The direct impact of the use of music to improve literacy through the use of songs and singing has not been clearly demonstrated (e.g. Ebisutani *et al.* 1991), although music lessons designed to develop auditory, visual and motor skills have benefited reading (Douglas and Willats 1994), as have studies aimed at improving rhythmic skills (Long 2007), and there is evidence that there is a relationship between phonemic awareness, simply reading ability and pitch discrimination (e.g. Anvari *et al.* 2002). Early skill with music might enhance reading acquisition to the extent that reading depends on the same basic auditory analysis skills.

Social and personal learning outcomes

In formal education, increasing the number of classroom music lessons has been shown to have a positive impact on social behaviour. In a large-scale European study, children receiving additional music lessons demonstrated increased social cohesion within class, greater self-reliance, better social adjustment and more positive attitudes. These effects were particularly marked in low ability, disaffected pupils (Spychiger *et al.* 1993). In the UK, Harland and colleagues (2000) showed that the most frequent overall influences of engagement with music on pupils were related to their personal and social development, in particular confidence and self-esteem.

Music has also been used to change problem behaviours in particular groups of students. DeCarlo (2001) used rap music, with some success, with young urban African American adolescents with behaviour problems to promote the development of appropriate social skills related to morality, identity, judgement, decision-making, anger management, impulse control, and crime and punishment. Also in the USA, after school music programmes have been shown to be especially beneficial for reducing the likelihood of disaffection in at-risk children (e.g. Otterbourg 2000).

The impact of background music in educational settings

Issues in studying the impact of background music

There are a number of methodological and theoretical issues which have bedevilled research exploring the impact of background music on learning and behaviour in educational settings: finding robust ways of categorizing the nature of the music itself; considering how to systematically measure its impact; and how to take account of individual differences in response.

Early research tended to ignore the characteristics of the particular music being played, assuming that all music would have a similar impact. More recent research has attempted to address this issue by differentiating music on the basis of genre, its perceived potential to stimulate or relax, whether it is vocal or instrumental, and in relation to its cognitive complexity. While all of these approaches have some merit, none have been able to capture the complexity of music as it occurs in real time. This particularly applies to Western classical music with its frequent changes of mood, tempo, timbre, complexity, and volume.

The second key methodological issue relates to the way that impact is assessed. A range of methods has been adopted including physiological and neurological measures, observation of behaviour, assessment of task performance, and the use of rating scales. However, the relationships between outcomes assessed by these various measures are complex. While arousing music tends to lead to an increase in a variety of physiological responses in children (e.g. Furman 1978) this is not always the case with adults. For instance, Iwanaga and colleagues (1996) found that university students reported increased excitation when listening to the Sacrifice Dance from the Rite of Spring but their heart rate and respiration rates did not change, although

calming effects reported accompanying listening to Satie's Gymnopedie No. 1 were matched with a decrease in heart rate and respiration. Favourite music, whether stimulating or relaxing, also tends to lower subjective tension without necessarily having a similar impact on physiological responses (Iwanaga and Moroki 1999).

The third methodological issue relates to the subjective aspects of music perception. Individuals respond to the same music in very different ways, depending on their musical preferences and their individual characteristics. The structural features of the music (e.g. tempo, modality, instrumentation, genre); cultural factors (aspects of our environment including tonality and the way that musical associations are culturally shaped and learned); and associative factors (personal and subjective meanings we place on a particular piece of music depending on our musical experiences) all play a part in our responses to music. Where associative factors come into play, the structural and cultural aspects of the music are superseded by the personal and associative aspects (see Figure 44.1). Preference may therefore render very different types of music *functionally equivalent.* For example, the music which young people may chose to play while studying may differ widely but lead to similar physiological effects.

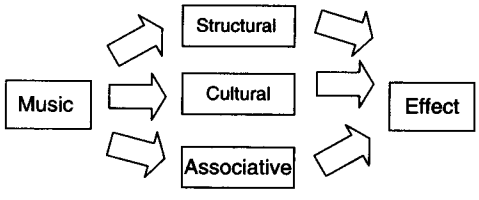

Fig. 44.1 Influences on music perception.

Explanations for the differential impact of background music include those invoking music's ability to affect arousal and mood, interfere with processing, and reduce distraction. The Yerkes–Dodson law provides one explanation stating that the arousal level of the individual increases performance up to an optimal level beyond which over-arousal leads to deterioration. This occurs more quickly when the task to be performed is complex or under-learned. Completing a simple task requires a higher level of arousal for concentration to be maintained, complex tasks require lower arousal levels (Konecni and Sargent-Pollock 1976). Personality factors are also implicated in optimal arousal levels. Introverts have higher resting levels of arousal than extroverts and are more susceptible to over arousal. Closely related to arousal theories are those related to mood and emotions, there being considerable evidence that music can affect mood (e.g. Niedenthal and Setterland 1994) and alertness (Sousou 1997).

An alternative explanation for the impact of background music is that it reduces the cognitive processing capacity available for other material. Concentrated listening to music requires cognitive effort for processing, analysis and extracting meaning (Berlyne 1971). Listening to complex, arousal-evoking music may therefore reduce the attentional space available for task performance (e.g. Broadbent 1971). However, when people play background music they do not attend to both the music and the task simultaneously. Attention switches between the two (Madsen 1987). Depending on their interest, their focus may be greater on the task or the music. A further complication is the role of meta-cognition—participants being aware that the music is interfering with task performance and consciously adopting strategies to prevent this. This may explain age-related differences in the actual and perceived impact of music on performance (Kaniel and Aram 1998; Kotsopoulou and Hallam 2006).

The impact of background music on behaviour and task performance

Research on background music in educational contexts has explored the impact on children at different ages, with special educational needs, and undertaking a range of different tasks. For instance, in young children there is evidence that arousing music increases activity (Reiber 1965) and interactive play (Gunsberg 1991), while in older children calming music can enhance reported altruistic behaviour (Hallam *et al.* 2002). Calming music has also been found to have a positive impact on the behaviour of children with emotional and behavioural difficulties, reducing their stress and anxiety in a

variety of settings (Hallam and Price 1998; Savan 1998). Sedative music can result in a greater increase in activity level in children with learning difficulties than stimulating music, the latter replacing the children's need for activity and self-stimulation. These differences in response mean that music interventions aimed at changing behaviour need to be tailored to the requirements of specific groups of children (Reardon and Bell 1970).

Much of the research on the impact of background music has lacked a clear theoretical basis for predicting outcomes, and findings often appear to be contradictory. For instance, in research relating to memorization, when music has been played concurrently with material to be remembered aurally it has not facilitated memory (Furnman 1978), paired associate recall (Myers 1979), or phonological short-term memory (Salame and Baddeley 1989), but when recall is of written sentences presented visually primary-aged children perform better when calming music is playing as opposed to silence (Hallam *et al.* 2002). Music may interfere with aural presentation and recall because of shared cognitive structures reducing processing capacity. Written presentation does not interfere in this way so arousal effects come into play. Similarly, where background music has words it may have a greater negative impact on reading comprehension and other literacy tasks (Martin *et al.* 1988).

Much of the research exploring the impact on tasks in other domains, for instance, mathematics, can be explained through the impact of music on arousal levels (e.g. Mayfield and Moss 1989), although other factors may also be important, for instance, the extent to which learners are used to working with music playing in the background (e.g. Etaugh and Michal 1975), the familiarity of the particular music being played (Hilliard and Tolin 1979), or whether the music is vocal or instrumental (Donlan 1976). Well-learned skills are less affected by high levels of arousal than those requiring creativity or high levels of concentration (Hallam and Godwin 2000) and older students may also be better able to adopt strategies which minimize the negative impact of the music on task outcomes (Kotsopoulou and Hallam 2006). Overall, the impact of background music on performance on any particular task depends on many interacting factors.

A framework for future research

Figure 44.2 sets out a model of possible contributory factors including the nature of the music itself: its genre; whether it is stimulating or relaxing; its complexity; whether it is familiar; liked; and has been selected by the individual listening to it or imposed by others. The model suggests that the effects of music are mediated by the characteristics of the individual; their age, ability; personality; meta-cognitive skills; musical expertise; familiarity with the music being played; and the frequency with which they normally listen to music when they are studying. The current emotional arousal and mood state of the individual may also be influenced by individual characteristics and recent life events. Individual characteristics also have a direct effect on learning outcomes and a further indirect effect through meta-cognitive activity. The environment within which the activity is taking place may also be important, for instance, whether the individual is alone, in a familiar place, whether there are other distractions. The characteristics of the task, for instance, the nature of the processing required, its difficulty, whether it is perceived as interesting or boring will also play a part. Currently little research takes account of these factors.

Issues for future research

Many similar factors are important in relation to assessing the impact of active music-making as in assessing the impact of background music, for instance, taking account of the characteristics of the individual, the nature of the music itself, and the context within which the activity takes place. However, there are important differences. Crucially, when making music the focus is the musical task, which of itself may be rewarding. In addition, playing background music to support non-musical task completion has an immediate, time-limited impact restricted to that task which is unlikely to bring about long-term change in the individual. In contrast, active engagement with music making may have a longer-term impact on the individual's

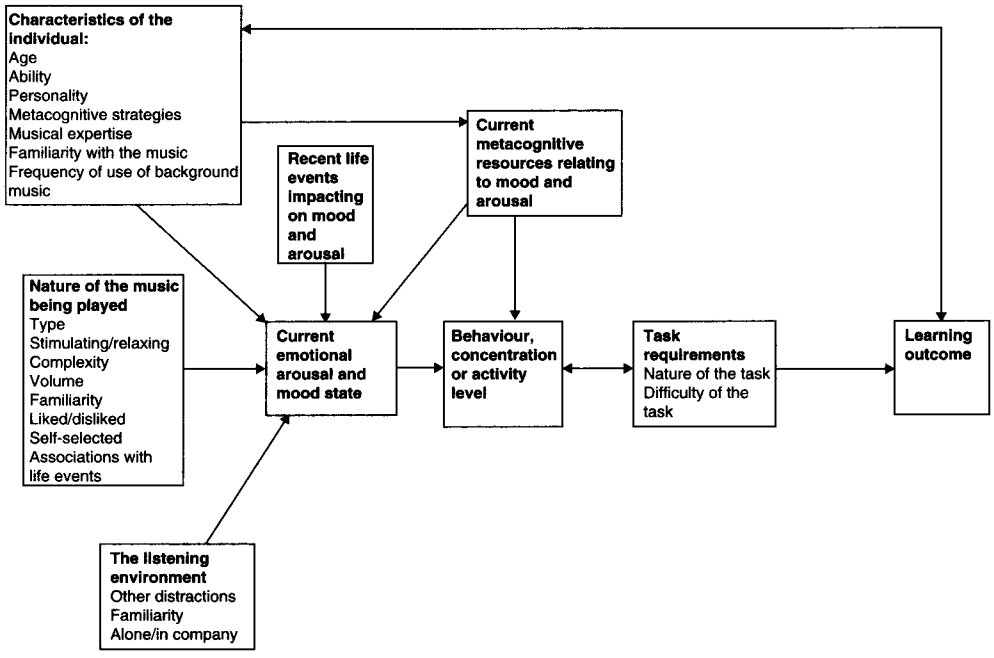

Fig. 44.2 Model of the effects of background music and learning (derived from Hallam and Goodwin 2000).

intellectual, personal, social and spiritual development. A range of different issues therefore need to be considered by researchers including:

- over what timescale does the impact occur?
- how long is it maintained?
- does participation have to be voluntary for there to be a positive impact?
- to what extent is the musical activity as opposed to any concurrent social activity important in determining the impact?

Conclusions

In the modern world all kinds of music are available to most people 24 hours a day. It pervades our everyday lives and influences our behaviour. Children are exposed to it at home and in the wider community. In contrast to this, in schools, music is rarely used to enhance behaviour and subsequently learning, although it can have powerful effects and create an environment which is more conducive to on-task behaviour. It may be that educators feel that it is inappropriate to use music in this way or that it may interfere with the learning of some students, even though it may benefit others. Music can also support learning in other subjects through transfer effects and the way in which it can provide additional cues for remembering. This may be particularly beneficial for young children.

There are now more opportunities than ever before for all sections of society to engage in organized music-making through the growth of community music interventions around the world including signing groups for older adults, percussion workshops for disadvantaged young people, gamelan groups for individuals with special needs, and song-writing classes. There is growing evidence to suggest that these community music interventions not only help people develop musical skills but that they also are psychologically beneficial in a variety of ways.

However, there is a need for more systematic research in community and formal education contexts which establishes the conditions under which music can enhance a variety of learning, intellectual, personal, and social outcomes. Such research would be invaluable in helping to develop our knowledge of the processes and

outcomes of music listening and participation, increasing our understanding of the ways in which music impacts on learning and behaviour, and enabling us to guide musicians working in education and the community as to how to maximize the positive benefits.

CHAPTER 45

Music and consumer behaviour

Adrian C. North and David J. Hargreaves

THE past 20 years has seen a massive increase in research on the effects of music on consumers in both retail and commercial leisure settings such as restaurants, hotels, bars, gyms, and the like. There are at least two reasons for this, namely an increasing interest among music psychologists in social psychological factors and the application of findings to practice (North and Hargreaves 2008), and an increasing interest among consumer psychologists (and people in cognate disciplines) in how aspects of the service environment can influence customers. Indeed, the quantity of research has reached such a level that North and Hargreaves (2008) were able to devote an extended chapter to a detailed review, and Garlin and Owen (2006) were able to conduct a meta-analysis based on only a portion of the number of studies published. Garlin and Owen's analysis showed 'small-to-moderate, yet quite robust effects in terms of background music and the dependents: value returns, behaviour duration and affective response' (p. 755): North and Hargreaves' (2008) review concurred. Indeed in addition to our extended chapter on the subject in *The social and applied psychology of music*, we have been invited to contribute chapters to edited volumes on four separate occasions over recent years (North and Hargreaves 1997, 2005, 2006; North *et al.* 2002) which suggests that, if nothing else, the field has become a recognized part of the psychology of music.

Given the recency of these other reviews it would be a wasted opportunity to merely reiterate the same arguments here. Instead we have opted to take this opportunity to focus solely on our own research on the subject that has been carried out over the past decade. Each of these studies has had its own particular theoretical perspective of course, but as a whole our research in this area has had a broader ambition, namely to begin mapping out the *range* of influences that music might have. In short, the question we have asked is 'What effects can music have on consumers?'

There is both a theoretical and a practical motivation behind this question. From a theoretical perspective, the existing research points to three psychological processes that underlie many effects. The first of these processes concerns the effect of music on physiological arousal. As we shall see shortly, several studies have argued that faster music speeds up customer activity, and explain this by referring to (now fairly antiquated) evidence from experimental aesthetics concerning how factors such as musical tempo might increase activity in the autonomic nervous system. The second process concerns the ability of music to prime certain thoughts. Several specific variations of the theory have been proposed (e.g. Hansen and Hansen 1990; Martindale and Moore 1989; North *et al.* 2004), but all of them describe how hearing a piece of music can activate several related ideas that are either expressed directly or indirectly in the music and lyrics or expressed indirectly as a result of shared cultural understanding of the meaning of the music in question. For example, hearing the *Sergeant Pepper* album by The Beatles primes thoughts related to 'love' as a

result of not just those lyrics that directly address the subject, but also because, on a cultural level, we associate the album with the 'flower power' movement of the late 1960s. Finally, the research suggests that the emotional effects of music can also influence consumers. There are many specific manifestations of this approach, although most involve some aspect of emotional response to music having a subsequent influence on the processing of commercially relevant information.

Of course three of the key explanations evoked by over a century of experimental psychology have also concerned arousal-based effects, priming effects, and the impact of emotion on behaviour. For example, classic research on skilled performance (e.g. Yerkes and Dodson 1908) has focused on how the arousal and information-processing load evoked by a stimulus can mediate performance across numerous domains. Similarly one of the central tenets of social cognition is that each new stimulus is processed in the light of stimuli encountered previously, such that responses to the latter prime responses to the former. Furthermore, large sections of social psychology (e.g. prosocial behaviour, environmental psychology) have considered the impact of emotional states on the ways in which people behave in everyday situations. Since arousal-, priming-, and emotion-based effects have such fundamental relevance to a range of human behaviours and can all result from hearing music, it seems reasonable to make the starting assumption that arousal-, priming-, and emotion-based effects of music might influence a broad range of consumer behaviours.

It also makes practical sense to map out the range of influences of music on consumer behaviour. In short, a store manager may use a certain type of music because they have read reports suggesting that it increases the speed with which customers shop. However, the music could be extremely counter-productive from a commercial standpoint if it nonetheless decreases customers' propensity to spend money, distracts their attention from special offers, makes the store feel crowded, or annoys customers so much that they decide to leave, to name but a few of the possible unintended outcomes. In short, the store manager can only use music optimally if they understand *all* the effects that a given piece of music will have. In particular, the commercial world should be interested in purely theoretical research, as we have long-subscribed to the maxim that 'There is nothing so practical as a good theory': in a commercial context, this means that if a store manager understands how music has the effects that it does, then they can control those effects and use them to their best advantage. A theoretical and a practical understanding of the effects of music in commercial environments go hand in hand with one another.

We begin the chapter with a brief overview of two particular effects of music that have received a considerable amount of attention. From here we go on to use our own research to illustrate the many other commercially relevant processes that can be influenced by music.

Speed of activity and time perception

Two particular topics have dominated research on music and consumer behaviour. These are the effect of music on the speed with which customers behave, and the impact of music on time perception.

Several studies indicate that the speed of customer activity is related positively to the tempo and volume of background music. Many researchers have drawn on the findings of research on experimental aesthetics from the 1960s and 1970s (e.g. Berlyne 1971) which argued that louder or faster music lead to greater levels of physiological arousal, whereas slower or quieter music lead to correspondingly lower levels of physiological arousal. For example, Milliman (1982) found that slow music led to customers in a supermarket shopping 15 per cent more slowly than when fast music was played. Furthermore, customers in the slow music condition also spent around 33 per cent more money, and this is probably because the act of shopping more slowly also gave customers more opportunity to browse a range of products. Smith and Curnow (1966) produced similar results when they manipulated musical volume rather than tempo in a supermarket. Similarly Milliman (1986) studied 1392 groups of restaurant customers over 8 weekends.

Slow music led to customers eating more slowly, completing their meal in 56 minutes on average compared to 45 minutes when fast music was played. This also affected spending. Customers in the slow music condition, who ate more slowly, ending up spending more money on drinks ($30.47 vs $21.62 in the fast music condition). Roballey *et al.* (1985) adopted a dependent variable that is surely unique in the entirety of published psychology, namely bites per minute, finding that fast music in a cafeteria led to 4.40 bites per minute whereas slow music led to only 3.83 bites per minute.

Effects such as these highlight a theme that we will return to several times in this chapter, namely that almost all uses of music in commercial environments reflect a trade-off in which practitioners must decide what type of music they want to use in order to achieve what specific commercial gain. In this case, there is a clear trade-off between the speed of customer activity and spending. For example, if someone is the manager of a café then on Saturday lunchtime all the tables will be full. It is consequently in their interest to play fast music, free up some tables, and therefore maximize profit. If it is Tuesday morning and the café is quite empty then it makes more sense to play slower music in the hope that Milliman's (1986) findings would be replicated and customers would spend more money on drinks.

The second topic that has received considerable research attention has concerned the possible impact of music on time perception. There are numerous, slightly differing, explanations of this effect. However, common to many is the notion, drawn from mainstream research on time perception, that the perception of the passage of time is related to the amount of information encoded during the period in question. This explanation states that the mind invokes an heuristic to the effect that 'if more has happened then more time must have passed'. Research using this approach has, for example, suggested that louder music should therefore lead to the perception of more time having passed. Louder music imposes a greater information-processing load, 'tricks' people into believing that more has happened, and therefore leads to the perception that more time has passed (e.g. Kellaris and Altsech 1992). Another version of this argument reasons that if music imposes a greater processing load on the listener (i.e. by being loud, fast, or complex) then this distracts attention from an internal cognitive timer that monitors the passage of time. Other research has gone on from here and related time perception to whether people like the music they hear. This research employs the intuitive notion that people pay more attention to stimuli that they like. So if somebody likes music that they hear then they pay more attention to it. Because they pay more attention to it, the music imposes a greater information processing load, and so liked music leads to the perception that more time has passed (e.g. Kellaris and Mantel 1994). Although there is evidence to support the arguments set out here, unfortunately this neat theorizing has not led to consistently neat findings. If correct, however, this line of reasoning again implies the existence of another trade-off for practitioners. Followed through to the logical conclusion, research on time perception implies that if a business aims solely to reduce the amount of time that people think they have been waiting for then it might be better to play music that the customers don't like! Alternately, disliked music will nonetheless annoy customers of course, so if perceptions of service quality are more important than waiting time customers should hear music that they like.

The range of effects of music

In 1996 we began a series of studies that have aimed to outline the range of consumer behaviours that might be influenced by music. The remainder of this chapter is devoted to an overview of seven of these influences.

Visiting

North and Hargreaves (1996a) used an emotion-based approach to investigate whether music could influence where people went. We set up an 'advice stall' in an on-campus cafeteria. In effect, the stall was a couple of tables pushed together on which were leaflets offering advice on a range of typical student welfare issues such as safe sex, recommended maximum levels of alcohol consumption, how to find good housing, and similar issues. From the stall we played

pop music of three levels of complexity. Melodic complexity is the extent to which the music is erratic, varied, and difficult to predict. Several lab-based studies in experimental aesthetics (see Berlyne 1971) have shown that moderately complex music seems to be liked most: music of low and high complexity tends to be unpopular.

We measured the impact of the music on the number of people visiting the stall. 'Visiting' was measured in two ways. First, diners in the cafeteria were asked to complete a questionnaire asking them to state how likely they were to visit the stall. Measured this way, people's propensity to visit the advice stall was not influenced by the music. However, a behavioural measure of visiting produced a very different conclusion. On the floor, about one metre from the stall, were a series of small stickers that marked the boundary of an 'approach zone'. Someone was counted as having visited the stall if they put one foot inside this zone and took another step towards the stall. When moderately complex pop music was played then 10.71 people visited the stall every 10 minutes, and this represented significantly more people than when no music (4.01 people) and high complexity pop music (3.67 people) was played.

This has several implications. First, people were predisposed to visit the physical source of liked music. This suggests strongly that playing liked music, in a shop for instance, would encourage people to enter the premises, or could attract people to areas of the premises that they tend not to visit otherwise (e.g. the point farthest from the door or upstairs). Second, the effect of the no music condition relative to the moderate and high complexity pop was interesting. The 'right' music was better at attracting people to the stall than was playing nothing: the 'wrong' music was worse than playing nothing. In short, the real question facing practitioners is not 'Should I play music or not?' but rather 'What is the right kind of music to play?': music that is liked is commercially 'better' than no music, whereas music that is disliked is commercially 'worse' than no music. Again, practitioners face a decision. If a manager is not confident that customers will like the music that is played then they should turn it off: if they are confident that customers will like the music then this should bestow a considerable commercial advantage. Third, these findings show that complexity is one of the variables that allows managers to determine what the 'right' kind of music is: laws of musical preference derived from the lab can be applied in commercial premises to produce music that customers like. Indeed, when completing the questionnaire diners were asked to say how much they liked the music (see North and Hargreaves 1996b), with data showing that moderately complex music was most popular. Diners' answers to the questionnaire also showed however that the more they disliked the music so the more noticeable it became: if a business plays the 'right' kind of music then it will get no thanks, but if it plays the 'wrong' kind of music then everyone will notice! This probably goes a long way to explaining the negative stereotype that the general public holds concerning piped music.

Arousal-based goals

North and Hargreaves (2000) adopted an arousal-based approach to investigate further what the 'right' kind of music might be for commercial premises. As noted earlier, research on experimental aesthetics has argued that people like moderately complex music the most. Researchers such as Berlyne (1971; see also e.g. North and Hargreaves 1996c) have argued that this is because moderately complex music brings about a moderate level of arousal in the autonomic nervous system: Berlyne's theory says that high complexity music brings about too much arousal, and low complexity music brings about too little arousal. Berlyne's theory also argues that factors other than complexity can also cause music to have arousal-evoking properties. For example, louder or faster music is claimed to bring about more arousal than quieter or slower music.

However, if Berlyne's theory is correct and people always use musical complexity, tempo, and volume to bring about a state of moderate arousal, then why do gyms and nightclubs play music that is loud, fast, and otherwise designed apparently to increase an already very *high* level of arousal? According to Berlyne's theory, this music ought to be disliked. Indeed, North and

Hargreaves (1996d) found that when people were asked to imagine themselves in a nightclub then they claimed that they would want to hear arousing music, which suggests that this type of music is not simply being foisted upon an ungrateful public but is instead what people want to hear. In short, there is a problem when attempting to apply Berlyne's theory to common practice in commercial premises.

North and Hargreaves (2000) investigated this by using an experimental simulation of a gym and also a relaxing situation. In our first experiment we asked people to ride an exercise bike or lie down and relax. *After* doing these tasks, people could choose between a loud, fast (i.e. arousing) piece of music or a slow, quiet (i.e. much less arousing) version of the same piece. Consistent with Berlyne's theory, people who had just finished exercising chose to listen to the slow, quiet music that would reduce the level of arousal brought about by cycling to a moderate level: people who had just finished relaxing chose to listen to the fast, loud music that would raise their level of arousal from the low level brought about by relaxation back up to a moderate level. However, in the second experiment we asked people to choose between the two types of music *while* they either exercised or relaxed. This time we got the opposite pattern of results. People who were cycling chose to listen to loud, fast music that would further increase their level of arousal: people who were relaxing chose slow, quiet music that would further reduce their level of arousal. In other words, although most of the time (e.g. when sitting in a café at lunchtime) people like moderately arousing music, we sometimes choose to put ourselves in a state of very high or very low arousal and, under these circumstances, we use music to help achieve these arousal-based goals. In particular, people in gyms and nightclubs want to be in a state of high arousal and loud, fast music can help them to achieve this goal: people in hotels, health spas, or on long-haul flights want to be in a state of low arousal, and would want access to slow, quiet music that helps to achieve this goal.

Store image and purchasing

North and Hargreaves (1998) used a priming-based approach to investigate the effect of music on the atmosphere or 'image' of a store and also actual purchasing. We returned to the same café that we used in our 'visiting' study. Rather than focus on complexity, this time we played different musical styles. Over four days we played pop music, classical music, easy listening music (that was modelled on the 'sweeping strings' stereotype of piped music), and no music. Customers were asked to complete a questionnaire. First they were given a list of 14 items on sale in the café such as a can of Diet Coke and a slice of vegetarian pizza. Customers had to say the *maximum* that they would be prepared to spend on each item in turn. They also had to rate the atmosphere in the café according to 20 different adjectives.

Different musical styles gave rise to very different 'atmospheres'. Pop music led to the perception that the café was lively and youthful, classical music led to the perception that the café was upmarket and sophisticated, whereas the stereotypical piped music led to the perception that the café was downmarket. This is quite interesting in its own right. However, where store atmosphere really seemed to make itself felt was in customers' statements of how much they were prepared to spend in the café. When no music was played, customers were prepared to spend a total of £14.30 on the 14 items. When stereotypical piped music was played, customers were prepared to spend a total of £14.51 on the 14 items. However, when pop music was played (which made the café seem lively and youthful), customers were then prepared to spend £16.61 on the 14 items. Furthermore, when classical music was played (which made the café seem upmarket and sophisticated) then customers were prepared to spend £17.23 on precisely the same items in precisely the same place. Remember also that the customers were exclusively students who would prefer pop music over classical music: although the effect of pop music on the amount that customers were prepared to spend can probably be attributed to liking for that music, the greater effect of classical music cannot be. Rather it seems that customers were tapping in to the atmosphere portrayed by the music and acting accordingly. To put it bluntly, the upmarket and sophisticated atmosphere promoted by classical seemed to prime customers to feel more affluent.

This idea of using music to predispose people to behave in a particular way has been referred to sometimes as 'musical fit', and has been studied by several researchers over the past few years. For example, Areni and Kim (1993) played classical music and pop music in a wine cellar. They found that although the two different types of music did not lead to customers buying any more wine, classical music led to customers buying more *expensive* wine, and they argue that this was because the classical music primed customers to feel more affluent and act accordingly. This notion of musical fit was the subject of a follow-up study that we carried out. North *et al.*'s (2003) study was carried out in a restaurant in the town of Market Bosworth in Leicestershire. Classical music, pop music, and no music were played over three weeks, and customers' spending seemed to be influenced by the apparent effects of musical fit. When classical music was played, customers spent £32.52 on average, whereas when pop music was played customers spent £29.46, and when no music was played customers spent £29.73. Since the restaurant management, quite understandably, did not want us to approach customers we were unable to measure their degree of liking for the music and rule this out as an explanation for the results. However, in apparent support for the 'musical fit' explanation of diners' spending, the positive effects of classical music on spending were particularly strong in the case of starters and coffee; in other words, items that it is possible for customers to avoid while nonetheless being able to tell themselves that they had 'eaten out'. Did they spend more on starters and coffee because the classical music made them feel more affluent?

Product choice

North and colleagues (1997, 1999a) also used a priming-based approach to investigate another aspect of musical fit, namely product choice. We used an aisle-end display in a local supermarket that featured several French and German wines. Each shelf on the display featured one type of French wine and one type of German wine, with the two wines on that shelf representing a similar degree of 'dryness' and being of very similar price. In other words, the main distinction between the two types of wine on each shelf (at least for non-connoisseurs) was arguably the country of origin. On the top shelf of the display was a small tape player. On alternate days this played either French or German music. Note that this manipulation of the music did not require customers to know that for example, Debussy was French or that Beethoven was German. Rather the manipulation went for the lowest common denominator such that 'French music' featured accordions heavily (as well as other stereotypically 'French' features), whereas the 'German music' featured an oompah band performance of songs concerning, among other issues, the pleasures of drinking white wine on the Rhein. The display was in view of the checkouts, and we sat behind these, next to a taxi phone, with carrier bags full of shopping to create the impression that we were normal customers waiting for our taxi to arrive. In reality we were observing the number of bottles of wine sold.

The results were consistent with the notion of musical fit. When French music was played then French wine outsold German by five bottles to one. When German music was played then German wine outsold French by two bottles to one. We investigated this further using a questionnaire. Once customers left the wines section (and entered the frozen pizza aisle!) they were approached by a researcher who asked them to state whether the type of wine they had bought had been influenced by the music that was playing. The sales data showed that they ought to answer that it had been. Unfortunately only 44 customers agreed to answer this question. However, although the sales data indicated that wine choices had been influenced by the music, only one customer was prepared to admit this on the questionnaire.

Findings such as these have obvious implications. First and most obviously they suggest that musical fit can influence product choice as well as spending. Second, the difference between actual wine sales and responses to the questionnaire could be taken as implying that customers were in some way unaware of the effect of musical fit on their behaviour. If this were so, it would of course have serious ethical implications (and indeed one national newspaper headline at the time claimed that psychologists had

discovered a way of making consumers buy things that they didn't want). We suspect strongly, however, that a far more mundane explanation is correct. We noted earlier that the music played from our display was crass. Consequently we find it hard to believe that, when asked midway through a shopping trip, people would be prepared to say that 'in effect, yes, all it took to get me to buy French wine was a bit of music played from a tinny speaker': they had a far stronger motivation to tell the researcher, in effect, that 'no, I was not influenced, and I can assure you that I always buy this type of wine'. Instead the music probably worked in just the same way as an advert placed by the entrance, advertising the fact that French (or German) products were on sale and raising their salience. Indeed we would actually go a step further than this and argue that the effects of musical fit will probably occur only under conditions where customers are otherwise undecided about which course of action to take. For example, if the supermarket study had replaced wines with cars, then it seems almost inconceivable that music could have affected people choosing between buying a Renault and a Volkswagen (although this does of course remain to be shown by data). When other information is available to demonstrate which of the available options is best, or when people otherwise have a very strong motivation to think about the options in detail, we expect that musical fit would become a relatively unimportant factor in their decision-making. Balanced against this of course is the fact that consumers do make many decisions on the spur of the moment with little thought: a shopper may have pasta on their shopping list but no firm opinion about which of two brands is best, and be even less inclined to stand in the supermarket for a few moments and think about it. There is tremendous scope for the application of musical fit.

Musical 'fit' in advertising

If musical fit does operate by raising the salience of ideas related to the music, then this greater salience ought to have implications for memory. North *et al.* (2004) studied musical fit in radio advertising. We reasoned that if music in the adverts 'fitted' with the advertised product then, by raising the salience of the product, the music should help people to remember it. We prepared radio adverts for five brands, an online bank, a people carrier, a bathroom cleaner, a chocolate bar, and an energy (i.e. high-sugar) drink. On top of the voiceover in each advert we played music that either did or did not fit with the characteristics of each brand. After hearing the adverts, people were asked to read a short story before then being asked to recall what they had heard. Recall was indeed higher when the adverts had featured music that 'fitted' the advertised product. This is consistent with the notion that musical fit had primed listeners' thought processes, such that this priming aided recall. Rather less profoundly, these results show that musical fit also operates in the context of advertising. Also, if musical fit improves memory by raising the salience of certain ideas or causing a greater degree of thought, then it may also be the case that very low levels of congruity between music and product achieve the same effect: people would be expected to try to resolve the extreme incongruity between music and product, and the greater amount of thought devoted subsequently to the product may also have the effect of improving memory for it.

Music on-hold

Several other studies have considered time-related effects of music. North *et al.* (1999b) investigated a simple question, namely whether on-hold phone music should work. The research was set up to look into two competing hypotheses. On the one hand, as described earlier, the research on time perception indicates that liked music should lead to longer time duration estimates. This means that hearing liked music while waiting on hold ought to produce longer estimated waiting times and an increased propensity to hang up. On the other hand, an emotion-based approach led us to reason that if callers like the music they hear while on-hold then they ought to be more inclined to stay on the line: if North and Hargreaves (1996a) showed that that liked music could attract people to an advice stall then why shouldn't liked music attract people to a phone line? Alternately, another emotion-based possibility was that liking for the

music was less relevant than the potential ability of music to simply calm callers down and counteract their irritation at being kept waiting.

To test these ideas we placed an advert in our local newspaper. This asked people to call a phone number in order to take part in a survey. When people called we automatically put them on hold. While waiting they heard one of three things. Some people heard 'liked music' which we operationalised as excerpts of three songs by The Beatles, namely *Yesterday*, *Eleanor Rigby*, and *Hey Jude*. Other people heard the 'weapon of choice' of most on-hold phone systems, namely pan-pipe music, which in this case featured cover versions of the same excerpts of the three Beatles' songs. A final group of people heard nothing at all apart from a brief, repeating spoken message encouraging them to keep waiting. At no point in the experiment did we actually answer to the phone: instead we simply timed how long people waited for before they lost patience and hung up.

The spoken message led to callers waiting, on average, for 197.76 seconds; and the original songs by The Beatles led to callers waiting for 229.50 seconds. However, the most successful condition was the pan-pipe cover versions, which led to callers waiting for an average of 257.28 seconds. Indeed, the success of the pan-pipes is best illustrated by pointing out that, in order to keep the line clear for new callers, we automatically cut people off once they had waited for 300 seconds. Given that some people hung up the moment they realized they had been put on hold, the average waiting time for the pan-pipe condition indicates in effect that we simply couldn't get rid of people in this condition!

In an attempt to explain the success of the pan-pipes (and arrange to pay people for their trouble) we used caller identification to call people back. Callers were asked to rate our telephone service on several dimensions. The Beatles and the pan-pipes conditions were liked as much as one another, and so liking for the music could not explain the effects of the pan-pipes on waiting time. However, when people were asked to rate the phone service according to five adjectives only one, 'peaceful', gave rise to significant differences between the conditions, with the pan-pipe condition receiving the highest ratings. In short, on-hold phone music can persuade people to wait for longer than can a spoken message, but it is important that this music should reduce stress and irritation in order to be successful.

Priming store image

Much of the research reviewed above highlights the importance of using music to control the impression that customers have of a particular set of commercial premises. This then raises the issue of how precisely music influences these impressions, and this was investigated by North *et al.* (2000). We studied music in a bank branch and a local bar. In the city centre bar we played classical music, pop music, and no music over nine days. Customers rated the extent to which the bar could be described in terms of 11 different adjectives. Factor analysis of these ratings indicated that the adjectives fell into three factors, namely 'dynamic/upbeat', 'cerebral', and 'aggressive/downmarket'. The bank study played classical music, easy listening music, and no music over three weeks. Customers rated the extent to which the bank could be described in terms of 20 different adjectives, and a factor analysis showed that these adjectives fell into four factors that were remarkably similar to those in response to the bar, namely 'dynamic/upbeat', 'dignified', 'assertive/aggressive', and 'inspirational'. In both the bar and the bank, different musical styles gave rise to different scores on these factors. More simply, any attempt to use music to control the impression that customers form of commercial premises should focus primarily on the factors described here, since these subsume many of the other, more fine-grained responses that customers might have.

Conclusions

The findings reviewed here provide initial positive signs that music can have a wide range of positive commercial benefits. Music can influence the places that customers go to, customers' ability to achieve a desired level of arousal, the atmosphere of commercial premises, the amount that customers are prepared to spend,

the amount they actually spend, the products they buy, their memory for advertising, and the amount of time they wait on hold. In addition to research by other academics on time perception and the impact of musical tempo and volume on the speed of customer behaviour, our own studies described here begin to map out the range of effects that music might have on consumers. Furthermore, the 10 effects described here seem to be based on fundamental psychological processes concerning arousal, priming, and the effects of emotions on behaviour, such that they may represent only the beginning of a list rather than a final definitive account.

Furthermore the research described here highlights an important issue for practitioners. If music can have many different effects it is important to prioritize those that correspond best with the business' marketing goals. Following from this, there can be no single 'right' type of music that is a universal commercial panacea, and the real issue is how to select music that addresses the most important marketing goals and does not hamper others. The specific answer to the question 'What music should my business play?' involves consideration of the psychological effects of music that are known to exist, the importance of various marketing goals, the musical preference of the customers (or at least careful steps to avoid annoying customers), along with numerous practical constraints such as budget or the need to install appropriate equipment.

Note also that we say that the evidence here provides only 'initial signs' of a positive effect of music because of the obvious difficulty of devising a detailed model of the process and testing all the possible aspects of this. The typical customer is engaged in a complex decision-making task, weighing up at least two competing alternative products along numerous cognitive and social psychological dimensions (e.g. a consideration of price vs benefit, product quality, relevance to self-concept, prevailing fashions etc.). Furthermore, some of these dimensions will only have become salient very recently, whereas others have been evaluated in detail over extended periods of time (as a result of prior experience of the products, advertising, or the opinions of friends, to name just three). At the same time, the customer will be managing several competing attentional demands (e.g. the presence of others, other time pressures etc.). As if understanding this were not complicated enough, music itself of course varies along numerous dimensions, all of which affect a customer in some way, with some of these effects being complementary and others less so. Devising an explanation of how all these factors interact is a daunting task, but at least work has begun on the basic building blocks, namely an outline of the various effects of music on consumers.

PART 10

Music Therapy

Edited by Michael Thaut

CHAPTER 46

Processes of music therapy

Clinical and scientific rationales and models

Shannon de l' Etoile

> To apprehend music as an essential form of human behavior is to make more secure the foundations of music in therapy. Music therapy has long needed such a platform for its theoretical constructs, one that would be in accord with biological as well as psychological concepts.
>
> Gaston 1968

Introduction

These groundbreaking words clarified the need for a theoretical basis for music therapy practice; however, decades later, a consistent theory has yet to be recognized. The problem may stem from poorly organized research that has little relevance to clinical practice, thus limiting its applicability (Aigen 1991; Asmus and Gilbert 1981; Gfeller 1995; Nicholas and Gilbert 1980; Wheeler 1983). Furthermore, music therapists have traditionally borrowed research paradigms from other disciplines, such as psychology or the biological sciences (Aigen 1991). While such efforts might have initially helped the profession to gain recognition in scientific or academic settings, they do not clarify the unique role of music in changing human behaviour. Consequently, these external paradigms may not be appropriate for guiding music therapy practice.

To explore this idea, Gfeller (1987) conducted a content analysis of 243 articles published in the *Journal of Music Therapy (JMT)* between 1964 and 1985 that related to theory or practice in music therapy. Her results revealed that no single theory or philosophy appeared to be prominent in music therapy practice. Rather, 48 per cent of the articles utilized various theories in psychology, including psychoanalytic (11 per cent), behavioural (26 per cent) or other prominent schools (11 per cent), including cognitive, humanistic and developmental theories.

Without a common theory, music therapists may struggle to produce consistent clinical outcomes and to communicate effectively with other health care professionals (Scovel and Gardstrom 2002). A unified theory may best emerge from a review of previous theories. While it would not be within the purview of this chapter to review all theories ever applied in music therapy practice, Gfeller's research (1987) provides a logical point of reference. Based on her findings, this chapter will review behavioural, psychoanalytic and humanistic music therapy. This discussion will culminate in the presentation of two newly developed theories that demonstrate a mutually beneficial relationship between research and clinical practice.

Behavioural music therapy

Behaviourism grew out of B.F. Skinner's work, which dominated the practice of psychology between 1920 and the middle of the twentieth century (Scovel and Gardstrom 2002). Skinner claimed that learning happens when events are paired with consequences. Originally, behaviourism emphasized the study of objective behaviour of individuals while interacting with the environment and relied on experimental methods, thus minimizing a focus on mental processes or emotions.

Since its inception, behaviourism has evolved and become less mechanistic in its current clinical applications. Contemporary behaviour therapy offers three basic approaches, starting with operant conditioning, in which behaviour is a function of its consequences (Standley *et al.* 2004). A second approach is classical conditioning, which involves manipulation of the environment to alter cognitive processes. More recently, social learning theory has emerged as another approach that incorporates strategies from social, personality and developmental psychology, such as vicarious learning and self-regulation (Standley *et al.* 2004).

Behavioural music therapy was most prominent during the 1960s and 1970s; peaked from 1976–1978, and slightly declined after that time (Gfeller 1987; Standley *et al.* 2004). Results from a more recent content analysis of the *JMT* (Gregory 2002) further indicate that behaviourism was emphasized in the literature during the 1970s and 1980s, and continued throughout the 1990s. The approach has most often been reported with children in educational settings, but has also been used with a variety of other clinical populations, including premature infants, adults with developmental disabilities and older adults with Alzheimer's disease (Standley *et al.* 2004).

A behavioural music therapist manipulates musical stimuli to facilitate a change in the client's observable, measurable behaviour (Scovel and Gardstrom 2002). A well-known behavioural approach is Applied Behaviour Analysis (ABA), which utilizes principles of operant conditioning. With ABA, the therapist first establishes a baseline of the client's behaviour, implements a strategy for change, and then documents the client's response (Brownell 2002; Hanser 1995). Another common application of behavioural music therapy is the use of music as contingent reinforcement. The opportunity to play a favourite instrument, for example, could reinforce a desired behaviour (Scovel and Gardstrom 2002).

Standley (1996) conducted a meta-analysis of 98 studies that used music as a contingent reinforcer for educational and therapeutic behaviours. Results indicated that contingent music is more effective than other, non-musical contingent reinforcers, and is more effective than continuous music at facilitating positive changes in behaviour. While Standley's findings provide strong evidence of music's effectiveness as a contingent reinforcer, other researchers may disagree. In an earlier study by Wolfe and Hom (1993), typically developing preschool-age children participated in a number of musical and non-musical interventions designed to help them learn phone numbers. Results revealed that the contingent use of music (i.e., being able to play a preferred musical instrument) was not effective in helping the children to memorize the numbers. Rather, the children were most successful at learning during the intervention involving singing the phone numbers to the melodies of familiar songs.

