour has been observed in adult music performers, who demonstrate a desire to repeat the strong feelings they experience while performing, so much so that a survey of pop and rock musicians uncovered a tendency to turn to drugs to induce the same feelings (Boyd and George-Warren 1992). Interestingly, veteran skydivers showed similar peak-seeking rationale for their continued desire to engage in their work (Lipscombe 1999), which suggests that peaks are of great consequence to the continued pursuit of both professions.

Despite the preceding evidence in support of Maslow's (1999) list of after-effects, there is a significant methodological pitfall in peak research, namely the attempt to measure an effect without a baseline. As a result of the unpredictability of the peak, it is hard to establish any independent, pre-peak data. Thus when a study discovers a 'more positive view' or an 'altered perception', these are derived from retrospective comparisons provided in the narratives of participants. One method for overcoming this limitation would be testing a large number of people who all attend the same musical event, monitoring experience before, during, and after. This would permit statistical comparison of pre and post-experience scores among peakers. This approach is currently being pursued by two of the current authors.

In conclusion, existing research provides evidence that music-related peak experiences have meaningful after-effects, and that most people who experience peaks report such effects (Ebersole 1972). The fact that reports in Gabrielsson and Lindström Wik (2003) contain all of Maslow's (1999) and Panzarella's (1980) after effects further supports this conclusion. The effects of the musical peak experience, it seems, do not end after the fleeting moment, but carry on in the lives of the peaker.

Methodology

The majority of the music-related peak experience literature is based on what Sloboda (2005) calls the 'autobiographical memory technique', which he finds both 'rich and workable'(p. 188). Relying on participants' memories for these significant moments, researchers using this technique simply ask participants to produce narratives about experiences with music. The prompt can be as simple as asking participants to describe 'the ... most intense experience of music that you have ever had' (Gabrielsson and Lindström Wik 2003, p. 163), or more generic like that used by Maslow (1999), who asked participants to describe 'the most wonderful experience of [their lives]'(p. 83). Variations on these prompts are found in numerous articles (Laski 1961; Panzarella 1980; Lanier *et al.* 1996; Minassian *et al* 2003; Sloboda 2005).

The autobiographical memory technique is not, however, without its methodological limitations. There is some doubt about participants' ability to recall specific details about an experience, particularly when recall is many years after the episode. There are also disclosure issues, as strong verbal and expressive skills are critical to describing the experience (Thorne 1963; McClain and Andrews 1969). This could mean that many potential peakers, including children, are expressively incapable of describing their peak experiences. Finally, the qualitative methods of this technique afford somewhat limited quantitative analyses.

As a response to the latter, peak experience researchers have developed hybrid methodologies which combine the autobiographical memory technique with a set of quantitative methods. After asking participants to freely 'describe one incident in your life characterized by highest happiness', the Experience Questionnaire (Privette 1983, 1984; Privette and Bundrick 1987) presents a series of 42 Likert-scale questions and five scaled descriptions of the peak experience, to which participants rate their agreement. Reliability of this

technique is well within reasonable limits (Privette and Sherry 1986), and the quantitative data produced permits more aggressive statistical analyses.

This method has been successfully applied to music-specific experiences. Participants in Gabrielsson and Lindström Wik (2003) not only produced free descriptions of their strong experiences but also rated how well their reactions corresponded with a large set of statements on strong experiences with music. Across participants, statements indicating positive feelings and other salient characteristics in SEM (e.g. absorption, confirmation, transcendence) received high ratings, whereas statements indicating negative feelings received low ratings. Factor analysis revealed up to 14 factors accounting for 64 per cent of the total variance. Most of these factors corresponded to (and thus confirmed) various categories in the SEM-DS, though there were also factors revealing co-occurrence of different categories (e.g, one factor included transcendent state, perfection, peace and happiness, healing experience), which may be difficult using solely content analysis of free descriptions. Notable, however, is the fact that these 14 factors fail to account for over one-third of the total variance—a testament to the extremely multifaceted character of SEM. Nevertheless, using these hybrid qualitative/quantitative methods, this study is able to collect bias-free, ecologically valid narratives and use quantitative techniques to test for the presence of correlated elements. For further discussion, see Gabrielsson and Lindström Wik (2003, p. 186 onwards).

Despite the benefits of these newer techniques, the ability to derive sound conclusions from qualitative data should not be underestimated. In his autobiographical memory research, for instance, Sloboda (2005) coded qualitative statements for the presence or absence of certain situational elements. These included internal significance (where the significance of the event was attributed to some factor internal to the music—such as a particular sound event or quality) and external significance (where the significance was attributed to some factor external to the music—such as the social context). Analysis showed a statistically significant relationship between internal and external significance. There were no cases of internal significance when the external significance was negative. This qualitative data thus clearly reveals something about the necessary conditions for a peak.