These contrasting findings may cast some doubt on the behaviourism's appropriateness as a comprehensive theory to explain music's therapeutic mechanism. The fact that contingent music is not consistently effective points to the idea that the behavioural principle of contingency is not the agent of change. Rather, the clients' behaviour is likely to change due to their response to the perceived, inherent value of the music. Understanding the reward value of music should then become the central focus of both research and therapy.

To explain further, while behaviourism has benefited the music therapy profession, the theory does not explain how music is functioning to change behaviour. For example, certain behavioural principles are necessary and effective in a number of therapeutic settings, including the use of contingent reinforcement (musical or otherwise), adherence to group rules and the ability to self-regulate. These constructs; however, may be applied in any

therapeutic situation (musical or otherwise) and may have little to do with the music itself. Furthermore, within schools of psychology, clinical applications of behaviourism tend to fall under the 'psychotherapy' heading. While music therapy certainly does address many psychotherapeutic goals, it can also focus on other clinical needs, such as language development or gait training, which clearly would be misplaced under the psychotherapy heading. Aligning music therapy strictly with behaviourism could potentially be an inaccurate and restrictive manoeuvre.

While behavioural research approaches (i.e., single subject and multiple baseline designs) can effectively identify treatment outcomes, they must be substantiated by a scientific understanding of how the music is functioning within the design. Critical questions remain unanswered, such as: *why* does the behaviour change only when the music is present? Is the music rewarding due to timbre, style, familiarity, tempo, or pitch range? Does simple pattern repetition provide an appropriate level of sensory stimulation that the client finds innately rewarding?

Music therapists should not operate from blind assumptions about how the music is functioning. As Gfeller (1987) states, recognizing music as an effective reinforcement in behavioural therapy may not adequately explain music's influence on human behaviour. Rather, the therapist's application of music must be based on an extensive and systematic examination of the involved musical elements (i.e., novelty, complexity, redundancy, etc.), and the ways that these elements interact with the individual and the environment (Gfeller 1987). Without this knowledge, generalization of techniques will be limited at best. In summary, despite its widespread usage and demonstrated efficacy, behavioural music therapy does not offer a complete theoretical explanation for practice and research in music therapy.

Psychoanalytic music therapy

Psychoanalysis is based on the work of Sigmund Freud, whose groundbreaking ideas transformed the practice of psychotherapy during the early twentieth century (Scovel and Gardstrom 2002). More contemporary adaptations of Freud's ideas have since been developed by Alfred Adler, Carl Jung, Erik Erikson, Melanie Klein, and others (Hadley 2002; Scovel and Gardstrom 2002). Freud claimed that people function at various levels of awareness, including unconscious, preconscious and conscious. For some individuals, unresolved emotional conflicts may reside in the unconscious and thus create personality abnormalities. Consequently, the personality must be reconstructed to achieve optimum health. According to Freud, repressed unconscious material must be brought into the client's awareness and then processed through the experiences of transference and countertransference (Bruscia 1998a; Scovel and Gardstrom 2002). Common psychoanalytic techniques include free association, dream analysis and interpretation.

To avoid confusion, various terms may be used interchangeably with psychoanalytic psychotherapy, including 'psychodynamic psychotherapy' and 'insight-oriented psychotherapy' (Isenberg-Grzeda *et al.* 2004). For the purposes of this chapter, all of these terms pertain to clinical techniques that have evolved from Freud's classical psychoanalytic technique.

Gfeller's (1987) content analysis of the *JMT* showed that from 1964 to 1984, 11 per cent of the articles published were linked to psychoanalytic theory. In addition, psychoanalytic theory dominated the *JMT* within its first six months of publication before declining in the mid 1970s. In psychoanalytic music therapy, music experiences may be used to supplement or replace traditional verbal psychoanalysis (Bruscia 1998a). The music therapist creates experiences to stimulate thoughts and feelings related to the client's past and present life, thus eliciting repressed unconscious material. One of the most common techniques used in psychoanalytic music therapy is vocal and/or instrumental improvisation between therapist and client (Bruscia 1998a). Improvisation gives the client the opportunity to engage in free expression of all thoughts, feelings and sensations; thus, a musical free association.

Mary Priestley and colleagues expanded these fundamental ideas in the 1970s by establishing the Analytical Music Therapy (AMT) approach,

which combines musical improvisation with movement and verbal processing (Scovel and Gardstrom 2002). In AMT, therapist and patient improvise together, and subsequently use psychoanalytic techniques to determine what happened or what they were thinking about during the improvisation (Eschen 2002). According to Priestley, improvised music essentially provides a gateway to the unconscious, as it allows for non-verbal expression of unconscious processes (Hadley 2002). The therapist works as a non-directive partner with the patient and maintains an openness to the processes of transference and countertransference (Eschen 2002). Transference occurs when the client projects unfinished emotional business onto the therapist or the music, while countertransference pertains to the therapist's emotional response to the patient (Priestley 1975). The technique is most often used with patients in psychiatric settings and in other areas of health care. While AMT has not gained strong acceptance in the United States, it is widely practised in Europe.

Another common technique in psychoanalytic music therapy is imaging to music, which is often achieved through the Bonny Method of Guided Imagery and Music (GIM) (Scovel and Gardstrom 2002). With this technique, the therapist provides carefully sequenced classical music selections to help the client achieve altered states of consciousness. In these altered states, repressed emotional themes may emerge through imagery, which can be processed with the therapist through verbal dialogue (Bonny 1994).

While AMT and GIM offer guidelines for how a clinician should proceed during a therapy session, psychoanalytic music therapy does not typically utilize specific techniques (Isenberg-Grzeda *et al.* 2004). Rather, the clinician will use any number of strategies, such as vocal or instrumental improvisation, songwriting, lyric analysis or imaging to music, based on his understanding of the therapeutic process as it unfolds. While this flexibility might seem appealing initially, the lack of consistent, standardized techniques can hinder general understanding and application of the theory.

Furthermore, some disagreement exists among psychoanalytic clinicians regarding the agent of change in the therapeutic process: is it the musical experience, the verbal exchange, or the combination of the two? (Isenberg-Grzeda *et al.* 2004). The fact that at least part of the technique's success depends on the nature of the relationship between patient and therapist also raises some concerns, as this highly subjective variable is not easily replicated, generalized or measured. Additionally, much of the explanation for the therapeutic mechanism in psychoanalytic music therapy seems to result from the therapist's *interpretation* of the client's behaviour (i.e., the meaning of the instrument that the client selects, the way that the instrument is played, recurring themes within melodic and rhythmic patterns, etc.). This interpretation is also subject to bias, including the clinician's level of training and amount of clinical experience.

The subjective nature of psychoanalytic music therapy also does not lend itself well to empirical examination. Consequently, most of the research conducted in this area has been qualitative with some documentation of treatment effects published via case studies (e.g., Bruscia 1991). Certainly qualitative research can guide clinical practice and inform subsequent quantitative investigation. Additionally, a recent proliferation of literature on psychoanalytic music therapy indicates a growing interest in this application and belief in its efficacy (Isenberg-Grzeda *et al.* 2004). Overall, however, little empirical evidence exists pertaining to the effectiveness of psychoanalytic music therapy or its direct generalizability to other clients and settings. This lack of data limits the theory's growth as well as its acceptance and recognition within the medical community.

Another issue regarding psychoanalytic music therapy pertains to music's ability to elicit unconscious material, as well as to create opportunities for transference and countertransference. These processes are considered fundamental to the client's experience in psychoanalysis, yet the theory lacks a scientific description of the precise way in which music facilitates these events. If a therapist does not understand how a technique works, he will be restricted in his ability to use it effectively and risks using the technique inappropriately.

Like behavioural music therapy, the psychoanalytic approach is considered a psychotherapeutic modality. Limiting music therapy to this one application may be detrimental to the profession's growth and viability. Even casual observation reveals that musical experiences can improve numerous skills outside the psychotherapeutic realm, such as short-term memory, or movement accuracy. Despite the many clients who have benefited from this approach, psychoanalytic music therapy does not offer standardized techniques, nor does it provide a scientific explanation for music's therapeutic mechanism. For these reasons, psychoanalytic music therapy does not provide a comprehensive theory for clinical practice and research.

Humanistic music therapy

In the 1960s and 1970s, therapists developed alternatives to the behavioural and psychoanalytic approaches, thus producing several new theories with a humanistic approach, including existential therapy (Viktor Frankl, Rollo May), person-centred therapy (Carl Rogers) and Gestalt therapy (Fritz Perls) (Corey 2005). While each approach includes unique tenets and techniques, all humanistic approaches share common elements, including a respect for the client's experience and a belief in the client's ability to make constructive choices (Corey 2005). Perhaps at the heart of the humanistic movement is the concept that each human being has an innate potential that can be actualized and through which one can find meaning.

Abraham Maslow was one of the earliest and most influential proponents of the humanistic movement (Scovel and Gardstrom 2002). He described a hierarchy of human needs, ranging from biological requirements to self-actualization, or the need to move toward wholeness and fulfillment. Mental disorders result when one fails to progress through the hierarchy, thus inhibiting the ability to find meaning and be responsible for oneself and others. By providing unconditional acceptance and maintaining a focus on the here-and-now, the humanistic therapist helps the client to identify and address factors that are blocking his self-actualization and to take greater responsibility for his choices and actions.

In her content analysis of the *JMT* from 1964–1984, Gfeller (1987) discovered that 11 per cent of the articles pertained to theories borrowed from various schools of psychology, including humanistic, and that these articles were most prominent after 1970. The humanistic music therapist uses music to identify the client's needs and facilitate the process of self-actualization (Scovel and Gardstrom 2002). A variety of methods may be used, ranging from active (i.e., improvisation) to receptive (i.e., listening) (Bruscia 1998b).

One of the most well-known approaches within humanistic music therapy is Creative Music Therapy (CMT), developed by Paul Nordoff and Clive Robbins (Aigen *et al.* 2004; Scovel and Gardstrom 2002). Both Nordoff and Robbins were drawn to Maslow's humanistic concepts, which they adopted and integrated with the ongoing development of their approach in the 1970s (Robbins 1993). In particular, they appreciated Maslow's emphasis on developing a client's strengths and potentials, rather than focusing on his deficiencies (Aigen *et al.* 2004).

With CMT, the clinician uses vocal and/or instrumental improvisation to encourage growth of the client's inner creative drive, thus accessing unknown developmental potentials that are blocked due to disability (Nordoff and Robbins 1977; Robbins 1993). Through the improvisation, the therapist can describe the client's personality, match the client's mood, mirror the client's facial expression or physical bearing, as well as imitate sounds that the client is making (Aigen *et al.*, 2004). Consequently, a client should experience increased emotional awareness as well as improved personality organization, and be able to interact with the environment in a more meaningful way (Nordoff and Robbins 1977; Turry 1998). CMT has been used primarily with children who have cognitive and motor deficits, and also adults in medical, psychiatric and geriatric settings (Andsell 1995; Scovel and Gardstrom 2002).

CMT does not prescribe a format or procedural sequence for the improvisations (Aigen *et al.* 2004). Rather, the therapist matches and enhances the client's emotions from moment to moment and the process is one of trial and error. A wide spectrum of beliefs exists among CMT clinicians regarding application of the technique

and whether or not it should be combined with various modes of psychotherapy. Some practitioners are more interpretive regarding client behaviour, and others are more music-centred, believing that interpretation can distort the musical interaction (Aigen *et al.* 2004; Turry 1998). Ultimately, CMT stems from a music-centred philosophy, in that music functions as the primary agent of change and offers unique therapeutic benefits that cannot be achieved verbally.

Similar to psychoanalytic music therapy, the humanistic approach is highly subjective, and thus difficult to examine using traditional scientific methods. Consequently, most research in humanistic music therapy has been qualitative, using the case study format (Aigen *et al.* 2004; Aigen 1995, 1998). To document treatment outcome, CMT clinicians typically do not collect data pertaining to specific target behaviours (Aigen *et al.* 2004). Rather, sessions are recorded and then reviewed in an extensive process known as indexing, which identifies ongoing changes in the client as well as in the music.

The humanistic approach has benefited the music therapy profession in several ways. Philosophically, a belief in the client's ability to change and grow should underlie any effective approach to treatment. Musically, the CMT focus on the aesthetic quality of the music and artistic acumen of the therapist certainly elevates standards of professional competence. Despite these benefits, the humanistic approach offers no consistent, standardized techniques, as would be expected of a therapeutic intervention in a medical setting. Data collection within CMT, albeit extensive, appears to focus more on musical outcomes as opposed to functional outcomes that may translate to improved behaviour beyond the therapy session.

Additionally, humanistic music therapy lacks a scientific explanation for how music functions as the agent of change. For instance, how does music access the inner creative drive? How does music facilitate personality organization, or improved perceptual processes? While client responses are evident from behavioural observation, a thorough understanding of music therapy's effect must include scientific knowledge of internal processes. Without this information, a clinician is essentially 'reinventing the wheel' in every therapy session, and will struggle to produce reliable outcomes. These issues undermine the strength of humanistic music therapy as an all-encompassing paradigm for the profession.

Paradigm shift: from social science to neuroscience

The above theories reveal that music therapy practice has been based largely on a social science framework; that is, music has been valued for its ability to facilitate emotional expression and social integration (Thaut 2005). While these musical effects continue to have merit in contemporary practice, more recent evidence has prompted the profession toward a paradigm shift. Since the early 1990s, the advent of modern research techniques in cognitive neuroscience, such as brain imaging, brain-wave recordings and kinematic motion analysis, have provided a greater understanding of the neural processes involved in the perception and production of music. These data collection methods provide an understanding of how music 'works' in a therapy session. With this knowledge, music therapists can operate from a scientific framework and produce stronger, more specific outcomes than general well-being. Consequently, music therapy has evolved from a social science model to a neuroscience model of clinical practice and research.

This evolution has resulted in the formation of a new theory for research and clinical practice, known as Neurologic Music Therapy (NMT) (Clair and Pasiali 2004; Thaut 2005). NMT techniques address cognitive, sensory, and motor dysfunction resulting from disease of the human nervous system. Such techniques are designed to produce functional outcomes and are evidence-based, drawing from scientific data in basic and clinical research. Furthermore, while NMT techniques should be modified to meet each patient's unique needs, they are standardized in terminology and application, thus enhancing communication and clinical efficacy among music therapists and with other health care providers. Specific details regarding NMT techniques are provided elsewhere in this volume. The purpose of this chapter is to elucidate the theoretical components of the NMT model.

The Rational-Scientific Mediating Model

NMT theory is founded in a neuroscience model of music perception, known as the Rational-Scientific Mediating Model (R-SMM), which explains how music functions as a mediating stimulus (Clair and Pasiali 2004; Thaut 2000, 2005). To explain further, aesthetic stimuli such as music typically evoke two sequential responses (Berlyne 1971). The initial response produces some type of feedback or internal stimulation in the recipient. This response joins with the stimulation coming directly from the music, thus producing a mediating response that determines what the recipient will do. Consequently, overt behaviour results from the stimulation coming from the music itself, as well as the stimulation arising from one's initial reactions to the music. Mikiten (1996) eloquently describes how a mediating response to music produces a desirable outcome:

> It is hard to frame a hypothesis and conduct research into how playing a certain song makes a cancer patient 'feel' better. Further, different songs affect patients differently. However, it does make sense to hypothesize that sound structures are detected by brain structures involved in memory. The act of recognition by brain circuits triggers endorphin release that modulates the brain structures responsible for pain. This point of view facilitates the design of hypotheses for experimental verification.
>
> Mitiken (1996, p. 21)

The mediating response in this case is recognition of sound structures and subsequent endorphin release. With knowledge of these internal processes, the music therapist understands how the intervention works and can apply it most effectively. The R-SMM explains how music functions to elicit a mediating response that eventually produces a desired, overt, behavioural response. Understanding of the mediating response is based on scientific evidence and not on speculation inferred from behavioural observations.

The R-SMM provides a framework for exploring and understanding mediating responses to music within the domains of affect, cognition and sensorimotor processes (Clair and Pasiali 2004; Thaut 2000, 2005). The model is rooted in the idea that the scientific basis for music therapy is found in the neurological, physiological and psychological foundations of music perception and production. Application of the R-SMM proceeds in the following four steps:

1 Musical response models: research in music therapy must begin with a solid understanding of musical behaviour, including its neurological, physiological and psychological components. At this step, the researcher might ask, how do humans perceive, produce or respond to music? What systems of the body, underlying neural pathways or perceptual processes are involved?

2 Non-musical parallel models: research at this level examines processes in non-musical brain and behaviour function. Through comparative analysis with step 1, this step establishes a meaningful link between musical behaviour and non-musical behaviour. A parallel process between musical and non-musical functioning must be established, before suggesting that music can influence non-musical behaviour.

3 Mediating models: if a parallel process has been identified at step 2, the researcher can move forward by examining or conducting research to explore the influence of music on non-musical brain and behaviour function. Mediating research does not involve investigation of long-term treatment effects; rather, it explores music's immediate effect on both typical and clinical populations. Results clarify the scientific mechanisms of music's effect on behaviour, or mediating response, thus providing the foundation for clinical research.

4 Clinical research models: when positive mediating effects have been established at step 3, the researcher can design and implement a clinical protocol examining the long-term, therapeutic effects of music. The focus at this level is on lasting functional behaviour change and carry-over after treatment.

As an example of the R-SMM, a researcher may explore music therapy for memory deficits in children with learning disabilities. In Step 1,

musical response models, the researcher gathers evidence regarding how music is memorized. In perusing the literature, he may discover that when learning music, Gestalt laws of perceptual grouping are commonly used to combine similar musical elements, thus reducing the memory load and allowing for more effective storage and recall of musical information. In Step 2, non-musical parallel models, the researcher explores how non-musical information is typically memorized, and looks for any shared strategies with memory for music. Examination of previous literature reveals that when memorizing visual or textual information (i.e., lists of words or phone numbers), Gestalt laws of perception are also utilized to group items based on similar features, thus facilitating efficient storage and recall.

With this parallel process established, the researcher can proceed to Step 3, mediating models. Here the researcher examines the effect of the musical behaviour (i.e., memory strategies for music) on the non-musical behaviour (i.e., memory strategies for textual information). The mediating response is the innate human tendency to perceive order and groupings in music stimuli. Perceptual grouping then provides a framework or vehicle for organizing and rehearsing the new information, thus leading to improved storage and recall.

The researcher might first implement his idea with a typical population, such as teaching a new phone number to preschool-age children by singing it to the melody of a familiar song. If positive results are obtained, then the researcher may apply the technique to children with memory deficits due to learning disabilities. Promising evidence at this stage would logically support systematic research at step 4, clinical research models. The researcher could then design a long-term treatment study, investigating the effect of a musical mnemonic device as a memory strategy for children with learning disabilities.

The Transformational Design Model

The R-SMM provides clear guidelines for conducting research regarding music's therapeutic effects. A supplemental model is needed; however, to assist the clinician in translating research findings from the R-SMM into everyday practice (Thaut 2005). The Transformational Design Model (TDM) meets this need by providing a systematic, step-by-step approach to designing, implementing and evaluating clinical interventions (Clair and Pasiali 2004; Thaut 2000, 2005). The five steps of the TDM include:

1 Diagnostic and functional assessment of the patient
2 Development of therapeutic goals and objectives
3 Design of functional, non-musical therapeutic exercises and stimuli
4 Translation of step 3 into functional therapeutic music experiences
5 Transfer of therapeutic learning to functional, non-musical, real world applications.

Steps 1, 2, 3 and 5 of the TDM are common to all therapeutic disciplines (Thaut 2000, 2005). Step 1 involves a diagnostic and etiological assessment of the client which leads to Step 2, establishment of functional goals with corresponding measurable objectives. This information informs Step 3, the design of therapeutic exercises and activities to address the goals and objectives. A critical component of Step 3 is designing such exercises according to the functional behaviours of the patient and not on musical considerations. This approach to treatment planning ensures a functional outcome, not a musical outcome, and enhances collaborative efforts with other disciplines, thus producing more specific and meaningful treatment outcomes.

Step 4 makes the TDM unique to neurologic music therapy practice. Here the music therapist translates the functional and therapeutic exercises from Step 3 into musical experiences that are isomorphic; that is, they share the same functional structure (Thaut 2000, 2005). For example, if a patient has recently experienced a right hemisphere stroke, he may have weakness in his left arm and hand, including difficulty with independent finger movement. The functional exercise in this case would be repetitive movement of the affected arm, hand and fingers, for an appropriate duration of time and

at an adequate pace, in order to increase range of motion and to increase strength and endurance. The musical translation of this functional exercise could consist of playing simple fingering exercises on the piano, while being guided by the therapist's accompaniment which determines tempo, frequency and duration of movement, in addition to providing aesthetic motivation.

To ensure the isomorphic nature of the therapeutic music experience (TME), three types of logic must be incorporated (Thaut 2005):

1 Functional logic: the TME must serve as a musical analogue of the non-musical experience. Furthermore, the TME must give the client multiple or sustained opportunities to practice the non-musical behaviour. By incorporating functional logic, the therapist can facilitate positive changes in a functional behaviour that the client will utilize in everyday life.

2 Musical logic: the musical component of the TME must meet the aesthetic and artistic principles of good musical forms. To explain further, the music must be aesthetically pleasing, whether it is provided in active (i.e., improvisation) or receptive (i.e., listening) forms. Regardless of complexity, only with optimal musical patterns can the beneficial effects of music be manifest.

3 Scientific logic: the most effective TME will draw from the scientific evidence established using the R-SMM. Whenever possible, the music therapist must design TMEs based on a solid understanding of the parallel process between musical and non-musical experiences in order to elicit a mediating response to influence behaviour. By utilizing the research evidence, the therapist need not reinvent the wheel in each therapy session, and can instead, select the most appropriate technique from a validated taxonomy of strategies.

Summary

The R-SMM and the TDM give music therapists two critical tools for research and clinical practice. The R-SMM integrates the understanding of musical and non-musical behaviours into a framework for effective therapy and rehabilitation (Thaut 2005). Its dynamic and open-ended nature allows for incorporation of future research efforts to continuously establish new evidence and rationales for the music's therapeutic effects. Meanwhile, the TDM provides a practical guide for music therapists to create goal-oriented interventions based on scientific evidence. Together, the models offer an approach to research and practice based on an understanding of how music influences behaviour to produce functional outcomes. Clinicians cannot assume that music magically or automatically brings about a desired change in behaviour. Rather, interventions must be founded in empirical knowledge of the internal processes and mechanisms at work during musical experiences.

By providing a scientific understanding of music's influence on behaviours in all domains of functioning, as well as standardized techniques, NMT addresses the profession's needs. Simultaneously, NMT fulfills Gaston's original appeal for a theory that incorporates both biological and psychological constructs. Furthermore, NMT provides an approach to practice and research that is unique to the music therapy profession and not borrowed from other disciplines. As a theoretical foundation, NMT will secure the profession's acceptance, credibility and future viability as a valid therapeutic modality.

CHAPTER 47

Clinical practice in music therapy

Corene Hurt-Thaut

Introduction

What is music therapy?

Music therapy is a health care profession in which music is used as a therapeutic medium to address developmental, adaptive, and rehabilitative goals in the areas of psychosocial, cognitive, and sensorimotor behaviour of individuals with disabilities. A music therapist designs therapeutic music interventions which address the client's functional goals and are adapted to the client's functional level. Over 5000 music therapist are employed throughout the United States, serving a wide range of clients, including the elderly, developmentally disabled adults and children, mental health populations, physically disabled, school-aged children, early childhood, substance abuse, sensory impaired, neurologically impaired, and terminally ill (AMTA 2006).

There are three critical components when considering the use of music in therapy: musical creativity and proficiency, scientific logic, and therapeutic logic. First, the music used in therapy must come from a trained professional who has a high quality of understanding of music theory, history, and performance. Therefore, a music therapist background involves extensive training in music, including proficiency in voice, guitar, and piano. Second, in order to use music as a therapeutic tool, a therapist must understand the scientific foundations of the influence of music on functional changes in non-musical brain and behaviour functions. Although course work at different universities varies considerably, music therapist are exposed to, and in some cases, take extensive course work in the sciences in order to gain an understanding of anatomy and physiology, neuroanatomy, biology, and psychological functions. Thirdly, in order to use music in therapy, music interventions must make sense therapeutically. It is essential for music therapist to be trained in group and individual counselling skills, therapeutic design, and selection of music interventions based on functional goals and objectives.

The music therapy treatment process

Music therapists typically work in conjunction with a team of professionals including physicians, nurses, social workers, physical therapist, occupational therapist, and speech therapist. A music therapist must receive a referral or request for music therapy services, upon which they are responsible for completing an assessment, developing a treatment plan including goals and objectives, documenting the progress of a client throughout treatment, evaluating progress toward goals and objectives, and developing a termination plan for their clients.

Referrals typically come from the physician in a hospital setting, but in other settings they may come from the psychologist, another therapist, teachers, parents, social workers, and even from the client themselves.

Once a referral is received, the therapist must do an assessment, of the person's strengths, needs and problems, including information about the client's medical history, cognition,

social abilities, physical abilities, vocational or educational background, emotional status, communication skills, family, and leisure skills. A music therapy assessment is typically non-musical in nature, and designed to identify whether a client is appropriate for music therapy and then assist the music therapist in treatment selection based on need areas.

Once an assessment has determined the strength and need areas, a treatment plan can be established. The treatment plan identifies the goals and objectives that will be addressed with the client during treatment. The goal identifies and area that is in need of improvement (e.g. to improve fine motor skills). The objective identifies the specific parameters of the behaviour that the client needs to accomplish, the criterion and qualifiers for that behaviour, and the target date of achievement.

Documentation of treatment progress is essential not only to monitor the quality, cost effectiveness, and efficiency of treatment, but also as a means to communicate with other members of the treatment team and to justify charges to insurance companies. Documentation requirements and formats vary greatly depending on the type of facility that a therapist is working at.

Once a client has met their treatment goals, or is recommended for discharge, the music therapist must complete a final evaluation of treatment. This evaluation includes a review of the entire music therapy process, from the initial goals and objectives to the final progress made toward them.

The history of music therapy

The profession of music therapy was established in the United States in 1950, as a result of work being done with patients in veterans' hospitals following the Second World War. Music was being used with returning soldiers to boost the morale, and help with the rehabilitation of physical, social and emotional health. However, evidence of the powerful value of music has been documented for thousands of years in all cultures. David played the harp to sooth Saul; in Egypt, certain songs were legally ordained in the education of youth to promote virtue and morality; Pythagoras directed certain mental disorders to be treated by music; Xenocrates cured maniacs by melodious sounds, and Asclepiades conquered deafness with a trumpet (Davis *et al.* 1999). Music therapy has grown substantially in the research and clinical knowledge since 1950, and today is recognized in the medical community as a solid, thriving profession.

Application of music therapy to clinical populations

Music therapy in psychiatric populations

During the early development of music therapy, most therapists were working with psychiatric populations. Although the use of music in therapy has become much more diverse since then, mental health accounts for 21 per cent of the populations served by music therapist (AMTA 2006). Treatment most often addresses thought disorders, mood disorders, personality disorders and anxiety disorders.

Wheeler (1983) classified the treatment of adults with mental disorders into three levels: (1) supportive music therapy as an activity therapy: (2) insight music therapy with re-educative goals, and (3) insight music therapy with reconstructive goals. Each level of classification requires a higher degree of insight and participation from the client.

On the level of supportive music therapy, the therapist main goals are to promote mood-lifting stimulation and healthy behaviours. Music therapy experiences at this level require active involvement and awareness of the here and now.

On the level of insight and process-oriented music therapy with re-educative goals, the client is now at a higher level of insight and is ready to reflect and process interpersonal relationships and emotions with a greater level of verbal participation. A client at this level is well oriented to reality, demonstrates appropriate interaction skills and is ready to focus on conscious conflicts and associated unhealthy defence mechanisms.

The last level of intervention involves reconstructive, analytically and catharsis-oriented

music therapy. At this level, the music therapy interventions are used to uncover and process subconscious conflicts resulting from past traumatic situations. Therapist working at this level require advanced training in psychotherapeutic techniques.

In addition to different levels of treatment, music therapy clinical practice with mental disorders is guided within the framework of several different psychotherapeutic models. The therapist typically chooses different treatment approaches based on the needs of a particular client or the philosophy of a treatment facility. Some of the most frequently used models include: psychodynamic, cognitive, humanistic/existential, cognitive neuropsychiatric, biomedical, behavioural, and holistic.

Interventions

A wide range of music therapy programmes and techniques are currently used in the treatment of mental disorders, including music performance, music psychotherapy, music and movement, music combined with other expressive arts, recreational music, and music for relaxation.

Music performance addresses goal areas such as affective self-expression, identification of feelings, appropriate outlet for negative feeling processes, reality testing, retraining auditory and perceptual skills and memory function, executive functions, motivation, self-esteem, and socialization. Music therapy techniques may be process- or product-oriented, depending on the therapeutic goal, and often include instrumental group improvisation, instrumental and vocal performance ensembles, group singing therapy, individual instrumental or vocal instruction, and individual music improvisation (Unkefer and Thaut 2002).

Music psychotherapy implements music therapy techniques such as supportive, interactive, and catalytic music groups and individual therapy. A supportive music group would address goals in the areas of identification and expression of feeling responses, expanding range of expressiveness, appropriate outlets for negative feelings, reality focus, task-oriented activities, attention-focusing activities and social participations. An intervention may involve guided music listening techniques to focus attention, provide theme-centred structure for verbal interaction, and evoke feeling responses or alter feeling states. In an interactive music group or individual therapy, the main goal areas become focused on the identification and expression of one's own feelings, problem-solving, awareness of one's own behaviours, and facilitation of behaviour changes (Unkefer and Thaut 2002). Music therapy interventions may frequently consist of guided music listening which leads to discussion of lyric content, mood of the music, and relevance of the music to the client's personal life. The catalytic music group encourages the the client to become more aware of feelings, thoughts, and experiences that have previously been repressed, through music therapy interventions such as guided listening techniques, guided imagery and music (GIM), and psychodrama.

Music and Movement can be used on many different levels in order to address a variety of goals ranging from awareness and expression of feelings and emotions, to social interaction and physical exercise. *Movement awareness* is a technique which encourages clients to move and express themselves on a non-threatening level through beginning music and movement exercises in a group setting. Another technique called *Movement exploration* uses elements of music and movement to help the client develop a repertoire of body movements as they improve their body image and begin to feel competent in moving effectively. *Movement interaction* is a technique which uses music and movement to provide the opportunity to experience social and emotional concepts in a non-verbal modality. At this level of movement, the focus is on the client and the client's relationship to others. *Expressive movement* is a technique using music and movement to help a client become aware of feelings and emotions that relate to their personal functioning and coping skills in daily life. Musical themes are used to encourage the experience and expression of feeling concepts such a love, loss, grief, depression, social isolation and withdrawal, interpersonal conflict, hope, and joy. *Dance* is another form of music and movement which uses prestructured dance forms, steps, and styles with music to encourage social interaction, self-confidence, and recreational skills. *Music and exercise* can be used with any

age group and level of movement ability to address strength, endurance, muscle tone, flexibility, agility, body control, vital capacity, and cardiovascular efficiency. Music becomes not only a motivator for movement, but also provides a rhythmic structure to pace and cue movement patterns (Thaut 2002).

Music combined with other expressive arts is frequently used in the treatment of mental disorders as a multisensory external stimulus to provide pleasant and motivating reality experiences. The technique *music and fine arts* integrates music with other mediums such as drawing, drama and sculpting in order to allow for expression of feelings and emotions. *Music and writing* pairs music with writing such as poetry or prose, which also provides experiences for expression of feelings and cognitive responses. Both of these techniques can be used in a group or individual setting.

Recreational music programmes can address goals such as non-threatening reality orientation, involvement in goal-directed activity, completion of task, and social participation.

Music therapy interventions may include music games, recreational music, music appreciation awareness, and leisure-time skill development.

Music and relaxation programmes can be very effective at providing an outlet for negative feeling processes, providing feedback and support for movement control, pairing physical exercise with relaxation, increasing frustration tolerance, promoting coping skills, and focusing attention in a structured and calming environment. Numerous music therapy techniques are currently used for relaxation. *Music and progressive muscle relaxation training* pairs relaxing music with the relaxing and tensing of different muscle groups, in order to help a client discriminate between relaxation and tension responses. *Music for surface relaxation* allows a client's preferred music to provide a temporary respite from anxiety-provoking or stressful situations. *Music imagery* encourages a client to explore altered states of consciousness for the purpose of allowing imagery, symbols, and latent feelings to surface from the inner self. *Music-centred relaxation* is a technique which uses music to divert a client's attention from states of psychological and physical tension. Through this technique the client's focus on the music helps them gain a safe, pleasant perceptual experience.

Future direction

Currently, music therapy practice in mental health has primarily been based on borrowed theories from other disciplines. Thaut (2002) purposed that a major mechanism of the therapeutic effectiveness is embedded in music's unique ability to access affective/motivational systems in the brain. Therefore, a theoretical paradigm of music therapy in psychiatry must integrate musical response models in music perception and music cognition with the understanding of music's influence on non-musical human behaviour, psychologically and neurobiologically, and with concepts of behavioural learning and therapeutic change (Gaston 1968, Thaut 2000).

Research in psychology and the neurosciences has increasingly pointed to the important relationship between affect and cognition. According to Izard *et al.* (1984), emotions are an essential part of cognitive processing. He stated that emotion is the main force for motivation, and motivation is and essential force that drives behaviour and cognition. Rachman (1981) also believed that emotions accompany all cognition, but emotional reactions occur before cognitive processing. The associative network theory purposed by Bower (1981) states that the human memory can be compared to an associative network of events and emotions. In this network, events are considered to be memory units that become associated with certain emotional states experienced while the event is occurring. Thus, when memory units feed in to our emotional state they become attached. Therefore, during cognitive learning, people associate emotion with certain elements of environmental context. These three theories are important in establishing the relationship between mood, behaviour, and cognition.

Other research has compared the effects of musical and non-musical mood-induction techniques. Studies by Clark (1983), Sutherland (1982), Teasdale and Spencer (1984), and Thaut and de L'Etoile (1993) have shown music induction techniques to produce stronger and longer

lasting results than other non-musical techniques in affect modification.

Nielzen and Cesarec (1982) and Steinberg *et al.* (1985), compared the emotional experience of music in normal and psychiatric subjects. Findings of their studies indicated that music communicated the same emotional experience to both normal and psychiatric groups.

Martin *et al.* (1988) and Eifert *et al.* (1988) examined affect modification through music. Martin looked at the relationship between the intensity of a headache and mood, finding that a positive change in affect decreased the intensity of headaches while the negative change in affect increased headache intensity. Eifert, when looking at affect modification through evaluative conditioning with music, identified that liked and disliked music provided strong positive and negative conditioning, respectively.

A cognition–affect model in neuropsychiatric music therapy, based on scientific mechanisms relating the perceptual experience in music to brain and behaviour, could lead to meaningful therapeutic applications within an understanding of the biological basis and the role of affect–cognition processes in mental disorders (Halligan and David 2001).

Music therapy with children

Music therapy addresses three goal areas in order to increase cognitive, motor, social, communicative, musical and emotional functioning in disabled children: (a) educational, (b) rehabilitative, and (c) developmental (Thaut1999). A music therapist works closely with the interdisciplinary treatment team and must be familiar with developmental, psychological, and medical information that pertains to each disability in order to address these goals appropriately. Music therapists work with children, ranging from early childhood to school-aged. Diagnosis can include autism, cerebral palsy, developmental delays, burn injuries, traumatic brain injury, and other neurological impairments.

Educational goals focus on the academic development of a child. These goals may address social, cognitive, or physical skills. Examples of this may be using a musical mnemonic to teach a child his phone number and address, practicing learning colours and shapes by filling in the blanks of a song, doing creative movement to music, or practicing social skills while participating in a group instrumental playing experience.

Rehabilitative goals work toward restoration or compensatory strategies to improve movement, respiration, posture and sensory perception. For example, using rhythmic auditory stimulation to address gait in a 10-year-old who has developmentally already learned to walk, but recently suffered a traumatic brain injury which has left him with ataxic gait.

Developmental goals strive toward enhancing the normal development of a child by providing normal social, emotional, and sensorimotor experiences through music. Musical experiences are used to submerge the child in normal recreational and leisure experiences that meet the child on their existing functional level. For example, teaching a child how to play a musical instrument, using adaptive equipment, in order for the child to play in the school orchestra.

Interventions

Motor function

Music therapy offers a variety of musical interventions and experiences to address motor function in disabled children. The possibilities are limitless for creatively challenging children to reach, balance, stretch, and utilize their upper and lower extremities in functional movements. Musical instruments can provide a specific target for the children to aim towards, defining the parameters of the desired movement. The music therapist uses the music to help facilitate the client's participation while simplifying and readily adapting to the functional level of the child. Simple, repetitive melodies, familiar or not, have been most successful with children. The music therapist's ability to distil the lyrics to an appropriate vocabulary level, or simply create their own, more appropriate musical compositions, leads to much more effective interaction with children of all functional levels.

Communication skills

Music therapy can play a large role in the development and rehabilitation of both verbal and non-verbal communication skills in children. Music therapist can address disorders such

as apraxia; fluency disorders such as stuttering and cluttering; aphasia; and voice disorders which may result in abnormal pitch, loudness, timbre, breath control, or prosody of speech. Goals in the area of speech and communication address issues such as functional and spontaneous speech, speech comprehension, motor control and coordination essential for articulation, fluency of speech, vocal production and sequencing of speech sounds, and rate and intelligibility. When working with children it is especially important to be aware of their developmental stage when choosing an intervention that would best address their current needs. Developmental Speech and Language Training Through Music (DSLM) is one neurologic music therapy technique which uses developmentally appropriate musical materials and experiences to enhance speech and language development through singing, chanting, playing musical instruments, and combining music, speech and movement.

Cognitive learning

Several music therapy interventions are used to address cognitive learning in children in order to aid in memory, attention, and executive function skills. Musical mnemonics can be an organizational tool, using grouping or chunking through melodic and rhythmic patterns to assist in text recall with children. Many studies have looked at the relationship between music and the performance of autistic children on cognitive tasks such as attention (Kostka 1993), auditory processing (Heaton *et al.* 1988, 2001), affective perception (Heaton *et al.*1999), improvisation (Hermelin *et al.* 1989), local and global processing of music (Mottron *et al.* 2000), auditory discrimination (McGovern *et al.* 1991), and learning and retention of information (Wolfe 1993).

Emotional and social development

Children with disabilities have the same need for healthy emotional and social development and opportunities to express their feelings as do normal children. Because of the experiences of their disabilities, these children may actually have an increased need to cope with feelings such as grief, depression, or loneliness (Thaut 1999). On the other hand, they may also be withdrawn socially, causing them to miss out on the support systems that develop through peer relationships. A combination of a lack of ability to participate in some of the more traditional channels to express emotions and a decreased social support system can become a real dilemma for these children.

Music therapy interventions can provide an effective medium to create rewarding social and emotional experiences for children. In addition to working on physical, sensory, cognitive or speech goals, music can also help to increase self-esteem and provide an outlet for emotional expression through success-oriented experiences at any level of functioning. Music can also be used in a group setting to provide opportunities for peer interaction and support. Learning how to enjoy the recreational use of music or even developing a lifelong musical skill such as playing an instrument are also important in the overall strategy to normalize the life of a disabled child.

Music therapy in neurological rehabilitation

Neurological rehabilitation is an area in music therapy that is strongly substantiated by the basic science and clinical research coming from scientists in and out of the field of music therapy since the mid-1990s. Advanced training is strongly recommended when working with this population due to the knowledge of neuroanatomy, brain pathology, and medical terminology, that is required by the therapist. A wide variety of techniques are used to address motor control, cognition, and psychosocial behaviour with neurological disorders such as stroke, Parkinson's disease, Huntington's disease, traumatic brain injury, multiple sclerosis, and spinal cord injuries.

Interventions

The following intervention are based on neurologic music therapy (NMT), a research-based system of standardized clinical techniques for sensorimotor training, speech and language training, and cognitive training. NMT is used in neurologic rehabilitation, neuropaediatric therapy, neurogeriatric therapy, and neurodevelopmental therapy. It is based on the Rational

Scientific Mediating Model (R-SMM), a neuroscience model of music perception and production and the influence of music on functional changes in non-musical brain and behaviour function (Thaut 2005).

Sensorimotor rehabilitation

Music therapy offers a variety of musical interventions and experiences to address motor skills in neurological rehabilitation. Common goals that are addressed include gait and mobility, strength and endurance, coordination, balance and posture and range of motion. These goals are addressed through techniques such a: Rhythmic Auditory Stimulation (RAS), Patterned Sensory Enhancement (PSE), and Therapeutic Instrumental Music Performance (TIMP).

Rhythmic auditory stimulation (RAS) is a neurologic technique used to facilitate the rehabilitation of movements that are intrinsically biologically rhythmical, most importantly gait. RAS uses the physiological effects of auditory rhythm on the motor system to improve the control of movement in rehabilitation of functional, stable and adaptive gait patterns in patients with significant gait deficits due to neurological impairment. RAS can be used in two different ways: (1) as an immediate entrainment stimulus providing rhythmic cues during movement, and (2) as a facilitating stimulus for training in order to achieve more functional gait patterns.

Patterned sensory enhancement (PSE) is a technique which uses the rhythmic, melodic, harmonic and dynamic–acoustical elements of music to provide temporal, spatial, and force cues for movements which reflect functional exercises and activities of daily living. PSE is broader in application than RAS, because it is (a) applied to movements that are not rhythmical by nature (e.g., most arm and hand movements, functional movement sequences such as dressing or sit-to-stand transfers) and (b) it provides more than just temporal cues. PSE uses musical patterns to assemble single, discrete motions (e.g., arm and hand movements during reaching and grasping), into functional movement patterns and sequences. PSE cues movements temporally, spatially, and dynamically during training exercises (Thaut *et al.* 1991).

Therapeutic instrumental music performance (TIMP) is the playing of musical instruments in order to exercise and stimulate functional movement patterns. Appropriate musical instruments are selected in a therapeutically meaningful way in order to emphasize range of motion, endurance, strength, functional hand movements, finger dexterity, and limb coordination (Elliot 1982, Clark and Chadwick 1980). During TIMP, instruments are not typically played in the traditional manner, but are placed in different locations to facilitate practice of the desired functional movements.

Speech rehabilitation

Music therapy can play a large role in the development and rehabilitation of both verbal and nonverbal communication skills. Techniques in music therapy can be used to address disorders such as apraxia; fluency disorders such as stuttering and cluttering; aphasia; and voice disorders which may result in abnormal pitch, loudness, timbre, breath control, or prosody of speech. Goals in the area of speech and communication address issues such as functional and spontaneous speech, speech comprehension, motor control and coordination essential for articulation, fluency of speech, vocal production and sequencing of speech sounds, and rate and intelligibility.

The following eight techniques address speech disorders, based on the current research in this area:

1 Melodic intonation therapy (MIT) is a treatment technique developed for expressive aphasia rehabilitation which utilizes a patient's unimpaired ability to sing, to facilitate spontaneous and voluntary speech through sung and chanted melodies which resemble natural speech intonation patterns (Sparks *et al.* 1974). When using MIT with aphasia, the emphasis is in increasing the linguistic or semantic aspects of verbal utterances.