In sum, the study of musical peak experience poses substantial methodological challenges which require empirical ingenuity to overcome. Progress is likely to be furthered by a broader combination of qualitative and quantitative methods. Such progress should never blind us, however, to the fact that a full appreciation of peak experiences requires us to keep hold of the uniqueness and unrepeatability of each individual experience. Such uniqueness is not 'irrelevant noise' to be filtered out of analyses, but is a core component of what makes these experiences what they are.

Conclusions

Musical peak experiences are a significant component of the lives of many people. They are powerful, valued, have lasting effects, and—for some—are a reason for continued engagement with music. They involve elements of life that could be described as transcendent, transformational, even spiritual. Indeed, it is perhaps no coincidence that music has been such an essential part of many religious traditions and rituals, aimed at encouraging various states of 'uplift', be they contemplative or ecstatic (e.g. Becker 2001). Nonetheless, psychology rightly and necessarily concentrates on the inner characteristics of such experiences rather than their wider social and cultural meanings.

The research reviewed in this chapter shows that, despite significant methodological difficulties and a relatively small literature, a number of facts about the musical peak experience are known with some certainty:

1 Not all individuals are equally prone to peak experiences. Some elements of personality (specifically flexibility and openness) seem to encourage these experiences. On the other hand, demographic factors such as age, gender, and education seem to be of little importance.

2 All types and genres of music can engender peaks, though perception of aesthetic value seems important.

3 Many different settings and environmental circumstances can be found in descriptions of peaks, including both formal and informal music listening and performance.

4 Peaks contain strong and distinctive perceptual, cognitive, physical, and emotional components which make them highly salient to the person experiencing them.

5 Peaks are often remembered, and ascribed causal significance for various after-effects, long after their occurrence.

Relative to other areas of music psychology (e.g. cognition/perception, developmental topics), the study of peaks has not attracted as large a body of research. As a result, the topic has not benefited to the full extent from recent methodological developments in the field, for instance, the use of multivariate statistical methods, or innovative experience-sampling methods. With such methods, it should be possible to make progress on some of the unanswered questions in the field, such as whether there are distinct syndromes within the larger phenomenon, and whether specific enabling conditions can be more precisely characterized, thus potentially helping people to find their way more reliably to these high-value and life-enhancing experiences.

CHAPTER 43

Musical identities

Raymond MacDonald, David J. Hargreaves and Dorothy Miell

Introduction

Many chapters within this Handbook have highlighted just how important music is for us all, and the extent to which music is ever-present within modern society. This ubiquitous aspect of music signals many features about how we as humans respond to music and highlights the universal importance of musical communication. Indeed, the notion that we all respond emotionally to music is not a vague utopian ideal, but the conclusion drawn by an increasing number of academic researchers interested in researching the foundations of musical behaviour (Juslin and Sloboda 2001; Trevarthen 2002). We suggest, given the importance of music within our lives, that it influences how we see ourselves and how we relate to the world around us. In short, we contend that music crucially influences our identity.

This chapter presents a number of key themes relating to the concept of musical identities. We provide a definition of identity, with a discussion of why identity is a timely topic for consideration. Also presented is a specific definition of musical identities, and we implicate music as an important feature of personal identity. We then move on and consider a number of specific research examples to shed further light upon the importance of musical identities. We present an overview of a series of studies investigating musical identities of jazz musicians. These highlight the utility of qualitative techniques, and in particular focus group and semi-structured interview methods, for understanding how professional musicians construct their identities in relation to both their musical activities and wider psychological and cultural issues. The chapter looks next at how theories of motivation and the self can help to explain some of the behavioural aspects of musical identities. We provide evidence that children's self-concepts, and in particular their levels of confidence (both of which are related to musical identities), can influence the rate of musical development and musical achievement, drawing briefly on a study which compares the views of pupils, parents and teachers about what it is to be 'good at music'.

Defining identities

Our contention is that music is not only important for us all, but that it plays a fundamental role in the development, negotiation and maintenance of our personal identities (MacDonald *et al.* 2002; Roe 1999; Stålhammar 2006). Any individual involved in musical activities (i.e. both listening and performing) develops aspects of personal identity that are inextricably linked to these musical behaviours. Moreover, for young people at least, it seems that music may play an absolutely fundamental role in the development and maintenance of identity: a number of researchers have provided evidence to suggest that music is the most important recreational activity in which young people engage (Zillman and Gan 1997; Roe 1999). In terms of signalling to the world fundamental aspects about a young person's sense of self, music is often used as a kind of 'badge of identity' (Tarrant *et al.* 2002; MacDonald and Miell 2000). Furthermore, there is growing evidence that music remains a fundamental part of our identity across the life span (Applegate and Potter 2002; Carlton 2006).