2 Speech stimulation (STIM) is the use of musical materials such as songs, rhymes, chants, and musical phrases simulating prosodic speech gestures to stimulate non-propositional speech. STIM uses completion or initiation of over learned familiar song lyrics, association of words with familiar tunes, or musical phrases to elicit

functional speech responses (Basso *et al.* 1979). For example, spontaneous completion of familiar sentences is stimulated through familiar tunes or obvious melodic phrases (e.g., 'You are my'..., or 'How are you ...?').

3 Rhythmic speech cuing (RSC) is the use of rhythmic cuing to control the initiation and rate of speech thru cuing and pacing. The therapist may use the client's hand, a drum, or possibly a metronome to prime speech patterns or pace the rate of speech. This technique can be useful to facilitate motor planning for an apraxic patient, cue muscular coordination for dysarthria, or assist in pacing with fluency disorders.

4 Vocal intonation therapy (VIT) is the use of intoned phrases simulating the prosody, inflection, and pacing of normal speech. This is done through vocal exercises which train all aspects of voice control including: inflection, pitch, breath control, timbre, and dynamics. An example would be to sing a five-note scale and gradually move the starting pitch up or down by half steps with a child who has a limited pitch range in their normal speaking voice. This exercise could be further expanded by adding a functional sentence i.e., 'Let's go out and play.'

5 Therapeutic singing (TS) is a technique which involves the unspecified use of singing activities to facilitate initiation, development, and articulation in speech and language as well as to increase functions of the respiratory apparatus. Therapeutic singing can be used with a variety of neurological or developmental speech and language dysfunctions (Glover *et al.* 1996; Jackson *et al.* 1997).

6 Oral motor and respiratory exercises (OMREX) involves the use of musical materials and exercises, mainly through sound vocalization and wind instrument playing, to enhance articulatory control and respiratory strength and function of the speech apparatus. This technique would be used with such populations as developmental disorders, dysarthria, and muscular dystrophy (Hass and Distenfield 1986).

7 Developmental Speech and Language Training Through Music (DSLM) is the specific use of developmentally appropriate musical materials and experiences to enhance speech and language development through singing, chanting, playing musical instruments, and combining music, speech, and movement.

8 Symbolic communication training through music (SYCOM) is the use of musical performance exercises using structured instrumental or vocal improvisation to train communication behaviour, language pragmatics, appropriate speech gestures, emotional communication in non-verbal language systems, that is sensory structured, has strong affective saliency, and can simulate communication structures in social interaction patterns in real time.

Cognitive rehabilitation

Several music therapy interventions have been developed to address cognitive learning, based on research evidence providing clinical support in the role of music to aid in memory, attention, and executive function training. Three areas are addressed in cognitive training techniques: auditory attention and perception training, memory training, and executive function training.

1 Musical sensory orientation training (MSOT) is the use of music, presented live or recorded, to stimulate arousal and recovery of wake states and facilitate meaningful responsiveness and orientation to time, place, and person. In more advanced recovery of developmental stages, training would involve active engagement in simple musical exercises to increase vigilance and train basic attention maintenance with emphasis on quantity rather than quality of response (Ogata 1995).

2 Musical neglect training (MNT) involves active performance exercises on musical instruments, which are structured in time, tempo, and rhythm, with an appropriate spatial configuration of instruments to focus attention to neglected or unattended visual field. It may also involve receptive music listening to stimulate hemispheric brain arousal while engaging in exercises addressing visual neglect or inattention (Hommel *et al.* 1990; Frasinetti *et al.* 2002; Anderson and Phelps 2001).

3 Auditory perception training (APT) is the use of musical exercises to discriminate and identify different components of sound, such as time, tempo, duration, pitch, timbre, and rhythmic patterns, as well as speech sounds. Integration of different sensory modalities such as visual, tactile, and kinaesthetic input are used during active musical exercises such as playing from symbolic or graphic notion, using tactile sound transmission, or integrating movement to music (Bettison 1996; Gfeller *et al.* 1997; Heaton *et al.* 1988).

4 Musical attention control training (MACT) involves structured active or receptive musical exercises, using pre-composed performance or improvisation, in which musical elements cue different musical responses in order to practice sustained, selective, divided, and alternating attention functions (Thaut 2005).

5 Musical mnemonics training (MMT) is the use of musical exercises to address various memory encoding and decoding/recall functions. Immediate recall of sounds or sung words using musical stimuli may be used to address echoic functions. Musical stimuli may be used as a mnemonic device or memory template in a song, rhyme, chant, or to facilitate learning of nonmusical information by sequencing and organizing the information in temporally structured patterns or chunks (Deutsch 1982; Gfeller 1983; Wallace 1994; Claussen and Thaut 1997; Maeller 1996).

6 Associative mood and memory training (AMMT) involves musical mood induction techniques to instate (a) a mood-congruent mood state to facilitate memory recall, or (b) to access associative mood and memory function through inducing a positive emotional state in the learning and recall process (Bower 1981; Dolan 2002).

7 Musical executive function training (MEFT) is the use of improvisation and composition exercises in a group or individually to practice executive function skills such as organization, problem-solving, decision-making, reasoning, and comprehension, within a social context that provides important therapeutic elements such as performance products in real time, temporal structure, creative process, affective content, sensory structure, and social interaction patterns (Dolan 2002).

Music therapy in the geriatric population

Due to advances in research and increased medical knowledge, the life expectancy of the average American has continues to grow, resulting in an estimated 21 per cent of the population over the age of 65 by 2030. The growing number of elderly has forced an increased interest in the unique challenges associated with aging, particularly among health care professionals.

Music therapy has demonstrated great success with the geriatric population, and is currently used in hospitals, nursing homes, assisted living facilities, psychiatric settings, adult day care, and wellness programmes, in order to address cognitive, sensorimotor, and psychosocial skills. A vast range of both rehabilitative and adaptive goals are addressed through music therapy techniques, including increasing upper and lower extremity range of motion, strength and endurance, and mobility; increasing independence in activities of daily living; improving attention, long- and short-term memory and executive functions; increasing reality orientation; improving verbal and non-verbal communication skills; decreasing agitation and wandering; promoting relaxation; leisure skill training; increasing social interaction and participation; and enhancing reminiscence.

Interventions

Numerous music therapy interventions are used with the geriatric population to help validate or orient them to their environment. Reality orientation through music can help a disoriented client remember information pertaining to where they are and why, what day it is, and what their schedule will be.

Validation therapy may also be used with a late stage Alzheimer's or dementia patient who is unable to orient to current information, but is perhaps living in a memory of the past. With this technique, the music therapist's role is to meet the patient where they are at, and try to listen and validate their point of view.

Reminiscence in a group or individual setting can be a powerful structural tool in therapy to

help clients remember past events and experiences in their life. Music can effectively set the mood for a discussion, stimulate or validate past memories, and create a theme for dialogue. Reminiscence also promotes social interaction, participation and positive sense of self.

Leisure skill reintegration or training can be another effective use of music in therapy. Many elderly people no longer participate in past leisure interest due to lack of motivation, or decreased physical or cognitive functioning. Reintegrating a client into a past interest or teaching them a new skill can provide opportunities for self-expression, intellectual stimulation, and social integration. A music therapist may teach a client compensatory strategies in order to play a musical instrument that they once played, or utilize their past musical knowledge to teach them a new instrument which is more suited to their current level of functioning. Another form of leisure integration may involve assisting a client in finding community resources in order to pursue their leisure interest (ie. singing in a church choir or attending a performance).

Intergenerational music programmes are frequently integrated in residential care facilities for older adults. Music can be an excellent tool to promote interaction between generations through movement, instrument playing, singing, and performance experiences.

Elderly people frequently experience decrease activity levels due to difficulty with mobility, lack of motivation or even lack of transportation. Research has shown that exercise is an important factor in promoting health and well-being. Lack of exercise can contribute to heart disease, decreased energy levels, and increased risk of falls in the elderly. Music paired with exercise in a group setting can be an effective tool to help motivate, improve coordination and timing of movement patterns, and increase endurance, as well as promote socialization.

Summary and future directions

The field of music therapy has grown substantially since it was founded in 1950. The advances in research and medical knowledge continue to help explain the therapeutic effects of music on behaviour based on scientific evidence; providing the framework to systematically and creatively transform musical responses into therapeutic responses.

When looking at the use of music in therapy for mental disorders, Thaut (2002) purposed that a major mechanism of the therapeutic effectiveness is embedded in music's unique ability to access affective/motivational systems in the brain. Research in psychology and the neurosciences has increasingly pointed to the important relationship between affect and cognition. Halligan and David (2001), addressed the movement toward a cognition–affect model in neuropsychiatric music therapy, leading to meaningful therapeutic applications within an understanding of the biological basis and the role of affect–cognition processes in mental disorders.

In addition to working on physical, sensory, cognitive and speech goals, music therapy interventions can also help to increase self-esteem and provide an outlet for emotional expression. Music can be used in an individual or group setting to provide and teach overall strategies to normalize the life of a disabled child.

The use of music in therapy in neurological rehabilitation continues to grow, as scientific models provide evidence which explains the therapeutic effects of music on behaviour. Based on the evidence provided in the areas of cognition, speech and language, and motor behaviours, a taxonomy of music therapy techniques can be used to select applications of music in therapy that have predictable therapeutic outcome and benefits for this population.

In 2006, geriatrics accounted for about 15 per cent of the populations served by music therapist. As the elderly population continues to grow, the demand for music therapy will also grow.

Research has shown that music can be a very effective tool in the treatment of the elderly. Interventions such as reality orientation, reminiscence, leisure skill reintegration and training, intergenerational music programmes, and music and exercise, have been implemented with excellent success with this populations.

In the past 15 years, new approaches to scientific research based on a neuroscience model

of music perception and production and the influence of music on functional changes in non-musical brain and behaviour functions, have helped begin to answer the questions that need to be addressed in order for future growth of scientific and medical acceptance of music therapy. In many areas of motor control, cognition, and affective behaviour, research clearly explains the therapeutic effect of music on behaviour based on scientific evidence, therefore providing the framework to systematically and creatively transform music into therapy.

CHAPTER 48

Research and evaluation in music therapy

Barbara L. Wheeler

RESEARCH has been an integral part of music therapy since the inception of the National Association for Music Therapy (NAMT) in 1950. The first of the original six objectives of NAMT was 'to encourage and report research projects' (Gilliland 1952, p. v). Gfeller (1995) states:

> Research activities were included immediately in the publications of this fledgling organization. *Music Therapy 1951* (Gilliland 1952), the first Book of Proceedings of NAMT, included a small offering of research abstracts by music therapists and a bibliography of pertinent research from fields such as psychology and physiology. This bibliography was no doubt intended to raise professional awareness of and competence in scientific research. Each subsequent Book of Proceedings (*Music Therapy 1952–1962*) included a section entitled Research, which contained not only abstracts but also philosophical addresses by music therapists, psychologists, and physicians espousing the need for scientific experiments to justify music therapy.
>
> Gfeller (1995, p. 38)

Research was also included prominently in the Certificate of Incorporation of the American Association for Music Therapy (AAMT), founded in 1971, including:

- To stimulate, guide, and direct research of music therapists nationally.
- To publish the results of such research in scientific papers and in professional journals and to authorize publication of the results of such research by other educational institutions without compensation payable to the corporation. ...
- To furnish grants in aid to investigators who propose to undertake study and research in the field of music therapy.
- To promote the exchange of information among the various individuals and institutions engaged in the practice and research of music therapy nationally (Dena Condron, personal communication, 27 January 1993, in Gfeller 1995, pp. 41–42).

The Bylaws of the American Music Therapy Association (AMTA), formed when NAMT and AAMT unified in 1998, include this statement: 'The Association serves as the primary organizational agency for the advancement of education, clinical practice, research, and ethical standards in the music therapy profession' (AMTA 2005b, p. 11). Research was adopted as a strategic priority by the AMTA Board of Directors in 2005, including the development of an operational plan that:

> (a) addresses the direction of research in support of evidence-based music therapy practice and improved workforce demand; and, (b) recognizes and incorporates, where necessary, federal, state and other entity requirements

> for evidence-driven research as it relates to practice policy and reimbursement.
>
> Hairston (2005, p. 8)

The AMTA Professional Competencies (AMTA 2003) include:

- Interpret information in the professional research literature;
- Determine if conclusions drawn in a study are supported by the results;
- Demonstrate basic knowledge of the purpose and methodology of historical, quantitative, and qualitative research;
- Perform a data-based literature search;
- Apply selected research findings to clinical practice.

NAMT began publication of the *Journal of Music Therapy* in 1964. This journal has served as an important venue for disseminating music therapy research in the United States and internationally. Other publications that include some research are *Music Therapy: Journal of the American Association for Music Therapy* (published from 1981 to 1996) and *Music Therapy Perspectives.*

Music therapy research has, of course, not been limited to the United States. Edwards (2005) summarizes the refereed journals in music therapy in Table 48.1. This shows the remarkable growth in the number of publications, growing from one in 1970 to two in 1980 and six in 1990 and continuing to the present.

Numerous analyses of the music therapy literature have been done (see Edwards 2005 for a summary). Several analyses (Brooks 2003; Edwards 2005; Gregory 2002) illuminate recent changes in the focus of music therapy research.

Brooks (2003) examined 1521 articles from nine music therapy journals over a 37-year period. She tallied the numbers of research articles classified as quantitative, qualitative, clinical, historical, philosophical/theoretical, and professional.[1] The number of articles published in each of these journals is, of course, related to the length of time that the journal has been

[1] Since the focus of this chapter is music therapy research, clinical and professional articles are not included in this summary, although they were part of Brooks' (2003) analysis.

published and the number of issues a year. Brooks found quantitative research articles to be the predominant category across all journals, with 542 articles. She found 55 historical articles and 136 philosophical/theoretical articles.

Of course, only a portion of music therapy research is published in journals for which music therapy is the primary focus. Many music therapy studies are found in medical publications, including those devoted to nursing, rehabilitation, and neuropsychology. Music therapists also publish in special education, psychology, and psychotherapy publications journals and books and in other interdisciplinary areas. Systematic music therapy reviews are also conducted and published as part of the Cochrane reviews (see http://www.cochrane.org/reviews/index.htm).

Examples of music therapy research

Music therapy research is approached from various perspectives and thus employs a number of methodologies. The value and use of quantitative and qualitative research has been debated by music therapists (Aigen 1995; Bruscia 1995a; Wheeler 1995). Questions about when each is appropriate and whether and/or when they can be combined are of interest.

One of the considerations when thinking of the differences between quantitative and qualitative research is the purpose of the research. Research conducted within a positivistic paradigm is concerned with cause and effect and uses the natural science model of discovery, while research conducted within a non-positivistic paradigm aims to increase understanding of people's multiple constructions of reality. These are very different positions and goals. The distinctions between quantitative and qualitative research thus go far beyond the type of data with which they deal to encompass differences in philosophy, research interests, and methodology. These different purposes should be kept in mind in the discussion that follows.

Bruscia (2005) suggests that there are three broad topical areas of music therapy research: discipline, profession, and foundational. Much of the discussion that follows will be organized around these three broad topical areas. Because music therapy is an applied discipline, most music therapy research is related to clinical or translational research (National Advisory Mental Health Council 2000; Nunes *et al.* 2002), although some research may be more strictly clinical than others.

Discipline research, according to Bruscia (2005), 'includes all those studies that examine the myriad facets of music therapy practice. As such, it deals with clinical topics such as assessment, treatment, and evaluation' (p. 81), areas that are at the heart of music therapy. The AMTA definition of music therapy, 'the clinical and evidence-based use of music interventions to accomplish individualized goals within a therapeutic relationship by a credentialed professional who has completed an approved music therapy program' (AMTA 2005a), points to the importance of data and research for providing evidence-based interventions.

Profession research includes

> studies that deal with music therapists and what they do collectively to establish and promote music therapy as a healthcare service. It deals with psychological, socioeconomic, political, legal, and educational aspects of music therapy as an organized profession.
>
> Bruscia (2005, p. 81)

Bruscia suggests that topics of profession music therapy research include employment practices, music therapists (characteristics, attitudes, etc.), professional education and training, professional standards, legislation and public relations, and history and culture.

Foundational research includes

> all those studies that relate partially but not completely to the discipline or profession of music therapy. It deals with topics that emanate from related fields (for example, psychology, music, medicine, education) but have important implications for music therapy.
>
> Bruscia (2005, p. 81)

Because music therapy is an interdisciplinary endeavor, topics in these related areas are important. Bruscia says, 'Such research can be considered foundational because the findings often provide empirical or theoretical support for practices, principles, or constructs used in music therapy, but, strictly speaking, were not originally focused on music therapy matters' (p. 81).

Some foundational research is basic research (Borg and Gall 1989) in that it is done primarily to increase knowledge without necessarily having in mind an application of the research findings, but much of it is applied research in areas other than music therapy. Foundational research may study either the discipline or the profession of music therapy.

This section will consider quantitative and qualitative music therapy research.

Quantitative research

As research is so important to music therapy, it is not surprising that it covers a number of topics. With increased reliance on evidence-based practice,[2] the amount and quality of the research that is available has increased in importance.

One way of making sense of a large number of research studies is through a review. Dileo (2005) suggests that there are two primary types of reviews, qualitative and systematic. A qualitative review involves a narrative presentation of relevant literature, while a systematic review 'involves the application of scientific strategies, in ways that limit bias, to the assembly, critical appraisal, and synthesis of all relevant studies that address a specific clinical question' (Cook *et al.* 1997, p. 376). Quantitative systematic reviews use statistical techniques to combine or evaluate studies, while qualitative systematic reviews summarize studies but do not combine them statistically.

The Cochrane Database of Systematic Reviews (http://www.cochrane.org) includes numerous reviews of various healthcare interventions. While the results of Cochrane reviews of some medical areas (e.g., drug trials) are accepted with little controversy, there is considerable discussion of their applicability to some clinical areas,[3] as well as the implications of their exclusion of certain ways of knowing.[4] Cochrane reviews have been done of music therapy for people with dementia (Vink *et al.* 2003/2006), autistic spectrum disorder (Gold *et al.* 2006), and schizophrenia (Gold *et al.* 2005), and music for pain relief (Cepeda *et al.* 2006).

Some systematic reviews are meta-analyses, in which the researcher combines the numerical results of studies with various research methods and findings and looks for consistencies among these findings (meta-analyses are also often used in Cochrane reviews). The researcher who performs a meta-analysis calculates a standard effect size for each study, giving an indication of the size and variability of the phenomenon under investigation and allowing the studies to then be compared among themselves across all measures and variables. Although concerns have been raised about several aspects of meta-analyses (Bailar 1997; Eysenck 1994; Naylor 1988), meta-analysis is generally considered to be a useful technique for discerning patterns among disparate studies and reaching conclusions. Meta-analyses in music therapy have been done of the following populations and types of treatment: medical and dental treatment (Standley 1986, 2000), medical treatment (Dileo and Bradt 2005), medical treatment of paediatric patients (Standley and Whipple 2003), premature infants in neonatal intensive care units (NICU) (Standley 2002), dementia (Koger *et al.* 1999), children and adolescents with autism (Whipple 2004), children and adolescents with psychopathology (Gold *et al.* 2004), symptoms of psychosis (Silverman 2003), neurologic rehabilitation of upper and lower limbs (Chandra 2005), and stress reduction (Pelletier 2004).

In general, meta-analyses have shown quite positive results for music therapy while the Cochrane reviews, which tend to have more stringent requirements for inclusion of studies and thus generally include far fewer studies, have been less positive. Some results from meta-analyses and Cochrane reviews are discussed below.

Discipline research

Research and results will be reviewed for autistic spectrum disorders, neurological disorders, and medical problems of children and adults. These are a few of the areas in which music therapy research exists.

[2] Evidence-based practice (EBP) refers to 'integrating individual clinical expertise with the best available external clinical evidence from systematic research' (Sackett *et al.* 1996, p.71). It is also referred to as evidence-based medicine (EBM).

[3] See Hömberg's (2005) discussion which asks, 'How far can principles of EBM practice be applied to training techniques in neurological rehabilitation?' (p. 3).

[4] Morse (2006) discusses the implications of the lack of acceptance of qualitative research in the evidence-based movement.

Autistic spectrum disorder

There is a great deal of clinical literature on music therapy with children with autistic spectrum disorders (see Alvin and Warwick 1991; Nordoff and Robbins 2007) but much less research. Two systematic analyses of music therapy research with autism have been done. Whipple (2004) analysed 12 dependent variables from nine quantitative studies that compared music to no-music conditions during treatment of children and adolescents with autism and concluded that all music interventions, regardless of purpose or implementation, have been effective. A Cochrane review by Gold *et al.* (2006) of all randomized controlled trials or controlled clinical trials that compared music therapy or music therapy added to standard care to placebo therapy, no treatment, or standard care included three small studies. It found music therapy to be superior to placebo therapy with respect to verbal and gestural skills, but without significant effects on behavioural problems. It is clear that additional research on music therapy and autism is needed.

Neurological disorders

A large amount of empirical research has been done on music therapy with neurological problems, including people who have had cerebral vascular accidents (CVA, stroke), traumatic brain injuries (TBI), Parkinson's disease, and cerebral palsy. Many of the studies in this area have been of Neurologic Music Therapy (NMT), a model developed at the Center for Biomedical Research in Music at Colorado State University (http://www.colostate.edu/depts/cbrm/) and based in findings from empirical research that have demonstrated the effects of music on sensorimotor training as well as on speech and language training and cognitive training. As a model that integrates scientific research into the biological effects of music with parallel models of non-music therapy treatment (Thaut 2005), it tries to build a systematic path from basic science research to various stages of translational and clinical research. NMT has been accepted as a proven effective intervention for this population. One of the methods of NMT, Rhythmic Auditory Stimulation (RAS), is listed as one of 10 higher-level evidence-based motor therapies in a critical review of this area (Hömberg 2005). Chandra's (2005) meta-analysis on neurologic rehabilitation of upper and lower limbs, including many NMT techniques, provided evidence for the effectiveness of these procedures.

Medical problems

Meta-analyses have provided important information on the effectiveness of music and music therapy in medicine. Standley did the first of these in 1986 and has updated them several times. In the most recent meta-analysis (2000), she found an overall average effect size (ES) of 0.84 for music versus non-music conditions in all of the 92 studies and 232 dependent variables that were included. When including only the primary dependent variables of the 92 studies, she found an average ES of 1.17 and an average ES of 1.40 in the studies that utilized patients' preferred music. Both are considered large effect sizes (Cohen 1977).

Standley and Whipple (2003) did a meta-analysis of empirical research studies that contrasted music versus no music conditions during medical treatment of paediatric patients. They found a medium effect size (Cohen 1977) in an analysis of 29 studies, indicating that including music is better than not including music in paediatric medical treatment. Standley (2002) also performed a meta-analysis of 10 research studies on the effectiveness of music with premature infants in neonatal intensive care units. She concluded that music has significantly positive effects that remain consistent across a number of variables.

Most recently, Dileo and Bradt (2005) completed a meta-analysis of 184 studies involving music in medical treatment. They included only studies that had a no-music control group and only those dependent variables for which two or more study results were available, and included 47 dependent variables. Effects of music and music therapy were reported for each dependent variable, grouped according to 11 medical specialty areas: premature infants, fetal responses to music, paediatric, obstetrics/gynaecology, cardiology/intensive care, oncology and terminal illness, general hospital, surgery, rehabilitation, dementia, and dentistry. Nearly all showed statistically significant effect sizes, although with a lack of consistency across studies.

Profession research

Profession research topics to be presented here include ethical issues and employment practices, a sample of the topics for which music therapy research exists. The studies analysing music therapy research trends, discussed earlier, are also examples of profession research. To this author's knowledge, no meta-analyses or systematic reviews of the quantitative profession music therapy literature have been done.

Ethical issues

Most of the research on ethical issues in music therapy has been done by Dileo and her colleagues and has included a broad range of topics. Dileo (2000) wrote a textbook on music therapy ethics, built on her research and that of others, that makes the study of ethics in music therapy accessible to students and others.

Employment practices

Employment practices of music therapists have been investigated periodically for many years, primarily through surveys. These surveys focus on several areas.

Some surveys are of the clinical practice of music therapists. Recent surveys have been of music therapists in specific settings, including school settings (Smith and Hairston 1999), correctional psychiatry (Codding 2002), and private practice (Silverman and Hairston 2005); of music therapy methods in the treatment of early elementary school children with ADHD (Jackson 2003); and of the collaboration and consultation of music therapists (Register 2002). A comparative analysis of surveys focused on hospice administrators' knowledge of music therapy (Hilliard 2004).

Other surveys have focused on the educational process, including clinical training. Maranto and Bruscia (1988) conducted separate surveys of music therapy educators, music therapy clinical training supervisors, music therapy clinicians, and university catalogues to gather information on a number of areas. Jensen and McKinney (1990) studied university curricula by studying the catalogues to compare the requirements in music therapy and related areas with the curricular requirements of NAMT. Groene and Pembrook (2000) surveyed collegiate faculty for their views of new knowledge and skills needed, competency-based assessment, and clinical training practices and potential changes.

Some surveys sought music therapists' opinions of the usefulness of their educational and clinical training for their later work as music therapists. These include surveys on the perceptions of the quality of collegiate training by Gault (1978) and of the relationship of applied music requirements to clinical practice by Cohen *et al.* (1997).

Some surveys were of the tasks and competencies required of music therapists. Some of these have been done and are done on a regular basis by the music therapy organizations and by the Certification Board for Music Therapists (CBMT) and the results are often published in their professional newsletters and other publications, while others have been done by individuals.

Several surveys of professional practices of music therapists have been conducted in the United Kingdom. Hills *et al.* (2000) used the Maslach Burnout Inventory to study how burnout varied among people working in multidisciplinary teams and those who worked independently. Stewart (2000) surveyed UK music therapists to assess personal qualities of music therapists, working models, support networks, and job satisfaction.

Foundational research

Many studies that are done in disciplines outside of music therapy, with no direct relationship to music, can be foundational to music therapy. In addition, much of the content of the psychology of music that is presented in this book, when it is research-based, can be foundational to music therapy. An overview of types of research in the psychology of music, psychology, music, medicine, and education that can be foundational to music therapy will be given here, although it is beyond the scope of this chapter to provide specific examples.

Psychology of music

Studies of the perception and cognition of music would be included as foundational to music therapy. Similarly, studies of people's responses to music, including physiological, behavioural, emotional, cognitive, and aesthetic, would be in

this area, as would studies of the neural processing of music. Many other topics in the psychology of music could also be included.

Music

Research on various types of music can also be foundational to music therapy. An analysis of a particular piece of music as done by a musicologist might be useful for a music therapist to use to enhance the understanding of music used in music therapy.

Psychology

The same areas that were listed as possible foundational studies for the psychology of music, but without application to music, could begin this section. Thus, we include perception and cognition; physiological, behavioural, emotional, cognitive, and aesthetic responses; and research on neural processing of stimuli. We might also add studies of personality and of the social behaviour of humans. Any area of psychological research can potentially be foundational to music therapy.

Medicine

Research on medical areas is foundational to music therapists who work in those specialties. Examples include research on medical areas such as cancer, cardiac problems, respiratory problems, neurological disorders, and so forth, and issues surrounding medical care such as pain, pre-surgical anxiety, and family support.

Education

Both regular education and special education can be foundational to music therapy. Development and teaching methods are among the areas that may be relevant from education research. Examples of special education research that is foundational to music therapy includes research on the assessment, needs, and education of children who are enrolled in special education classes and on the benefits of inclusion or of children's responses to children with special needs who are in their classes.

Qualitative research

Qualitative research generally has a different focus than does quantitative research, and the assumptions that underlie it are different. As stated earlier, a general goal of qualitative research is to increase understanding of people's multiple constructions of reality. The purpose of qualitative research is often to lead to a deeper understanding of the music therapy process. Qualitative research goes beyond the use of qualitative data to reflect the beliefs of its followers

> that not all that is important can be reduced to measurements [and] it is essential to take into account the interaction between the researcher and the participant(s) being studied. Findings cannot be generalized beyond the context in which they are discovered, and values are inherent in and central to any investigation.
>
> Wheeler (2005b, p. 13)

Although qualitative research is newer in most disciplines than is quantitative research, its regular use in music therapy began in the 1980s and has grown greatly in the last few decades. A recent book on music therapy research (Wheeler 2005a) includes 12 chapters on types of qualitative research, reflecting the growth of this type of research.

Discipline research

Qualitative discipline research in music therapy focuses on understanding the client and therapy better. This improved understanding of therapy is important for understanding the music therapy process. A number of studies in this area examine the therapy process and thus contribute to understanding music therapy. Some of these, selected to give an overview of some of the research in this area, are shared here. No attempt is made to summarize their 'results', as results have a different meaning in qualitative research, and a summary of any of the findings would not do justice to the research.

One of the early music therapy qualitative studies led to a theory of a field of play as underlying the improvisational music therapy process (Kenny 1989, 2006). In 'A suspiciously cheerful lady', Aasgaard (2000), looked at what happened to a song after it was composed. Aigen (1997) studied a group of adolescents over a year, including videotaping and analysing the sessions and interviewing the therapists about

the sessions and, in a separate study (Aigen 2002) examined the music therapy process of a young adult with a developmental disability. Gardstrom (2004) and Skewes (2001) studied adolescents in improvisationally based music therapy groups, while Langenberg and her colleagues (Langenberg *et al.* 1993, 1995) developed a set of research procedures to study psychoanalytically informed music therapy.

Several studies have looked at aspects of the music therapist's experience or interaction in the music therapy process; some studies look at both therapists' and clients' experiences. Because the focus of these studies is on the therapy, they are considered examples of discipline research. Bruscia (1995b) examined several modes of consciousness in Guided Imagery and Music (GIM), Forinash (1992) examined therapists' experience of clinical improvisation, Amir (1993, 1996) examined meaningful moments in music therapy, Grocke (1999) studied pivotal moments in GIM, and Comeau (2004) studied music therapists' experiences of being effective and ineffective. Wheeler (1999) looked at her experience of pleasure when working with children with multiple severe disabilities.

Profession research

The only completed profession qualitative research study of which the author is aware is an investigation of students' experiences during music therapy practice (Wheeler 2002).

Foundational research

Foundational research can be found in many related disciplines. It has a long history in anthropology; more recent extensive applications in education, psychology, and nursing; and has been used for research in numerous other disciplines, many of which can potentially be useful as foundations for music therapy.

One study that was done by a music therapist but could be considered foundational is Racette's (2004) study of the experience of listening to music when upset. Ferrara's (1984) 'Phenomenology as a tool for musical analysis', a study and set of research methods that focused on music but influenced music therapy research, served as the basis for adaptations of phenomenological research methods to music therapy (Forinash and Gonzalez 1989; Ruud 1987).

Other types of research

Additional types of research make important contributions to the music therapy literature. These are listed in a recent book on music therapy research (Wheeler 2005a) as music research, philosophical inquiry, and historical research, with an additional chapter that focuses on developing theory. Examples of these types of music therapy research are available in the literature.

Summary

Music therapy research is an integral part of music therapy and has been since the beginning of the US music therapy associations. Numerous journals, both in music therapy and related disciplines, include music therapy research. Quantitative, qualitative, and other types of research are important in music therapy, each fulfilling different purposes.

CHAPTER 49

Music therapy in medical and neurological rehabilitation settings

Anne Kathrin Leins, Ralph Spintge and Michael Thaut

SINCE the 1990s treatment models for the functional use of music in specific clinical pictures were developed under the label 'musicmedicine' or 'medical music therapy'. The new understanding of the biological basis of music and the influence of music on non-musical behaviour and brain function has led to a redefinition of music and its working mechanisms as a therapeutic tool.

Focus so far has been on the theoretically founded application of music in pain therapy and neurological rehabilitation, while the term 'neurological rehabilitation' is not understood in the narrow sense that its semantic meaning might imply. It applies not only to the actual restoration of function, e.g. post-stroke or traumatic brain injury, but also to degenerative illnesses and disorders such as Alzheimer's or Parkinson's disease (Thaut 2005).

Music therapy in neurological rehabilitation settings

Introduction

Research of the last 20 years on neuroplasticity and cortical reorganization has led to the development of innovative, neuroscientifically founded treatment models for neurologic rehabilitation. Music as a complex, temporally structured 'sound language' arouses the human brain on a sensory, motor, perceptive–cognitive and emotional level simultaneously and stimulates and integrates neuronal pathways in a music-specific way. This stimulation can enhance and modify behaviour, processing and perception processes by specific and well-directed use in therapeutic approaches, which are based on active training (Thaut 2005).

The therapeutic application of music to cognitive, sensory and motor dysfunctions due to neurologic disease of the human nervous system has been subsumed under the term 'neurologic music therapy (NMT)'.

NMT encompasses a wide variety of standardized treatment techniques which are evidence-based on scientific and clinical research and directed toward functional non-musical therapeutic goals.

Clinical applications of NMT are subdivided into three domains of rehabilitation:

- sensorimotor rehabilitation,
- speech and language rehabilitation and
- cognitive rehabilitation.

In each domain NMT can be applied to treat patients within different clinical fields and disciplines, such as inpatient and outpatient neurologic rehabilitation, neurogeriatrics, neuropaediatrics and neurodevelopmental therapies. Depending on the patient's needs, therapeutic goals are directed towards functional rehabilitative, developmental or adaptive efforts.

Clinical outcome studies

Clinical research provides evidence that NMT training has a positive effect on relevant outcome criteria. Focus of research so far has been

NMT in motor rehabilitation. In several studies it has shown to significantly improve gait and other movement parameters (e.g. upper extremity function) in hemiparetic motor rehabilitation (cf. Luft *et al.* 2004; Schauer and Mauritz 2003; Thaut *et al.* 1993, 1997, 2002, 2007; Whitall *et al.* 2000) as well as gait training in Parkinson's disease (cf. Bernatzky *et al.* 2004; Del Olmo and Cudeiro 2003; Howe *et al.* 2003; Lim *et al.* 2005; McIntosh *et al.* 1997; Morris *et al.* 2004; Pacchetti *et al.* 2000; Rochester *et al.* 2005; Thaut *et al.* 1996;).

A smaller number of studies has found positive results also in cerebral palsy (Malherbe 1992; Thaut *et al.* 1998), traumatic brain injury (Hurt *et al.* 1998; Kenyon and Thaut 2000) and developmental disabilities (Robertson *et al.* 2002a, b). NMT in gait rehabilitation can be used as a self-contained training protocol but its principles of rhythmic cuing and temporal regulation can also be integrated into other intervention methods.

Research efforts on the effect of rhythm on motor facilitation started with the evaluation of the effect of rhythmic cuing on stride and muscle activation patterns through use of electromyography (EMG) in the gait of healthy individuals (Thaut *et al.* 1992). Improvement in stride symmetry and EMG patterns, particularly the amplitude variability in muscle contractions across the stride cycle, was observed (Thaut *et al.* 1992). Based on these results the immediate effect of rhythm on gait ability in stroke patients was explored (Thaut *et al.* 1993). Results of this study showed that most patients were clearly able to synchronize their step times to the rhythm. In the course of synchronizing gait movements to the rhythm, stride time symmetry and stride length symmetry improved significantly, as did weight-bearing time on the paretic side. Stride time variability decreased to a significant degree. Subjects also showed a more balanced muscular activation pattern on EMG between the paretic and non-paretic leg, and EMG patterns on the paretic side became significantly more consistent.

In order to evaluate the long-term use of NMT in gait rehabilitation, a two-armed parallel group design was used comparing the NMT-method 'rhythmic auditory stimulation' (RAS) (for details see Thaut 2005) to conventional physical therapy gait training (Thaut *et al.* 1997a). Results demonstrated a statistically significant superiority of the RAS-group compared to the physiotherapy group with regard to the kinematic parameters gait velocity and stride length. This positive outcome has been undermined in a multicentre study (Thaut *et al.* 2007). Thaut *et al.* (2007) found a significant superiority of the RAS-group as compared to the physiotherapy group concerning gait velocity, stride length and frequency.

The immediate effect of RAS on repetitive flexion–extension–reaching movements of the paretic arm in hemiparetic stroke patients was the subject of another study (Thaut *et al.* 1998b). Results revealed immediate improved performance with RAS.

As to Parkinson's disease (PD) patients, results of an initial study revealed that patients could synchronize their step patterns to auditory rhythm even when not taking medication and this effect produced significant improvements in mean gait velocity, cadence and stride length over walking without RAS. Based on this data, it was shown in a controlled study design that PD patients profit from a music-based 3-week home-based walking programme of 30 minutes each day (Thaut *et al.* 1996a) and that the therapeutic effect lasts for 3–4 weeks (Mc Intosh *et al.* 1998).

Data on the differential use of metronome vs rhythmic–auditory stimulation in a music context are not consistent. Thaut *et al.* (1997a) have provided evidence in an experimental setting that the temporal synchronization of a sensorimotor task is more precise with rhythmically accentuated musical stimulation than with metronome clicks in healthy subjects. In relation to the improvement of the quality of gait in Parkinson's disease patients, Enzensberger *et al.* (1997), however, found a superiority of metronome stimulation as compared to stimulation by rhythmically accentuated music.

In the course of the development of innovative methods of rhythmical auditory stimulation in neurologic motor rehabilitation, the therapeutic use of music was also applied to speech and language training. Thaut *et al.* (2001) provided evidence for a significant improvement of PD patients with dysarthria as to intelligibility after 'rhythmic speech cuing' (see Thaut 2005). There is also empirical evidence for 'melodic

intonation therapy' with patients suffering from Broca aphasia (Sparks and Holland 1976).

NMT techniques in motor therapy have found their way into the corpus of scientific medical survey literature (cf. Adler and Ahlskog 2000; Hömberg 2005; Hummelsheim 1999; Jeffrey and Gould 1995).

As to the application of music in the therapy of cognitive functions—focusing on memory and attention training—a number of studies have been published within the last years (cf. Chan *et al.* 1998; Claussen and Thaut 1997; Foster and Valentine 2001; Haslam and Cook 2002; Knox and Jutai 1996; Ma *et al.* 2001). These studies broaden the evidence-base for NMT as a therapeutic technique in the rehabilitation of neurologic diseases.

Neuroscientific foundation of NMT: a working model

Thaut (2005) suggests a preliminary working model of specific mechanisms of music as a rehabilitative stimulus. The aim is to summarize evidence as a step toward a clearer understanding of the biomedical properties embedded in music perception. He advises that these mechanisms cannot be considered as working linearly in a mutually exclusive manner.

Thaut (2005) identifies four such mechanisms or underlying rationales for biomedical application of music and rhythm:

1 *Rhythmic stimulation and entrainment.* Rhythmic stimulation has profound effects as coordinative sensory input to entrain timing functions (cf. Paltsev and Elner 1967; Rossignol and Melvill 1976; Thaut *et al.* 1999; Thaut 2003), especially in motor control and speech. Rhythm provides temporal structure through metrical organization, predictability and patterning. Rhythm regulates physiological and behavioural functions via entrainment mechanisms (cf. Aschersleben and Prinz 1995; Molinari *et al.* 2003; Stephan *et al.* 2002, 2003; Tecchio *et al.* 2000; Thaut and Schauer 1997b; Thaut *et al.* 1998e). Rhythmic entrainment provides immediate time regulation but can also be accessed to enhance long-term training effects. Temporal regulation not only affects timing issues but also provides templates for optimization of spatial and force dynamics (cf. Thaut *et al.* 1996).

2 *Patterned information processing.* Timing is a key component in neural information processing in regard to perception and learning (cf. Galaretta and Hestrin 2001). Rhythm and synchronization are critical parameters in this processing, creating temporal structure in neural network activation (cf. Ikegaya *et al.* 2004; Fries *et al.* 2001). Time cues in the objects and stimuli of perception and learning themselves may be important facilitators to enhance the underlying physiology of temporal pattern formation, thus enhancing critical aspects of cognitive processes (cf. Lee and Blake 1999). Music is a very complex temporal stimulus. In all dimensions of its temporal architecture—from the spectral patterns of its psychoacoustical foundations to the most complex compositional principles of rhythm and polyphony—we find pattern structures of timing and synchronization embedded as building principles (see Kenyon and Thaut 2003; Thaut 1998c). Research suggests that music can uniquely engage the brain as a language of time (cf. Buonomano and Merzenich 1995), providing temporal structure to enhance learning and perception, especially in the areas of cognition, language and motor learning (Thaut 2005).

3 *Differential neurological processing.* The neuroanatomy and neurophysiology of music processing show shared, parallel and distinct neural processing systems for non-musical functions (Thaut 2005). For example, speech and singing are mediated by different neural networks (Patel 2003). Music regulates attention and arousal in the brain in a complex, bilaterally distributed fashion (Coull *et al.* 2004). Learning verbal material through song accesses different neural network configurations than learning through verbal presentation (Thaut and Peterson 2003). Auditory rhythm is a powerful sensory cue that can regulate motor timing and coordination in the presence of a deficient internal timing system in the brain. These are examples of how music can be used as an alternative modality to access functions or provide alternative transmission routes for information processing in the brain.

4 *Affective–aesthetic response: arousal, motivation, emotion.* Music communicates emotion

and meaning through the perception of its intrinsic symbol structure of musical elements as well as through emotional responses that have become connected to it through an associative learning process (cf. Berlyne 1971; Juslin and Sloboda 2001; Meyer 1956). Many theories of the meaning of music see the primary purpose of music as expressing and representing emotions and feelings. Regardless of its precise nature, music is a powerful stimulus that induces emotions (cf. Juslin and Sloboda 2001). As such, it has a strong influence on affective states. Arousal, motivation and emotions have important regulatory functions in behaviour organization, behaviour change and learning. Attention, perception, memory, executive function, physical response and learning can be effectively influenced and enhanced by appropriate affective states (cf. Thaut 2005).

Summary

Neurologic music therapy encompasses evidence-based methods of the functional application of music in the rehabilitation of neurologic disorders.

One of the most widely implemented clinical areas is its application in sensorimotor therapy, focusing on gait training. These methods are based on neurophysiological and neuroanatomic research on auditory–motor synchronization. It has been demonstrated that rhythm can serve as an anticipatory and continuous time reference onto which the movement is mapped within a stable temporal template. Furthermore, a clinical research basis is rapidly developing in the application of neurologic music therapy in speech/language rehabilitation and cognitive rehabilitation.

Music therapy and pain therapy

Introduction

Meta-analyses (Bunt 1997; Standley 1986) underline the effectiveness of music therapy in acute pain. Dileo (2003) finds small to medium effect sizes in children and medium to large effect sizes in adult pain management. A Cochrane review (Cepeda *et al.* 2006) on music for pain relief finds that listening to music reduces pain intensity levels and opioid requirements, but evaluates the overall magnitude of the benefits as small. Spintge (cf. 2000) has provided extensive evidence on the effectiveness of music therapy in pain management an on its psychophysiological effects.

There is anecdotal evidence for the use of both receptive and active music therapy in pediatric pain management, but research studies in this field are scarce. Bradt (2001) finds music therapy to be effective in postoperative pain management of orthopaedic paediatric patients. Results of a pilot study from Barrera *et al.* (2002) reveal that interactive music therapy is effective in reducing anxiety and pain of hospitalized children with cancer. Earlier studies of music therapy during medical invasive procedures provide inconsistent results (cf. Arts *et al.* 1994; Fowler-Kerry and Lander 1987). It seems that with children interactive music therapy approaches during painful medical invasive procedures are preferable to the use of receptive music therapy, because the use of headphones during these procedures may enhance feelings of insecurity.

Music therapy is also applied effectively in chronic pain therapy (Chesky *et al.* 1997; Hillecke 2005; Leins 2006; Müller-Busch 1997; Nickel *et al.* 2005; Rider 1985, 1987; Sedei-Godley 1987; Shorr 1993). It is usually administered within an interdisciplinary framework and aims at improving pain sensation, but also coping with pain and comorbid disorders.