Turning to identity research at a more general level, Anthony Giddens asserts that identity, within contemporary society, is the most

important issue with which humans must engage (Giddens 1991). We all have to make choices about our lives; from mundane questions about what to wear when we get up in the morning, to life-changing decisions about family, friendships and career paths. A key point here is that in earlier times, when traditional social order with clearly defined roles gave much more specific guidance regarding our life choices, these decisions were much easier to make and in some ways made for us. However, we now have many more options open to us and we have to make these decisions, what Giddens calls 'identity work', in a much more individualized and detailed manner. As Giddens states:

> What to do? How to act? Who to be? These are focal questions for everyone living in circumstances of late modernity—and ones which, on some level or another, all of us answer, either discursively or through day-to-day social behaviour.
>
> (1991, p. 70)

Consequently, identity research is now established as a multidisciplinary field, taking place in a wide variety of academic contexts, to such an extent that there exists a international organization called *The Society for Research on Identity Formation*, and a related journal, *Identity*, whose aim is 'to provide a forum for identity theorists and researchers around the globe to share their ideas and findings regarding the problems and prospects of human self-definition'. We find identity research not only in all branches of the arts and humanities, but also within the much more positivistic worlds of medicine and science. No single discipline has exclusive rights to identity research, nor can each identity research project be informed by all current thinking on identity (MacDonald *et al.* 2004). Of course, each research project will highlight different facets of identity processes and, in many cases, may involve differing definitions of identity. For example, the studies of jazz musicians outlined below utilize a discursive definition of identity, and emphasize how language shapes and constructs our sense of self, whereas the motivational theories presented later on in the chapter take a more social cognitive approach to the self. While there is no agreed definition of identity, researchers generally emphasize aspects that relate to how individuals construct themselves in relation to one or more phenomena. There is also an acknowledgement that each of us has many identities relating to the different roles we adopt (mother, musician, friend, colleague etc.). These identities are not discrete, will often merge and are constantly being negotiated and evolving. Identity is currently a very topical research issue for academics from many disciplines, perhaps because it is a fundamental issue for individuals worldwide in this period of postmodernity.

Musical identities

Moving on to the specific domain of music, we contend that music plays an important role in the negotiation, construction and maintenance of identities. For example, an individual who is a keen Bob Dylan fan will maintain a sense of self that is influenced by this liking for Bob Dylan: many of his friends may also be Bob Dylan fans, and his choice of clothes and political beliefs may be influenced by his taste in music. His linguistic devices may be influenced by his musical tastes, and in conversation he may choose to signal these musical tastes as a marker of his individuality. Thus, music plays a central role in this individual's identity. Zillman and Gan (1997), Tarrant *et al.* (2002), and DeNora (2000) all investigate the role that music plays in identity construction and maintenance. Zillman and Gan (1997) provide evidence to suggest that music is the primary leisure activity and, in terms of identity construction, the most important recreational activity undertaken young people. Tarrant *et al.* (2002) highlight the importance that shared musical tastes have in forming and maintaining friendship groups. This demonstrates how music can be an important marker of identity and now young people in particular want to have musical tastes in common with their friends. De Nora (2000) takes a sociological perspective in demonstrating how enmeshed music is within everyday life, and quite clearly draws a direct link between the importance of music and the construction of the self.

Individuals who are involved in music-making (be that as a professional opera singer or

an occasional singer in the bath tub) develop an identity that is crucially influenced by these activities. For example, a young child going to piano lessons for the first time may be praised by her parents for practising and, over a period of time, sees her piano playing as one of many important activities in which she is engaged. Thus, when talking about her routine and weekly activities to friends and family her view of herself as a piano player influences how she talks and thinks about herself: as such, she develops an identity as a musician in the broadest sense of the word.

Another important point to note is that the identity of being a musician is a socially and culturally defined concept. We don't acquire the label 'musician' simply by attaining advanced technical skills. By this we mean that viewing ourselves as musical is not directly linked to the levels of technical ability or knowledge that we have. Similarly, there is no legal control over who can or can not call themselves musicians. It appears that whether or not we view ourselves as 'musicians' or 'musical' is crucially influenced by our social and cultural surroundings and by the ways in which we relate to people around us (Green 2002). The notion of being a musician is influenced by certain non-musical factors, which involves what we have termed *identity paradoxes*. Lamont (2002) highlights how the school setting plays a role in a child's developing musical identity by taking a detailed look at the music education environment, and demonstrating how the organization of lessons within a school has a crucial effect upon a child developing musical identity. Borthwick and Davidson (2002), on the other hand, look at more informal family environments, and how communication within the family influences children's developing sense of musicality. Specifically, these authors show how one sibling adopts the identity of *musician* while other siblings, who may be musically experienced, view themselves as not musical in comparison to this sibling. O'Neill (2002) investigates how young people learn to view themselves as musicians and uses a qualitative social constructionist approach to investigate the relationship between a young person's sense of musicality and wider social influences.

Gender issues are also important to take into consideration when thinking about how musical identities develop and are maintained. A number of researchers have highlighted how cultural expectations and hegemonic influences affect the developing musical identities of males and females differently, both in terms of musical tastes and participation (Dibben 2002; Green 1997; McClary 1991; O'Neill 1997a; Welch 2006). For example, Dibben (2002) and McClary (1991) discuss how women are underrepresented within the professional music world and Green (1997) provides evidence to support the notion that hegemonic masculine identities facilitate the development of a composer's identity. This may help explain why there are proportionally far fewer women, in comparison to men, working as composers within Western classical music. O'Neill (1997a) shows how gender stereotypes influence musical instrument choices made by boys and girls while Welch (2006) points out that the exclusion of women from cathedral choirs dates back to AD 597.