Concepts and effects of anxioalgolytic music against acute pain and stress in medical settings

Musical stimuli alleviating psychophysiological responses to stress and pain are comprised as anxioalgolytic music (AAM) (Spintge 1983). Medico-functional applications of AAM include, for instance, perioperative stress in surgery and dental care, anaesthesia and pain medicine, intensive care, behavioural disorders, obstetrical care, geriatrics, neurological and psychological motor dysfunctions, and palliative care (Avancini *et al.* 2003, 2005; Droh and Spintge 1987; Leins 2006; Pratt and Spintge 1996, Spintge 1998, 2000, 2007; Spintge *et al.* 1999; Spintge and Droh 1991, 1992). The psychophysical condition of a patient in such situations is characterized by emotional distress, anxiety, and, very often, pain (spintge 1991). The traditional

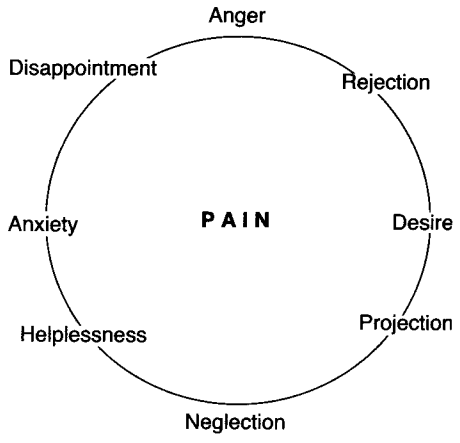

Fig. 49.1 Circulus vitiosus of pain.

medical interventions, using analgesics and sedatives, for example, often fall short when drugs prove insufficient or reduce the ability of a patient to cooperate. In the following we focus upon acute pain and stress.

The so-called circulus vitiousus of stress and pain (Figure 49.1) describes the psychophysiological situation. Conscious perception, self-esteem, and subjective feeling are as significantly impaired as the central nervous (neurovegetative) regulation of cardiovascular and cardiorespiratory systems. Hormonal control, motor control, sensory and perceptive information processing are disturbed.

Over the course of 30 years in more than 160 000 patients, the routine application of AAM demonstrates that music, as the most intense emotional means of communication, has its special significance as part of a multimodal treatment regime. In this instance, multimodal means to consider illness as a holistic phenomenon, demanding a therapeutic approach, which includes emotional, psychological, social and biological (somatic) aspects (see the so-called biopsychosocial model of pain and the definition of health as given by the WHO).

At present medico-functional music research has identified several target areas for AAM, as explained in Table 49.1. Musical rhythm is an especially effective structural parameter (Koepchen *et al.* 1992; Spintge 1996).

Within a multimodal treatment regime of both acute and chronic distress and pain, music can be used both as a complementary and therapeutic means itself, with impacts upon different levels of neurophysiological processing of pain and stress.

On the one hand, the influence of music (a very complex stimulus) on consciousness is very powerful compared to other environmental stimuli. Averse stimuli are less or even no longer perceived and processed 'under music'. On the other hand, subcortical centres of pain-processing and emotional control, such as the limbic system, are directly influenced. In addition, descending pain-inhibiting structures of the central nervous system are activated in the same way as Melzack and Wall (1965) describe in their (adapted version of the) gate-control-theory. Also, the new concept of neuroplasticity explains the genetical re-programming of dorsal root nerve cells that have been sensitized against pain input before (Zieglgaensberger 1998). These concepts force us to reconsider the role of so-called complementary therapies in general, because we find that the genome of nerve cells can be reprogrammed, thereby changing their functional capacities. Furthermore, the continuous input of similar stimuli for instance through a piece of music enhances this reprogramming.

Another target area for the influence of music upon pain perception lies in musicogenic muscle detonization. Proprioception from skeletal muscles influences emotional state as well as pain perception, and vice versa (David 1985; Gellhorn *et al.* 1964; Simons 1988).

Also, there is a direct pain-decreasing impact of music on reticular formation and thalamus in the central nervous system (Avanzini *et al.* 2003, 2005; David 1985). This process reduces the sensitivity of other areas in the brain to incoming pain signals as well as decreasing the release of stress hormones and catecholamines.

Last, but not least, subjective perception of ongoing, pain-accompanying vegetative activation can be changed through the parallel input of external musical stimuli. By listening to music a situation can be re-construed as being less threatening and less stressful and painful.

Research findings lead to what we call the 'missing link concept' of rhythmicity as a bridge between AAM on one side and physiology and medicine on the other side (Spintge 1996).

Music stimuli are processed through interdependent mechanisms that are as yet not fully understood, by themselves or together. It is clear, however, that the aggregate of all the mechanisms

involved is responsible for the observable psychophysiological effects of AAM music.

Through methodological and technical effort and with the help of up-to-date central nervous system (CNS) monitoring equipment such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET), it is possible, however, to scientifically correlate quantitatively and qualitatively physiological parameters and subjective measures with the structure of medico-functional music stimuli (cf. Avanzini *et al.* 2003, 2005; Hodges *et al.* 2005; Sergent 1993).

The practical relevance of all these findings and concepts expresses itself in many ways (see Table 49.1) and leads for instance to improved motor coordination in rehabilitation programmes for low back pain, Parkinson's disease, stroke, etc. (McIntosh *et al.* 1996; Thaut 1997, 2003).

Music therapy with chronic pain patients

In earlier studies predominantly receptive music therapy approaches are used (Chesky *et al.* 1997; Rider 1985, 1987; Sedei-Godley 1987; Shorr 1993) but within the last ten years active music therapy approaches with chronic pain patients have gained more attention (Hillecke 2005; Leins 2006; Müller-Busch 1997).

Müller-Busch (1997) proved the effectiveness of music therapy for patients with muscle-related pain. Hillecke (2005) found significant effects in the pre-post-comparison and the

Table 49.1 Music in pain therapy - psychophysiological effects and treatment outcome

System/Parameter	Reaction
cardiovascular	decrease of heartrate decrease of arterial bloodpressure anti arrhythmic
respiration	decrease of respiratory minute-volume decrease of oxygen-consumption synchronisation/harmonisation of rhythm
inner secretion & metabolism	reduced release of: catecholamines ACTH Cortisol Prolactin β-Endorphin decrease in basal metabolic rate sleep induction
immune system	psychomeuronal modulation of neuroendocrine receptors for catecholamines, endorphins, substance P, dopamine leading to: rise in IgA-salive-levels rise in T-cell activity relief of inflammatory pain
external secreation & excretion	reduced salivation and perspiration
reception & perception	rise in pain tolerance
motor control	reduced restlessness reduced muscle tonus muscle spasms dissolved psychomotor facilitation
drug consumption	50% to 100% reduced premedication
hospital treatment period	reduced: premature infants intensive care: 3 days surgery in the elderly: 1 day

group comparison condition in a sample of chronic pain patients. Music therapy enhanced effectiveness in a clinically significant way in pain and psychological measures.

Leins (2006) investigated the effectiveness of music therapy with children with migraine headache in a randomized, placebo-controlled, three-armed parallel group design. A specific music therapy concept has been developed (Nickel *et al.* 2002) which takes particular developmental stages of children into account and integrates the patients family. It focuses on the re-establishment of well-being and on coping with pain and pain-inducing situations/emotions through specific music therapeutic interventions. After therapy and in the follow-up measure the music therapy condition showed a significant placebo superiority with regard to relative reduction of headache frequency (Leins 2006).

Summary

Music therapy is widely applied in pain therapy. Meta-analyses underline the effectiveness of music therapy in acute pain of adult pain patients. Research focuses on clinical outcome, but also investigates possible underlying mechanisms such as the psychophysiological effects of music. There is large anecdotal evidence for the use of receptive but also active music therapy in paediatric pain management, research studies in this field are however scarce. Music therapy is also applied effectively in chronic pain therapy. It is usually administered within an interdisciplinary framework and aims at improving pain sensation, but also coping with pain and comorbid disorders.

PART 11

Conceptual frameworks, research methods and future directions

Edited by Susan Hallam, Ian Cross and Michael Thaut

CHAPTER 50

Beyond music psychology

Adam Ockelford

ALTHOUGH music psychology in the latter part of the twentieth century was dominated by the principles of cognitive–psychological thinking, these never completely drove nor, indeed, constrained this domain of research: even in 1970s, 80s and 90s, before the explosion of activity related to music and the cognitive sciences that has characterized the early years of the twenty-first century, music psychology did not function as a tightly defined academic discipline operating within a single, clear-cut epistemological framework. One can speculate as to the reasons why this should have been so. Partly, no doubt, different views as to what constituted valid music–psychological 'evidence' arose as a consequence of the heterogeneous and constantly evolving nature of musicological discourse, which provided a starting point for some who were seeking to adopt a psychological approach. The lack of an homogenous depth to the corpus of music–psychological research may be attributable to the relatively few participants who were active in the area, and their diverse disciplinary and institutional locations. Also, the field may have attracted visitors whose concerns lay primarily at the periphery of mainstream music–psychological work because they could find no other home for their theoretical or empirical endeavours. Finally, the very interdisciplinary nature of music psychology itself meant that as a conceptual territory it had extensive borders that offered many opportunities for intellectual interlopers to cross.

It is notable that the first journal to be devoted exclusively to the subject (*Psychology of Music*, which dates from 1973)[1] was founded by the (then) Society for Research in Psychology of Music *and Music Education*,[2] conferring on the publication a multidisciplinary focus that it has maintained ever since. Today, the stated aim of *Psychology of Music* is to 'increase scientific understanding of all psychological aspects of music and music education', a desideratum which 'includes studies on listening, performing, creating, memorizing, analysing, learning and teaching as well as applied social, developmental, attitudinal and therapeutic studies'.[3] This breadth of intention is fully reflected in the journal's content. Of the 471 papers published between 1973 and the first half of 2007, an informal classification suggests that only 207 (44 per cent) can reasonably be defined as falling within the realm of cognitive psychology (including the measurement of musical abilities, the perception of musical sounds, the cognition of musical structures, learning, memory and the development of music-related skills). Sixty papers (12.5 per cent) are concerned with issues pertaining to performing (including improvisation and performance anxiety). Notwithstanding the journal's stated aims, only 55 articles (11.5 per cent) relate directly to music education, although a further

[1] Until that time publication was solely in mainstream psychology journals.
[2] Italics added; from 2003 known as 'SEMPRE'—the Society for Education, Music and Psychology Research.
[3] From the journal's 'aims and scope', *Psychology of Music*, 35(2), 2007.

15 (3 per cent) investigate the use and potential effect of music in wider educational or developmental contexts. Fifty-four (11.5 per cent) explore aesthetics or affective response to music in one form or another. Thirteen articles (3 per cent) are primarily ethnomusicological in content. Eleven (2.5 per cent) engage with issues of epistemology or methodology (matters to which we shall return). Eight (1.5 per cent) involve research in music therapy. Seven (1.5 per cent) have a music–theoretical focus. The remaining 41 (9 per cent) are not readily categorizable, by virtue of small numbers or idiosyncratic content—ranging from the philosophy of melody to a consideration of the potential relevance of music to extra-terrestrials!

Music Perception, which first appeared in 1983 under the editorship of Diana Deutsch at the University of California, while having cognitive–psychological research as its primary focus, was always more explicit than *Psychology of Music* about its wide-ranging academic purview, which has changed little over the last quarter of a century. Today, *Music Perception* is overtly interdisciplinary in nature, with an editorial policy that seeks to publish 'theoretical and empirical papers, methodological articles and critical reviews concerning the study of music', incorporating articles from a broad range of disciplines, including 'psychology, psychophysics, neuroscience, music theory, acoustics, artificial intelligence, linguistics, philosophy, anthropology and cognitive science'.[4] Similarly, *Musicae Scientiae*, the journal of the European Society for the Cognitive Sciences of Music (ESCOM), which first appeared in 1997, is interdisciplinary in nature too, although cognitive psychology is, once again, the predominant strand in its fabric. *Musicae Scientiae* accepts 'empirical, theoretical and critical articles directed at increasing understanding of how music is perceived, represented and generated'. Consideration is given to any 'systematic work within the domains of psychology, philosophy, aesthetics, music analysis, historic musicology, cognitive science, education, artificial intelligence, modelling and neuropsychology'[5,6]

The broad church espoused by the three specialist journals currently active in the field of music psychology is reflected in the conferences and seminars organized by its proponents. Chief among these, the International Conference of Music Perception and Cognition (ICMPC), which was first staged in 1989, and since 1992 has occurred biennially, attracts a remarkable breadth of contributions.[7] For example, ICMPC 9, which was held in Bologna in 2006, called for presentations on the following topics: pitch and tonal perception; rhythm, metre, and timing; aesthetic perception and response; computational models; timbre and orchestration; emotion in music; memory and music; neuroscience; development; education; music, meaning, and language; performance and composition; the singing voice; acoustics and psychoacoustics; the social psychology of music; cognitive musicology; and music therapy. These were realized in some 526 papers, posters, workshops and symposia (a fivefold growth over the 17 years since ICMPC 1).

Surely (it could be argued), such eclecticism is unreservedly a good thing, presumably resulting in a rich cross-fertilization of ideas and approaches, yielding new, broad-based research that is rooted in a range of epistemologies and utilizing a variety of methodologies? Actually the position turns out to be much more complicated than this: as we shall see, conceptual cross-pollination often proves to be difficult to pull off; and where some see epistemological hybridization as a strength, others are wary of diluting the relative purity of purpose and procedure characteristic of a single discipline.

Given such issues, it is hardly surprising that the manner in which music psychology could

[4] From 'Information for authors', *Music Perception*, **24**(4), 2007.

[5] From 'Information for authors', *Musicae Scientiae*, **11**(1), 2007.

[6] The interdisciplinary output of *Psychology of Music*, *Music Perception* and *Musicae Scientiae* contrasts with that of the fourth specialist publication in the field, *Psychomusicology*, which, styling itself as a 'journal of music cognition', first appeared in the US in 1981 and continued to appear until 1997. Throughout these 16 years, *Psychomusicology* adhered closely to its initial editorial brief.

[7] See http://www.icmpc.org/organisation.html#history for a brief history of the ICMPC series.

and should relate to its sister disciplines has exercised a number of those working in these fields over the years. An early and perhaps inevitable tension that emerged in *Psychology of Music*, which was articulated by John Sloboda (then editor) in his 'open letter' of 1986,[8] was between music psychology and music education. In particular (to make explicit what was implicit in Sloboda's statement), one could sense a certain discomfort in his having to consider for publication certain music *education* research within the context of a music *psychology* journal, with its rather different perceptions of what constituted an appropriate level of rigour and objectivity. With their distinct epistemologies, could the two disciplines every work together productively? Was the latter ever likely to be of value to the former? A number of responses to Sloboda's letter were made, including one by David Hargreaves,[9] who, in looking back over the first decade of *Psychology of Music*'s output, acknowledged that 'Contributions tend to be *either* psychological *or* educational, and those which combine theoretical and practical concerns tend to be few and far between.' He concluded that 'the end result is something of a shotgun wedding'. Hargreaves suggested that the most fruitful way forward might lie in the *developmental* psychology of music, an area to which he gave a focus and impetus in the mid-1980s, and which has flourished ever since—particularly in relation to the early years (see, for example, Deliège and Sloboda 1996; the special issue of *Musicae Scientiae* 1999/2000; McPherson 2006) and, more recently, special educational needs (for example, Pring and Ockelford 2005; Ockelford *et al.* 2006; Ockelford 2008). Beyond developmental psychology, in the 1990s, a number of new fronts opened up between music psychologists and educationists in what has proved to be a highly fruitful union (Parncutt and McPherson 2002; Williamon 2004). For example, research of relevance to those learning to perform has been undertaken in the areas of practice and the acquisition of expertise (Hallam 1995, 2001; Jørgensen 2004); memorization (Ginsborg 2007); sight-reading (Lehmann and McArthur 2002; Thompson and Lehmann 2004) and improvisation (Kenny and Gellrich 2002).

Returning, for a moment, to the 1980s, further contributions followed in *Psychology of Music* on other interdisciplinary issues, including the report of a seminar held at The City University, London, in 1987 concerning the relationship between music therapy and music psychology (whose discussants were Leslie Bunt, Ian Cross, Eric Clarke and Sarah Hoskyns).[10] With echoes of the perennial quantitative/qualitative dichotomy, key elements in the debate were the relevance to therapy of what was measurable in psychological terms, and, conversely, the psychological status of the inferences that therapists were content to accept as admissible evidence. It was agreed that what mattered was whether the insights so gained—which, ideally, should be couched within a theoretical framework—were relevant and interesting rather than ultimately 'provable'. The long-term impact thinking such as this can be felt today in collected editions such as *Microanalysis in Music Therapy* edited by Thomas Wosch and Tony Wigram (2007). Here, as Barbara Wheeler notes in the Foreword (p. 11), the common thread linking the contributions is a new-found rigour in analysing therapy sessions, involving the study of 'specific responses and experiences and precise musical and behavioral responses and interactions' (see also Ockelford 2008).

During the 1990s, comparable interdisciplinary discourse rumbled on in other areas too, leading, for example, to Elizabeth Tolbert's (2001) exploration of the evolution of musical meaning through an attempt to bridge ethnomusicological and psychological approaches (between which she considered there had been little rapprochement up to that time). In particular, she pointed to differing perspectives on the relative importance of individual as opposed to collective meaning, and divergent views as to the significance of universal rather than culturally embedded musical processes and structures.

Arguably the interface about which there has been most vociferous debate in recent years,

[8] *Psychology of Music*, **14**(2), 144–145.

[10] *Psychology of Music*, **16**(1), 62–70.

however, is that between music psychology and music *theory* (as it is generally known in the US) or music *analysis* (the term most widely used in the UK). Why the contention? Perhaps because proponents from the two camps feel that they have an equal claim over a common territory: an understanding of how music 'works'. Their aims, though, are quite different, and this appears to be where the difficulties arise. Writing in 1989, Eric Clarke put it like this:

> Broadly speaking, the aim of musicologists and composers in tackling issues of musical structure can be characterized as the attempt to formulate theories of the structural relations within and between musical works, and their origins, development and effectiveness as formal devices. A correspondingly brief summary of the aim of psychologists of music is the development of theories of the mental processing of musical events, or the relationship between the listener, performer or composer and the musical environment. In a number of respects these aims are quite complementary, but the different disciplines that they represent come into conflict in the way in which they describe their material, and in what they extract and evaluate as significant findings.
>
> Clarke (1989, pp. 1–2)

At times this conflict has become quite heated. In his 'Fortenotes' that appeared in *Music Analysis*, 17(2) (a tribute volume to the Yale music theorist Allen Forte, who introduced 'pitch-class set analysis' to musicology in his seminal book *The structure of atonal music* [1973]), Jonathan Dunsby satirizes music psychologists as would-be enforcers of an imaginary law which dictates that musicological validity necessarily equates to perceptibility:

> I cannot be alone in having taught, *StrAMly* [*The structure of atonal music*], surreptitiously, 'hunt the hexachord'. That's the way you make a set complex work, asking a student to interrogate whether that embarrassing challenger-set really mattered so much and could not perhaps be excluded as a feature of the music, or whether there were not many more lurking hexachords that s/he had heard/seen (I am almost tempted to add '/played', but presumably in this forum I can write shielded from the Perception Police).
>
> Dunsby (1998, p. 179)

In order to understand how academic discourse on music could have become so polarized, one has to appreciate that groups within the music-theoretical community had felt themselves under attack from music psychologists who had shown, for example, that the perception of octave equivalence in pitch sequences—a 'given' in the composition of serial music and pitch-class set analysis—was by no means a 'given' to the musical ear operating in the absence of a score (Deustch and Boulanger 1984),[11] and that the measures of similarity between pitch-class sets as developed by Robert Morris (1979–1980)—measures that lay at the heart of this music-theoretical enterprise—did not accord with similarity judgements made aurally.[12]

However, the traffic was not all one way. Still on the subject of differing perceptions of similarity, in 1994, Nicholas Cook launched a scathing attack on Rita Wolpert's (1990) research, in which musicians and 'non-musicians' (so-called) were asked, among other things, to compare a tune and accompaniment played (a) on a different instrument and (b) on the same instrument as the original, but with the accompaniment transposed down a fifth. The musicians consistently chose option (a)—for them, playing the accompaniment in the wrong key made a bigger difference than playing the music on a different instrument—whereas the non-musicians almost exclusively opted for (b): for them, the identity of the instrument outweighed any changes they noticed in the accompaniment. According to Wolpert, these findings show that musicians do not listen in the same way as non-musicians: their choice of instrumentation over correct harmonic accompaniment 'suggests a profound overestimation of what most listeners hear'. As Cook points out, though, this is a far-fetched conclusion: what Wolpert's experiment actually reveals is that listeners with different backgrounds respond in different ways to questions

[11] See also the psychologically inspired critique of serialism by Fred Lerdahl (1992).
[12] Cheryl Bruner (1984).

as to whether one musical extract is more or less like another (1994, p. 68).[13]

These two examples bring sharply into focus just how different the aims and values of music psychology and music theory continued to be in the years that followed Eric Clarke's (1989) exhortation to researchers to seek to establish a rapport between them.[14] In 2003, David Temperley summarized the ongoing division thus:

> music psychology tends to focus on how people typically hear (or play or compose) pieces, tending towards generalities or commonalities; whereas music theory and analysis usually seek to discover what listeners could (or should) hear, and bear largely on specific compositions.[15]

In similar vein, in reviewing Kevin Korsyn's *Decentering Music* of 2003, Elizabeth Margulis (2005) wrote:

> Music cognition tends to explore those aspects of musical experience that are relatively robust and shared across large populations (betraying a dependence on what Korsyn sees as the problematic construct of 'normalcy'), rather than those that are unique and more amenable to the committed introspection of a single listener. ... Music analysts who rely on introspection as a methodology might manifest a commitment to music as an individual experience, constructed as fully by the listener as by the composer and performer. This vision elevates the specialist, and promotes the importance of training. Researchers who rely on empirical methodologies might reveal a commitment to music as more of a shared experience, with invariant features that characterize the hearing of a neophyte as much as a person with decades of training.
>
> Margulis (2005, pp. 334–335)

Joshua Mailman (2007), in his review of Adam Ockelford's *Repetition in music: theoretical and metatheoretical perspectives* (2005a) refers to the music-cognitive approach as 'populist', as opposed to the 'progressive' tack taken by theorists and analysts, which seeks to extend the boundaries of musical understanding, rather than defining what may be 'typical' or 'usual'. Mailman cites Joseph Dubiel (1999) in support:

> The crucial condition for any increase in musical knowledge is to keep yourself ready to be struck by aspects of sound that you weren't listening for. [This means that] the value of analyses will ultimately be their value as ear-openers.
>
> (p. 274)

In accordance with this sentiment, Mailman takes Ockelford to task for his critique of David Lewin's analysis of the opening of the development section of Mozart's Symphony No. 40, K. 550, which had appeared in Lewin's landmark text *Generalized musical intervals and transformations* (1987)—a mathematically based theory of musical structure. The passage in question, Lewin had observed, can be interpreted as a chain of retrograde inversions (RICH); see Figure 50.1.

However, the ontological status of this pattern is unclear. As Ockelford (2005a, p. 99) asserts: 'There is no evidence that Mozart conceived the passage in this way, nor that listeners perceive it so, nor even that analysts typically construe the sequence as being structured thus,[16] although there are precedents.'[17] Ockelford hypothesizes that listeners would be more likely to make sense of the passage by (subconsciously) modelling its structure as a series of transpositions: a more direct interpretation than Lewin's, which requires less cognitive manipulation of the musical information that is available.

Mailman, however, considers Ockelford's approach to the passage to be 'too narrowly conceived' (op. cit, p. 369), contending that he

> overlooks what we gain from Lewin's discovery of RICH in Mozart's symphony: when we notice RICHs in Webern's 12-tone works, we

[13] Ironically, Cook himself comes in for comparable methodological criticism in relation to his foray into experimental psychology which investigated the perception of large-scale tonal closure (1987); see Gjerdingen (1999).

> can relate these conceptually to the RICHs in Mozart—a lucrative inter-repertoire link ... Abstractions like RICH push beyond the everyday experience of repertoire that the 'populist' approach often assumes.

However, as Ockelford points out, in a conceptual thread that weaves its way through *Repetition in music*, there is a serious problem with this line of thinking. To understand why, let us first take a step back to the theory that lies at the heart of the volume: namely, that all internal musical structure relies ultimately on repetition, in one manifestation or another. For example, as Sloboda noted in his first book *The musical mind: the cognitive psychology of music* (1985), for music perception to 'get off the ground', there is a need for a framework of discrete and re-identifiable locations in pitch and perceived time, without which the dialectics of tension/resolution and motion/rest could not

exist (pp. 154 and 259). That is to say, in order for our perceptual and cognitive processing abilities not to be overwhelmed, composers have to work within tight constraints, whereby the number of different categories of pitch, interval, and the time between the onsets of successive notes is limited. This means that a high degree of 'background' repetition is inevitable in any piece. Furthermore, while the burden of the musical message tends to be conveyed by characteristic combinations of pitch and rhythm, further background restrictions typically apply to other qualities of perceived sound too, such as timbre and loudness. These almost invariably fulfil a secondary role as 'carriers' of the principal stream of information, and as a consequence tend towards coherence based on uniformity or incremental change—features which, once more, are founded on repetition.[18] Hence, behind the creation of every work lie constraints that mean that many musical events, and the relationships between them, will be the same, regardless of the subsequent choices of the composer. A key issue, therefore, for those trying to fathom how we make sense of musical structures is not so much about the discovery of sameness and similarity per se, but of analysing the *significance of commonality in different contexts.*

To give an idea of the scale of this issue, take, for example, Chopin's Prelude in B minor, Op. 28, No. 6, which comprises 403 separate notes that are played on the piano, typically within a period of two to three minutes. If one considers the relationships between (any) pairs of pitches the same as being of potential structural significance, then the analyst is faced with around 13 000 candidates. If it is the relationships between pairs of *intervals* the same that are thought to be of possible structural relevance, then she or he would have 500 *million* to choose from. And this is in just one domain: pitch.

Arresting statistics, one might think, but of no possible musicological value, since they ignore two key factors in the creation of musical structure: the sequence of events and their associated rhythm. Yet that is exactly what Allen Forte's set theory, alluded to above, does. The theory was originally intended to offer a mechanism through which the structure of the atonal music of Schoenberg, Webern and Berg and other composers written at the beginning of the twentieth century could be explained systematically. In undertaking set-theoretical analysis, one makes the initial assumption that all pitches and intervals (unlike those in tonal music) are potentially equal in structural terms. Hence the immediate analytical challenge posed is one of scale: how to reduce the available data to manageable proportions. To tackle this problem, a process of reduction was devised that borrowed a number of concepts from Schoenberg's 'serial' compositional procedures. This holds that one set of pitches can be regarded as equivalent to another, irrespective of transposition or inversion, the octave in which values are realized, whether or not they are repeated and, additionally, the order in which they occur. Ferreting out equivalent sets (as the citation from Dunsby above indicates) is fundamental to this type of analysis. But how is it to be done? Although some sets can be isolated as units 'by conventional means, such as a rhythmically distinct melodic figure' (Forte 1973, p. 83), such techniques do not necessarily 'adequately reveal structural components', since methods of segmentation may be 'concealed' (ibid.). In order to uncover the hidden organization of pitch, Forte recommends a procedure termed 'imbrication': 'the systematic (sequential) extraction of subcomponents of some configuration'—that is, listing all the pitch-class sets contained within a passage in the hope that this will reveal relationships that were not otherwise apparent.[19]

While it is conceivable that such a process may uncover pitch structures of musical interest that listening alone would have failed to detect (and which may inform subsequent audition), there remain a number of problems with this technique. For example, sets may not have been apparent in the first instance for the very good reason that they could not be extracted perceptually from large and complex aggregations of notes—and how, therefore, could they *ever* be structurally relevant to any listener, novice or expert? Again, the scale of the enterprise presents a huge problem. Take, for example, Schoenberg's

[18] See, for example, Boulez (1963/71, p. 37); Erickson (1975, p. 12).

[19] See, for example, John Roeder's (1988) analysis of Webern's Piece for Cello and Piano, Op. 11, No. 3.

Three Piano Pieces, Op. 11, No. 1—one of the first atonal works to be composed. The opening 4½ bars comprise 24 events in the form of a right-hand melody supported with discrete chords and traces of counterpoint, together lasting no more than 10 seconds. Forte (1981) undertakes an analysis, in which he identifies 14 different pitch-class sets, occurring in total 28 times. However, by adopting a systematic approach, using Forte's recommended technique of imbrication, it becomes apparent that all of the 208 possible pitch-class sets are actually present! These occur with mind-numbing frequency: for example, there are 262 appearances of 3-note sets, 884 4-note sets, 3152 5-note sets and (preliminary analysis suggests) over 10000 6-note sets. How is the analyst ever to make sense of these data? Presumably by reverting to the musical intuitions that were abandoned in the first place in the interests of scientific rigour!

Although analysis of this type occupies only one region in the broad domain of music theory—arguably in an area that is furthest away in epistemological and methodological terms from music psychology—the issues of perceptibility and relevance for different groups of listeners apply to other music-theoretical approaches too. For example, Heinrich Schenker's multilayered analyses, which are based on the notion that, in the context of tonal music, some pitches and harmonies can structurally 'prolong' others, are not contentious in music-psychological terms when the prolongations are relatively near to the musical 'surface' and last only a few seconds.[20] However, Schenker's own application of this principle deep into the structural foundations of a piece, whereby it is asserted that single chords may in some sense control events lasting many minutes, has found no empirical support (see note 13). Unlike much pitch-class set analysis, however, it is conceivable, particularly for those with 'absolute pitch', that pieces *could* be heard as Schenker analyses them—as long-term prolongations of the tonic and dominant chords—if expert listeners chose to do so. The same applies to other music-analytical approaches too. Take, for example, Rudolph Réti's modus operandi, as set out in *The thematic process in music* (1951), through which he seeks to unearth (typically) 'hidden' motivic relationships that he claims exist within and between the movements of pieces, subconsciously unifying them in the ears of listeners. Again, despite the feeling that Réti may be confusing the 'background' repetition that, as we have seen, is inevitable in any comprehensible piece of music, with the 'foreground' that a composer may choose to overlay upon it, it is conceivable for expert listeners to hear music in line with Réti's analyses if they elect to do so.

Where do approaches such as this leave the relationship between music psychology and music theory? Let us return to Eric Clarke's proposed 'rapport' of 1989, which, he suggests, could be achieved by developing a kind of description that recognizes the mutual relationship between a perceiver and his or her environment.

> The aim of such an approach would be to describe musical events for a particular kind of perceiver [ranging, we may surmise, in Mailman's terminology, from a 'populist' listener to a 'progressive' theorist], taking account of the stimulus material, the perceptual systems that exist, and the cultural systems within which evaluations of musical function are made. This is in essence an argument for an ecological description, since it proposes that while there is an indefinite number of possible descriptions of the same state of affairs from a variety of different perspectives, and at a number of different levels, the kind of description that is of primary interest to us will be at a level, and of a breadth appropriate to human beings, their musical artifacts and activities, and the natural and cultural environment within which they are situated.
>
> Clarke (1989, p. 12)

Ockelford (2005b) proposes a way in which such a description could be modelled. He suggests that all potential music–structural relationships[21] can be considered to exist on a continuum with

[20] As the recent empirical work of Isabel Martinez shows (The cognitive reality of prolongational structures in tonal music, unpublished Ph.D. dissertation, University of Roehampton, 2007.)

[21] That is, in terms of Ockelford's 'zygonic' theory, between events the same, where one could conceivably be deemed to derive from the other.

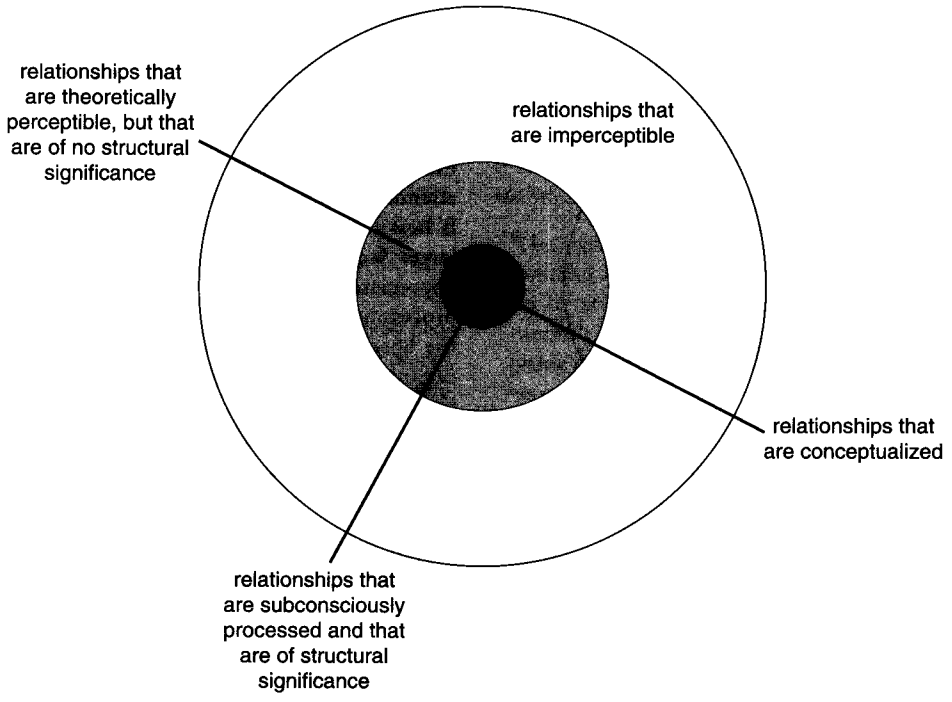

Fig. 50.3 Representation through different shading of a set of potentially structural relationships as they are hypothesized to exist in relation to mental processing.

three distinct sectors: those that are (1) imperceptible or non-cognizable; (2) perceptible but of no direct significance to musical structure (arising, for example, by chance, as a result of 'background' repetition); and (3) subconsciously processed and of direct relevance to the cognition of structure. Inevitably, the boundaries between these sectors are fuzzy, since which potential relationships actually become reified in cognition, and the significance of these, is, as Clarke's ecological standpoint indicates, liable to vary from listener to listener, and even with the same listener on different occasions. However, where a given relationship is likely to reside on the continuum can in broad terms be predicted in relation to cognitive constraints and preferences that could be empirically tested (Ockelford 2002). A fourth condition—structural relationships that are consciously processed/conceptualized (by composers and theorists or analysts, for example)—is subject to even greater variation, having the potential to be overlaid anywhere on the other three regions.

This model can be represented graphically as shown in Figure 50.3. In order to interpret the diagram correctly, one has to imagine an exponential growth in the number of potential relationships as one moves outwards from the centre. Using the model, it is possible to capture visually the epistemological issues raised above and clarify some of the misunderstandings that are reported—a necessary step in seeking to resolve them.

First, we will use the model to depict the case of a listener relatively familiar with a piece and its broader stylistic context, though not approaching matters with a mindset to conceptualize what is being heard (an example of Mailman's 'populist' perceiver). Intuitively, the music makes sense to the person concerned, and so we can surmise that he or she must be processing structural relationships subconsciously—a situation represented in Scenario A (shown in Figure 50.4). Turning next to Margulis's neophyte, one could imagine that she or he would pick up on rather fewer structural relationships,

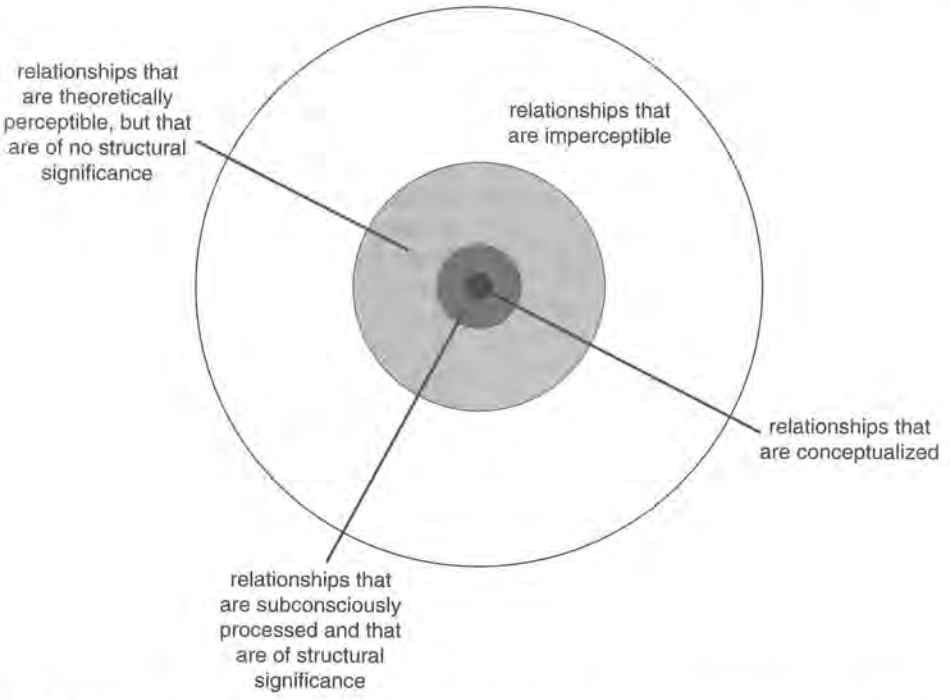

Fig. 50.3 Representation through different shading of a set of potentially structural relationships as they are hypothesized to exist in relation to mental processing.

three distinct sectors: those that are (1) imperceptible or non-cognizable; (2) perceptible but of no direct significance to musical structure (arising, for example, by chance, as a result of 'background' repetition); and (3) subconsciously processed and of direct relevance to the cognition of structure. Inevitably, the boundaries between these sectors are fuzzy, since which potential relationships actually become reified in cognition, and the significance of these, is, as Clarke's ecological standpoint indicates, liable to vary from listener to listener, and even with the same listener on different occasions. However, where a given relationship is likely to reside on the continuum can in broad terms be predicted in relation to cognitive constraints and preferences that could be empirically tested (Ockelford 2002). A fourth condition—structural relationships that are consciously processed/conceptualized (by composers and theorists or analysts, for example)—is subject to even greater variation, having the potential to be overlaid anywhere on the other three regions.

This model can be represented graphically as shown in Figure 50.3. In order to interpret the diagram correctly, one has to imagine an exponential growth in the number of potential relationships as one moves outwards from the centre. Using the model, it is possible to capture visually the epistemological issues raised above and clarify some of the misunderstandings that are reported—a necessary step in seeking to resolve them.

First, we will use the model to depict the case of a listener relatively familiar with a piece and its broader stylistic context, though not approaching matters with a mindset to conceptualize what is being heard (an example of Mailman's 'populist' perceiver). Intuitively, the music makes sense to the person concerned, and so we can surmise that he or she must be processing structural relationships subconsciously—a situation represented in Scenario A (shown in Figure 50.4). Turning next to Margulis's neophyte, one could imagine that she or he would pick up on rather fewer structural relationships,

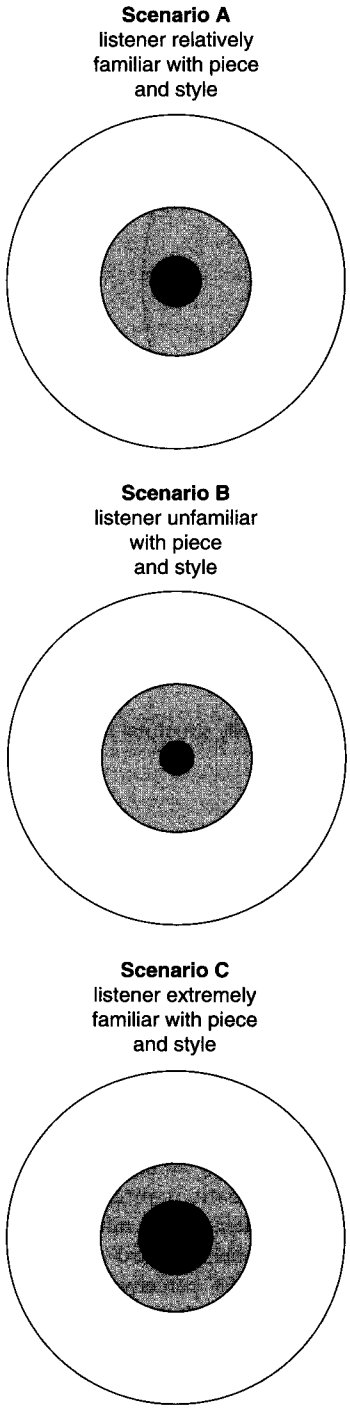

Fig. 50.4 Varying state of relationships hypothesized to exist in different scenarios pertaining to listening.

though still presumably enough for the music to be recognizable as abstract patterns in sound that in this case convey a certain, rather limited, meaning. This is depicted in Scenario B. Notice that Sector 1 is diminished in size. Conversely, the situation with an expert listener, who is attending to piece without conceptualizing what is heard, may be illustrated with a somewhat larger Sector 1: Scenario C. It is important to appreciate that in Scenarios A, B and C, the processing of musical structure can occur within the absence of description or analysis of the organization that is present—indeed, without the listener having had any formal musical education—the recognition of perceived sonic patterns and the ascription of meanings to them being enabled purely through repeated exposure.

Naturally, when composers, performers or listeners, whether functioning as psychologists, theorists, educators, therapists or others, consciously *think about* music—or ask others to—the situation changes. Take, for example, Wolpert's experiment, mentioned above. Her results show that the musicians in her experiment were able to conceptualize structural relationships in the domains of pitch and perceived time that they would otherwise have been likely to hear subconsciously. Hence, the situation arose that is depicted in Scenario D (see Figure 50.5). However, it appears that Wolpert's so-called non-musicians, when required to effect the same comparisons, were drawn by the nature of the question they were asked: to conceptualize *different* perceptible relationships, this time in the domain of timbre, that are not generally considered by musicians to be 'structural' (rather, residing in the musical 'background'). Hence we have Scenario E. Clearly, both Scenarios D and E have a certain intrinsic validity (since they both represent sets of empirical findings), but the situations they model are quite different, and the danger occurs when the two are subjected to a common interpretational framework.

We move next to the scenarios engendered by the music analyses that have been discussed, beginning with Forte's account of Schoenberg's Op. 11, No. 1. Now it may be that some of the relationships between pitch-class sets of three notes, which we can assume would pass the great majority of listeners by unnoticed (and which

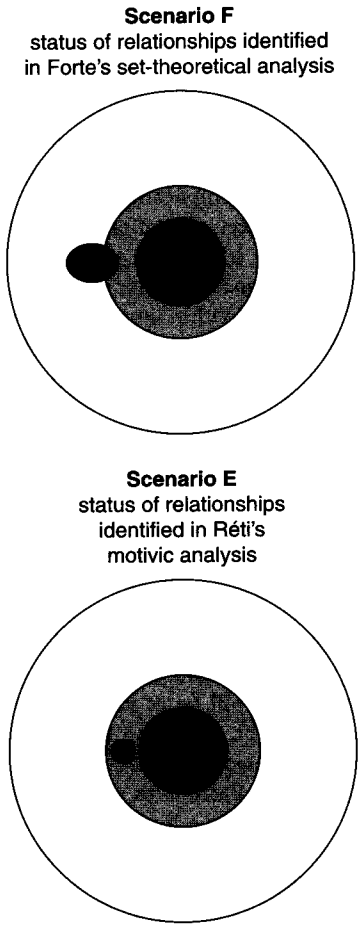

Fig. 50.6 Interpretation and representation of Forte's and Réti's styles of analysis.

would therefore in most circumstances be deemed structurally non-essential), could be perceived with practice, although there are others that would appear to be inaudible, no matter how well-prepared the listener were to be: for example, when the analysis decrees that a pitch within a four-note chord should be heard as functioning in three different four-note sets simultaneously. Hence it seems that Forte's analysis spans Sectors 2 and 3—see Scenario F (in Figure 50.6). Réti's analyses, on the other hand, would on the whole be perceptible once they have been drawn to listeners attention: hence Scenario G. However, these arguably imbue the regular warp and the weft of the musical fabric with significance over and above the melodic and harmonic patterns that composers have woven through it, and they have failed to gain acceptance among musicologists or musicians.

A similar situation holds in relation to Mailman's critique of Ockelford's assessment of Lewin's late-Mozart analysis, which is discussed above. In terms of the three-sector model, Lewin's approach, using the transformation 'RICH', conceptualizes relationships that would typically be in Sector 2, whereas it is possible to assign the same musical structure to transpositional relationships, which exist in Sector 1. To return to Mailman's argument, however, if we

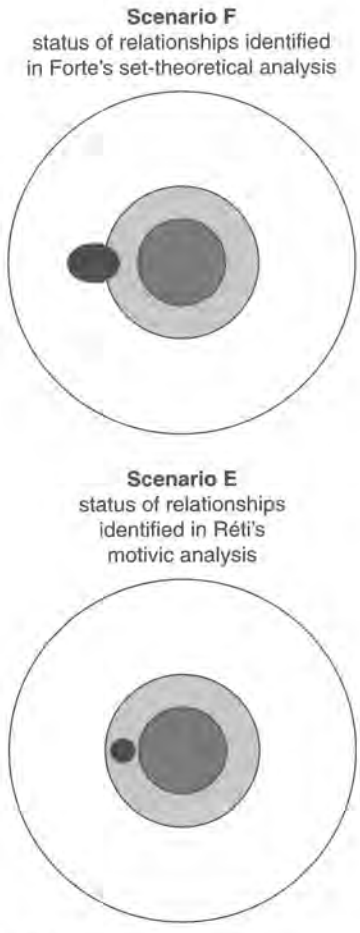

Fig. 50.6 Interpretation and representation of Forte's and Réti's styles of analysis.

would therefore in most circumstances be deemed structurally non-essential), could be perceived with practice, although there are others that would appear to be inaudible, no matter how well-prepared the listener were to be: for example, when the analysis decrees that a pitch within a four-note chord should be heard as functioning in three different four-note sets simultaneously. Hence it seems that Forte's analysis spans Sectors 2 and 3—see Scenario F (in Figure 50.6). Réti's analyses, on the other hand, would on the whole be perceptible once they have been drawn to listeners attention: hence Scenario G. However, these arguably imbue the regular warp and the weft of the musical fabric with significance over and above the melodic and harmonic patterns that composers have woven through it, and they have failed to gain acceptance among musicologists or musicians.

A similar situation holds in relation to Mailman's critique of Ockelford's assessment of Lewin's late-Mozart analysis, which is discussed above. In terms of the three-sector model, Lewin's approach, using the transformation 'RICH', conceptualizes relationships that would typically be in Sector 2, whereas it is possible to assign the same musical structure to transpositional relationships, which exist in Sector 1. To return to Mailman's argument, however, if we

are ever to *expand* Sector 1—to be 'progressive', which he sees as a crucial part of music theorists' role—then we need to push out the boundaries beyond those which the ear would otherwise determine unassisted. That is, there is virtue in consciously seeking to claim structural territory from Sector 2. The implication is that conceptualization may affect perception and, in effect, a migratory effect is possible, whereby relationships that were once in Sector 2 metaphorically shift to Sector 1. Within limits, this seems reasonable enough. The author can recall such an experience, when, having become acquainted with Schoenberg's analysis of Brahms's fourth symphony, motivic relationships became apparent that were subsequently embedded in listening experiences (1947/75, pp. 405–408). However, this is a long way from saying that much set-theoretical analysis could ever have intrinsically *musical* relevance, no matter now practised the listener. As we have seen, because all music is supersaturated with repetition, any piece contains a virtually infinite number of potential patterns, which will be of varying degrees of interest, no doubt, according to one's point of view, but the majority of these should not be intellectually conflated with *musical* structure. Rather, they exist as a by-product of the way that music is put together in order for it to be comprehensible. It is surely at this point that the music psychology's relationship with music theory reaches a boundary (and arguably where music theory itself becomes something rather different).

Summary

In summary, then, music psychology overlaps with a number of other disciplines, including music education, therapy, ethnomusicology, and music theory and analysis. There are tensions in each case, but, as the citations above have indicated, benefits too for those who are prepared to explore with an open mind. Ultimately, however, music psychology cannot be extended beyond the boundaries of its epistemological box, always granted that the sides are flexible and subject to change: indeed, such movement is likely to come about through the influence of adjacent disciplines. This has been shown, for example, in the groundbreaking work of Aaron Williamon and his colleagues at the Royal College of Music in London—the first UK conservatoire to establish a music–psychological research centre, which has aimed to support students in improving their performance skills and managing the high levels of stress that are often induced by performing in public. In terms of the common space occupied by elements of music psychology and music theory, further developments may well mean having to accept that the initial research questions and the *evaluation* of data may well be guided by musical intuitions, but that the gathering and *analysis* of data should be rigorous and undertaken with a 'scientific' detachment. Two decades on from Clarke's appeal to 'Mind the gap', there is now a greater clarity as to what this conceptual intersection might look like, how it might function, and even what it should be called: 'empirical musicology'. According to Honing (2006), empirical musicology, which now has its own journal (*Empirical Musicology Review*) 'grew out of a desire to ground theories on empirical observation and to construct theories on the basis of the analysis and interpretation of such observations'. And as Cook and Clarke put it in the introduction to their book *Empirical musicology: aims, methods, prospects* (2004), 'Empirical musicology. can be thought of as musicology that embodies a principled awareness of both the potential to engage with large bodies of relevant data, and the appropriate methods for achieving this' (p. 5). Hence one senses that in this sphere of activity the influence of music psychology may be keenly felt in the next decade.

CHAPTER 51

History and research

Michael Thaut

THIS chapter will provide an introductory synopsis of the history of research developments and research themes in music psychology from its inception in the nineteenth century until the early twenty-first century. The synopsis has to be broad to fit into the limitations of a book chapter, but a broader approach also offers the advantage to lay out more clearly discernible lines of evolution of large research themes over time. That is of particular interest in music psychology as it is a research-based field with an intrinsically inter- or multidisciplinary character. A bibliography of books rather than a reference list of specific papers should provide the appropriate data support for this synopsis.

Psychology of music as a new and independent scientific discipline started its development in the middle of the nineteenth century. It was a component part of the arrival of psychology as a new discipline studying human behaviour through observation, measurement, and testing using scientific methods (experiments, hypotheses, statistics). Previously, the scholarly discourse about music as an artistic and human phenomenon was mostly dominated by philosophy and—perhaps surprisingly to the modern reader—the discourses in the early natural sciences. The first work that is usually associated with the original impetus for studies in the psychology of music was Helmholtz' book *On the sensation of tones as a physiological basis for the theory of music* (Die Lehre von den Tonempfindungen als physiologische Grundlage fuer die Theorie der Musik, 1863), a primarily physiological study on tone perception. Helmholtz was a physician, physiologist, and physicist whose landmark work on sensory perception (visual and auditory) refuted at that time the still dominating schools of Naturphilosophie (natural philosophy), a speculative way of thinking and interpreting the physical world. Helmholtz was an empiricist and a very influential scientific thinker of his times. Interestingly, Wilhelm Wundt—who is considered with William James to be one of the founders of modern experimental psychology—was for a while a student in Helmholtz' laboratories in Berlin.

It is important to remember some of the beginnings of the psychology of music, in order to understand the fundamental and extraordinarily radical change and determination of the future directions in studying music that was brought on by this new discipline. Only a few decades earlier, the German philosopher Schopenhauer had called music the purest incarnation of the human will, the embodiment and expression of human feelings (sadness, joy, love) in their abstract interpretation as metaphysical ideas. Even while a new experimental science of music as human behaviour emerged, contemporary philosophers such as Nietzsche still interpreted music philosophically, for example, as transcending reality, redemptive to the human condition, and either destructive (Dionysiac) or idealizing (Apollonic) reality and dissolving individuality to become one with the governing forces of the universe.

The new psychology of music diverged quickly from such centuries-old traditions of philosophical interpretation of music as human behaviour. The physicist Carl Stumpf was in 1883 the first to utilize modern scientific methodologies (experimental testing, hypotheses, statistical analysis) applied to investigations of musical–psychological phenomena—in his particular case to perceptions of consonance and dissonance—in his publication *Tonpsychologie* (Psychology of Tones) and other works.

The early and foundational works in psychology of music were mostly driven by experimental investigations into sound perception, linking psychology and psychophysics—or specifically psychoacoustics in regard to music—to understanding human responses to music. Interestingly, psychoacoustics remains to this day an important part of research agendas and teaching curricula in psychology of music. Carl Seashore, who in many ways is considered the primary pioneer in American psychology of music, developed the first objective test of musical aptitude in 1919, conceptually it was strongly connected to the psychophysical origins of the psychology of music. He designed a test, consisting of acoustical stimulus pairs, for which the test subject had to decide if both stimuli were same or different. The test items measured, e.g., differences in the perception of pitch, timbre, duration, or rhythmic pattern structure. Test items were produced by tone generators to avoid bias and influence for the test subjects on test performance through differences in musical exposure and familiarity. Seashore's ideas were rigorously scientific and revolutionary for his times: however, in many follow-up studies his test showed fairly low predictive power for future musical success and achievement in people. Seashore's ideas were so rigorously perception-based in psychophysics that his test is nowadays still considered an objective measure of acoustical acuity, but not a good measure of the more complex nature of musical abilities. Interestingly, the rhythm section of the Seashore test has survived and continues to show its validity as part of a neuropsychological assessment test for brain injuries (Halstead–Reitan), testing in all probability abstract auditory temporal perception as a measure of cognitive-perceptual functioning in an injured brain.

In the 1920s and 30s, a new focus entered the original research focus of psychology of music. This shift is often referred to as a shift from a psychology of tone to a more analytical and penetrating psychology of 'music', emphasizing the comprehensive perception and evaluation of complex pattern structures of melody, harmony, form, and rhythm as constituent building blocks of the language of music. Ernst Kurth's work *Musikpsychologie* (1931) is often cited as one of the first works to proceed with this new shift. This new shift was well supported experimentally and theoretically by the emergence of a new direction in the psychology of perception, the new school of Gestalt perception which holds—in basic tenet—that the sum of individual parts in a complex pattern structure assume a new perceptual quality as a 'whole' that is different from simply viewing a stimulus pattern as collection of individual parts. One of the simplest experiments to illustrate this concept was based on the so-called phi phenomenon or phenomenon of apparent movement. The rapid alteration of blinking lights being turned on and off periodically and in sequence creates the optical illusion of light moving back and forth along a line from point to point. Musical forms follow a complex architecture of sound patterns, assembled in rule-based systems, and acoustically and perceptually organized in five dimensions simultaneously and sequentially: rhythm/time—pitch/melody/polyphony—space—timbre—loudness. It is an interesting observation, that music is the only sensory language code that proceeds sequentially and simultaneously at the same time within its rhythm–polyphony dimensions and thus presents unique challenges to complexity thinking in the perception/cognition of information processing. Contrarily, verbal language, for example, only proceeds in sequentiality. A large amount of research has followed and continues to follow this direction of investigating experimentally complex music perception, following gestalt principles of perception. The vitality of this field shows the continued benefits of this approach, also in light of modern brain research within the models of cognitive neuroscience. We will return to this subject again later in this chapter.

Roughly in tandem with the emergence of Gestalt psychology and its extensions on the study of music perception, a third strand of research became subject of new investigations: the affective response to music. Verbal responses to quantify and categorize affective responses to music appeared in the early twentieth century as a new study focus, differentiating affective responses into studies of emotional responses, mood states, and perceived feeling states.. One of the first and widely used such verbal tests was Hevner's Adjective Circle (1936), a checklist of

adjectives characterizing and categorizing subjective feeling responses to music. Researchers tried to find useful categories in music that would allow them to study potential links how musical variables would influence affective responses. Among the first categorizations of music al variables were consonance vs dissonance and minor vs major modes. Soon other variables were examined, such as tempo, pitch, and variations in melody, harmony, and rhythm, frequently subcategorized under descriptors like sedative or stimulative music. Other variables investigated included repetition, familiarity, and various investigations into the function of musical taste. Many leading music psychologists of the first half of the twentieth century, such s Farnsworth, Hevner, Schoen, and Seashore, engaged in studies of the affective response in music. An impressive array of data demonstrated overwhelming evidence that music can evoke deep and complex affective responses, but direct linear cause–effect linkages between music variables and specific affective responses were difficult to pinpoint. Predictive power in such studies remained very low. Data showed on the contrary that affective responses to music were often highly idiosyncratic to individual listeners and their musical enculturation as well as to the specific conditions in which the listening and testing took place, e.g., mood states or arousal needs the subjects brought into the listening condition. Studies of the affective response in music were also complicated by the difficulties in the general psychological studies of affect, mood, and emotion to conceptualize affective states. Two theoretical approaches have dominated and continue to shape such discussion: a categorical approach to defining emotional states, using a limited number of emotion states, such as happiness, anger, disgust, surprise, sadness, etc. A second school of thinking is often called a dimensional approach in which emotion states are not categorically defined but emotions occur only within two or more dimensions, such as levels of perceived pleasure and levels of perceived intensity. A dimensional approach has obviously had more attraction to music research as music is void of connotative semantic meaning, and therefore a dimensional response to affect in music would bypass the dilemma of exact verbal descriptors of felt emotion in music and definitions of what musical variables are associated with exactly what categorical states in affect and emotion. However, dimensional approaches have the disadvantage for emotion research in music that the determination of affective states remains somewhat diffuse, and causal or predictive linkage with musical variables is difficult to conceptualize. Not until the second half of the twentieth century did several new landmark theories in aesthetics—influential for re-approaching affective response research in music—move this area of research in psychology of music decidedly forward.

In conjunction with studying verbal responses in affective responses to music, a very active line of physiological investigations emerged in this particular area, holding with the original impetus of the new psychology of music to study perception objectively as close to the human nervous system as possible. The research into the affective response to music as a physiological response spanned almost the full circle of the twentieth century, until it was superseded by breakthrough developments in brain research technology that allowed researchers to study brain responses *in vivo* under complex affective and cognitive stimulus conditions that began to include music at a very early stage of using these new technologies.

Prior to this new development, starting in the first years of the twentieth century, a huge amount literature begin to be amassed for the next 70 to 80 years, studying mostly physiological responses of the autonomic nervous system such as cardiac (heart rate), respiratory function, vascular changes (blood pressure), or galvanic skin response (GSR: changes in electrical skin conductance). This research showed many fascinating insights into the reactivity and sensitivity of physiological responses to music. The research has shown unequivocally that music elicits physiological changes that are indicative of changes in the perception and interpretation of the music by the listener. However, after those basic insights the data picture quickly became more complicated. Changes in physiological responses to musical stimuli did not seem to follow clear linear relationships with characteristics and changes in musical variables. For example, slower tempi in music do not always show slower heart rates, higher loudness levels or brighter timbres do not consistently create

increases in vascular constriction or other measures. To create better interpretations of the physiology, studies quickly went to design paradigms combining verbal responses with physiological measures. Also in such a two-pronged assessment approach, simple cause–effect relationships remained elusive. For example, studies have shown that increases in self-reported relaxation measures may coexist with increases in physiological measures, e.g., accelerated heart rates.

Data seemed to suggest that the physiological response per se appears contentless, i.e., similar changes in heart rate or GSR can be associated with very different interpretations as to behavioural meaning. Secondly, the data suggested that interpretations of musical pieces or changes in musical elements (e.g., tempo) are highly idiosyncratic and contingent upon a listener's complex personal interpretation system. Therefore, in later developments many studies began to move away from music that was pre-selected or pre-categorized by the researcher to musical stimuli that—often self-selected by the experimental participants—could be very different in structure, style, and genre but had consistent meanings across listeners. In addition to recognizing complex idiosyncratic response models that made generalized investigations and interpretations of responses in physiology and verbal reports to pre-categorized music styles almost meaningless, further insight came from arousal theories that pointed out that changes in physiological reactions are highly dependent in their meaning and interpretations on existing arousal states preceding the stimulus-elicited changes. For example, temporary boosts to high arousal may be perceived as pleasant inductors and precursors of subsequent relaxation (the gym effect). In states of low arousal, moderate boosts of arousal (e.g., increases in heart rates) may be perceived as pleasant and relaxing.

Considerable breakthroughs in aesthetic theory began to influence psychology of music research in the second half of the twentieth century. Two highly influential theories—that still continue to influence most new developments in theories of meaning and music—were proposed respectively by Leonard Meyer in the 1950s and Daniel Berlyne in the 1960s and 70s.

Meyer proposed a model mechanism how music elicits meaningful affective responses in the music recipient—be it performer or listener. Based on Dewey's conflict theory of emotion which states that emotional responses are triggered when a tendency to respond is inhibited, expectations are built in music through compositional schemes that are continuously delayed, inhibited, and resolved—creating a complexly woven sound architecture based on building musical structures of anticipation–tension–resolution. In the interplay between the build-up of anticipation, the interjection of tension, and the creation of resolutions, the suspense evokes arousal—especially during the tension phase, i.e., the temporary inhibition of expectations—accompanied by a search for resolutions that is subsequently resolved within the musical structure. The resolution may then serve dialectically as the next springboard to renew the sequence of events since the resolution sets up a new set of expectations. The stronger the build-up of suspense or tension, the stronger will be the arousal build-up, and consequently the stronger will be the emotional release upon resolution. In order to have an appropriately structured experience, the music must have a well-balanced mixture of elements of novelty or uncertainty and redundancy or certainty in order to build meaningful tension-release schemes. Meyer's model, which was initially a purely theoretical proposal, has received considerable empirical support and is at the basis of many newer aesthetic models using tension–release mechanisms to explain musical meaning and affective experience in music elicited by the perception of music structures. Proponents of this view are usually called absolute expressionists because they believe that although musical meaning is communicated intrinsically through the perception of musical elements, i.e., the syntax of music, the perception of the melodic, rhythmic, and harmonic patterns and structures of the music can evoke meaningful affective experiences, however, not in the categorical semantic sense of emotion as previously discussed. Meyer's model constituted significant progress in explanatory accounts of understanding the nature and causation of meaning in music, including affective responses. His model and later models, connected to him, have received a slow but steady appreciation in the cognitive neuroscience of music, influencing study designs and hypothesis development for assessing brain responses to music.

Berlyne was the main proponent of another new development in aesthetic theory which is still highly relevant for modern brain research in music and aesthetic theories in the psychology of music. Berlyne founded the movement of 'experimental aesthetics' which was in many ways ahead of its time. He laid out a framework for how the perception of elements and patterns in artworks contain arousal-inducing attributes that constitute physiological arousal as the basis for affective–aesthetic behaviour in art perception. Berlyne—whose views on how we respond and how we perceive artworks was clearly influenced by gestalt theories of perception—showed at least in principle how artworks can have a profound effect on brain and behaviour by linking perceptual and arousal processes that are intrinsic to the human brain. At the time, his physiological elaborations on how aesthetically ordered visual and sound patterns in the visual arts and music have unique arousal-inducing properties that—when perceived as 'Good Gestalts'—create meaningful and affectively rich perceptual experiences, did not have the benefit of new research models and deeper knowledge of human brain function in cognitive neuroscience. However, his basic framework has been not so much rejected but simply vastly expanded by modern human brain imaging and neurophysiology. Berlyne was perhaps the first scholar in music psychology close to suggesting a basis for a new biological aesthetics that includes music as a biological core function of the human brain. We will come back to this point later.

In the last 25 years of the twentieth century, music psychology underwent its most fundamental change with the advent of brain imaging as an entirely new technology of studying the human *in vivo*, involved in complex cognitive operations. Up that point, human brain research could learn much from animal models in regard to motor system function or the neuroanatomy of various perceptual systems, but higher cognitive functions could only be diffusely approximated through animal brain research. Other techniques had major limitations in creating large samples, establishing testable hypotheses, or studying brain processes during complex cognitive tasks. For example, posthumous brain research from persons who had known and well described behavioural dysfunctions, research with persons who had undergone well-defined neurosurgical interventions (e.g., split brain surgery), or dichotic listening tests linking ear preference with hemispheric preference in perceptual processing, all had helped contribute knowledge on cognitive brain function and were widely used in music research, but could never accomplish what the development of comprehensive knowledge on brain function measuring a human brain *in vivo* could deliver.

The two most prevalent brain imaging techniques, positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), allowed unprecedented access to studying the brain basis of human cognition and helped establish a new field of scientific inquiry, appropriately referred to as cognitive neuroscience. Cognitive neuroscience in many ways has begun to change psychology as a mostly behaviourally based research discipline. Interestingly, music became rather quickly—even in the pioneer stages of these new technologies—a subject of immediate interest, and music studies are among some of the first human brain imaging studies carried out. The cognitive neuroscience of music is now an integral part music psychology, its research efforts and the knowledge base of the biology underlying music behaviour. Brain imaging has profoundly altered the traditional nature of research in music psychology.

Initially, research paradigms using brain imaging in music were relatively basic and looked for simple contrasts. For example, typical early studies compared listening to music vs listening to a narrated text, or compared musical responses of professional musicians vs non-musicians. Based on such baseline designs, some of the early findings focused on differential hemispheric activations in music compared to non-musical tasks, where the right hemisphere seemed particularly involved in music processing compared to the left brain hemisphere. Such findings created a certain amount of publicity and notoriety in considering that the right hemisphere may be the site of artistic abilities in the brain. As research designs became more sophisticated and more complex designs investigated specific musical responses, such notions turned out to be highly oversimplified. Music as a complex sound language that engages multiple processing systems

in the brain in the area of perceptual, motor, and cognitive functions, actually turned out to be a stimulus that is best characterized by very complex activations patterns in highly distributed patterns across the whole brain on cortical and subcortical levels. The brain imaging research of the past 20 years has evolved in roughly four categories: music perception—broader cognitive processes, e.g., regarding emotional saliency—music learning and plasticity—biomedical applications of music.

In music perception, a wide array of studies have investigated the functional neuroanatamy of music perception (and production) relative to specific musical elements or specific production tasks. Perception of smaller elements such as pitch, harmony, rhythm, timbre, and perception of larger pattern elements such as melodies or scales, vs full musical excerpts, and other structural components of music have been studied in respect to underlying brain function. Additionally, aspects of music production such as motor control in instrumental and vocal (singing vs speech) performance have been extensively studied. Investigations into rhythm perception and rhythm production—especially issues in rhythmic sensorimotor synchronization—have received particular attention in brain imaging research as an important component aspect of music perception.

Broader aspects of music responses—for example more interpretative responses in regard to meaning and emotional saliency—have been studied less to date than more structural music perception questions. However, recent attempts are beginning to make up for this noticeable lag. Imaging studies in regard to emotion and music may still face age-old challenges in regard to the previously discussed difficulties in appropriate conceptualizations and theoretical underpinnings of meaning and emotional behaviour in music. Also, brain research into the meaning and emotion in music must be based on solid theoretical foundations in aesthetic theory and may require more intense and integrative collaborative efforts between musicologists, music psychologists, and cognitive neuroscientists in the future. However, a very important and fertile field for future research seems wide open in this area.

New findings in the neurobiology of learning have motivated considerable efforts in musical brain imaging. The discovery that experience, learning, and training can drive brain plasticity—i.e., changes in the neural organization and connectivity of the brain—led to a number of studies investigating brain plasticity induced by music learning and music training. The evidence shows impressively that music changes the brain and that certain areas, e.g., motor areas involved in instrumental training (keyboard, violin, etc.) or visuospatial and cognitive areas trained through intense music training can become enlarged and preferentially activated via the establishment of new and well-developed neural circuits. There is a broader impact implied by many of these studies because changes in brain plasticity through music learning—especially if they involve brain areas that also mediate critical non-musical cognitive and perceptual functions—may suggest that music learning can confer a wider cognitive benefit to general non-musical cognition and intellectual functions. Such notions have considerable importance for all forms of music training as well as the role of music education in public education.

Finally, since the early 1990s a combination of brain imaging and clinical behavioural studies has investigated the biomedical effect of music in a neurorehabilitation environment, where music is used as a therapeutic stimulus to retrain motor, language, and cognitive function in persons with brain injuries and neurological disorders, such as stroke, Parkinson's disease, traumatic brain injury, dementia, cerebral palsy, and other dysfunctions of the human nervous system. Studies have shown impressively that music is an effective sensory language to facilitate the recovery of neurologic function when used in a therapeutic context that emphasizes learning and training models to re-educate the brain via mechanisms of brain plasticity. In that respect, the new neuroscience research in music has led to a fairly radical reformulation of concepts and principles for the role of music in therapy and medicine, away from traditional social science-based concepts of music therapy—traditionally emphasizing notions of well-being and cultural values in relationship building and human interaction—to neuroscience-based models, emphasizing music as a language that can actively address the rehabilitation of perception, cognition, and motor function.

Brain imaging has brought about enormous changes in research directions and virtually reinvented the cognitive science of music embedded in music psychology form its early origins. However, as a technique it has several serious limitations that need to be kept in mind when assessing its importance. Interestingly these limitations are particularly relevant in music research. The current techniques in neuroimaging provide a detailed look at brain activation based on topography, i.e., maps of highly developed spatial resolution. Brain imaging creates maps of brain activity, measured over a relatively long period of recording time in the second range (e.g., 20–30 secs). In other words, the time resolution—i.e., when something happens rather than where—has limits in assessing with exactitude the timing of brain activations. This is important in music research because music is physically based on vibration patterns of air molecules, and as such the perception of sound is based on time parameters of vibrating objects. Music is a temporally based sensory language and brain activations in music perception must respond to information processing in the range of milliseconds (or below). To that end, the auditory system which processes music is a highly sensitive system in regard to speed and precision in responding to very small fluctuations in temporal changes in the vibrations patterns that constitute sound. Thus, neuroimaging can make important contributions to the mapping of music perception and musical responses but can only add limited information to the temporal aspects of music processing in the brain.

For this reason, two other techniques measuring brain activations—one new and one older—have received considerable attention in music research, providing an excellent complement to brain imaging via PET or fMRI. The techniques are called electroencephalography (EEG) and magnetoencephalography (MEG). Their respective mechanisms of signal recording are somewhat different although they record the same brain signal. EEG records brain waves—usually via sensors attached to the scalp—by detecting the electrical currents that are emitted by the electrochemical potentials of neurons during their firing activity. MEG records the same electrochemical signal but measures it by the measuring the magnetic field created by the electrochemical signal. EEG is a technique going back at least 50 years that was developed initially to detect any abnormalities in the patterns of neuronal firing activity which occur in an oscillatory 'rhythmic' fashion: hence the somewhat misleading term brain 'waves' was created. Data recordings and analysis of brain rhythms have become exceedingly more detailed and complex, so that EEG research has experienced a very fruitful renaissance. EEG measures have very high temporal resolution down to 1 millisecond—however, they have poor spatial precision because surface sensors receive and record signals from widely distributed neuron ensembles and exact spatial determination of the source of the signals is not possible. MEG has a major advantage over EEG because a technique called dipole analysis in the magnetic field allow the creation of fairly good spatial locators for the brain signal source. Both EEG and MEG can record brain activity associated with a certain behavioural task with high accuracy of timing of the signal processing in the brain. In music, EEG and MEG can be used to study the time course of music perception across different brain areas in millisecond ranges which give an excellent picture of the brain's temporal processing of music. In conjunction with PET or fMRI imaging, a very complete spatial and temporal map of music processing in the brain can be established. However, combining techniques requires complex equipment interfaces that are not easy to carry out technologically.

One of the most innovative current approaches to studying music perception is to compare music perception on analogue variables to verbal language. The comparison makes sense in many ways as both music and verbal language are auditory-based communication systems, hold vital function in human society, and have several systems of structural organization in parallel, such as phonological sound category systems and syntactical rule systems. There are also some obvious differences, of course. For instance, both systems have pitch and timbre as sound categories, but in music pitch is the primary categorical system to organize sounds into musical patterns, whereas in verbal language timbre is a primary organizer of speech sounds (vowels, consonants). One of the

most critical differences lies in the absence of semantics in music, whereas linguistic semantics is a critical component of verbal language. The semantic meaning of a word is the reference to objects or experiences in reality and to the mental representations of such reality. Semantic meaning is referential, making propositions about reality. Those are fairly philosophical concepts that show how deeply linguistics is embedded in concepts of mind and thought. Musical statements or communication symbols—melodic motifs, rhythmic phrases, harmonic sequences—are non-semantic in the sense that they only refer to themselves within the rules of the musical syntax used. That brings up another important point for consideration. Both music and verbal language can be said to be based on rules of how structures of sounds or words are constructed, via linguistic grammar or compositional grammar (in music). Both grammars are generative in that they have rules that can generate and predict meaningful 'correct' statements in many combinatorial ways in a given language. They also have, however, decisive differences. Violations of linguistic grammar can be determined to be incorrect and rendering statements meaningless. Violations of musical 'grammar' rules are soft and not absolute. Violations of musical grammar are common and often deliberate in order to discover new musically meaningful 'grammars'. Therefore, direct comparisons between musical syntax violations and linguistic syntax violations are not entirely possible and reveal little about shared or parallel brain processing for different language systems. However, carefully constructed comparisons between analogue language processes in music and linguistics have been recently attempted in brain imaging, and can yield insight not only into music-specific cognitive brain processes but also into aspects of cognitive processing systems in the brain that may operate cross-modally for different 'language' systems.

A new model may push investigations in music research one step further within the language model. Instead of investigating music in comparison to verbal language, a new model may investigate music as an autonomous biological language of the brain in relationship to other verbal and non-verbal language systems. In this model, the brain is considered a multiple language generator. The brain generates and operates in multiple languages of thought. Thoughts as mental representations occur in verbal language form but also other forms of languages in non-verbal systems come easily to mind, e.g., the language of quantities and size expressed through numbers. The arts and music would be a specific case within the languages of images and percepts. Music as a language is based on the ability to think in sound, to perceive relationships between sounds and to generate rules to build sound events into complex sound scapes. The whole architecture of music as such would then be considered based on the ability of complex non-verbal temporal auditory thinking, which is by definition a deeply cognitive process. Human beings are clearly born with that ability, just as they are born with a biologically innate knowledge of verbal language. It is of great interest in this matter to study pre-historic artworks which show figurines and paintings of highly modern design, shape, and with highly evolved aesthetic qualities of abstraction and symbolism. We find artifacts like that dated 70 000 or more years old—tens of thousands of years before the first emergence of written documents for word languages and basic numerical concepts. Artefacts of musical instruments can currently be dated as far back as 35–45 000 years. Recent brain investigations regarding music processing show interestingly many areas involved that are also involved in complex linguistic (verbal language) processing and other cognitive functions. These findings may provide support for a 'music as a language' model within a comprehensive model of multiple brain languages.

Modern psychology of music has engaged in other areas of investigation and analysis besides the ones discussed so far. Social communication in regard to cultural values, uses, and function of music have always been an important aspect of research in music psychology. Music psychology and music anthropology have interacted in studies of music perception as well as historical roles of music in human culture. Music education and music therapy often consider psychology of music as a foundational field of study for their disciplines, and music psychology has indeed contributed important knowledge to such those fields. However, it is probably fair to

say that the majority of research effort in music psychology has not been in applied or translational research for educational, developmental, or therapeutic purposes. However, such applied or translational focus may become one of many new future directions in the psychology of music.

CHAPTER 52

Where now?

Susan Hallam, Ian Cross and Michael Thaut

THE purpose of this chapter is to draw together emerging themes from across all sections of the book. The themes identified are not exhaustive but capture broad trends, ideas, issues and questions which have resonance across the whole of music psychology. The themes are not mutually exclusive. There is overlap between them. Each theme has implications for many areas of music psychology. The first theme concerns the power of music, the second the way that modern technology has enhanced music's influence through increasing access and enabling individuals to listen to the music of their choice at any time or place. Subsequent themes relate to our understanding of basic perceptual and cognitive processes, and music as language, communication and interaction. A key issue is the need to take greater account of culture and context, with more research being undertaken in non-Western cultures. The chapter concludes with a consideration of methodological advances and the need for those from different disciplines with an interest in music psychology to work more closely together.

The power of music

Music has a multiplicity of functions which operate at several levels: that of the individual, the social group and society in general. In relation to each of these music can have a very powerful impact influencing behaviour, emotions, and moods in a variety of settings frequently without our conscious awareness (see Chapters 11–15 and 40–45). The exceptional power of music may be related to it being able to stimulate us aurally, visually, intellectually, emotionally and physically, simultaneously.

Background music selected by others and music accompanying visual images and verbal messages can have a very immediate impact through its power to invoke associations and change moods and arousal levels. This has led to its use in a variety of leisure, commercial and employment settings (see Chapters 40, 41 and 45). The ever-growing body of research in this area has made considerable progress in understanding the nature of the relationships between musical stimuli and behaviour but there is still much work to do to establish the particular conditions, contexts and musical characteristics which lead to specific outcomes and to identify those characteristics of the individual which may ameliorate the impact. We also need to establish the factors that are important in determining negative responses to music.

Concentrated engagement with music, usually through listening, can evoke peak emotional experiences which can have permanent and powerful therapeutic effects enhancing relationships, attitudes, general appreciation of art or music, aesthetic sensitivity and perception of everyday reality (see Chapter 42). To understand these powerful responses better we need to be able to identify the specific conditions, individual and contextual, which pertain at the time. There is also a growing body of evidence of the longer-term effects which active engagement with music in educational, community, therapeutic and medical contexts can have on health, well-being and intellectual development (see Chapters 23, 44, 46–49). Traditionally, active engagement with music and music therapy, informed by cultural values and social science models, has been assigned a rather global and diffuse role in bringing about long-term change

in behaviour, relying on concepts of well-being, social relationship building and the development of transferable skills. Recent developments in the neurobiology of music have enabled more concrete evidence about what music can achieve. By studying the brain basis of musical behaviour and learning, it has become clear how music learning reciprocally effects changes in the brain (Chapters 16 and 18). The concept of neuroplasticity applied to musical learning in relation to the initial education of the brain and re-educating the injured brain (Chapters 17, 18, 23, 46–49) has created the conditions for new scientific research on the effects of music in educational, medical, therapeutic, and rehabilitation settings that can be transferred and generalized to a wide range of non-musical functions, for instance, motor and speech training and cognitive functions such as memory, attention, and executive functions. In music therapy and medicine much promising research has been accumulated and has begun to be translated into practice (Chapters 46–49). In educational and community contexts progress is slower (see Chapters 23 and 44), but overall these developments will continue to present a powerful research agenda in the future, creating a new form of neurologically and evidence-based music research in education, medicine and related disciplines, and therapy for the twenty-first century.

Music also has a powerful impact on social interactions, the identities individuals create for themselves, the social groups with which they engage, and the meanings that they construct and experience in and through music (see Chapters 1–4, 27 and 43). A limitation of research to date is that most has been undertaken within Western musical cultures. Its validity needs to be tested within other musical contexts and cultures to explore whether similar phenomena occur elsewhere. Other relatively neglected issues relate to the extent to which identification with particular musical genres determines behaviour beyond the musical. For instance, with regard to engendering violent, antisocial or rebellious behaviour, are particular musical genres preferred because they reflect already existing behavioural tendencies, or does the music itself encourage particular behaviours? We also need to explore the relationships between the extent, quality and antecedents of the individual's involvement with music and their identification with particular genres, taking account of the experiences of individuals for whom music is relatively unimportant. Understanding why some individuals do not engage with music may shed light on a range of issues relating to musical ability, musical preferences and motivation.

The impact of technology

Technological advances in the twentieth century changed the ways in which music could be experienced. They not only made music more accessible but made it possible for each individual to select the music that they wished to listen to in any combination of genres in any environment. People now use music to meet a range of psychological needs: as a distraction, to focus attention or energize, to manipulate moods, and to work through emotional issues (see Chapter 40). Music plays a key role in people's lives as they travel, and engage in domestic and social activities in the home and community, and at leisure. Considerable progress has been made in identifying the ways in which music is used at the individual level, but we know little about how it is selected for particular purposes, or how successful this process is. The way that music impacts on and is used in our daily lives will clearly continue to be a major focus of research in the future.

The easy availability of music and its commodification challenges earlier idealized conceptions of music listening as a concentrated process with a focus on the spiritual or aesthetic. Currently, we lack knowledge about different approaches to listening, and the way that music used as background moves from the periphery to the centre of attention. This is an area for future development.

Technology has not only led to the increased availability of music but also its globalization and commercialization. These changes will inevitably have impacted on those involved in the creation and performance of music. As yet we know relatively little about this. Research which explored the nature of the work of professional performers and composers in the twenty-first century and the impact of this on learning, motivation and performance would have major implications for the future training of musicians (see Chapters 30–38).

Understanding of basic perceptual and cognitive processes

Although there now exists a considerable body of empirical research on music perception and cognition, many 'primitive' perceptual processes are not yet known in sufficient detail to allow us to feel that we fully understand the processes of music perception and cognition (see Chapters 5–10). Many fundamental aspects of musical sound are not yet well enough understood in terms of their physics in order for us to be confident that we can develop predictive theories about how we experience such sounds. For example, the ways in which our perception of a violin's sound may be shaped by the pattern of the radiation of sound from the instrument is constrained by the fact that, as yet, there exists no complete physical account of how the instrument's structure, and mode and physical context of performance, might shape that pattern of radiation. The nature of the factors that influence how we hear sounds as having particular timbral qualities is not wholly clear (see Chapter 7), nor do we know how judgements about sound quality relate to issues of attention and memory (see Chapter 10). These are all questions for future research.

There is also the question of the contribution to music perception and cognition of sensory modalities other than the auditory (see Chapter 3). Several researchers have theorized and explored ways in which music perception and cognition appear to involve cross-domain mappings between the auditory attributes of music and features of other domains of human experience (visual, haptic, motional, etc., as well as cognitively higher-order constructs such as body-image schemas). At present, it is not clear how integral these cross-domain mappings might be for our experience of music and there is immense scope for future exploration.

Music and language/music as language

Recently, there has been a regeneration of interest in the relationship between music and language as communicative systems, and as manifesting common properties as representation systems within the brain. The parallel and shared components between these two auditorily based systems of communication and mental representation offer new opportunities for research and early findings are promising, with notions of generativity, syntax and grammar suggested as accounting for the processes involved in the experience of musical structures (see Chapters 6 and 19). The extent to which syntactical aspects of music can be regarded as being of the same order—in terms of scope and complexity—as syntax in language is still unclear, as is the nature of the factors that enable complex serial structures to be perceived and remembered in both language and music. If music can be conceived of and perceived as though it conforms to grammatical principles, what types of grammar are entailed, and do these constitute 'true' grammars of the type that form foci of linguistic research, or are they more constrained in their scope and power? If the grammars of music and language were to be found to be closely comparable, the question then arises of how music can be differentiated from language as a domain of human thought and behaviour (see Chapters 1–4). There is also the issue of how different musical practices have arisen in different cultures.

This research agenda may be strengthened by studying music—within a broader concept of all the arts—as an autonomous language itself, i.e., a representation of thought in non-verbal aesthetic images and percepts. Such conceptualization may create new and productive insights into music as an innate biological language of the brain, its origins, its role and function in the cognitive and intellectual development of the human brain, and its unique contributions to the complexity of human brain function—not as an enriching cultural phenomenon, but as a core modality of human cognition.

Music as communication and interaction

A key emerging theme is that of music as communication. Advances in technology have enabled more detailed consideration of the assessment and modelling of performance processes providing new insights into performance practices, communication issues relating to playing from

memory, the role of movement, collaboration between performers and issues relating to performance anxiety and the medical problems that can arise from a lengthy career in the music profession (see Chapters 30–36). This research has focused almost exclusively on Western classical music, and we know little about these issues as they relate to other genres and musical cultures.

There is also a dearth of research on the way that audiences participate in the communicative process. The relationship between music in the individual mind and music as an interactive behaviour is not well understood, we know little about how our private musical cognitions relate to our public musical interactions. Musical performance may appear as the exercise of individual musical skills, but equally as the outcome of joint musical endeavour. To date we have few insights regarding the way in which the musical behaviours of others, our perceptions of those behaviours, and our conceptions of the mental processes that we infer as underlying them, contribute to the experience of music as performance or as interaction. While some empirical research has begun to explore these issues and to develop theories of music cognition in interaction (see Chapters 1, 4, 34 and 38), the vast majority of research has focused on individual music cognitions and perceptions. Exploration of capacities that are likely to be central to interactive musicality, such as that for entrainment (see Chapters 4 and 8) is in its infancy, and questions of how such capacities relate to broader human capacities for complex social communicative interaction have barely been addressed. Indeed, the question of whether or not at least some types of musical judgement may be exercised as social and interactive behaviours rather than being evidenced in acts of individual judgement (as much music sociology would suggest) remain to be explored, as does the problem of how such situations might be investigated scientifically.

The interface between the biological and cultural

An ongoing issue is the relationship between what is biologically determined at the species or individual level and what is determined by the cultural environment in which the individual develops. Are aspects of the human capacity for music found in the behavioural and mental capacities of any non-human animal species (see Chapter 1)? If so, are those human capacities interpretable as evolutionarily homologous to those of non-human species (which would indicate common evolutionary descent), or are they best construed as analogous (likely to have arisen because of similar selection pressures)? Answers to these questions would greatly advance our understanding of the significance of music as a human faculty, and require to be pursued by music psychologists in collaboration with ethnologists, geneticists, and evolutionary biologists and psychologists. Investigations of the 'social mind' and the 'social brain' are now major foci for cognitive and neuroscientific investigation, in part precipitated by the realization that the complexity of human sociality is one of the principal defining characteristics that appears to differentiate us from other species. Behavioural research has focused on issues such as theory of mind, social reasoning, and decision-making, and has often adverted to evolutionary approaches in seeking explanations for the scope of, and the constraints on, human social behaviours. Neuroscientific research has also begun to turn its attention to these and other aspects of human social capacities, and exploration of the place of music in human social capacities must be a primary focus for future research.

There are also unresolved issues relating to the propensity for individual differences in musical ability (see Chapter 24). Advances in research on genetics, to date, have had little impact on the debate. Few human behaviours or traits have been traced to specific gene pairs and it is likely that those who exhibit musical skills are drawing on a range of different gene combinations, which exert an influence on physical make-up in addition to cognitive and emotional development. Interactive rather than additive models of the relationship between the environment and genetic inheritance are now generally accepted. These interactions begin in the womb and continue throughout the lifespan (see Chapters 20–22).