Crucially, all of the work highlighted above demonstrates how environmental and wider cultural influences are brought to bear on self-perceptions of musicianship and musical tastes. In particular, this work also demonstrates how essentially non-musical variables fulfill fundamental roles in an individual's sense of developing musical identity.

Identities in jazz

One particular approach to studying musical identities is to consider how musicians talk about their musical lives. This approach was utilized in series of studies that investigated how jazz musicians construct, maintain and negotiate their musical identities in a variety of different contexts (Wilson and MacDonald 2005; MacDonald and Wilson 2005, 2006). This approach is presented as an exemplar of how research into musical identities can be conducted from a qualitative perspective. The key methodological points are that this research can utilize both focus group and interview methodology. Additionally, the data can be analysed using a range of theoretical perspectives including thematic analysis, interpretative phenomenological analysis, discourse analysis and narrative analysis. The jazz context provides

a particular useful and timely way to study identity. On the one hand the performance of this music represents a unique form of collaborative creativity (Sawyer 1992; Meadows 2003; Berliner 1994). Secondly, while there is a growing literature investigating the particular psychological and musical processes of jazz music (Cooke and Horne 2002), there is a need for research to focus upon the social aspects of identity maintenance, and in particular the multifaceted ways in which the collaborative context of jazz performance influences these identity projects (Sawyer 2003).

The first study utilized a thematic analysis of focus group data to investigate how jazz musicians talked about improvisation (Wilson and MacDonald 2005). What emerged from focus group data was a negotiated social construct rooted in the understanding of the participants themselves and an excellent method for investigating musical identities. From the analysis two main themes were identified. The first theme was termed '*Jazz is*'. While there was considerable debate around the topic of what jazz music is, the discussions centred around: *improvising and composing; swing elements of jazz* and *collective processes involved in jazz playing.* Improvisation was seen as a stronger expectation in jazz than in other forms of music, and was discussed both as the elaboration of a tune and as a looser form of collective creativity. *Swing*, the maintenance of a common and consistent pulse of a particular quality, was widely seen as a central yet intangible quality in the collaboration of musicians playing jazz. A perceived tension between collective and individual creativity, such as that identified by Sawyer (1992), also emerged in the accounts presented, however; achieving the requisite collective interaction was voiced as more important than individual goals of self-expression. Individual and collective creativity were often viewed as existing in balance with each other in jazz. Social interaction therefore becomes extremely important in its execution. The second broad theme that emerged from the data was termed '*Jazz life is*' and related to wider social and cultural issues pertaining how jazz musicians live. Within this category discussion centred around: *social context, professional context, being in a group* and *self and others.* These four themes gave detailed accounts of what the participants reported as being the key features of a jazz musician's life style.

This focus group analysis presented a thematic account highlighting the importance of shared understandings and practices in musical, social and cultural terms and features of identity for these participants. This thematic analysis coded what participants said into descriptive categories, and this is a common approach within qualitative studies of musical identity (e.g. Monson 1996). However, discourse analysis seeks to move beyond the categorical grouping of thematic content analysis to investigate structural features in discourse and to explore how particular speech acts perform a range of functions for a speaker and move beyond a thematic account (Edwards and Potter 1992).

With this issue in mind we examined discursive features of dialogue between jazz practitioners during the focus group interviews to reveal the relationship between the construction of specific meanings for the music and musicians and the negotiation of musical identities (Wilson and MacDonald 2005). This paper reported three key elements of identity work from a discursive analytic position: interpretative repertoires for jazz; the resolution of uncertainties created in handling these repertoires within the conversation; and ways in which the data are characterized by the focus group context. Two distinct interpretative repertoires (cf. Gilbert and Mulkay 1984) were employed in these data, which we termed the 'expert' and the 'naïve'. These were used flexibly to support participants' claims to identity as jazz musicians, while positioning others as separate from this identity. In the expert repertoire, jazz was accounted for as music produced by groups of individuals whose hard-won knowledge and skills gave them a particular insight into the music. In the 'naïve' repertoire participants emphasized the ineffable and soulful aspects of jazz music that were seen as being beyond complete comprehension.

The two papers discussed above give accounts of focus group data analyses and suggested a number of themes and features that we wished to follow up outwith the group context. In particular, we wanted to gather the views of both male and female practitioners (all focus group participants had been men) who were not

previously known to the interviewer (both researchers had known the focus group participants personally and professionally). A series of ten individual in-depth interviews with professional jazz musicians in London was therefore conducted to provide rich data on individual identities, social contexts, and the experience of improvising (MacDonald and Wilson 2006). The findings highlighted how identity as a jazz musician was negotiated with other individual identities. For example, the relationship between gendered identities and identity as a jazz musician was examined as an instance of how conflict between these identities may allow hegemonic influences to operate.