Developing empirical methodologies are making it increasingly possible to carry out

methodologically sound investigations relating to the prenatal period. As our understanding of prenatal influences increases we need to be able to relate these to postnatal behaviour. Cross-cultural longitudinal research following individuals from birth would enable us to identify those factors which contribute to the development of different musical skills in particular contexts. This would enable us to explore how children acquire musicality in non-Western, particularly traditional cultures and establish the factors which are common across cultures in child rearing and other social practices which encourage the acquisition of musical skills (see Chapters 20–22 and 28 and 29). While the family plays an important role in the early stages of engagement with music in Western cultures, this may not be the case elsewhere. Cultural influences on families, for instance the extent to which music is valued in the subculture to which the family belongs and the nature of the value placed on music in society, may be important, for instance, whether it is viewed as related to religion, as entertainment, as a form of protest, or as a way of life. Cross-cultural research would also enable us to establish if what we know about practice and performance applies equally to all cultures and musical genres (see Chapters 25 and 30–36). Currently there is little research on learning, practice, memorization processes, and performance outside the Western classical tradition. Realistically, longitudinal cross-cultural research is unlikely to be funded (though highly desirable) but it would be possible to undertake cross-cultural, cross-sectional research which would offer some insights. This would elaborate our knowledge of the impact of different cultural and familial traditions on perception, learning, cognition, and responses to music. The research would need to acknowledge that musical potential manifests itself in a range of different ways, creating further challenges for researchers in developing appropriate methodologies for exploring the processes of learning, assessing change, and attempting to identify the contribution of particular environmental influences. A number of systemic interactive models have been developed which would assist this process (see Chapters 26–29).

While existing research has made a major contribution to understanding the way in which specialist musical skills are acquired in a Western musical context, there still remain a number of key questions. For instance, how important is the child's choice of instrument in determining motivation and the level of expertise attained? To what extent do opportunities to engage in a wide range of musical activities contribute to the development of expertise as opposed to deliberate practice on a single instrument? To what extent do other factors, apart from those relating to musical expertise, contribute to success in the music profession (see Chapters 24–29)? There is also a developing research agenda in relation to amateur engagement with music. With the population in the Western world having more time for leisure and living longer, more people are developing musical skills as a hobby. We know relatively little about the factors that contribute to individuals returning to or taking up musical activities in later life, whether their motivation is musical, social or a combination of these, and how it is sustained.

The processes of composition and improvisation are situated within particular musical contexts which have their own conventions and rules. Existing research has largely taken place within a Western context, with a focus on professional musicians or the activities of young people working within the school curriculum (see Chapters 37–39). The relative lack of research in non-Western cultures means that we do not know whether the approaches and strategies identified in expert and novice composers and improvisers are specific to Western musical contexts or whether they have relevance elsewhere. We also know relatively little about the long-term development of composers and the way that their thinking, skills and careers change over time and may differ between genres. For instance, has the increasing commercialization of music had an impact on their working practices and output? The other ongoing challenge for research in this area relates to assessment and developing ways of judging the relative value or creativity of particular compositions or improvisations.

The majority of music cognition research has been laboratory-based, using Western-encultured listeners and Western–generally common-practice period–musical materials. While these studies, with the tight controls and

replicable methodologies required by a scientific approach, have yielded many insights into music in mind, very few studies have managed to investigate non-Western musical perceptions with the same degree of rigour. In some ways this is not surprising; the exigencies of conducting empirical research in field contexts are not particularly consonant with the need to be able to control experimental variables and exclude those that cannot be controlled. Nevertheless, it is vital that future research should aim to investigate the ways in which non-Western musical perceptions and cognitions are aligned with, or differ from, those of the Western participants from whom our current knowledge is principally derived, ideally by using means that will enable the exploration of a wide range of emic perceptions and conceptions.

Methodological limitations and advances

All research is limited by the methodologies available to it, and music psychology is no exception. A wide range of approaches and methodologies have been adopted across the field in attempts to develop our understanding of musical practices and processes many of which are unavailable to conscious awareness. There has been much reliance on self-report (interviews, diaries, rating scales), either concurrent or retrospective, and experiments or observations the outcomes of which are used to infer musical processes. The advent of *in vivo* brain imaging technology in the field of cognitive neuroscience has emerged as a new force complementing existing methods, enabling the integration of behavioural research designs in psychology with concomitant studies into the functional neuroanatomy underlying these cognitive behaviour functions (see Chapter 51). An important and highly fruitful trend is likely to be the fusing of many areas of research. We see the beginnings of this already, for instance, when more and more sophisticated and musicologically sound behavioural studies in the perception of musical structure are combined with investigations into the underlying neurobiology of music. Advances in technology and the use of innovative experimental methods might also enable exploration and comparison of the brain states of participants in musical interaction, which could greatly illuminate the dynamics of music as social process.

Collaboration in research

Emerging throughout the book are issues relating to the need for collaboration between those working in different disciplines. The historic synopsis of research developments in music psychology illustrates the high degree of diversity as well as the unique dynamics of forming interdisciplinary research agendas that have continuously driven the field forward in a number of different directions (see Chapters 50 and 51). Music psychology has never presented itself as a uniform field of investigation and research goals. Various influences from different fields have converged on a scientific study of music and shaped the research, including aesthetics, cognitive psychology, physics, physiology, social sciences, anthropology, and most recently, cognitive neuroscience. Music psychology also overlaps with a number of other disciplines, including music education, therapy, ethnomusicology, and music theory and analysis. To further our understanding in many areas of work greater collaboration is required. For instance, in developing understanding of musical learning and development, music psychologists need to join forces with researchers in music education and with ethnomusicologists, as the types of information, theory and research practice that the questions demand require that developmental theories of music be elaborated and tested in a wide range of ethnographic contexts.

A continual multidisciplinary integration of and collaboration with musicology, i.e., music theorists, composers, and historians, into scientific research agendas where musicologists, musicians, psychologists, and other sciences work shoulder to shoulder in equal partnerships would also greatly benefit music psychology. For instance, there is much research by both musicologists and psychologists on expressive performance, particularly rubato. However, these two strands of work rarely make reference to each other. Yet both seek to explain and describe musical behaviours and cross-fertilization

of methodologies and knowledge would aid a deeper understanding.

In relation to developing our understanding of the perceptual and cognitive processes in music, it is essential for music psychologists to collaborate closely with engineers, physicists, psychoacousticians, linguists, and others in order to develop the field. This is necessary not only to ensure that theory and experiment in music psychology is informed and guided by well-founded understandings of physical and psychoacoustical facts and processes, but also to make clear to those with whom we are collaborating the ways in which the complexities of the questions raised by music perception and cognition may be informative in the development of their own disciplines.

There would also be benefits in closer collaboration with researchers working in relation to other art forms. The study of creativity in performance, improvisation and composition would benefit from collaboration with those working in the visual arts, drama and dance. This would enable communalities and differences to be identified and shared issues, for instance in relation to assessment, to be better understood.

Endnote

Music psychology does not function as a tightly defined academic discipline operating within a single, focused epistemological framework. It is interdisciplinary. This has led to contributions from a wide range of related fields, although from time to time there are tensions between them. While some may argue that the interdicsplinary nature of music psychology is a weakness leading to a lack of focus, there have been clear benefits to the quantity and quality of research generated when compared with the other visual and performing arts. From this perspective interdisciplinarity is a cause for celebration.

The *Oxford Handbooks* series is a major initiative in academic publishing. Each volume offers an authoritative and state-of-the-art survey of current thinking and research in a particular subject area. Specially commissioned essays from leading international figures in the discipline give critical examinations of the progress and direction of debates. *Oxford Handbooks* provide scholars and graduate students with compelling new perspectives upon a wide range of subjects in psychology.

Preface

In a delightful short scene about the protagonists Mozart and Salieri, Alexander Pushkin (1799–1837) described the different characters of the two contemporary composers. In the opening monologue, Salieri contemplates his career, how he mastered initial difficulties in executing the 'dry finger movements' until they were 'adequate for his ears'. But now, having met Mozart, Salieri develops a great jealousy toward his young, brilliant competitor, lamenting that he remained an artisan of music: 'I strangled and dissected my music—it was algebra, not music'. The scene ends with Salieri poisoning Mozart, now considered as a most unlikely story! What Pushkin is telling us in this paradigm, however, has to do with the two aspects of mastering music: the technicalities against the full flavour of music creation and performance. There is no doubt that music research deals with many of the difficult technical problems, especially of music performance. Helmholtz (1821–1894) was trained as a medical doctor in Berlin, but was actually most interested in mathematics, physics, as well as in the emerging physiology of the time. Moreover, he was also a passionate piano player (apparently of concert quality). His interest and love for music induced him to write his famous *opus magnum*, 'Die Lehre von den Tonempfindungen als physiologische Grundlage für die Theorie der Musik' (Helmholtz 1863). His was probably the first physical–physiological approach to the world of music, incorporating knowledge that emerged from the period of the Enlightenment.

Since Leopold Mozart's school of violin playing, numerous books of musical education have provided information on how to tackle the practical-technical problems. Scales and etudes have to be practiced again and again over many years. But even mastering tricky and difficult exercises is no guarantee of becoming a great musician. Many factors are, however, more difficult to prescribe in details, for example modulations and articulations of tone sequences, timbre, and intentional variations of tempo that all contribute to the essential emotional feeling. But these factors contribute strongly to the excellence of the individual performing artist.

The chapters of this book deal much with the nevertheless essential physiological mechanisms and technical rules of the musician's performance—Salieri's contribution in Pushkin's sketch! A number of chapters provide new knowledge on the extraordinary execution of complex, slow and fast movements on the musician's instrument, or vocal cords, and about the integration of performance with the auditory return. Our choice to emphasize motor performance was motivated by the fact that technology for efficient measurement of biomechanical, auditory, and neural representations of music performance has recently become available. Chapters on timing and rhythm, important ingredients of music performance, are also included. The selected body segments, notably hand,

fingers, and airway effectors, have to be coordinated in complex synergistic actions, often also with different temporal constraints between the two limbs. Virtuoso music requires incredibly high speeds, particularly of finger movements. The multiple spatial–temporal selection of effectors acting on the various instruments have their physical and physiological constraints that the brain has to deal with. In turn, auditory feedback is also transmitted to the brain after a short delay. Thus, two major streams (motor and sensory) are running almost in parallel.

We are now in the era of brain imaging, the great challenge being to learn about representational 'hot spots' of music, i.e. the locations and constellations of activated neuronal assemblies during passive listening to music as well as during its (more difficult!) execution. It has become clear that *modules* are variably activated as interconnected neural networks—there is no single large centre for music in the brain.

Professional musicians play for thousands of hours during their lives. Unfortunately, as a result of overuse, musicians may develop various pathologies such as musician's finger cramps (hand dystonia). Health problems in performing artists ('Apollo's curse') are not rare and may tragically end a musician's career. Fortunately, new insights into pathophysiology shed light on the cause of musician's cramp. Mapping studies have revealed brain representations of the effectors involved (notably fingers) that tend to be less discretely delimited compared with the normal situation. As a consequence the independent use of effectors, like two fingers, is disturbed or lost. Medical therapies and novel approaches to retraining over prolonged periods have led to improvements. Examples of remarkably increased cortical representations in professional musicians have been observed. This plasticity depends on the behavioural use: there is an ongoing give and take! Brain plasticity in professional musicians appears to be outstanding, probably because the specific effectors, like the fingers, are used on a daily basis and often for hours to control the sounds of the music instrument.

We thank Oxford University Press and the contributing authors for this publication. Most of the chapters are based on an international conference that took place on the Monte Verità, Ascona, Switzerland, which was organized by Mario Wiesendanger with the help of Eckart Altenmüller and Jürg Kesselring. Our thanks go to the Foundation Stefano Franscini of the Eidgenössische Technischen Hochschule, Zürich, Switzerland.

Part1

History

Chapter 1

Historical increases in expert music performance skills: optimizing instruments, playing techniques, and training*

Andreas C. Lehmann

Introduction

Throughout history, some human achievements have gone beyond what contemporaries considered possible at the time and have changed our cultural heritage forever, often in a revolutionary fashion. Adult soloists and especially child prodigies surprise—'*surprenieren*' as the term was in Mozart's time—their audiences by their musical wizardry. There is no doubt that musical performance features among the most comprehensive cultural practices. The seemingly effortless display of star pianists, singers, violinists, rock guitarists, and percussionists cloaks the fact that the skills involved rank among the most exacting that the human brain and body is capable of.

Experts in all domains have to acquire certain skills; they need incentives to acquire those and subsequently make creative contributions to the domain. For example, the desire to overcome previous performance limitations or to compete successfully with other musicians will motivate individuals to search for new solutions to technical problems. In the quest for these solutions, they may take advantage of changing circumstances that offer possibilities which were hitherto unknown. We can assume that a field such as music tends to stimulate ever higher and more complex levels of performance as long as there are incentives for performers to be drawn into the business. Incentives to choose a domain such as music are, as Csikszentmihalyi (1996) points out, strongly related to the possibility of earning a living.

* This chapter is based in part on Lehmann A.C. and Ericsson K.A. (1998). The historical development of domains of expertise: performance standards and innovations in music. In: A. Steptoe (ed.) *Genius and the mind: studies of creativity and temperament in the historical record*, pp. 64–97. Oxford University Press, Oxford.

In the twentieth century many philosophers and scientists discussed the issue of progress in Western civilization (e.g. Nisbet 1980). Although everyone agrees that scientific and technological advances have led to higher productivity and affluence, there is considerable controversy about whether quality of life has improved as a result of these changes. Likewise, evaluative judgements about what type of performance or what type of music is more enjoyable to listeners in a given historical period cannot be made, as the aesthetic criteria are likely to differ across periods. It is therefore likely that technical artistry (virtuosity) is unrelated to the aesthetic enjoyment of a piece of music. Still, the ongoing musicological discussion attests to the problematic status of technical prowess in music, and recent physiological insights give rise to some concerns (see elsewhere in this volume).

In this chapter we propose that the skills of high-level performing musicians have gradually improved over the last three centuries—at least for instruments with possibilities for solos and for those in great demand. This is a result of the efforts of individual musicians to surpass their contemporaries. We first assess changes in public music performance across historical periods and contemplate the problem of objectively assessing the performance skills for past times. Aspects of performance are then identified that allow us to study musical performance objectively, irrespective of style or period. Another factor concerns the emergence of instrumental music for individual performers or soloists, which has allowed audiences to compare the performances of different artists. The next section discusses the increases in preparation and specialization over time that have led to the achievement of higher levels of performance. We then present the strong empirical evidence for our claim that the skills required of musicians have increased. In addition, we describe other mechanisms that allow musicians to excel, such as innovative playing techniques and improvements made to musical instruments. We go on to discuss the assimilation of these changes into a body of shared knowledge which has allowed later generations of performers to acquire superior techniques and thus surpass their predecessors. The final section summarizes and integrates our findings into a model of competition and increase of performance skills.

How can we assess skills retrospectively?

Our quantifying view of skill is new, but it is gaining increased attention in musicology because scholars are traditionally more concerned with the structure of composed music and the composers themselves than with the performers. On the contrary, the notion of increase in skill is obvious in sports, another domain in which motor performance is important. Achievements here have always been objectively recorded in terms of times, distances, or scores. New records have

naturally been accepted as temporary. An example from competitive swimming should make this obvious (see Fig. 1.1). When, in 1924, Johnny Weissmuller a.k.a. "Tarzan", was the first to swim the 100 m freestyle in less than 1 min, the media were frantic, and he earned himself a role in the first Tarzan movies. At the time women were far from reaching similar times. Forty years later, Dawn Fraser broke the 1-min time also, creating great excitement. Today, 1 min is a good amateur time, as a casual internet search will disclose. 'Higher' and 'faster' are clear objectives in sports, whereas in music the situation is much more complicated.

Since we lack sound recordings of musicians from previous centuries, the level of skilled performance of earlier musicians has to be inferred from other sources. Our analysis focuses on the piano and the time period over which it was developed. Similar analyses for more recent instruments (e.g. the saxophone in classical music, double bass in jazz music) where evidence from recordings can be used are currently under way and appear to confirm the results for the piano. For the piano we can assess the approximate levels of skill required for performance. Since historically most music was performed in public, we think it safe to assume that past musicians were able at least to play what was written down more or less accurately. Unfortunately, this type of inference is only appropriate for certain periods and musical cultures. In other periods, performers added extra-notational features such as ornaments, and the complexity and skill demands of such pieces are clearly underestimated by the notes that appear on the manuscript or printed page. Furthermore, published music may have been composed for execution by contemporary amateurs and may, therefore, hardly reflect the skills of professional musicians (see Küster (1993) for an insightful discussion). Although objective data about the expressive playing skills and artistic interpretations of past musicians are virtually impossible to obtain, the capacity of

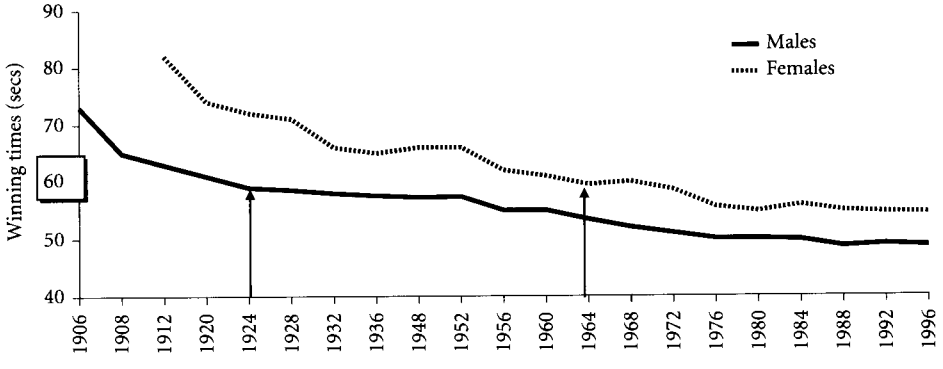

Fig. 1.1 Decreasing swimming times for the 100 m freestyle during the twentieth century (1924, Johnny Weissmuller; 1964, Dawn Fraser). The data show Oympic gold-medal-winning times.

instruments at any given historical time gives clues to the skills required for effective performance.

Reasons for historical increases in expert music performance over time

Despite numerous historical changes in performance conditions, the musician's job of performing music for the entertainment of the public has remained the same well-defined task. The most extreme situation is that of the solo performance. Although most of our examples here relate to traditional Western art music, it is plausible to assume that our model could also be modified to apply to jazz, popular music, or music of non-Western cultures.

The organization of society during a particular historical period will dictate in a rather unpredictable fashion how, where, and when music is made. The performance conditions for instrumental music have therefore undergone significant changes throughout history (e.g. Seaton 1991). At the risk of simplification, we can say that by gaining independence from singing, instrumental music has acknowledged its unique characteristics. Also, classical musicians have come more and more to play notated music that is not necessarily their own, relying less on their improvisational skills. Today, hardly any classically trained pianist improvises in public as did Ludwig van Beethoven or Franz Liszt. Expert musicians have to adapt to the performance conditions and task demands they encounter: it is within these limits that they strive to improve their performance.

Today, the situations that stimulate public performances of the greatest technical sophistication and involve the highest personal motivation are probably international competitions for pianists and violinists. Winning a prestigious competition is necessary for a career as an international soloist (Sosniak 1985), so these competitions are probably the best available objective measure of outstanding music performance today.

The biographies of famous performers attest to the fact that today's elite musicians spend months and years preparing and perfecting their performance of few pieces before they are presented at a competition or concert. In contrast, the preparation for a public performance was generally shorter in earlier times. Contemporary records indicate that many pieces were more or less sight-read by orchestral musicians: Beethoven's orchestral works, which were extremely difficult for the time, were premiered after only a few rehearsals by orchestras that included amateurs (Cook 1993; McVeigh 1993). Keyboard and other performers often relied on their improvisational skills when working from short-hand notation, most obviously in the seventeenth and eighteenth centuries

when the system of thorough-bass (harmonies being indicated by figures) was commonplace (Bailey 1992).

Because sight-reading or *ad hoc* improvisations are carried out under severe time constraints, performers may not be able to take full advantage of their technical and artistic prowess. By allowing more time for preparing an improvisation or rehearsing and memorizing notated music, a performance of higher quality with fewer mistakes, faster speeds, and greater technical difficulty becomes possible. Although there may be individual differences in the biomechanical dispositions and correlates of the many components involved in skilled performance, optimizing motor performance still requires excessive training (Kopiez, 2004). The axiom that public music-making can be improved through prior preparation is important because the audience cannot know how much preparation preceded a performance. A related point is the reduction of variability through preparation. Present-day audiences expect musicians to entertain them with performances of reproducible quality (maybe close to the CD recording available at the concert). Informal conversations with artists confirm this heightened expectation. Of course, we do not know what expectations audiences had in former times. However, reports dating from the early twentieth century about famous musicians such as Anton Rubinstein, Alfred Cortot, and Fritz Kreisler suggest that large day-to-day variability in performance was more acceptable than it is now (Dubal 1990; Elder 1993).

Today's performers seek out the best musical instruments that they can afford. Although to an untrained eye some instruments, such as the violin, look very similar to instruments used centuries ago, they have actually changed considerably (see, for example, Küster (1993) for examples regarding the horn, piano, and violin). Virtually all of the changes have involved increases in the instruments' capacity for changes in loudness (dynamics) and have tended to give the musician more flexibility and control when playing technically difficult passages. Over the last three centuries, the violin has been fitted with a chin and shoulder rest, a slightly longer neck, metal strings, and fine-tuners (Dilworth 1992). The extended possibilities of instruments, which will be documented later in this chapter for the piano, have led to more difficult playing techniques being possible.

There are at least two other significant differences between modern players and musicians of the past, namely specialization and training. During the last three centuries, the role of classical musicians has changed to allow them more time to develop their instrumental skills at the expense of other music-related skills they used to possess. Virtually all of today's elite performers specialize on a single instrument and perform a small number of rehearsed music pieces

(repertoire) for that instrument. In contrast, musicians in earlier historical periods usually played several different instruments (for example Wolfgang Amadeus Mozart performed his piano and violin concertos proficiently), they composed, and they taught. Furthermore, today's elite performers start their music training at an early age, often between the ages of 4 and 5. Highly experienced teachers design training programmes to allow these students to make maximum progress from the start (Sosniak 1985; Ericsson *et al.* 1993). In contrast, many musicians of earlier times acquired their initial music skills as apprentices at considerably older ages. Antonio Salieri, Mozart's contemporary, started in his teens, while Bach's students in Leipzig gained access to instrumental music instruction only after the age of 12 (Wolff *et al.* 1983). A recent analysis comparing Mozart to a sample of lesser known composers of the same age showed that the comparison group started training (not necessarily instrumental but vocal) at 6.8 years of age (Lehmann *et al.* 2002). But who had access to high-quality training? Explicit instruction and formal practice activities may have been more scarce than today. However, when appropriate instructional materials became available, scholars have noted an associated surprisingly rapid increase in level of performance (e.g. Woodfield (1984) for the viol and Baldauf-Berdes (1993) for singing).

Musical performance in a cultural context

The music that audiences have wished to hear and the physical location of performances have varied throughout history in response to changing philosophical ideas and social conditions (see Parakilas (2002) for examples regarding piano music, Salmen (1988) for the concert and Seaton (1991) for a general description). One of the foremost functions of music is the entertainment of an audience, and professional musicians have fulfilled this function differently in different times. For instance, in the Baroque period, music conveyed static emotional states (*Affekte*) using idiomatic ornamentations, figures, and phrases. Since the early Classical period, there has been an increase in the dramatic expressiveness of music that is paralleled by developments both in other arts and in philosophy. Improvements in instrument design have supported these trends. For example, in contrast to the harpsichord, the development of Cristofori's fortepiano allowed for variability in loudness and permitted increased expressivity (Komlos 1995). The need to amplify the soft guitar in twentieth-century jazz in larger ensembles that included brass instruments led to the invention of the electric guitar (and its virtuoso player). Thus, public music performance has changed as a function of preferred styles and playing conditions, and successful musicians have adapted to the demands of their times.

The majority of musicians accompany others most of the time, but more exposure is gained in solos. Over time, many instruments have developed a solo function (a good recent example is the viola). Every musical culture has its own way of selecting and allowing certain individuals to march to the forefront and display themselves. Soloists sometimes show off their skills, and on many occasions virtuosi have been accused of devaluing their performances for the purpose of self-enhancement (Baillot 1835/1991; Rowland-Jones, 1992). We will not delve into a musicological or aesthetic discussion on the pros and cons of the virtuosos—the fact is that they exist.

Competition among musicians or 'who is the best?'

Whenever employers or audiences are provided with choices among performing musicians, they will select the one who is viewed as better or has the better reputation. Therefore, in order to make a living, musicians have to compete with each other to attract audiences, fame, and patronage. The situation is even more dramatic in rock and popular music than it is in classical music. As a result, local musicians may not always be the first choice, and musicians from distant cultural centres may be favoured (think of the globalization and dominance of English-language popular music). In former times, the opportunities for such comparisons arose when musicians began to travel with nobility, or when musicians migrated in search of work. Such was the case in the fifteenth century when German musicians were sought after in Italy because of their superior skills (Polk 1994). Once they had taught their new skills to local musicians, their stranglehold on employment decreased and the 'importation' of musicians was no longer the norm (Polk 1991). Conversely, aspiring musicians, including the young Mozart, travelled to places with advanced musical cultures, such as Italy, to work with eminent musicians and learn new styles.

Musicians of different periods in history are known to have tried to outperform each other in veritable 'playoffs' (i.e. like Eurovision song contests but actually involving skills). The evidence is anecdotal and therefore not always reliable, but its mere existence is certainly telling. Here are some 'piano finals': Liszt versus Thalberg (Walker 1990), Mozart versus Clementi (Komlos 1995), Handel versus Scarlatti (Blume 1956), Beethoven versus Gelinek, and Bach versus Marchand (questionable; Breig 1998). Even today, jazz players continue to engage in friendly 'cutting contests' (Berliner 1994). Thus, despite the fact that there are aspects of musical performance difficult to evaluate objectively, playing in public is partly an exhibition of skills in which musicians compete for their audiences and for the respect of their peers.

At all times there have been members of the audience who could judge the performance. Today, through widespread musical training and the availability of

recordings, many concert-goers have attained a considerable level of (listening and) playing skills themselves, especially on solo instruments such as the piano and the violin. Along with their appreciation for the highest levels of music performance audiences have gained a greater ability to detect imperfections. This effect is increased through a strong canonization of the repertoire. Listening to recordings by the world's foremost musicians on high-fidelity stereo systems creates high expectations for the concert soloist—a problem that earlier musicians certainly encountered to a lesser degree.

Specialization and deliberate practice

Although specialization is a powerful instrument for increasing performance, it can also narrow the range of possible performances, thus changing the domain. Using keyboard players as an example, we will illustrate this process of professional specialization, which, incidentally, can also be observed in other domains of expertise such as science and sport (Ericsson and Charness 1994; Ericsson 1996). Beginning in the Middle Ages and continuing during the Baroque period, most musicians were relatively diversified. J. S. Bach, for example, was a composer, performer, music director, improviser, music teacher, and Latin teacher. As a rule, instrumentalists of the past were able to perform on more than one instrument in public, and keyboard players customarily played all possible instruments including the organ, harpsichord, and clavichord (e.g. Bowers 1992). Initially, music for keyboards was interchangeable, but during the seventeenth century composers started taking advantage of the specific characteristics of each individual instrument (Komlos 1995). During the Classical period, musicians such as the pianist Muzio Clementi started to specialize in public performances on a single instrument. As musicians specializing on single instruments, their careers also became more focused. By the beginning of the twentieth century, most pianists had completely specialized in the performance of the standard repertoire. Others, such as Carl Czerny, concentrated exclusively on teaching. With an emphasis on memorized performance, sight-reading in public declined, and opportunities for playing less rehearsed music became restricted to pianists who specialized in accompanying (coaching, chamber music, ballet). Some twentieth-century performers even specialized in one particular era or a limited number of composers, or became known for their interpretation of individual works (e.g. Vladimir Horowitz for Rachmaninov's Third Piano Concerto). Similar trends toward specialization can be observed in performers of orchestral instruments, such as the flute and violin (Bowers 1992; McVeigh 1993).

Why does specialization work? In general, training is limited by the starting age for a particular historical period and by the age at which the individual enters

the profession. Furthermore, higher levels of performance in several domains have been related to larger amounts of lifetime practice (see Ericsson and Lehmann (1996) for a review). Therefore, when future performers devote all their training exclusively to those aspects of their task that are most desired (marketable?), they should attain a higher final level of skill; alas, often at the expense of other skills. Not only are the years of training limited but also the amount of concentrated practice that can be sustained over extended periods of time, which appears to be limited to 4 or 5 hours a day for adults. As a result, today, by the age of 20, the most promising musicians have engaged in over 10,000 hours of deliberate practice (Ericsson *et al.* 1993). Attempts to maintain practice beyond this optimal limit may lead to overuse injuries and burnout, making it less likely that the musician will reach and maintain the required level. Although it might be tempting to think that earlier musicians simply worked longer and harder or had fewer distractions than today's musicians, the explanation above should dispense with this thought: today's music students practice at the limit of what is possible (often beyond!).

Empirical evidence for changes in performance expertise

At this point it is necessary to present empirical evidence for the increase in performance expertise in piano music (see Lehmann and Ericsson 1998*a*). Music teachers are frequently faced with the problem of assessing the difficulty of particular pieces they assign to their students. Therefore, experienced educators have devised repertoire lists that contain complexity ratings for specific pieces (e.g. the Syllabi of the Toronto Conservatory or the Associated Board Examinations) and that extensively cover the common repertoire for the instrument.

Depending on the intended starting age and duration of instruction, the different educational plans contain between 10 and 15 grades. The criteria applied by music experts for grading music are not explicitly stated and are most likely based on their experience as performers and teachers. Technical problems, such as speed, seem to be important criteria. For example, the demands on playing speed for scales increase from less than 150 notes per minute at level 1 to over 500 notes per minute at level 11 (Piano Syllabus, 1986). Interpretational complexity may also play a role, but there is less indication as to how this type of complexity is assessed. In a recent diary study with an advanced pianist who was preparing for a public performance, we found that complexity ratings for a given set of pieces correlated 0.71 ($P < 0.05$) with the accumulated practice time for these same pieces (Lehmann and Ericsson 1998*b*). Since the correlation between lists is also large ($r > 0.8$), one is tempted to view them as a useful source of data on the complexity of pieces. By choosing a modern perception of performance

complexity as the standard for cross-historical comparisons, we cannot capture additional technical difficulties that stemmed from performance practices in the past. However, we can analyse the difficulty that pieces from different times would pose for today's performers and determine when in history the more difficult techniques (by today's standards) were invented and introduced. We will now exemplify our procedure using the piano.

We assembled complexity ratings by Clementi, Haydn, Mozart, Beethoven, and Schubert for sonatas known to most amateur piano players, spanning roughly 100 years starting from 1750. We found a significant correlation between compositional dates and complexity ratings (from Pierce and Fuszek 1987) of $r = 0.68$ ($P < 0.01$) which shows that piano sonatas became more technically difficult over time. Further validation for our statistical results comes from the comments of the composers themselves. Joseph Haydn, for instance, realized that his piano sonatas were becoming increasingly difficult as he grew older (Rosenblum 1988). Interestingly, analysing only Haydn's sonatas confirms this statement from today's perspective ($r = 0.58$, $P < 0.01$, shown in Fig. 1.2). Similar analysis could probably be done with other genres and instruments. Our present results allow us to infer that the pianistic skills necessary to perform sonatas and other pieces must have increased.

Based on the above-mentioned educational plans, it is also possible to infer the difficulty of particular playing techniques by the grade level at which they are introduced. For a number of these techniques there is an approximate historical date at which they were invented and included in compositions. Some techniques are, of course, linked to the development of the instrument, while others emerged after the instrument had reached its modern form. Not surprisingly, dynamic change, which was impossible on the harpsichord, is taught to piano students from the very beginning of instruction. The complexity of the left hand

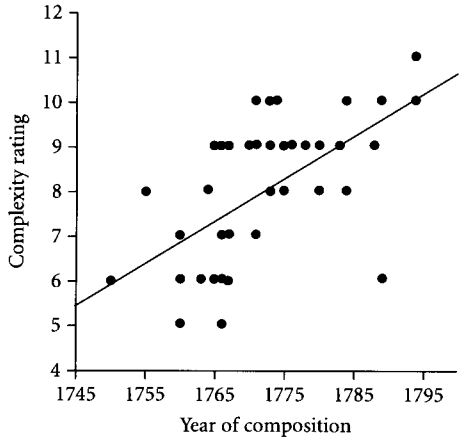

Fig. 1.2 Increase in technical complexity (from Pierce and Fuszek 1987) in the piano sonatas by Joseph Haydn.

of Mozart's (1756–1792) works has increased compared with previous works by Haydn (1732–1809) (Wier 1940). And starting with Czerny's (1791–1857) studies for the left hand a whole range of extremely difficult left-hand repertoire has been composed (e.g. by Ravel (1875–1937)), some of which was specially dedicated to the pianist Paul Wittgenstein who returned from World War I without his right arm. We cannot rule out that in some cases of practicing the non-dominant hand (oftentimes the left hand) extensively, and in combination with a disposition for decreased lateralisation, unexpectedly large increases in performance may be possible (Kopiez and Galley, in press). Alas, not much is known about the handedness and lateralisation of famous left-hand injured performers (e.g., Scrijabin, Brahms, most recently Rebstein). The standard fingering for double octave scales, codified by Johann Cramer (1771–1858), appears at level 7. Scales in double thirds and sixths, which appear at level 12 or higher, became necessary for the works of the nineteenth-century virtuosi. The modern use of the damper pedal was introduced by John Field around 1800, and very complex pedalling is necessary to perform the music of our times. In summary, the playing techniques that require more training for modern music students were introduced later in history. This finding is one of the strongest pieces of evidence for our claim that the technical mastery of musicians has increased over time.

Why has complexity increased over time?

Complexity has increased over time because musical instruments have been optimized, new and innovative playing techniques have been developed by leading performers, and music training has been made more widely accessible and efficient (see Lehmann and Ericsson (1998*a*) for additional details). Essentially, at this point research into expert performance intersects with research into creativity and motivation. We assume that elite experts want to contribute to their domain in creative ways by perfecting existing art or changing the domain (see Gardner 1997), and these elite experts can be found among the instrument makers as well as among the performers, composers, and teachers.

Increases in skill occur when individual elite performers go beyond the existing strictures and invent new techniques that make the most efficient use of instrumental capabilities. The success of instrument makers depends on their ability to produce superior musical instruments and to win endorsement of their instruments by famous performers. Admittedly, changes in instrument design involve trade-offs, as certain sound effects, nuances, and playing techniques are replaced by new ones (Baines 1992). The number of keys on the piano, for example, has nearly doubled since its invention. In the course of its development, the piano increased in dynamic (loudness) range, obtained the possibility of extremely fast repetition of notes, and gained many additional notes in the high

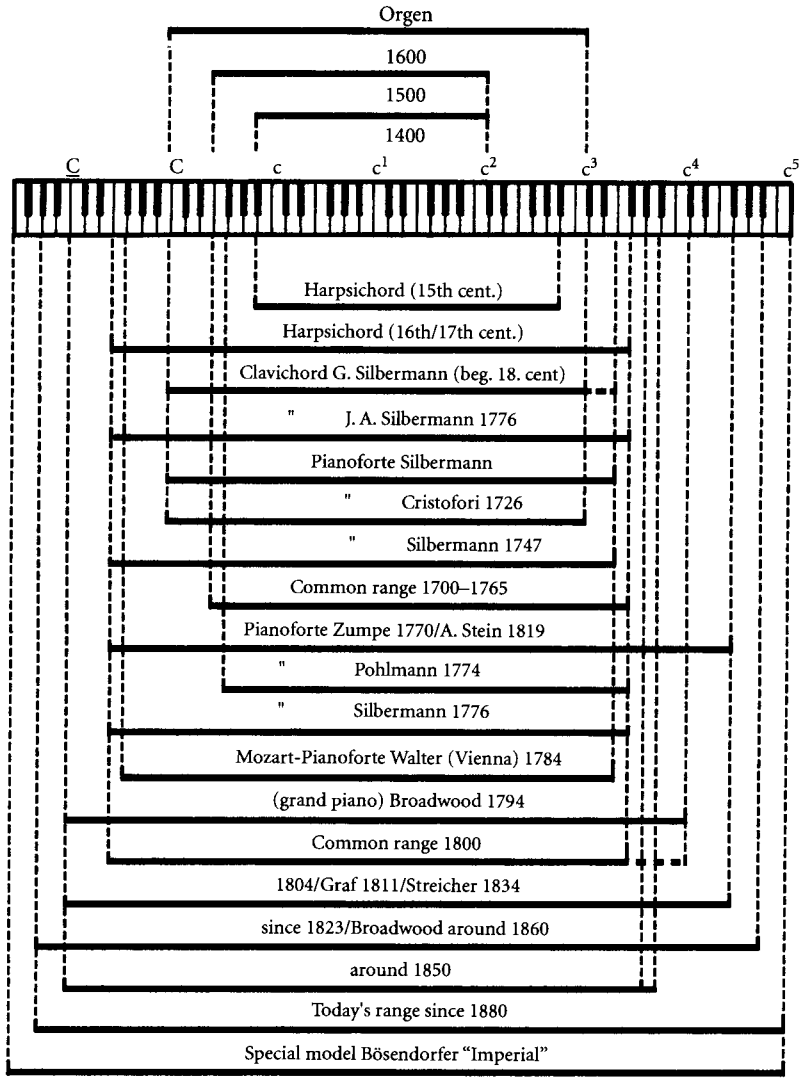

Fig. 1.3 Tonal ranges for different pianos (keyboard instruments) have increased over time from 4 octaves (48 notes) to 7.5 octaves (95 notes). (From Philip 2003, p. 764). Adapted with kind permission from G. Phillip (2003), Klavierspiel und Improvisation, Altenburg: Kamprad, p. 274 (Fig. 130).

and low register (see Marcuse (1964) for details; Fig. 1.3). An increase in tonal range over time is frequently found in the history of instruments. Very often performers and composers collaborate on such improvements. Successful mastery of the increased tonal range required the playing of larger horizontal leaps, and the dexterity to cover a broad span with scales and patterns (arpeggios) despite sometimes awkward hand positions or even hand crossings, while at the same time keeping control over shades of loudness.

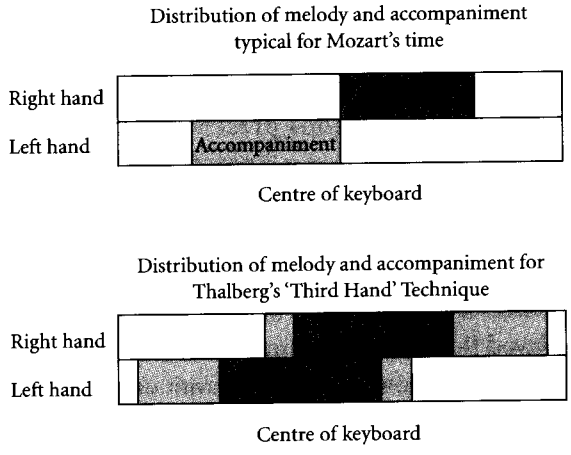

Fig. 1.4 Mapping of hands and dynamics to the keyboard layout for Mozart's time (top) and for Thalberg's 'third hand' technique (bottom). The horizontal range of the keyboard is shown schematically from above. The centre of the keyboard suggests middle C.

During many periods of musical history, virtuoso players have made creative contributions by incorporating their personal playing experiences and styles into their written compositions. Wolfgang Amadeus Mozart was known for his agile left hand and is said to have increased the complexity of the left hand in his compositions. Frederic Chopin's style took into account ergonomic factors related to the location of the black and white keys, and his music is consequently full of black keys, or accidentals. One specific technique, sometimes referred to as 'third hand' impression, was developed by the pianist Sigismund Thalberg in the 1830s (Hitchcock 1971). Instead of playing the melody with one hand, and the accompaniment with the other, the melody notes are distributed between hands in the middle of the keyboard, while the accompaniment is played by both hands to the left and right of the melody (see Fig. 1.4). This advanced technique destroys the classical mapping of hands onto the keyboard (right hand = melody, left hand = accompaniment). Maintaining a dynamic difference between the melody (louder) and the accompaniment (softer) on one keyboard, often within one hand, imposes great skill requirements on the performer.

New playing techniques and possibilities also emerge from the interaction between performers and composers. Composers have at all times sought to incorporate the most advanced contemporary skills into their works and have consulted with elite musicians to identify the full range of possibilities of particular instruments. The following examples derive from several centuries: Vivaldi is known to have tailored his compositions to the particular strengths of his soloists in eighteenth-century Venice (Baldauf-Berdes 1993); Bach consulted with some of the finest flute players of his time (Powell and Lasocki 1995); Mozart worked with the oboe virtuoso Ramm and the clarinetist Anton Stadler (Haynes 1992); Beethoven consulted the double bass virtuoso Dragonetti (Blume 1954, vol. 3,

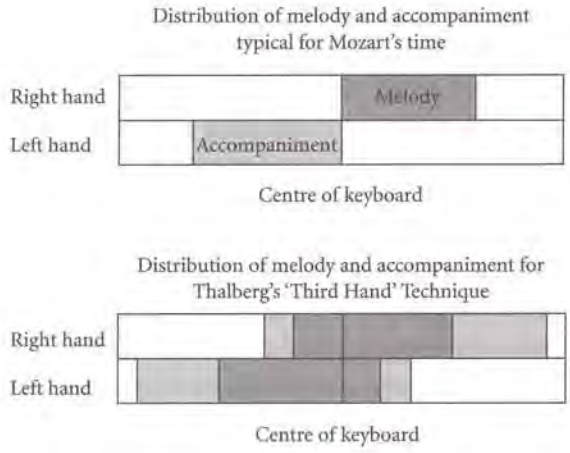

Fig. 1.4 Mapping of hands and dynamics to the keyboard layout for Mozart's time (top) and for Thalberg's 'third hand' technique (bottom). The horizontal range of the keyboard is shown schematically from above. The centre of the keyboard suggests middle C.

During many periods of musical history, virtuoso players have made creative contributions by incorporating their personal playing experiences and styles into their written compositions. Wolfgang Amadeus Mozart was known for his agile left hand and is said to have increased the complexity of the left hand in his compositions. Frederic Chopin's style took into account ergonomic factors related to the location of the black and white keys, and his music is consequently full of black keys, or accidentals. One specific technique, sometimes referred to as 'third hand' impression, was developed by the pianist Sigismund Thalberg in the 1830s (Hitchcock 1971). Instead of playing the melody with one hand, and the accompaniment with the other, the melody notes are distributed between hands in the middle of the keyboard, while the accompaniment is played by both hands to the left and right of the melody (see Fig. 1.4). This advanced technique destroys the classical mapping of hands onto the keyboard (right hand = melody, left hand = accompaniment). Maintaining a dynamic difference between the melody (louder) and the accompaniment (softer) on one keyboard, often within one hand, imposes great skill requirements on the performer.

New playing techniques and possibilities also emerge from the interaction between performers and composers. Composers have at all times sought to incorporate the most advanced contemporary skills into their works and have consulted with elite musicians to identify the full range of possibilities of particular instruments. The following examples derive from several centuries: Vivaldi is known to have tailored his compositions to the particular strengths of his soloists in eighteenth-century Venice (Baldauf-Berdes 1993); Bach consulted with some of the finest flute players of his time (Powell and Lasocki 1995); Mozart worked with the oboe virtuoso Ramm and the clarinetist Anton Stadler (Haynes 1992); Beethoven consulted the double bass virtuoso Dragonetti (Blume 1954, vol. 3,

p. 739), and from the piano virtuoso Steibelt he probably borrowed the special pianistic effect of rapid alteration between two notes (Stillings 1972); and Haydn worked with the cellist Kraft (Loesch 1992). Because composers work with the leading performers, the resulting compositions present difficulties during rehearsal and performance for lesser musicians (e.g. known examples arise from Richard Wagner's scores). Today these orchestral parts are standard fare for instrumentalists. Furthermore, there are numerous anecdotes for virtually all instruments about works that were regarded as unplayable at the time of their composition. Virtuoso performers impressed their audiences by playing exactly those works, e.g. when Liszt played Beethoven's Hammerklavier sonata.

Other innovations result from adaptations of methods from one instrument to another. For example, seventeenth-century texts suggest that expert singers and instrumentalists imitated each others' techniques and ornamentation (Brown 1976). In the fifteenth century, the organist Conrad Paumann transferred the playing of several simultaneous voices (polyphonic playing) from the keyboard to the lute (Polk 1994). Sigismund Thalberg's 'third hand' technique was inspired by the English harpist Parish-Alvars (Walker 1990), while Niccolo Paganini is known to have transferred his extensive knowledge of the guitar to the violin. Liszt in turn attempted to transfer Paganini's virtuoso violin technique to the piano. Modern bassoonists and oboists use a breathing technique (circular or continuous breathing) originally also used by players of the Australian didgeridoo. The jazz artist Bobby McFerrin vocally imitates every instrument. Transferred techniques are extremely taxing because they are likely to violate some standard ergonomic constraints of the instrument, thus adding to the level of difficulty.

The increased complexity of music performance at the highest levels has implications for training musicians because it forces music teachers to find ways to facilitate (accelerate) the acquisition of new techniques. Although detailed historical records of the relationship between instruction and levels of performance are virtually non-existent, child prodigies offer the possibility to look at individuals who are maximally immersed in learning and performing music. We can therefore compare the change in the rate at which piano playing prodigies have attained certain levels of skill in musical performance and find out if the acquisition of skills has accelerated over time. For this analysis, we have listed solo pieces played by child prodigies and the ages at which they performed these pieces in public. The musician had to be under age 13 at the time of performance to qualify as a child prodigy. Our sample is hardly random, but consists of some of the best known keyboard prodigies from Johann Sebastian Bach (born 1671) onwards. After finding the earliest public performance known for each individual, we assessed the difficulty level of the piece that was performed by looking it (or a comparable piece) up in the standard lists of graded repertoire mentioned

earlier. We then computed an index by dividing the number of years of study necessary to master the piece of music today by the actual number of years of study the prodigy had received prior to playing the piece in public. This fraction was then multiplied by 100. For example, if a modern-day student played Schubert's Moments Musicaux (rated level 7 by Pierce and Fuszek, 1987) after 7 years of instruction, this student would receive a score of 100 [(7/7) × 100]. If another student performed the same pieces after only 3.5 years of instruction, a score of 200 would result [(7/3.5) × 100]. Thus, the precocity of performers of the past relative to today's standards is tangible in numbers exceeding 100. In fact, there is a significant tendency for prodigies of later generations to play more difficult pieces after shorter periods of training than did earlier prodigies ($r = 0.67$, $P < 0.05$; see Fig. 1.5, filled squares). This index reflects an acceleration of acquisition of skills once training is initiated.

A second index was then computed to look at the age when certain pieces were performed. This was done by dividing the projected age of performance from modern curricula by the age at which a given prodigy actually performed the piece. Again, we find a significant correlation ($r = 0.85$, $P < 0.01$; see Fig. 1.5, open circles) demonstrating that by today's standards, more recent prodigies have been more advanced in their performance skills than prodigies from earlier times. But given that the difficulty of music in the repertoire has also increased over time, it is possible that the relationship we observed is merely due to more recent prodigies playing music that was unavailable to earlier generations. However, even after statistically controlling for the level of difficulty of the performed piece, we found that precociousness has increased reliably over time. The empirical evidence presented here is endorsed by a host of anecdotes that

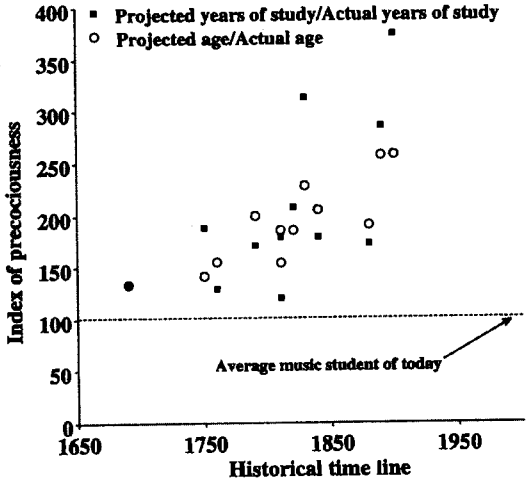

Fig. 1.5 Evidence for accelerated skill acquistion of 12 piano prodigies (J. S. Bach, W. A. Mozart, M. A. Mozart (Nannerl), C. Czerny, F. Mendelssohn, F. Liszt, Artur Rubinstein, Anton Rubinstein, C. Saint-Saens, E. Nyiregyhazi, J. Hofmann).

point to an increase in performance skills over time (e.g. McVeigh 1993, p. 221; cf. Lehmann and Ericsson (1998*a*) for extensive references). Recent media reports on young Chinese pianists suggest that this historical trend is unbroken.

Although we have carefully searched for contradictory evidence stating declines in skill, we have only been able to locate anecdotal evidence of a decline in florid singing skills (Henderson 1921), in improvisation (Donington 1963), and in sight-reading skills. But we have not found any examples contradicting the increase in technical proficiency of the performance of rehearsed music.

The factors that contribute to optimized training are manifold (see Lehmann and Ericsson (1998*a*) for details) and include the installation of systematic instruction which is often assisted by didactic materials (method books; e.g. Türk 1982). These manuals are generally written by the foremost music educators of their time, but once they are published, they can be used even by mediocre teachers to train large numbers of music students. Moreover, better performers receive lessons with fewer and more qualified teachers than less good performers (see Sosniak (1985) and Howe and Sloboda (1991) for modern-day examples), usually preferring individual over group instruction (Lehmann *et al.* (2002) for Mozart's time). It also appears that for young performers, external monitoring in the form of supervised practice is necessary (see Lehmann 1997, for historical prodigies, Davidson *et al.* (1996) for modern-day music students and Frederickson (1995) for a famous contemporary example). Ericsson *et al.* (1993) have suggested that an earlier start in training leads to higher performance at younger ages. Winning a competition or having a debut at a young age is likely to result in extra resources and access to the foremost teachers. Some modern-day teachers encourage earlier starting ages, and these are facilitated by instrument-makers who provide child-sized instruments (even Wolfgang Amadeus Mozart is known to have used a small violin as a child). For instance, Edler-Busch (1993) suggests that improvements in flute construction in the nineteenth century allowed for a younger starting age than was previously customary, while today adding a curved head-joint may reduce starting age even further (Rainey 1985). These ergonomic adaptations also enable longer practice and playing times, especially for children.

Summary and discussion

Many aspects of playing music in public have changed dramatically over the past several centuries. The repertoire has increased substantially through the steady accumulation of compositions, and—at least for the piano—the upper end of more recent compositions tends to be more complex and technically challenging than that of older ones. These increases have been attributed to improvements in instrumental design and to innovations and advances in performance technique.

Concurrently, the increased time spent preparing for performances, coupled with growing professional specialization, have given the performer the opportunity to master more complex pieces of music. Finally, the optimization of training has allowed young pianists to attain the high level of skills necessary for modern virtuosi. Ever increasing standards continue to determine the limits of adult performance until they too are surpassed. New standards and achievements are assimilated into education and training, allowing future musicians to match and to surpass the previously final level of high-quality performance.

At any given time in history, a small number of performers achieve the highest levels of adult skills for that era. We have looked at the performance of rehearsed music for the piano, but similar analyses could be done for any other instrument, such as the classical violin, or for improvisational skills in jazz, or for instrumental performance in rock music. Although one would have to look at different historical time spans, all would lead to similar conclusions. Using recordings it is now even possible to assess whether expert performers of primarily orally transmitted performance practices in jazz, non-Western music, or popular music have become more skilled, thereby broadening the scope of our claims (such work is currently under way).

To clarify again, this analysis is not meant to make any evaluative statements about the aesthetic achievements and importance of specific musical compositions. Regarding the expressive aspects of music performance, we follow Gerig (1974) and Ferrucio Busoni (1968) who argued that complete mastery of technical problems is a prerequisite for the production of expressive interpretations. Although beautiful music can be rendered with little virtuosity, musical performance undeniably allows for competitiveness and athleticism that has been a constant source of controversy among practitioners and aestheticians alike, an issue which is beyond the scope of this chapter.

We can speculate that the motor behind the increase in expert performance is the motivation of individuals to receive rewards and recognition (e.g. commercial success, media attention, filled concert halls). Eminent performers of their time will distinguish themselves by fully exploring the instrument's capacities, or by surpassing existing skills in creative ways. Eventually, these achievements are taught to others by the performers themselves or by specialized pedagogues. Teachers are eager to transmit new techniques because their reputations rest on the students who reach the highest levels of performance. Similarly, students will strive to display the greatest possible skills compared with their peers, so as to gain access to the best available teachers and resources. Ultimately, the implementation of new techniques through instruction leads the entire community of elite musical performers to a higher level of music performance skill. For many performance traditions, instruments, and repertoires of written music, the

historical developments have started to asymptote (like in many athletic events, see Fig. 1.1). This is understandable, since ever-decreasing returns require exponentially augmenting efforts during training, and given a highly optimized training situation there is simply not much room for further improvement. Moreover, for some instruments, certain physiological limits are starting to loom large (cf. Elbert *et al.* 1998; Münte *et al.* 2002; Kopiez 2004). Still, considering the unpredictable nature of past achievements in musical performance, it is reasonable to assume that as long as society offers appropriate incentives and elite performers and musical clowns keep striving to surpass the achievements of current and past masters, creative innovations will never cease to be made. Our guess would be that even physiological limits may stimulate even more creative solutions—in music as they would in other domains such as science and sports.

Part 2

Psychology

Chapter 2

From cognition to action

Lutz Jäncke

Musical abilities are traditionally linked to various cognitive fields like attention, memory, or visuospatial functions. In this context it is often argued that there is a kind of positive transfer between musical performance and the above-mentioned cognitions. In this chapter recent studies exploring the relationship between general cognitions and musical skills in musicians and non-musicians are reviewed. It will be shown that there are intimate links between musical ability and various cognitions including perception, sight-reading, memory, action planning and organizing, attention, and visuospatial functions. We will also discuss whether music might have an impact on the development of intellectual functions.

Introduction

In Western culture musical expertise and performance has traditionally been associated with various so-called non-musical cognitions (e.g. memory and attention or even intelligence). In former times it was conjectured that musicians are musically gifted because of a different cognitive structure (and the underlying cortical organization supporting these cognitive functions) furnishing them with extraordinary musical performance. Other lines of theory and evidence have proposed that the cognitive structure of musicians undergoes substantial changes due to the intensive musical training required to become a musician. This latter approach has attracted much interest within the last two decades because of its potential implications for education. Recently, it has also been debated that the presumed positive effect of musical performance on cognition (and thus, intelligence) could be exploited in neuropsychological therapies. Although the above-mentioned associations between cognition and musical expertise have received much attention, especially in the lay press, there are astonishingly few substantial scientific publications addressing this topic. In the following we will describe and discuss scientific findings which may help to elucidate the potential relationship between cognition and musical performance.

There is no doubt that specific cognitive and motor skills are required to perform music. For example, playing a musical instrument makes it necessary to

program, execute, and sequence various movements. In case of performing music from a musical score it is necessary to read printed music, which is different from reading letters. Thus, it is necessary to understand particular notes and to translate these visual forms into appropriate motor commands, usually very rapidly. If the musician is only reading the musical score without performing it (for example in a situation when s/he is composing musical pieces) s/he reads the score and transforms the notes into auditory representations which help them to imagine how the musical piece will sound. Another issue which emphasizes the multitude of cognitive functions associated with performing music is the fact that musicians often learn to play a musical piece by heart, thus relying strongly on memory functions. Finally, learning to play a musical instrument requires attention, concentration, discipline, and motivation. Although this short summary emphasizes the specific cognitive functions necessary to perform music, relatively little scientific work has been published on this topic. In the following we will focus on the particular cognitive functions believed to be strongly associated with musical expertise. We will first describe cognitive functions that are closely related to musical expertise (sight-reading, memory for retrieving musical information, auditory attention, and auditory perception), and will also discuss those so-called non-musical skills which are thought to be indirectly related to musical expertise.

Perception

For non-musicians, hearing of music is mostly associated with strong emotional reactions (pleasure and aesthetic feelings, but also negative emotions in situations where music is not appropriate). However, music can automatically evoke motor actions, even in non-musicians. The most obvious example is dancing or swaying to music. Thus, there must be a strong link between perception and action. For skilled musicians this sensorimotor association is very important. For example, playing music in an orchestra requires continuous ongoing adaptation and comparison of one's own performance with the auditory templates from the rest of the orchestra (feedback control). The musician has to play with the appropriate sound quality, register, rhythm, or tempo. In the case of composing, it is necessary to play a short musical phrase, evaluate the generated sound pattern by ear, and then put it on record by writing it up in musical notation.

From studies of human brain lesions and brain imaging it is known that specific brain structures specialize in analysing pitch, timbre, and contour relations, as well as musical timing and rhythm (Peretz and Zatorre, 2004). Most of these neural networks are functional in non-musicians, suggesting that these structures have evolved in the human brain independently of intensive training

or musical experience (for a summary see Münte *et al.* 2002). However, several studies have shown that these structures can be shaped by musical experience. For example, the timbre of a particular note (overtone structure) is differently processed in musicians and non-musicians. This has been shown in a number of behavioural experiments in which musicians and non-musicians had to decide which of two tones were similar or different in terms of pitch. If the pitch of the two tones remained the same but the timbre varied (e.g. a guitar tone versus a piano tone), non-musicians made significantly more errors than musicians. In one study there was even a strong correlation between accuracy of discrimination and performance in pitch–timbre discrimination ($r = 0.66$), indicating that musicians use pitch information to a greater extent than non-musicians (Pitt and Crowder 1992). Beal (1985) tested musically trained and untrained subjects on their ability to discriminate changes in timbre. Akin to the aforementioned experiment, Beal found that discrimination accuracy was almost perfect (98%) when timbre and pitch information remained constant. However, when pitch and timbre information varied (e.g. comparing tones of similar pitch but different timbres; guitar versus piano) the performance of the non-musicians dropped substantially; they were half as accurate as musicians. Pitt and Crowder made the claim that timbre information, and not pitch, is the more salient dimension for non-musicians because timbre delivers more relevant information about environmental events. However, analysis of pitch should therefore require more formal musical training. Thus, in non-musicians differences in timbre between two tones should be distracting even if the pitches are identical, causing problems with pitch discrimination.

Recent brain imaging studies have revealed that timbre processing is different in the auditory cortex depending on the familiarity of the presented tone. Specifically, it has been demonstrated that auditory cortical representations of tones of different timbre (violin and trumpet) are enhanced compared with sine wave tones in violinists and trumpeters, preferentially when they hear timbre tones of their own instrument (Pantev *et al.* 2001). These findings suggest that experience-dependent plasticity optimizes the auditory system in musicians.

While the above-cited experiments describe a characteristic formation and specialization of a musician's auditory system for processing timbre and pitch, another principle of learning is associated with the improved cognition of musicians. From the standpoint of cognitive psychology, optimization of musical perception is associated with the processing of larger perceptual chunks on lower processing levels with less processing capacity. Thus, during the course of musical training musical perception is optimized by making many steps more automatic. It has recently been shown that perception of pitch contour and

interval deviations in simple melodies is associated with a marked event-related brain response, termed mismatch negativity (MMN), which reflects automatic processing of incoming stimuli in skilled musicians. Thus it is suggested that musical training enhances the ability to automatically register abstract changes in the relative pitch structure of melodies (van Zuijen *et al.* 2004).

Besides improved musical perception, musicians also show some kind of changed memory processes for recognizing familiar tunes. This has recently been examined in an elegant experiment published by Bella *et al.* (2003). They used a specifically adapted recognition paradigm by sequentially presenting the tunes of a melody and requiring the subjects to provide a familiarity judgement or recognize the melody. Interestingly, musicians judged the familiarity of the musical pieces within fewer notes than did non-musicians (after four notes in musicians and five notes in non-musicians). Thus, familiarity evolves a little bit earlier in musicians, suggesting that perceptual memory (mostly working automatically) for melodies works faster in musicians.

Taken together, musicians outperform non-musicians in several aspects of musical perception, including perception of pitch, timbre, and timing. In addition, they also show improved performance in recognition of melodies. Altogether, these enhanced aspects of cognition are necessary for the performance of music even at moderate levels.

Sight-reading

Reading musical scores is in many ways similar to reading words. The special ability to read musical scores while playing an instrument is called sight-reading. In order to sight-read music, a musician must translate notes on a page to appropriate motor commands subserving specific movements. In addition, these notes should also be interpreted and translated into aesthetically appealing signals. Consider the really complicated task that a pianist has to perform while playing music from a score. At a basic level (the level of a beginning student) there is a direct translation between a note and the striking of a corresponding key. For example, reading the note F results in striking the key for note F on the keyboard. At a virtuoso level, the pianist looks at a series of notes and merges that immediate information with knowledge held in long-term memory about musical harmonies, global rhythm phrases, and the interpretation of the overall musical line. In addition, the experienced musician may relate the current piece of music to his or her musical schema. This may be fused with the emotional theme of the music. And these are only a few of the more obvious components inherent in musical playing and interpretation.

In order to accomplish all these cognitive processes during sight-reading it is basically impossible to play a musical piece 'note by note'. Therefore, skilled musicians must use a strategy allowing them to look ahead in the score so as to anticipate what may come next, in a similar way to which an experienced reader might read a book. Although the above given explanation of the sight-reading process in musicians is somehow plausible, only a few experiments have studied this phenomenon empirically. Sophisticated experiments have been carried out by Truitt *et al.* (1997). Using recordings of eye movement and sophisticated analysis of key strokes they analysed the so-called eye–hand span and the perceptual span. The eye–hand span is a measure of the distance between the note being looked at and the note being played. The perceptual span is the region around the note being looked at from which useful information is extracted. For example if one looks at a particular letter in a word the perceptual span is the number of neighbouring letters which are also perceived. The authors found that the perceptual span of skilled and less skilled pianists was approximately the same, ranging between two and four beats. However, the eye–hand span differed between skilled and less skilled pianists. For the less skilled pianists, the eye–hand span was only about half a beat, indicating that the fixation point was less than one beat ahead of the hands. The eye–hand span for the skilled pianists was about on average two to three beats; thus, the fixation point was much further ahead of the hands than in non-skilled pianists. In a few instances the skilled pianists focused behind the note currently being played, suggesting that the player may have been reflecting on the note just played. In a way these findings are astonishing in that they showed that the visual perceptual span is similar for skilled and less skilled pianists and that the eye–hand span of skilled pianists is not much different between skilled and less skilled pianists, although skilled pianists show a larger eye–hand span. Although the eye–hand span is larger in skilled pianists it does not explain the virtuoso level at which skilled pianists play their instrument. Thus, there is a discrepancy between these experimental data and the conventional wisdom that pianists might extract information from a wider region of vision than non-musicians. The reason for the apparent similarity (or small difference between skilled and less skilled musicians) is possibly due to the constraints of short-term memory. If the encoding process gets too far ahead of the motor output (i.e. when the eye–hand span becomes too large), there is probably a loss of information that is stored in short-term memory. However, the evidence that skilled musicians can perform at virtuoso levels emphasizes that some kind of optimization has been implemented not on the visual but rather on the motor side of this complex sensorimotor process. Obviously, skilled pianists have developed the ability to translate complex visual information (e.g. several notes) into a complex motor program subserving the fast movements associated with piano playing.

Cognitive control of musical performance

Playing a musical instrument or singing even at a low level of skill requires a highly adapted organization of many submovements. By preparing and executing a particular movement, an organism normally has great latitude in combining component movements in order to reach a goal. When the movement is actually executed, only a small number of the possible movements are used. The degrees of freedom problem refers to the number of distinct ways in which the movement can be performed. A movement can vary in many ways, including its angular direction, extent of muscle contraction, and motor neuron discharge. Thus, when practicing a particular movement various movement parameters have to be optimized. Rosenbaum (1991) identified at least three factors that are optimized during practising movements: efficiency, interaction, and mechanics:

1. Efficiency means the avoidance of extremes in movement parameters because it is known that extreme movement parameters are difficult to control. These parameters include rate changes in the velocity of movements, in muscle torque (the force to produce rotational motion), and in jerk (the rate of change of acceleration).
2. Interactions between limbs: the movements of our limbs tend to be coupled so that the movement of one limb or joint limits the movement of the other. For example, finger, hand, and arm movements are coupled. These and other interdependences between the limbs reduce the number of independent choices for the motor system when executing movements. Thus, programming a movement with one limb will inevitably cause particular movements in the coupled limb, a phenomenon reducing the degrees of freedom of movement.
3. The mechanical properties of the organism and of the environment aid in selecting and guiding movements without having to plan and to coordinate them. For example, moving a finger upwards needs muscle contractions. However, moving the finger downwards basically needs less muscle force because gravity takes over to bring the fingers back to the initial position.

Several models have tried to explain how the cognitive system accomplishes optimization in the context of skilled movements. Rosenbaum *et al.* (1993) proposed a knowledge-based model to explain the degrees-of-freedom problem. According to this model target postures (e.g. final movement positions including various constellations of submovements) are stored in movement memory. Each of the postures receives a weight that is based on the likelihood of the success of the posture. For each posture each degree of freedom also has a particular weight. The weights capture the costs of the posture, both in terms of the accuracy and

the effort of execution. Once a posture has been selected, a trajectory is chosen by the motor system incorporating biomechanical constraints. In relation to musicians one might speculate that as the level of musical skill increases the degrees of freedom are reduced to the control of particular music-related movements. Thus, musicians can control more complex movements with less control effort. This might explain the existence of the enlarged neural networks found in the sensorimotor system of professional musicians (Münte *et al.* 2002).

Motor learning is also related to adjustments of mental plans of movements. Mental plans are cognitive representations of movements which are independent of the limbs with which the movement can be performed. For example, mental plans contain conceptual relations of actions (e.g. the sequence of submovements). Whether mental plans and lower-level motor actions are learned independently and whether this learning is dependent on the level of skill is a long-standing matter of dispute. Palmer and Meyer (2000) have addressed this issue in more detail. They required skilled adult music performers and novice child pianists to learn a motor sequence task under speeded up conditions. After this initial practice phase they asked the subjects to perform a second sequence with the same or different motor assignments (hand or finger) and the same or different conceptual relations (pitch sequence). The results they found bear most important implications for understanding the relationship between cognition and movements in general and provide invaluable insight into the way in which skilled musicians organize and represent their movement control in particular. They found that with increasing skill, mental representations of performance become dissociated from the movements required to produce a musical sequence. Thus, it is plausible that the mental plans of advanced performers are based on abstract, conceptual pitch relations and are independent of the hand or finger movements. In contrast, novice child pianists showed transfer of learning reflecting the movements as much as the abstract pitch relationship. These findings suggest that the motor and conceptual dimensions become distinct within a sequence representation as learning to perform progresses. In addition, these findings throw a new light on the definition of motor skill in showing that cognitive *and* motor functions determine the level of motor skill.

Memory functions

Perception and production of music imposes specific demands on the various memory structures. One important reason for this assumption is based on the fact that musical sounds (like all auditory signals) unfold over time. Thus, it is necessary for the auditory system to integrate the sequentially ordered sounds into a coherent musical perception. This series-to-parallel transformation can be

considered a mechanism of working memory, temporarily storing auditory units and combining them to a single percept (e.g. a sound pattern). In addition, recognizing and generating musical tunes makes it necessary that some invariant properties of musical pieces are stored in long-term memory. Most researchers believe that a specific, more perceptually organized musical memory system represents information about the form and structure of musical events (perceptual representation). Thus, unlike in language, music is thought to be mainly perceptually driven while language memory systems are strongly related to a rigid semantic system. However, although musical information is not directly related to semantic information (name of the singer, title of the piece, date of recording, etc.) it could be associated with emotional and semantic information (associative memory). A very specific feature of the perceptually based music memory system is that the stored information is relatively abstract, allowing the recognition despite change in instrumentation, loudness, tempo, or register. Lesion studies as well as recent brain imaging studies have shown that this (perceptual) memory system is located bilaterally in the auditory cortex (including the supramarginal gyrus). In addition, inferior frontal and inferior temporal brain areas have been shown to be strongly involved in recognizing familiar tunes.

It is relatively simple for musicians to recall and recognize complex musical works for performance. This is not only true for performers playing an instrument or singers, it is also most evident for conductors who have to memorize not only the musical structure but a lot of detailed information about instrumentation, tempo, and many other aspects of the musical piece. Thus, musicians have to establish a kind of expert memory system for musical pieces. Recently, much work has been devoted to identifying the characteristics of the expert musical memory system. Several authorities argue that musical memory is a prototypical example for other kinds of expert memory shown by chess players, mnemonists, or scientists (Chase and Ericsson 1981; Williamon and Valentine 2002; Chaffin *et al.* 2003). The skilled memory theory has been proposed on theoretical grounds to account for the remarkable memory abilities observed in experts across several domains including musical performance. This theory is based on three core aspects. First, experts are able to use their existing knowledge structures in semantic memory to store new information during skilled performance of a given task. Second, this information is incorporated into a specific memory mechanism in which cues, item information, and associative information are used to facilitate encoding and retrieval of information in and from long-term memory. This memory mechanism is called the retrieval structure. Third, the time required for encoding and retrieval operations decreases with extended practice.

Ericsson and Kintsch (1995) have recently extended the skilled memory theory into the long-term working memory (LTWM) theory. Of crucial importance for the LTWM framework is the way in which domain-specific information is stored and accessed. Ericsson and Kintsch (1995) propose that information is encoded and retrieved by means of (1) a retrieval structure (as mentioned above) and/or (2) through knowledge-based associations connecting items to other items or to LTM patterns and schemas. According to this, musicians will use their 'individual' understanding of the music to organize the retrieval cues and the retrieval structure.

But how do musicians strengthen their retrieval structure compared with non-skilled musicians? All experts strengthen retention by mapping the to-be-remembered information in terms of something that is familiar, sensible, or important to them. Often the to-be-remembered information is also divided into structurally important and less (subjective) important information. The structurally important information provides the cue for the retrieval structure. Recently, Williamon and Egner (2004) showed that particular bars within a complex piece of music serve as structural markers for encoding to and retrieval from memory. Thus, not each specific bar or note is individually encoded or retrieved; only specific bars (the so-called structural bars) are preferentially processed during encoding and retrieval. However, this information is sufficient for superior memory processing in the context of a very efficient retrieval structure.

As well as the fact that expert musicians have a specific and most efficient retrieval structure which helps them to memorize musical pieces, non-professional (but also professional) musicians have consistently demonstrated an efficient verbal memory system superior to that of non-musicians—at least in tonal languages like Chinese. This has been shown in a series of experiments conducted by Chan *et al.* (1998). Recently, Sluming *et al.* (2002) found that in musicians there is an increase in grey matter in the frontal cortex known to accommodate neural networks involved in several important memory processes. Thus, one might conclude that a kind of positive transfer between musical performance and verbal memory functions has taken place. Further experiments are needed to clarify to what extent this transfer is indeed a transfer between different functions (music to verbal). Recent studies have elegantly demonstrated a considerable overlap of neural structures and processes underlying the perception of language and music (Schuppert *et al.* 2000; Sluming *et al.* 2002; Koelsch *et al.* 2002, 2004; Patel 2003). Thus, performing one domain will necessarily influence the other domain because both music and language are processed by the same network and/or similar processes.

Attention and perception

Playing music requires specific attentional abilities. For example, a performing orchestral musician has to simultaneously separate and integrate self-generated from externally generated musical stimuli while the motor actions necessary to play his/her instrument have to be executed. Attentional abilities are most evident in conductors, who can identify specific musicians within a multiplayer section. Münte *et al.* (2003) elegantly showed that conductors are endowed with exceptional auditory spatial abilities, enabling them to localize sounds even in positions of extremely eccentric peripheral auditory space. However, it is not only conductors who are endowed with superior auditory spatial attention but also musicians playing instruments at various levels of skill. For example, it has been shown that musicians, relative to non-musicians, pre-attentively extract more information from musically relevant stimuli (Rosenbaum *et al.* 1993). Since effects of long-term experience on pre-attentive auditory processing have so far only been reported for language-specific phonemes, these results indicate that sensory memory mechanisms can be modulated by training on a more general level.

Visuospatial functions

That visuospatial functions might be related to musical performance seems to be a little bit unusual at first sight. However, this issue has been raised by the seminal publication of Rauscher *et al.* (1993). In this paper the authors reported that listening to a Mozart sonata for several minutes enhanced visuospatial functions in kindergarten children. From then on this effect has found its way into the literature as the 'Mozart effect'. Based on this and similar findings the authors suggested a strong relationship between visuospatial performance and listening to or processing music. One of the authors (Shaw 2000) even argued that visuospatial and musical processing might be controlled by similar neural assemblies and neuronal firing rate. Although these publications have attracted much attention, debate, and follow-up studies, attempts to replicate this finding have been mostly unsuccessful in studies conducted by independent laboratories. Meanwhile, several studies have shown that emotional state (mostly positive ones) or a certain level of arousal should be considered a most important moderating variable in determining this effect. However, although the 'Mozart effect' has been shown to be fragile and not directly related to music, one can speculate that there might exist some (admittedly not well understood) relationships between visuospatial functions and musical performance. For example, many ways of performing musical pieces require spatial functions. For example, pianists need three-dimensional spatial processing to find the correct position of

the keys while they are playing. Recently, Lutz *et al.* (2005) showed in a functional magnetic resonance imaging study that simple finger sequencings in non-musicians (similar to those used during piano playing) evoked strong activations in parietal areas (including the intraparietal sulcus) known to be involved in spatial processing (Jordan *et al.* 2001). Thus, it might indeed be plausible that professional musicians automatically practice spatial functions while performing music. However, this is an issue which needs further research in the future.

Conclusion

This chapter has described several cognitive functions for which musicians (and in particular professional musicians) have developed specific cognitive functions. Most of these functions are specific to musical proficiency but some of these functions are not directly related to musical performance (e.g. verbal working memory). Recently, Schellenberg (2001, 2004) has demonstrated that the IQ is slightly enhanced in those children who have participated in musical lessons for about a year. Although the IQ-enhancing effect is small and within the normal variability range of IQ values (six IQ points), this finding is of special importance because it is the first report published in a reputable scientific journal demonstrating a direct positive transfer between different cognitive functions in musicians in the context of a longitudinal study. Although many might take this finding as support for the notion that musical training might be an ideal tool for educating pupils, this finding more strongly supports the notion that cognition is strongly associated with action, because it is not passive hearing of musical pieces that enhances the IQ, it is rather the active musical performance.

Chapter 3

The nature of memory for music performance skills

Caroline Palmer

Although most studies of memory for music performance focus on dimensions of musical structure, recent studies suggest that motor factors of performance are also represented. Brain imaging measures collected during mental practice or listening tasks suggest that both motor and auditory cortical areas are active during musical thought processes. Four types of behavioural study with performers reveal motor-based representations: performers' musical interpretations, transfer of learning from one musical task to another, mental practice effects, and anticipatory movements. These sources of evidence implicate distinct motor and non-motor (melodic) information in performers' memory for music. Implications from these behavioural tasks suggest that an accurate auditory and motor representation underlies successful performance from memory.

Introduction

Theories of memory often cite music performance as an example of expert memory, and many studies have examined the factors that influence performers' memory (for review see Palmer (1997) and Gabrielsson (1999)). Music performance can be depicted as a cognitive skill with large memory demands, or as a motor skill with large physical execution demands. Cognitive dimensions of performers' memory for music are often described in terms of musical structure, such as harmony, tonality, phrasing, and meter (Palmer 1997; Gabrielsson 1999; Palmer and Pfordresher 2003). Motor aspects of performance are measured in physical dimensions such as fluency, speed, rhythmic precision, and hand coordination (Krampe and Ericsson 1996; Drake and Palmer 2000). Musicians' memory that allows them to perform a specific musical piece, referred to as 'memory for performance', is distinguished here from other memories of performance (by oneself or someone else).

Music performance is of much interest to psychologists precisely because it is demanding both cognitively and in terms of motor skills. Memory for music entails sequences on the order of thousands of pitch events that are produced at

rates as high as 8–12 events per second, with less than 3% error (Palmer and van de Sande 1993; Repp 1996; Finney and Palmer 2003). In addition to categorical pitch events, listeners (infants as well as adults) remember fine expressive nuances of performances, including timing, intensity, and articulation information that distinguish different performances of the same music (Palmer *et al.* 2001). A more accurate conceptualization of the problem of describing memory for performance may be: what are the underlying features of music performance that are represented in memory? Which features are described in motor coordinates? How do factors such as maturation, musical acculturation, and training influence the representation of those features?

This chapter addresses these questions in the domain of piano performance. Piano is one of the most-often chosen instruments of study by children in North American schools (Johnson 1994). Piano has consistently been among the most-often performed instrument by amateur musicians in American households (Gallup Poll 1994, 2000) and piano performance is one of the most easily measured instruments with the advent of MIDI (music instrument digital interface). Thus, research in performance is based largely on measures of pianists' behaviours. Despite the rapid growth of research into piano performance during the past 20 years, less attention has been paid to the motor aspects of memory for performance (such as finger and hand movements) than to auditory (intensity, duration, etc.) or structural aspects (phrase structure, rhythm, etc.).

Motor representations of piano performance

The motor demands of piano performance are quite large, especially in terms of finger movements. One of the few models to attempt to capture aspects of motor difficulty is an ergonomic model of fingering in piano performance (Parncutt *et al.* 1997). This model, based on a series of rules, reflects specific ergonomic difficulties such as weak versus strong fingers and spans between finger pairs. Measures of the pianists' fingering consistency and performance accuracy for musical exercises correlated negatively with the model's predictions of fingering difficulty (Sloboda *et al.* 1998). The model compared favourably with performances that used the least difficult fingers; however, the model sometimes made predictions for simpler fingerings that were not preferred by the pianists.

Imagery techniques applied to brain organization also support motor and non-motor features of performers' memory for music. Pantev *et al.* (2001) found enlarged representations of the auditory and somatosensory cortex with musical practice. The somatosensory cortex showed neuronal changes specific to fingers used during practice. Pascual-Leone and colleagues (reviewed in Pascual-Leone

1995) found changes in cortical motor areas as non-pianists practised finger exercises; physical practice as well as a combination of mental and physical practice established those changes. With magnetoencephalograph (MEG) techniques, Haueisen and Knösche (2001) reported that pianists displayed motor activity in the contralateral primary motor cortex while listening to familiar music (music they had performed). In addition, functional magnetic resonance imaging (fMRI) measures in skilled violinists demonstrated activity in primary auditory regions while the violinists silently tapped the opening section of a violin concerto; the amateur violinists' fMRI results did not indicate auditory stimulation (Lotze *et al.* 2003). To address whether co-activation in auditory and motor cortical areas arises from years of joint auditory–motor practice or over shorter time spans, Bangert and Altenmüller (2003) used direct current electroencephalography (DC-EEG) with non-musicians who were trained to associate a purely auditory (passive listening) task with a purely motor (silent finger movement) task. One group had consistent mappings of auditory events to motor events, while another group learned with altered mappings. Only the consistent mapping group exhibited additional EEG activity in right anterior regions, which the authors took to indicate an audiomotor interface that developed in the first weeks of practice. Of interest is how far the behavioural changes following pairings of motor and auditory activity extend both in time and across tasks.

Interpretive influences on performance memory

The occasional errors that performers make (hitting the wrong key or chord) often display active memories for other to-be-performed events. For example, pitch errors tend to reflect tones intended for elsewhere in the same piece (Palmer and van de Sande 1993). Such performance errors also indicate motor features. Palmer and van de Sande (1993) documented pianists' errors in two-handed piano music; left-handed errors were more common than right-handed errors (regardless of the pianists' handedness), consistent with Peters (1985) findings of greater right-hand coordination skills among pianists. Harmonically related errors (a substituted pitch that arises from the same chord as the intended pitch) were more common than harmonically unrelated errors, even when their production required different hand or finger movements (Palmer and van de Sande 1993). Likewise, hand differences in errors occurred for both harmonically related and harmonically unrelated errors.

Do motor factors interact with non-motor features of memory for performance? Palmer and van de Sande (1993) asked pianists to perform the same music with different melodic interpretations. The melody or primary (most important) voice is not directly marked in musical notation, and performers often interpret

the voice intended as melody as more important (Palmer 1989). The voice interpreted as melody was less likely to contain errors, even when pianists changed their melodic interpretation for the same musical piece. Performers also made more errors in parts controlled by the left hand, regardless of hand dominance. Motor factors (hands and fingers used) did not interact with interpretive factors (melody being emphasized) in the likelihood of errors in the pianists' performance, suggesting that interpretive and motor factors are represented independently in memory for performance (Palmer and van de Sande 1993).

Transfer of performance skills

Another source of evidence for motor dimensions of memory for performance is the conditions under which performers generalize what they know from one performance situation to another. In typical transfer of learning tasks, participants learn one task and then perform a second task. The ease with which they perform the second task is thought to reflect what was learned in the first task. The mirror symmetry of hand and finger movements in piano performance provides a convenient format in which to test transfer of motor learning. Consider the sequence of finger movements 5–4–3–2–1 in the right hand (where thumb is 1), used to press adjacent keys on a piano; this sequence becomes 1–2–3–4–5 when the same keys are pressed by the left hand. Thus, the same melody can be played with different hand and finger movements in piano performance. In addition, different melodies (different pitch sequences) can be performed with the same hand and finger movements. Although the transfer of musical skills to math, spatial reasoning, and other tests of intelligence has been studied (Rauscher *et al.* 1995; Schellenberg 2004), fewer studies have examined the transfer of learning from one musical task to another musical task. Are well-learned motor movements transferred from one melody to another? Palmer and Meyer (2000) measured the transfer of pianists' hand and finger movements from one practised melody to a novel melody. When the second (novel) melody required the same finger movements as the initial melody performed, pianists were able to play it more quickly. Comparisons across age and skill levels indicated that the more advanced performers showed the greatest transfer across motor movements, suggesting that they were able to generalize from one hand and finger set to another. The least skilled pianists showed no ability to generalize beyond the particular finger sequence learned.

Does knowledge of a set of motor movements transfer across temporally distinct patterns in music performance? For example, can a pianist performing one rhythmic pattern with a set of finger movements such as 1–2–3–4–5 generalize those same finger movements to produce a different rhythmic pattern as fluently

as the first pattern? Using a similar transfer of learning task, Meyer and Palmer (2003) showed that pianists' finger movements did transfer across different rhythmic patterns: pianists could perform novel rhythms with the same finger movements as quickly as the first-learned rhythms. In addition, there was rhythmic transfer: pianists could perform well-learned rhythms with different hand and finger movements as quickly as with the first-learned movements. There was no interaction between rhythmic transfer and motor transfer; the times at which keys were pressed were remembered independently of the motor features that produced them. Similar findings were obtained when pianists transferred from one melody to another that differed in meter and motor movements. No interactions were observed among the temporal (meter and rhythm) and motor structures: retaining temporal structure from one melody to the next facilitated speeded performance more than retaining motor movements, and motor features played a smaller role in the transfer of knowledge across melodies. These findings are consistent with the general view that representations of timing in sequence production are not defined primarily in terms of motor features (MacKay 1982, 1987; Semjen and Ivry 2001), at least for performers with moderate to high levels of musical experience.

Mental and physical practice

Practice may be the single most important factor that influences memory for performance. Musicians' verbal reports of practice goals incorporate many levels of analysis, including structure, interpretation, and motor aspects of technique (Chaffin *et al.* 2003). Several studies suggest that deliberate rehearsal accounts for skill differences among music performers (Ericsson *et al.* 1993; Sloboda *et al.* 1996). More recently, comparisons have been made of the efficacy of physical practice with mental practice. When musicians practice the motor movements for performance in the absence of their physical instrument, they often make other overt movements such as drumming fingers on a tabletop or tapping feet under the table, suggesting that the motor features of performance are important for practice. If mental practice has effects on performance similar to those of physical practice, is it due to motor or non-motor components of mental practice? Are the thought processes underlying mental practice similar to those underlying physical practice?

Mental practice has been defined as the mental rehearsal of a specific task in the absence of actual physical movement (Coffman 1990; Driskell *et al.* 1994). Mental practice is distinguished from other mental techniques such as analytical study, general mental imagery, imitation, or self-arousal. Measurement of the effects of mental practice typically includes improvement in accuracy or time to

complete a task relative to some control task (such as no practice or normal practice). Meta-analyses of mental practice effects (Feltz and Landers 1983; Driskell *et al.* 1994) indicate two consistent findings. First, normal (physical) practice exceeds mental practice alone, which exceeds no practice (Coffman 1990). Second, physical practice plus mental practice instructions exceed physical practice alone (Rubin-Rabson 1937; Ross 1985). These findings suggest that improvement with practice in general is due to two components: a physical (motor) component and a mental (non-motor) component. The meta-studies interpret differences among mental practice findings as indicating that tasks with greater cognitive requirements (memory, attention, symbol manipulation) show greater effects of mental practice than tasks with high-motor requirements (coordination, endurance, strength). Examples of tasks with a high cognitive load include maze-learning and card-sorting. Examples of tasks with a low cognitive load include balancing and dart throwing.

Two common theoretical explanations of the effects of mental practice include the cognitive (symbolic) hypothesis and the psychoneuromuscular hypothesis. The cognitive hypothesis states that the effects of mental practice apply to the cognitive components of a skill: those that can be represented symbolically or visuospatially (Feltz and Landers 1983). In contrast, the psychoneuromuscular hypothesis (which grew out of the ideomotor view) holds that the effects of mental practice apply to the physical components of a skill, such as low-gain innervation of muscles used in the physical enactment of the skill (Jacobson 1930; Shaw 1938). However, potential problems with studies of mental practice make conclusions difficult. Instructions to participants that define mental practice often vary or are absent. In addition, mental practice conditions are often accompanied by some kind of physical practice, either overt, such as foot-tapping (Wollner and Williamon 2004), or covert, such as movements of throat muscles (Jacobson 1932). As a result, the components of mental practice that are considered cognitive or motor are often determined *a priori* by experimenters.

Although the effects of mental practice have been examined in many behavioural tasks, fewer studies have compared types of mental practice in the context of music performance. Coffman (1990) showed that mental practice by pianists improved their performance compared with no practice. Pianists' mental practice with an auditory model showed advantages over mental practice alone (Lim and Lippman 1991; Theiler and Lippman 1995). Rubin-Rabson (1937) showed that analytical pre-study of the score often aided performers' memorization of unfamiliar music; this analytical study may have involved auditory or motor imagery (Lim and Lippman 1991). Mental practice may help musicians learning unfamiliar music by facilitating the creation of an auditory and/or motor image. Comparison of different practice conditions showed that listening to a performance

was an effective aid to learning to perform unfamiliar music (Rosenthal 1984; Rosenthal *et al.* 1988). Not all studies show a facilitation of mental practice, however; Rosenthal *et al.* (1988) found that silent analysis (similar to mental practice, without explicit instructions) followed by sight-reading was no more effective than sight-reading alone.