In summary, these three papers highlight the importance of talking about music in terms of negotiating the constantly evolving musical identities of professional musicians. For these participants, musical identities were implicated as central to identity construction across a range of social situations. In the next section we move from analysing talk about music to investigating how motivation is related to musical participation and musical identities.

Musical identity and motivation

In our earlier discussion we cited the example of a young child, going to piano lessons for the first time, who gradually develops a view of herself as a pianist, or more generally as a musician. This development can be encouraged by praise from her parents and wider family about practising, or about particular musical achievements, and by talking to her friends and schoolmates about her progress. The positive feedback that she gets from these significant others in her social world will play an important role in her developing identity as a musician, and will thereby motivate her to higher levels of practice and achievement, which in turn will lead to further strengthening of the 'musician' role: and so a 'virtuous cycle' can develop in which growing levels of musical achievement and musical identity are interdependent. In other words, children's motivation to succeed in music is inextricably linked with aspects of their musical identity: the ways in which they think about their own abilities have a direct influence upon their motivation to engage in activities which develop those abilities, and vice versa. It therefore makes sense to consider how theories of motivation and the self can explain some of the effects of musical identities.

Motivation to learn in music is the topic of Chapter 27 in this volume, by Susan Hallam, and we refer the reader to that chapter: our distinctive emphasis in this section is on how musical identities give rise to certain aspects of motivation. An extensive body of theory and research has been conducted on motivation for educational attainment more generally—in subjects such as mathematics and reading—and this also has been applied to motivation in music learning by O'Neill and McPherson (2002), Hallam (2002) and Austin *et al.* (2006).

Self-theories form a central part of the theoretical models of educational and musical motivation which have emerged in recent decades, and Austin *et al.* (2006) illustrate this point very clearly in proposing a process model of motivation which is based on the work of Connell (1990). The model has four components—the *self system* (e.g. perceptions, beliefs, thoughts, emotions); the *social system* (e.g. teachers, peers, siblings); *actions* (e.g. motivated behaviours including learning and self-regulation); and *outcomes* (e.g. learning, achievements). Each of these four components is seen to have a reciprocal causal relationship with each of the others, such that the motivational system develops and changes as learning proceeds, and as new challenges are sought by the learner. Hallam (Chapter 27) goes further than this, proposing a wide-ranging model of musical motivation which sees 'malleable aspects of the personality and self-concept' feeding, along with various environmental influences, into motivation, interaction with the cognitive characteristics of the individual, and with the different cognitive processes involved.

Most writers in this area agree that expectancy –value theory (e.g., Eccles *et al.* 1983; Pintrich and Schunk 2002) is the most well established and useful theoretical approach, and models based on this approach have three main components. These are *value* components—the extent to which learners view a particular task, activity or domain as being important, and as being of value to them: *expectancy* components—learners' beliefs about their abilities to succeed

in the activity: and *affective* components, namely how learners feel about themselves in relation to the activity. Thus, our young pianist's motivation to progress to higher levels will depend on the extent to which she sees playing the piano as being important in her life, and in having future benefits and pay-offs: on whether or not she perceives she is capable of achieving higher levels of success; and on whether or not she simply enjoys playing the piano in relation to all her other interests and activities.

Eccles *et al.* (1983) proposed that there are four main aspects of the value component, namely its *attainment value* (the importance to the individual of success in the task); its *utility value* (its perceived usefulness to the individual); its *intrinsic interest* (the absorption in and enjoyment of the activity for its own sake); and its *perceived cost* (the loss of time spent on other activities as a result of engagement in musical activities, and the consequent loss of interest in them. Many parents, including the present authors, have faced the 'Saturday morning dilemma'—school sports team or band/orchestra?!). The third of these aspects raises the important distinction between intrinsic and extrinsic motivation: the former is evident when interest in an activity is natural, unforced and high, and the latter occurs when external rewards and punishments (such as praise and criticism) are involved.

Amabile's (1996) social psychological theory of creativity emphasizes the importance of intrinsic motivation, proposing that 'the intrinsically motivated state is conducive to creativity, whereas the extrinsically motivated state is detrimental' (p. 107). The *perceived cost* of engaging in an activity may involve both intrinsic and extrinsic motivation: children may decide that the time and work involved in practising an instrument is not worth the effort, for example, and consciously decide to give up in favour of other pursuits (e.g. Eccles *et al.* 1998). It is also worth pointing out that external rewards do not always lead to improvements in performance: if intrinsic motivation is already high, rewards can have the effect of undermining performance rather than of improving it.

The decision to either persist in music, or to give up, is clearly interdependent with the second, *expectancy* component of the expectancy–value model, which refers to learners' beliefs in their own ability to succeed on the task, and this is what Bandura (1997) calls *self-efficacy*. Learners' prior view of their own potential ability to succeed on a task—their competency beliefs—can be an important determinant of their actual performance on that task, and this leads to some further conceptual distinctions. Dweck (2000) suggests that people differ in the extent to which they display *mastery-oriented* as distinct from *helpless* behaviour, which in turn relates to their *locus of control.* Learners with an *internal* locus of control are likely to display mastery-oriented patterns of behaviour, for example in trying to persist with a task even when they meet difficulties or setbacks. Those with an *external* locus of control, however, feel that circumstances are beyond their own control, and may display helpless patterns of behaviour. In Chapter 27, Hallam draws on these concepts in describing how learners' competency beliefs can be an important determinant not only of whether they engage in that task as well as of their actual performance on that task.

O'Neill (1997b) investigated the longer term effects of these motivational patterns on children who were about to begin instrumental tuition by giving them problem-solving tasks which were arranged such that they were bound to fail. She found that those who displayed mastery-oriented behaviour after failing on the task made more progress after one year of instrumental music lessons than those who initially displayed helpless behaviour. This result leads us to a more general consideration of the third component of expectancy–value theory, namely the *affective* component: people's beliefs about and reactions to success and failure can be explained in terms of attribution theory (e.g. Weiner 1985, 1992). According to this, people attribute their success or failure on a task to four main factors: *ability* ('I am good/poor at this task'): *effort* ('I practised hard/insufficiently'); *task difficulty* ('this particular task was easy/difficult'); and *luck* ('I had a lucky/unlucky day'). The first and second of these are internal in the sense that they are under the control of the learner, and the third and fourth are subject to external influences.

These theoretical analyses of educational motivation, along with Hallam's discussion in Chapter 27, reveal some of the mechanisms by which musical achievement and development can be determined by musical identities. We referred earlier to a hypothetical 'virtuous cycle' according to which increasing levels of musical achievement give rise to higher levels of musical self-esteem, and vice versa; children who feel that they are competent musicians are likely to achieve higher levels of success than those who do not, as are those who find music intrinsically interesting, and value it positively (Eccles *et al.* 1983). This can work in both directions, of course: some children may get the idea that they are 'unmusical', perhaps because of an unwitting remark by a teacher, parent or another pupil, and this perception could correspondingly lead on to a downward spiral of not trying, therefore becoming less able, therefore trying even less, and so on.

The *content* of musical ability self-perceptions were investigated as part of a series of studies conducted within the Curriculum Development Project in the Arts and Music Monitoring Programme, sponsored by the Qualifications and Curriculum Authority (QCA) in England. Hargreaves and colleagues (2004) compared the views of pupils, parents and teachers about 'what it is to be good at music' along with parallel questions about art and design, dance, and drama, from the points of view of pupils, teachers and parents. Focus groups of pupils and parents, and individual teachers, were asked to discuss three questions: (a) what does it mean to be good at music (what does it involve)?; (b) can one 'be good at' some aspects of music and not others?; and (c) how can one get better at music, and how would others know whether or not this had occurred?

Performing, and knowledge about music, were both seen as especially important aspects, particularly by pupils and teachers. Music was seen as comprising a range of different skills and capacities, including non-musical skills such as learning quickly, leading a group, and having confidence. Teachers tended to emphasize the requirements of the English National Curriculum, and to conceive their views of musical ability and achievement in those terms. Parents tended to focus on skills and activities which are visible, notably those involving public performance. All three groups' responses suggested that music is no longer seen as a special talent which individuals either do or do not possess, and that it is perfectly possible to be good at some parts of it and not others. Qualifications and exams assumed lesser importance than might have been expected, and pupils' views were no less detailed and insightful than those of teachers and parents.

The pupils' views were explored in detail in a more recent report by Lamont *et al.* (2007) on a focus group investigation of 134 8–14-year-olds' understandings of what it means to be a musician, and of the differences between their descriptions of musicians in general with their own self-concepts as musicians. The results clearly showed that they defined musicians in terms of playing a musical instrument, making up music, and that closely related to this were being a singer, and being a music teacher. These children also emphasized effort, practice and hard work as being important characteristics of musicians. Their beliefs about themselves as musicians were more varied, however, and were more likely to include factors beyond their control (such as musical ability, and critical periods in their lives). There was a general acknowledgment of the role and importance of music in society, and of the possibility of music as a career and leisure choice. The motivation to be active and to succeed in music seems to be closely bound up with the development of positive musical identity.

Conclusions

In summary, recent developments within the psychology of music advocate a theoretically eclectic position for academics endeavouring to develop our understanding of the psychology of music (Miell *et al.* 2005). Much of the earlier research utilized a predominately quantitative empirical epistemology which focused on isolating discrete variables and was less concerned with the wider social and cultural influences on music perception (Hargreaves and North 1997; MacDonald *et al.* 2002). However, a more multidisciplinary and pluralistic position is entirely in keeping with postmodern research priorities

within the wider academic community, and so researchers interested in investigating musical identities including psychologists, music therapists, musicologists, music educationalists and others, can adopt quite different theoretical stances on the research processes. The current situation within musical identity research reflects these multidisciplinary features, and we find research that is empirical (using both qualitative and quantitative approaches), and review based.

In this chapter we have focused on key themes and approaches within musical identities research. We have highlighted these issues with examples from published material and from our own current research, and in doing so have concentrated on two broad areas: jazz identities and motivations and identity. These two areas highlight the pluralistic manner in which researchers are currently investigating musical identities. In particular the section above on jazz identities highlights how the way in which musicians talk about their musical experiences helps to construct their musical identities. Related to these observations, the section on motivation draws together recent thinking in this area to highlight the importance of motivational aspects of musical development and also how self-perceptions influence the development of music skills and, through these, the development of musical identities. This chapter highlights the crucial role of wider cultural and social variables in determining not only the extent to which we view ourselves as musical or not, but also the extent to which we engage in musical activities (both listening and playing).

Musical identities are an important consideration for researchers interested in the psychology of music, not least because we all have musical identities, but also because identity 'work' is a fundamental psychological process in which we all engage. This identity work can take the form of musicians reflecting on their own practice and how this practice is related to their lifestyle, or it can be how children view their own sense of musical skill and development. In short, we are suggesting that talking about music and, through this, developing and negotiating musical identities, influence our engagement with music in important ways.

CHAPTER 44

The effects of music in community and educational settings

Susan Hallam and Raymond MacDonald

Introduction

It has been recognized through the ages that music can have a very powerful influence on our emotions, moods and behaviour. In recent years technology has led to easy access to music listening, and individuals and organizations have taken advantage of this to utilize music to influence how we feel and act in many areas of our lives (see Chapters 40 and 45). Young people in particular spend a great deal of time playing music and often use it to accompany their studying. Alongside the increase in and ease of music listening, there has been an acknowledgement that there are wider benefits to active engagement with music beyond those emanating from its value as an art form. In the Western world, the latter part of twentieth century saw a huge growth in opportunities for making music within formal educational settings and more recently, through what is termed 'community music', playing, teaching and learning music outside of formal education (Elliot 2004). Research assessing the impact of such engagement has been used by music educators and community musicians to support the continued funding of such activities by policy makers.

In this chapter we will review the literature which has explored the ways that music may have benefits beyond those associated with our enjoyment of active engagement or listening in community and educational settings. We will outline developments in community music, consider research which has assessed its impact, explore the way that music has been used to attain educational aims beyond those relating to music education itself, and consider issues and findings relating to the use of background music when studying.

The impact of active engagement with making music in community and educational settings

In general, individuals actively engage with making music because they enjoy it, although where it is a compulsory element of the school curriculum this may not be the case. In recent years, perhaps in part because of the need to justify the place of music in the school curriculum and the continuance of funding for informal community music-making opportunities, there has been an increasing focus on the wider benefits of active engagement in music.

The impact of music in the community

Over the past 15 years there has been an explosion of interest in music making outside of formal educational settings. Much of this has come to be termed 'Community Music' and it is now an established area of research and practice with a dedicated journal, *The International Journal of*

Community Music and a commission of The International Society for Music Education. Veblen (2004) presented an overview of the many different ways in which community music is practiced around the world which highlighted the key concern of community music practitioners to increase access to music-making for all members of the public. The growing recognition of community music as an important musical activity is very much in keeping with current ideas of multidisciplinary practices that signal the integration of social, educational, medical, and therapeutic practices and thinking (Ruud 2004).

The growth of community education has in part been an acknowledgement that every human being has a social and biological guarantee of musicianship (Trevarthen 2002; MacDonald *et al.* 2002) and evidence that everybody, regardless of social, educational, psychological or medical aspects can communicate through music (Elliot 2004; Ansdell and Pavlicevic 2004; Miell *et al.* 2005). Musical skill develops through opportunities for musical engagement in childhood, adolescence and early adulthood, the influence of family, school and wider cultural factors being crucial in the individual's developing musicality (Borthwick and Davidson 2002; Lamont 2002; MacPherson in press; see also Chapters 22, 27, 28, and 29). Adult participation in community music is an extension of active music-making in childhood (e.g. Conda 1997), the pattern of engagement changing over the life course, diminishing in the middle years and increasing in retirement (Larson 1983), life-changing events sometimes providing an impetus for re-engagement (Conda 1997). The reasons for adults' participation in music have been grouped into three main categories: personal motivations (self-expression, recreation, self-improvement, and use of leisure time); musical motivations (love of music, performing for oneself and others, learning more about music); and social motivations (meeting new people, being with friends, and having a sense of belonging). No single reason consistently emerges as the most important (Coffman 2002). Hinkle (1988) suggests a further category—spirituality.

There is a growing body of evidence that involvement in music-making in community contexts has positive psychological or social benefits for the participants (Davidson 2004). While it is important to distinguish community music from music therapy (see Chapters 46 and 47), much has been written about the parallels and contrasts between community music-making, music education and music therapy. In particular Ansdell and Pavlicevic's edited text *Community music therapy* (2004) outlines how recent advances in community music-making and music therapy can facilitate a greater cross-fertilization of ideas between these areas of practice. Ockelford (2000) also discusses the need for greater communication between practitioners and researchers involved in music education and music therapy in order to develop our knowledge of the kinds of effects music may have.

The benefits of adult participation in music, in a professional or amateur capacity, are many and varied. Choral singing seems to have positive emotional, social, physical, and creative outcomes (Beck *et al.* 2000) which may also be spiritual (Clift and Hancox 2001). Bailey and Davidson (2002), researching members of choirs for homeless men and middle class participants, found that group singing and performance even at low levels of musicality yielded considerable emotional, social and cognitive benefits to participants. The emotional effects were similar regardless of training or socio-economic status, but interpersonal and cognitive components had different meanings for marginalized and middle-class singers. The marginalized individuals appeared to embrace all aspects of the group singing experience, while the middle class choristers were inhibited by prevalent social expectations of musicianship. Social and musical components appear to contribute equally to commitment to and enjoyment of membership of amateur operatic societies, the musical and acting components providing challenge, achievement, and opportunity to escape temporarily the frustrations of everyday living (Pitts 2004).

Community music interventions can provide senior citizens with a venue to make friends and encourage participation in intergenerational music activities between children, teenagers, and senior citizens, all of which have considerable social value (Bowers 1998; Darrow *et al.* 1994).

Music, through community education programmes, can also help adults move toward socio-political transformation (Kaltoft 1990). Engaging with music has a range of positive personal and social outcomes which do not seem to diminish with age. In older people music assists in developing self-identity, connecting with others, maintaining well-being, and experiencing and expressing spirituality, providing ways for people to maintain positive esteem, feel competent, independent, and avoid feelings of isolation or loneliness (Hays and Minichiello 2005). Although older adults require more time to encode and select information and have slower reaction times these can be minimized through task familiarity, sufficient structuring of information and regular exercise (Cavanaugh 1997). Primary mental abilities decline with age but higher-order mental activities do not, and adults may maintain or even increase mental abilities in areas of expertise including music (Pieters 1996).

There are direct health benefits for active musical participation. Choral performance increases secretory immunoglobulin A and reduces cortisol levels of professional (Beck *et al.* 2000) and amateur (Kreutz *et al.* 2004) choristers before and after singing. Playing the piano exercises the heart as much as a brisk walk (Parr 1985) and music-making contributes to perceived good health, quality of life, and mental well-being (Coffman and Adamek 1999; Vanderark *et al.* 1983).

Community music-making for adults with learning difficulties can facilitate both musical and psychological developments. MacDonald and colleagues (1999) reported that 12 weeks of community-based music workshops focused on playing a Javanese gamelan produced significant improvements in musical ability, communication skills and self-perception of musical ability. The improvement in communication skills may be linked to development in joint attention (O'Donnell *et al.* 1999). This is defined as a shared focus of attention on the same object by two individuals and is similar to the concept of 'shared social reality' (Nameera *et al.* 2007). MacDonald and Miell (2002) highlighted various ways in which community music-making was perceived by participants with special needs to be of benefit to them. The participants provided detailed accounts of how involvement was empowering and indicated that other people's expectations of their abilities changed positively. Important for them was that the music-making they were involved in was perceived to be of a professional standard. Other research has shown how improvisation workshops, percussion workshops, instrumental lessons, and singing workshops delivered to a variety of groups of adults with dementia, and adolescents with mental health disorders, can have beneficial effects on particular aspects of cognitive function (De Simone and MacDonald 2007).

The wider benefits of music in formal education

The impact of active engagement with music in the classroom is usually explained through transfer effects (see Chapter 23), the emphasis frequently being on intellectual rather than personal and social outcomes, although there has been some research considering the latter. One strand of research has focused on the impact of different types of music tuition, e.g. Dalcroze, Orff, Kodaly, while others have explored the way that music can be used to directly enhance learning materials.

Effects of particular teaching approaches

Over time, there has been considerable interest in the impact of the Kodaly method of teaching music on children's intellectual development. Positive effects have been found on temporal and spatial abilities (Hurwtiz *et al.* 1975), reading and arithmetic (Gardiner *et al.* 1996) and IQ (Schellenberg 2004), while activities involving music and movement have been found to have a positive impact on a range of outcomes including delayed development (Moore 1984) and motor performance (Zachopoulou *et al.* 2004) in comparison with controls (see also Chapter 23).

The role of music in enhancing language and literacy skills

Some researchers have focused on the impact of more general musical activities on language and literacy skills (e.g. McCarthy 1985). Using rhyme, rhythm and repetition has been shown to facilitate the learning of vocabulary (Baechtold

and Algier 1986), particularly in remedial readers (Newsom 1979), and has subsequently led to improvement in reading, comprehension, attitudes and motivation. Musical activities have also been shown to assist in developing second language learning in children (e.g. Kennedy and Scott 2005) and in improving memory for a range of other materials including multiplication tables (Clauson and Thaut 1997), and stories (e.g. Allen and Butler 1996).