An indirect source of evidence for mental practice is the lack of any detrimental effect that removal of auditory feedback causes to performers once they have learned a musical piece well. Finney and Palmer (2003) measured the amount of time performers took to play a familiar piece from memory on a silent electronic piano; total performance durations were within 5% of the durations when the pianists played the same piece with normal auditory feedback. This result was not specific to well-learned pieces; after playing a novel musical piece 10 times, the removal of auditory feedback caused no change in the duration of the performance. However, when auditory feedback was removed during the initial practice session, pianists' later performances (with auditory feedback) were significantly slower and contained more errors (Finney and Palmer 2003). Thus, the absence of auditory feedback during practice of an unfamiliar piece did not affect pianists' accuracy while the music notation was in front of them, but the absence of auditory feedback during practice did impair their later performance from memory. Ross' (1985) study of trombonists indicated that normal practice conditions with both auditory and kinesthetic feedback present allowed musicians to correct and adjust their performances; that ability decreased as feedback was removed during practice. In sum, these studies suggest that pianists can substitute mental feedback for auditory feedback once they have practised the music sufficiently to form a mental representation.

Highben and Palmer (2004) contrasted mental and physical practice, in terms of auditory and motor feedback, to determine their role in how pianists learn to perform unfamiliar music. Comparisons were made of different types of mental practice by replacing auditory or motor feedback with instructions to imagine the missing feedback: how the piece sounds, or how the finger movements feel, during practice. In a 'normal' practice condition, pianists moved their fingers on the keys and heard themselves play over headphones during practice. In a 'motor only' practice condition, the pianists moved their fingers on the keys but auditory feedback was removed; they were told to imagine what the piece would sound like. In an 'auditory only' practice condition, motor feedback was removed (the pianists held their fingers in loose fists) and auditory feedback was present in the form of a computer-generated recording of the piece, and pianists were told to imagine what the finger movements would feel like. In a 'covert' practice condition, both motor feedback and auditory feedback were removed during practice (pianists held their fingers in loose fists during silence), and they were

given both sets of instructions. Each participant performed in each condition with a different musical piece; a within-subject design was considered important to control for individual differences in mental practice abilities. After performers practised from a musical score, the score was removed, and pianists performed from memory under normal feedback conditions. Two independent measures of ability for mental imagery were collected: one for motor imagery and one for auditory imagery, for comparison with the effects of mental practice.

Both auditory and motor forms of practice facilitated pianists' subsequent performance from memory of unfamiliar music. Removal of auditory or motor feedback at practice caused significant memory deficits in later performance, despite the presence of both types of feedback at test. Physical practice conditions (in which auditory and/or motor feedback were present) led to better performance recall than conditions with mental practice. Recall was best following normal practice conditions, and worst when both auditory and motor feedback were removed during practice. Furthermore, pianists who scored higher on the test of aural skills performed better from memory following the absence of auditory feedback during practice, compared with pianists who scored lower on the test of aural skills. Thus, it is likely that performers with high aural skills were better able to use auditory imagery during learning than other performers (Highben and Palmer 2004). Whereas previous studies demonstrated the overall efficacy of mental practice in music performance (Ross 1985; Coffman 1990), Highben and Palmer's (2004) findings suggest specifically that auditory and motor forms of mental practice can aid the learning of unfamiliar music by performers. In addition, the presence of a motor component of mental practice that facilitates memory for performance indicates that explanations of the effects of mental practice based solely on symbolic, videospatial, or other cognitive (non-motor) forms of representation are not sufficient to explain memory for performance.

Individual differences in imagery abilities that are related to memory differences have implications for brain imaging studies as well as for behavioural studies. Most comparisons of methods of mental practice rely on cross-group comparisons (see Feltz and Landers 1983; Driskell *et al.* 1994), for which any correlated memory differences are not measured. The presence of individual differences suggests that within-subject designs—those that allow comparisons across all conditions within individual performers—combined with independent measures of behavioural correlates may be important controls for memory differences that result from differences in mental imagery abilities.

Anticipatory behaviour in music performance

One of the hallmarks of memory for performance is anticipatory planning: the preparation of events prior to their execution (Rosenbaum 1991). Anticipatory

behaviour is evidenced in occasional errors that reveal events intended for the future, and also in movements during the production of correct events that reveal trajectories toward future events. Studies of speech and music performance show anticipatory behaviour in the types of errors people make (such as a speaker producing 'I took the store . . . ' instead of the intended 'I took the car to the store' (Garrett 1980)). One of the main factors influencing anticipatory behaviour is practice. Drake and Palmer (2000) compared the anticipatory behaviours of child and adult pianists of various skill levels. The percentage of anticipatory pitch errors (compared with perseveratory errors, or produced pitches that were intended for earlier in the sequence) increased with both age and experience (Palmer and Drake 1997; Drake and Palmer 2000). Practice effects on anticipatory behaviour are found in many domains. Speech errors suggested that with more practice, speakers were more likely to anticipate a phoneme that was intended for later in the utterance (Dell *et al.* 1997). As the overall error rate decreased, speakers' percentages of anticipatory errors increased. Palmer and Pfordresher (2003) also found a consistent increase in anticipatory behaviour with practice in piano performance, and a general relationship between overall error rate and anticipatory behaviour: as pianists' pitch error rates decreased, the percentage of anticipatory errors increased. Furthermore, pianists' pitch errors were likely to span sequence distances of three or four events, termed the 'range' of planning: the faster the performance, the smaller the range over which anticipatory behaviour was evidenced (Palmer and Pfordresher 2003).

Analyses of finger movements in piano performance also display evidence of anticipatory behaviour. One of the earliest studies of musical motion (Ortmann 1929), using photographic techniques, documented finger movements during piano performance. Ortmann's records indicated anticipatory interactions among finger movements (movement of the second finger before the third finger strikes a key), as well as anatomical measures (arm weight, finger length, hand position) relevant for piano performance (such as the role of forearm bone length on rotation during production of tremolo). Ortmann (1929) documented general principles that are still the focus of movement research today: there are multiple routes to reach any key on the piano (the degrees of freedom problem), and the way in which each key is struck is influenced by the ways in which preceding and subsequent keys are struck (co-articulation).

Current techniques of measuring motion rely on optoelectronic systems. One type includes active markers or sensors that are placed on joints with wires and emit infrared signals 'captured' by cameras. Another motion capture technique uses passive markers that reflect light generated from a separate source that is detected by cameras. Both systems pinpoint the three-dimensional coordinates of each marker at each point in time. Engel *et al.* (1997) used an optoelectronic

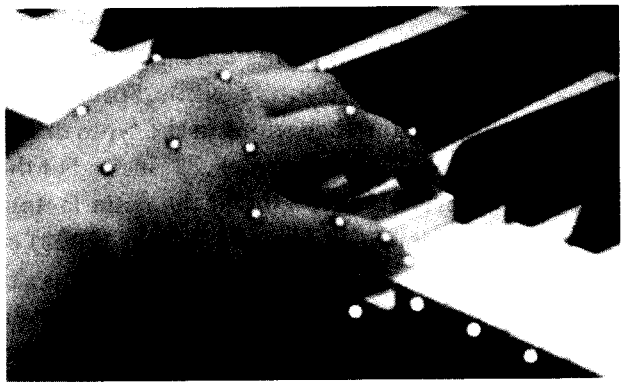

Fig. 3.1 Picture of reflective markers on a pianist's right-hand fingers and piano keys. (From Palmer and Dalla Bella 2004.)

system to measure the degree of anticipatory behaviour of fingers as pianists performed short musical excerpts that began with the same pitches but diverged in the middle of the excerpt. Pianists' finger motions changed about 160–500 ms prior to the point of notated divergence in the musical score. Because performances differed in tempo, they were normalized with respect to time and anticipatory times were not reported in number of events.

Palmer and Dalla Bella (2004) measured anticipatory movements in piano performance of simple melodies performed at a range of specified tempi. Pianists' finger motions were recorded with a Vicon-8 system with passive 3 mm markers placed on a pianist's right hand, as shown in Fig. 3.1, and 14 cameras placed around the pianist recorded light reflected from the markers. This system, also applied to violin bowing (Visentin and Gongbing, 2003), has the advantage of requiring no wires on the pianists' hands. An example of a pianist's trajectory of motion of the fifth finger of the right hand is shown in Fig. 3.2, during a performance of the simple melody shown at the top. The position, velocity, and acceleration graphs below refer to the position of the marker placed on the tip of the fingernail (the finger position of greatest motion) in the vertical plane (height above the keyboard). The top panel shows the finger height; minimum values indicate where the piano key was pressed. The middle panel shows the velocity of the finger motion, and the bottom panel shows the acceleration. In this melody, the pianist's fifth finger pressed the keys on note events 6, 8, and 10. The pianist's trajectories of motion indicated changes in velocity and acceleration patterns of each finger prior to its arrival on a key. The key arrival (indicated by minimum finger height, top panel) is marked by peak finger acceleration (bottom panel). Anticipatory motion is evidenced in the finger heights (top panel) during the event prior to arrival on a key (events 6, 8,10).

As shown in Fig. 3.2, the pianist's fingers reached peak amplitudes usually within one event prior to a keypress. However, the trajectories of each finger

system to measure the degree of anticipatory behaviour of fingers as pianists performed short musical excerpts that began with the same pitches but diverged in the middle of the excerpt. Pianists' finger motions changed about 160–500 ms prior to the point of notated divergence in the musical score. Because performances differed in tempo, they were normalized with respect to time and anticipatory times were not reported in number of events.

Palmer and Dalla Bella (2004) measured anticipatory movements in piano performance of simple melodies performed at a range of specified tempi. Pianists' finger motions were recorded with a Vicon-8 system with passive 3 mm markers placed on a pianist's right hand, as shown in Fig. 3.1, and 14 cameras placed around the pianist recorded light reflected from the markers. This system, also applied to violin bowing (Visentin and Gongbing, 2003), has the advantage of requiring no wires on the pianists' hands. An example of a pianist's trajectory of motion of the fifth finger of the right hand is shown in Fig. 3.2, during a performance of the simple melody shown at the top. The position, velocity, and acceleration graphs below refer to the position of the marker placed on the tip of the fingernail (the finger position of greatest motion) in the vertical plane (height above the keyboard). The top panel shows the finger height; minimum values indicate where the piano key was pressed. The middle panel shows the velocity of the finger motion, and the bottom panel shows the acceleration. In this melody, the pianist's fifth finger pressed the keys on note events 6, 8, and 10. The pianist's trajectories of motion indicated changes in velocity and acceleration patterns of each finger prior to its arrival on a key. The key arrival (indicated by minimum finger height, top panel) is marked by peak finger acceleration (bottom panel). Anticipatory motion is evidenced in the finger heights (top panel) during the event prior to arrival on a key (events 6, 8,10).

As shown in Fig. 3.2, the pianist's fingers reached peak amplitudes usually within one event prior to a keypress. However, the trajectories of each finger

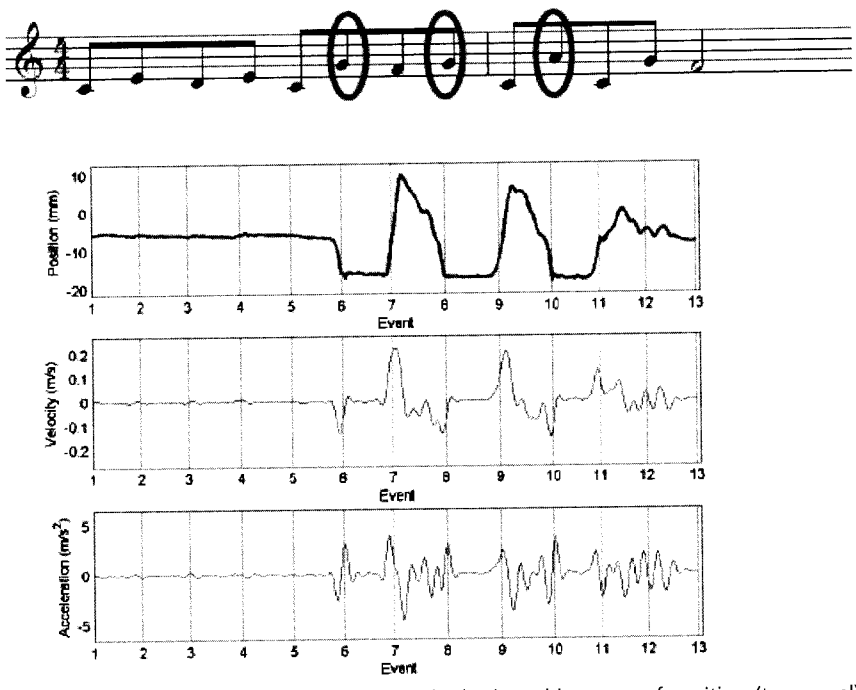

Fig. 3.2 Height of a pianist's fifth finger above the keyboard in terms of position (top panel), velocity (middle panel), and acceleration (bottom panel) during a single performance of the melody shown at the top, at a moderate tempo (120 beats/min). Vertical lines indicate the time of each keypress (as recorded on a MIDI keyboard).

began to change in velocity and acceleration one to three events prior to the anticipated arrival at the key by that finger; by four events prior, the trajectories showed the same amount of change in velocity and acceleration as when the finger had no upcoming keypress (resting level) (Dalla Bella and Palmer 2004). This anticipatory behaviour in finger trajectories is consistent with findings of memory retrieval occurring three to four events before the keypress (Palmer and Pfordresher 2003); finger trajectories toward keypresses must require some information about the arrival location prior to the execution of the movement. Furthermore, the faster the tempo, the less time there is for anticipatory movements, consistent with the memory retrieval model. Although statistical (morphometric) techniques that identify consistencies in shape and structural time patterns have not yet been applied to musical movement, motion capture techniques offer promise for rigorous measurement of co-articulation properties (how finger movements are influenced by subsequent and preceding fingers) and other shape/time constancies in musicians' movements that were first identified long ago (Ortmann 1929).

Summary

Research in music performance is beginning to document the nature of memory for the motor aspects of performance. Performers' hand and finger movements, as well as conceptual intentions, are encoded in memory for performance and tend to have independent effects on pitch accuracy. Performers' memory for melodies (specific pitch sequences) and finger/hand movements generalize in transfer tasks; furthermore, motor and melodic information transfer independently. Skilled performers show more transfer of learning across melodies that require different motor movements than do novices. Mental practice shows evidence of motor components that facilitate memory for performance. Finally, motion capture techniques for measuring music performance are beginning to document the time course of anticipatory movements.

One ramification of these findings is that memory for performance is flexible; performers can apply what they know about motor movements to different performance situations, and behavioural and neural changes result—as seen in the plasticity with which non-musicians learn aural–motor associations. Flexibility of motor movements is essential for the interpretive nature of music performance; otherwise, significant additional practice would be necessary before a musician could perform a familiar piece with an alternative interpretation. A second ramification is that performers differ in their individual abilities, as evidenced in interpretive effects on memory, in transfer of learning from one melody to another, and in mental practice benefits. Mental practice is appropriate for the study of brain states, measured in EEG, fMRI, and MEG studies, because of its avoidance of motion 'artefacts'. Scientific interest in applying imaging methods and motion capture techniques to music performance suggests that answers may soon be found to the interesting question of how motor aspects of music performance are represented in memory.

Chapter 4

Musical synchronization

Bruno H. Repp

The ability to coordinate rhythmic movement with rhythmic sound is fundamental to music performance and dance. This chapter begins by summarizing some of the most important findings about the synchronization of simple movements with simple rhythmic sequences, which constitutes the bulk of synchronization research. Three musical scenarios are then distinguished: (1) synchronization of simple movements with complex sequences (e.g. tapping to the beat of music), (2) synchronization of complex movements with a simple sequence (e.g. playing music with a metronome), and (3) synchronization of complex movements with a complex sequence (e.g. playing music in an ensemble). Research on each of these topics is reviewed, and possible future directions for research are considered.

Introduction

Sensorimotor synchronization (SMS), the coordination of rhythmic movement with rhythmic sensory stimuli, is a universal human skill that is fundamental to music and dance (Merker 1999–2000). Musical performance in a group requires the precise coordination of sound-producing movements with the sounds and movements produced by other musicians. Dance involves the coordination of (typically, quiet) movements with music and/or with the movements of other dancers. Some forms of dance, such as tap dancing and marching, also involve production of sound. Solo performers sometimes practice with a metronome, which is a form of SMS. Listeners to music and observers of dance may tap or sway along, and if so they are engaging in SMS.

Even if listeners are sitting still, their internal attentional rhythms may be entrained to the sensory input (Large and Jones 1999). Although this is an instance of synchronization and may even involve imaginary actions, it is not an instance of SMS because there is no overt movement. A solo pianist must coordinate the two hands and the fingers of each hand to achieve synchrony between a melody and its accompaniment, and between the tones of chords (Palmer 1996; Repp 1996). Although this involves both movement and sensory feedback, it is not an instance of SMS because there is no external rhythm that serves as a referent.

These examples delineate the subject matter of the present chapter, which is SMS in musical contexts. Most studies of SMS in the literature make no pretense of being concerned with music. They employ simple movements, typically finger tapping, and simple stimulus sequences, typically a metronome. Nevertheless, their results are relevant to music because they reveal the basic mechanisms underlying SMS. The next section summarizes the most important results of that research and gives selected references. (For a more detailed review and more complete references see Repp (2005c).)

Synchronization of simple movements with simple sequences

The mean negative asynchrony

One of the oldest findings in SMS research is that during tapping in synchrony with an auditory metronome the taps tend to precede the tones by a few tens of milliseconds (Miyake 1902). This is called the anticipation tendency or mean negative asynchrony (MNA). (An asynchrony is defined to be negative when the tap precedes the tone, positive otherwise.) It has been observed in nearly all simple SMS studies in the literature. Participants are generally unaware of this tendency. When they are trained by means of visual feedback to achieve a mean asynchrony close to zero, they feel they have to delay their taps in order to achieve this goal (Aschersleben 2003). Thus, the MNA corresponds to the subjective point of synchrony. In a classic study, Fraisse and Voillaume (1971) tricked unsuspecting participants in an SMS task by making the metronome tones contingent on their taps, thereby eliminating the MNA. The participants steadily accelerated their tapping tempo, as if trying to re-establish the MNA.

Many studies have been concerned specifically with the MNA because it seems to tell us something important about how perception and action are coordinated in time (see Aschersleben (2002) for a review). Various explanations for the MNA have been suggested, including different neural transmission times for different kinds of sensory information (Fraisse 1980), different central accumulation times for different amounts of sensory information (Aschersleben *et al.* 2004), an asymmetric cost function for asynchronies (Vos and Helsper 1992), minimization of variance through shortening of the internal tapping period (Vorberg and Wing 1996), and perceptual underestimation of empty intervals between tones (Wohlschläger and Koch 2000). Although each explanation has some merit, none of them seems to account for the full range of empirical findings.

Several of these findings suggest that the MNA is largely specific to simple SMS tasks and therefore not particularly relevant to musical SMS. First, the MNA decreases when auditory feedback (i.e. a tone) is made contingent on each

tap (Aschersleben and Prinz 1995), so that asynchronies can be gauged within the auditory modality. While such explicit auditory feedback is uncommon in SMS studies, it is the standard situation in music performance. In large part, the MNA seems to be a consequence of comparing auditory input with tactile and proprioceptive feedback from the movement. Second, the MNA tends to disappear when additional tones are inserted between the metronome tones or when additional movements intervene between taps (Wohlschläger and Koch 2000). This, too, occurs commonly in music, where rhythms are usually more complex than a simple beat. Third, musically trained individuals generally seem to show smaller MNAs than untrained individuals (Aschersleben 2002).

Nevertheless, the tendency to anticipate external referents may account for some phenomena observed in music performance, such as rushing when playing in an ensemble or coming in too soon after a rest.

Variability

Sensorimotor synchronization inevitably involves uncontrolled variability. Not only are movements inherently variable, but also the perception of a perfectly regular metronome is subject to variability arising in the neural circuitry. Wing and Kristofferson (1973) proposed an influential model according to which the variance of rhythmic movement has two additive components: one generated by a central timekeeper and the other contributed by more peripheral motor processes. Timekeeper variance increases with interval duration, whereas motor variance is relatively constant and thus makes less and less of a contribution to the total variance as the tempo decreases (Wing 1980). Perceptual variability likewise increases with interval duration and thus causes an increase in the perceptual threshold for changes in duration, which approximately follows Weber's law between about 300 and 2000 ms (Friberg and Sundberg 1995). Within these limits, a typical value for the coefficient of variation (the standard deviation as a percentage of the mean interval duration) of both movement timing and perception of timing is 4%, although musicians can show values less than half as large. The Wing–Kristofferson model was proposed to account for unpaced tapping, but it can easily be extended to SMS by adding error correction (see section on Error correction below).

Models of SMS typically assume variability to be random (i.e. white noise), but there is now strong evidence that biological noise does not have a flat spectrum but rather an increasing energy at low frequencies ($1/f$ or fractal noise; Gilden 2001). In unpaced tapping, this is reflected in fluctuations in tempo which occur at many time scales (Madison 2004). In SMS, such fluctuations in tempo are much smaller because of error correction with reference to the pacing sequence, but the asynchronies fluctuate in a similar manner (Chen *et al.* 1997,

2002). This is believed to reflect the workings of a complex dynamic system underlying performance.

Rate limits

Sensorimotor synchronization has both upper and lower rate limits, which roughly correspond to the interval durations beyond which Weber's law does not hold and may indeed be a consequence of a rapid increase in relative variability. The slowest rate at which SMS is possible corresponds to interval durations of about 2 s (Mates *et al.* 1994; Engström *et al.* 1996). At intervals longer than 2 s it becomes difficult to anticipate future events, and taps tend to follow rather than precede metronome tones. It is likely that this limit can be extended somewhat by mental subdivision strategies, such as musicians are likely to employ, but this has not yet been investigated.

The fastest rate at which synchronization with a metronome is possible depends strongly on the manner of synchronization. At least three different rate limits can be distinguished. When the task is to make one tap with each tone, the rate limit is set simply by the fastest rate at which the finger can move, which corresponds to inter-tap intervals of 150–200 ms for most people (Peters 1980). An even faster limit is evident when the task is to tap only with selected metronome tones, such as every fourth tone (Repp 2003) or only a single tone (Bartlett and Bartlett 1959), so that the biomechanical limit is avoided. In that case, synchronization is possible up to interval durations of 100–125 ms between tones. The eventual breakdown in coordination (which is evident as phase drift) suggests that the tones can no longer be attended to as individual events at such fast rates. A much slower limit is obtained when the task is off-beat (anti-phase) tapping, that is to tap at the midpoints of the intervals between tones. That limit is typically near interval durations of 350 ms (Repp 2005*a*, *b*). These values are for musically trained individuals; musically untrained participants may show considerably higher values.

The greater difficulty of anti-phase than in-phase coordination has been of particular interest to researchers who take a dynamic systems approach to SMS (e.g., Kelso *et al.* 1990). Their research usually focuses on continuous oscillatory limb movement, not on tapping. When the tempo is increased, a phase transition from anti-phase to in-phase coordination is commonly observed, which reflects a difference in the relative stability of these coordination modes. This difference is only evident when the system is stressed, however. Anti-phase tapping with a metronome tends to be *less* variable than in-phase tapping when the interval duration exceeds 400 ms (Semjen *et al.* 1992) because the taps subdivide the intervals, and shorter intervals afford lower variability as long as they exceed 200 ms (Repp 2003).

Empirical findings such as the ones reviewed here support London's (2002, 2004) contention that 200 ms is about the shortest possible interval between beats in music (cf. van Noorden and Moelants 1999), whereas 100 ms is the shortest possible interval between subdivisions of a beat.

Error correction

Sensorimotor synchronization cannot be achieved and sustained without error correction. Error correction prevents the inherent variability of the movement from having a cumulative effect on the times of occurrence of successive actions (Vorberg and Wing 1996). Two distinct error correction processes have been hypothesized to exist: phase correction and period correction (Mates 1994). Phase correction adjusts the time of occurrence of each successive action but does not affect the period of the underlying timekeeper or oscillator that governs the rate of the action. Period correction adjusts the interval of the timekeeper or period of the oscillator. A conceptual parallel can be seen between the two sources of variability postulated by the Wing–Kristofferson model and the two forms of error correction: In each case, a more central process and a more peripheral process are distinguished.

Both error correction processes occur against a background of uncontrolled variability, so that they cannot be observed easily in raw data. Two general approaches have been taken to investigate error correction: mathematical modelling and perturbation methods. The first approach estimates error correction parameters from raw time-series data (asynchronies and/or inter-tap intervals), whereas the second approach manipulates the timing of the pacing sequence and averages data across repeated trials in which the same timing perturbation occurs, thereby reducing the noise in the data.

Each error correction process is assumed to be based on sensory information about the temporal relationship between the taps and the pacing sequence. Phase correction is usually assumed to be based on perception of asynchronies. A linear phase correction model (Mates 1994; Pressing 1998; Vorberg and Schulze 2002) assumes that each tap is adjusted by a fixed proportion of the asynchrony generated by the preceding tap. This model has been quite successful in accounting for synchronization with a metronome, where there is little reason for period correction to occur. Period correction is assumed to be based on perception of a mismatch between the period of the internal timekeeper and the intervals of the pacing sequence, and the correction is assumed to be a linear function of that mismatch (Mates 1994). There are alternative ways of conceptualizing the perceptual information on which phase and period corrections are based, but discussion of this issue would lead too far here (see Hary and Moore 1985,

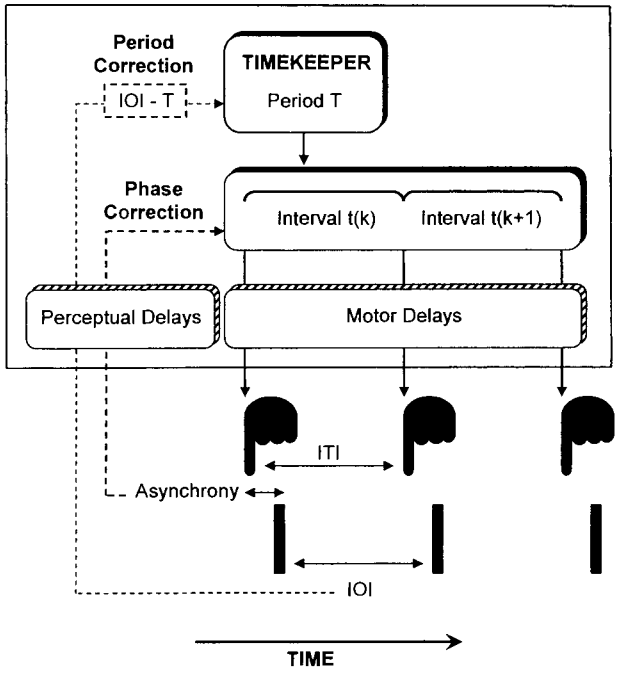

Fig. 4.1 Schematic diagram of the two-process error correction model for sensorimotor synchronization (after Mates 1994). A central timekeeper with period *T* is assumed to control the intervals [*t*(*k*), *t*(*k* +1), . . .] between successive motor commands. The period *T* can be adjusted on the basis of perceived discrepancies between its duration and the tone inter-onset interval (IOI) in the sequence (*period correction*). The intervals [*t*(*k*), *t*(*k* + 1), . . .] can further be adjusted individually on the basis of registered asynchronies between taps and tones (*phase correction*). The frame indicates internal processes; only inter-tap intervals (ITIs) and asynchronies are directly observable. They are affected by both period correction and phase correction. (From Repp and Keller 2004.) Reproduced with permission of The Experimental Psychology Society (http://www.psypress.co.uk/journals.asp)

1987; Repp 2005c). The dual-process model of error correction is illustrated schematically in Fig. 4.1.

Phase correction and period correction are hypothetical *internal* processes that affect the observable behaviour, namely the adaptation of the relative tapping phase (asynchronies) and tapping period (inter-tap intervals) to the pacing sequence. Each internal process affects *both* observable variables (Repp 2001*b*), and therefore the processes are difficult to separate when they occur in tandem. For that reason, statistical models have focused mainly on phase correction in SMS with a metronome, where period correction can be assumed to be minimal. Timing perturbations in the pacing sequence, however, may elicit both phase and period correction, most obviously when the perturbation is a persistent tempo change. An estimate of period correction may be obtained by stopping the pacing sequence at various points and asking participants to continue tapping at what they consider the final tempo (Repp and Keller 2004).

The period of continuation tapping provides a retrospective estimate of the period of the internal timekeeper at the point where synchronization changed to self-paced tapping.

There is a good deal of evidence that phase correction is relatively automatic whereas period correction is in large part consciously controlled. Phase correction is the process that maintains synchrony with a metronome, but people are rarely aware of the continuous corrective adjustments they are making. When a phase perturbation is introduced in the metronome sequence, phase correction occurs in response to the perturbation regardless of whether or not the perturbation itself or the resulting asynchrony is detectable (Repp 2000, 2001*a*). In fact, phase correction seems to be most effective in response to small perturbations. Phase correction is also unaffected by diversion of attention (Repp and Keller 2004). When participants are instructed not to react to a detectable perturbation, they can reduce their phase correction response but are unable to suppress it completely (Repp 2002*a*; Repp and Keller 2004). By contrast, period correction in response to a tempo change in the pacing sequence is more effective when the tempo change is detectable than when it is not (Repp 2001*b*), is affected negatively by diversion of attention, and can be suppressed voluntarily (Repp and Keller 2004). Thus, whereas phase correction is a relatively low-level process that serves to stabilize SMS, period correction is a higher-level strategic process that may be involved not only in SMS but in other activities that require modulation of an internal period, such as expressive timing in music performance. Most likely, phase correction and period correction also engage different neural networks (Stephan *et al.* 2002; Praamstra *et al.* 2004), although much more needs to be learned about their neural underpinnings. A reasonable hypothesis based on existing data is that phase correction involves the cerebellum whereas period correction involves a corticothalamic circuit.

We are now ready to consider studies of SMS in situations that are somewhat closer to music performance. The next three sections divide these studies into three groups, according to the relative complexity of the pacing sequence and/or the motor activity. We first review studies of simple tapping to complex rhythms (i.e. more complex than a metronome) or to music. Then we discuss the performance of complex rhythms or of music in synchrony with a metronome. Finally, we consider tasks in which both the motor activity and the pacing sequence are complex, as they are in performance in a musical ensemble.

Synchronization of simple movements with complex sequences

Tapping a beat

One of the most commonly observed forms of spontaneous SMS is tapping a foot to the beat of music. Not surprisingly, therefore, isochronous tapping is frequently

used as a way of determining the period and phase of perceived metrical beat(s) in rhythmic patterns or in music (e.g. Oshinsky and Handel 1978; Handel and Oshinsky 1981; Handel and Lawson 1983; Parncutt 1994; Jones and Pfordresher 1997; van Noorden and Moelants 1999; Drake *et al.* 2000). However, these *beat-finding* studies are usually concerned only with the approximate position of the taps, not with asynchronies, variability, or error correction. Their main goal is not to study SMS but simply to locate the beat in the rhythmic structure, and often also to compare human performance with that of a computer algorithm. A few recent studies, however, have looked at synchronization with a beat in some detail.

Snyder and Krumhansl (2001) required participants to tap to the beat of piano ragtime music which was played under computer control with metronomic timing and equalized tone amplitudes. The sequences presented were either the original musical excerpts or only the highly syncopated right-hand part of the piano score, and each version was also reduced to a monotone pitch. The pitch manipulation had no effect on synchronization, but variability was greater when participants tapped with the right-hand part alone than when they tapped with the combined left- and right-hand parts. There was no significant MNA, which is consistent with the finding of Wohlschläger and Koch (2000) that tones interpolated between beats eliminate the MNA.

Large (2000) modelled the Snyder and Krumhansl data successfully with a computer algorithm based on a network of coupled oscillators. The oscillators were coupled not only to each other but also to the auditory input (by means of a coupling function in the model), and this resulted in the entrainment of an appropriate oscillator to the beat. Coupling to input is a dynamic systems implementation of phase correction (cf. Pressing 1999). Period correction was not included in Large's model; instead, a large number of oscillators with fixed frequencies were employed, so that switching between oscillators with similar periods was equivalent to period correction.

Toiviainen and Snyder (2003) conducted a beat tapping study in which excerpts from pieces by J. S. Bach in 4/4 meter were presented in three versions: integral, left hand only, or right hand only. Some excerpts started on a downbeat, whereas others started on the second beat. Again, no MNA was found; in fact, the taps lagged slightly behind the beat. Tapping variability was slightly greater for the separate parts than for the integral version, and slightly greater when participants tapped on the third beat of each bar than when they tapped on the first beat (the nominal downbeat). Whether participants tapped on the first beat or on the third beat depended in large part on whether the excerpt started on a downbeat or on the second beat; in the latter case, the second beat was usually interpreted as an upbeat (i.e. as the fourth beat in the measure).

A recent study by Patel *et al.* (2005) was not concerned with beat finding but with tapping variability as a function of metrical structure when the period and

phase of the beat were prescribed. Strongly metrical (SM) and weakly metrical (WM) rhythms were constructed by concatenating monotone sequences used previously by Povel and Essens (1985). Povel and Essens had shown that SM rhythms induce the feeling of a strong beat, whereas in WM rhythms a beat is more difficult to perceive. The main structural difference between the two is that SM sequences have events in every beat location, whereas in WM sequences some beat events are missing. Patel *et al.* prefixed each type of sequence with an isochronous induction sequence marking the beat period. Participants started tapping with the induction sequence and continued tapping the beat after the rhythmic pattern started. The results showed that taps were significantly more variable in WM than in SM sequences.

Several other conditions were included in that study. In one condition, participants simply tapped with an isochronous sequence of beats. Variability in that condition was similar to that of tapping with SM sequences. Thus, the variously subdivided beats of the SM sequences did not stabilize tapping any more than did a simple sequence of beats. However, tapping was less variable when participants tapped with every other tone of an isochronous sequence that was twice as fast. Thus, simple regular subdivision did improve the precision of SMS (cf. Repp 2003). In another condition, participants tapped with a sequence that had been generated from an isochronous beat sequence by deleting the beats that corresponded to missing beats in the WM sequences. Taps were more variable in that condition than in tapping with an isochronous sequence of beats, which suggests that the greater variability of tapping with WM sequences than with SM sequences was due to the absence of a number of beat events in the WM sequences. Indeed, when—in yet another condition—the missing beats in WM sequences were filled in, the tapping results were just like those with SM sequences because the manipulation had turned the WM into SM sequences. The importance of beat events can be understood by considering that taps falling on empty beats do not generate any error feedback (i.e. no asynchrony). Therefore, there is no phase correction following such taps (cf. Repp 2002*c*), and this increases the variability of the subsequent tap and thereby increases the overall variability of the asynchronies.

Similarly, when a tone occurs without an accompanying tap—a likely occurrence in tapping to the beat of a complex rhythm—there is no asynchrony at that point. Nevertheless, such subdivision tones are monitored perceptually and do affect phase correction (Large *et al.* 2002). Intervening subdivision tones reduce the phase correction response to a perturbation of the beat, and they elicit a shift of the next tap when their own timing is perturbed (Repp 2002*d*). Thus, additional structure in a pacing sequence (which could be music) is readily used for guiding simple movements, but additional movements (which could be those of music making) do not necessarily help synchronization with a simple beat

(although they do reduce the MNA in non-musicians, as Wohlschläger and Koch (2000) have shown). The latter situation requires more detailed study, however.

On-beat versus off-beat tapping with rhythms

The task in beat tapping studies is generally to tap in phase with the perceived beat, although occasionally participants may prefer to tap in anti-phase. In music performance, however, various other forms of coordination can occur, such as playing a note on the second and/or third beats of a rhythm in 3/4 meter, or on the second and/or fourth beats of a rhythm in 4/4 meter. Such tasks have been investigated only very recently in the laboratory (Repp 2005 *a*, *b*).

In these studies, simple monotone rhythms were presented, consisting of cyclically repeated groups of two or three tones, with the between-group interval being twice as long as the within-group interval(s). Participants were asked to tap with a particular tone in each cycle or in the middle of the 'gap' (i.e. the long interval). In several experiments, the dependent variable was the fastest tempo at which synchrony could be maintained. The results showed that it was easier to tap with a group-initial or group-final tone (which, according to Povel and Essens (1985) carry a rhythmic grouping accent and therefore are likely carriers of the metrical beat) than with a group-medial tone or in a gap. When one of the tones was accentuated by means of higher intensity and pitch, it was easier to tap with that tone than with other tones. When the (musically trained) participants were instructed to intentionally 'hear' the metrical beat on a particular tone while tapping in various positions, this dissociation of the metrical beat from the taps had surprisingly little effect on task difficulty as measured by the rate limit of SMS. In other words, participants found it just as easy to tap off the beat as on the beat, as long as they were tapping in the same group position. However, participants found it quite difficult to dissociate the metrical beat from their taps at fast tempi. To facilitate this dissociation, another experiment used slower tempi and focused on the variability of the asynchronies. Metrical interpretation still had no effect. Surprisingly, however, the effect of accentuation also went away, and the effect of grouping accent changed as well. Clearly, further research along these lines is needed, as the pattern of results is more complicated than expected.

Tapping to slow music: effects of musical structure

In the research considered so far in this section, the number of tones in the rhythm typically exceeded the number of taps made. In other words, the beats were subdivided in various ways. Several studies have investigated instead tapping in synchrony with the lowest metrical level of very slow music, so that there were few or no subdivisions between the tones that served as synchronization targets. This is

like tapping with a metronome, except that the pacing sequence is real piano music. The question of interest is whether and how the musical structure (melody, harmony, meter, perhaps even expressive features) affects the timing of the taps.

Repp (1999*a*, *b*) asked participants to tap along with the sixteenth notes in the first few measures of Chopin's Etude in E major, a very slow piece. The music was performed metronomically under computer control. Interestingly, the asynchronies and inter-tap intervals, when averaged across a number of trials and participants, exhibited a systematic timing pattern, even though the music was in strict time. Thus it appears that some aspects of musical structure have an involuntary influence on the precise timing of coordinated movements. A later study (Repp 2002*b*) found exactly the same pattern of tap timing when participants synchronized their taps with an isochronous sequence of clicks that was superimposed on the music (Fig. 4.2b), and even when the participants merely imagined the music in synchrony with the clicks, although the variations were smaller in that case (Fig. 4.2c). When synchronizing with the clicks without imagining music, the average inter-tap intervals were essentially constant (Fig. 4.2a).

The original hypothesis leading to this research (Repp 1999*a*) was that the patterning of the taps would reflect expectations of expressive timing. However, there was only a weak resemblance between the timing pattern of the taps and the typical expressive timing profile of the music. The timing of the taps seemed to reflect more the metrical structure of the music, whereas expressive timing primarily reflects the melodic–rhythmic grouping structure. Similar conclusions were reached in a study that investigated tapping with two complete Preludes by Chopin (Repp 1999*c*). However, the structural determinants of tap timing in this situation have not been fully unravelled and are in need of further investigation.

Repp (1999*b*, 2002*b*) used the same Chopin Etude excerpt to investigate participants' ability to synchronize with expressively timed music. In the earlier study (Repp 1999*b*), the participants were pianists who had just played the excerpt on a digital piano. When they were asked to tap along with one of their own recorded performances or with a synthesized performance having a typical expressive timing pattern, they were clearly able to anticipate the expressive timing variations, but not perfectly: large deviations from regularity were usually underestimated, and the resulting asynchrony had to be corrected on the next tap(s). The later study (Repp 2002*b*) compared synchronization of taps with three kinds of sequences: expressively timed music; a monotone sequence with the same timing pattern; and music with an atypical or structurally inappropriate (phase-shifted) expressive timing pattern. Synchronization with the expressively timed music was relatively most accurate, and interestingly this advantage was already evident on the first trial. Thus, hearing the musical structure helps predict appropriate variation of expressive timing.

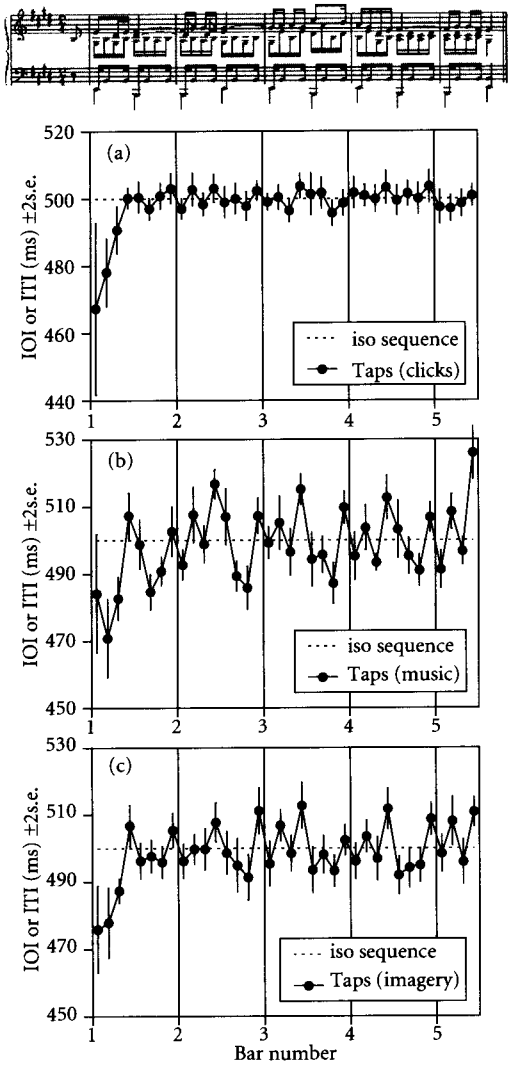

Fig. 4.2 Average inter-tap interval (ITI) profiles with double standard errors in three synchronization conditions: (a) tapping with an isochronous (iso) sequence of clicks; (b) tapping with the same sequence of clicks accompanied by isochronous music; (c) tapping with the same sequence of clicks while merely imagining the music in synchrony with the clicks. The initial three ITIs reflect the 'tuning in' to the sequence tempo. (From Repp 2002*b*.)

Synchronization with all three sequence types improved with practice (Repp 2002*b*). Initially, participants' prediction of the timing variation was relatively poor, and this was reflected in a large lag-1 correlation and a small lag-0 correlation between the sequence inter-onset intervals and the inter-tap intervals. In other words, participants mainly reacted to the variation in timing, tracking it rather than predicting it. In the course of 10 trials, however, the lag-1 correlation gradually decreased and the lag-0 correlation increased, which reflects increasing prediction. These changes can be interpreted in terms of the two error correction mechanisms, phase correction and period correction (see section on Error

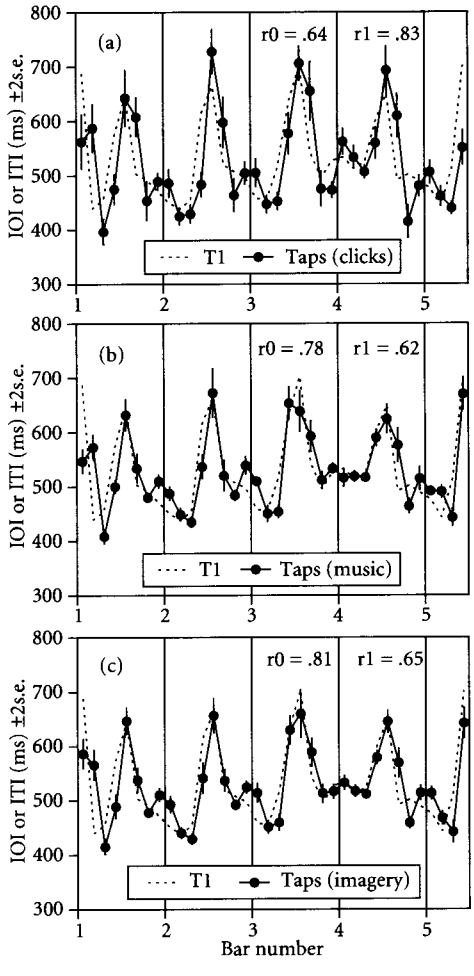

Fig. 4.3 Average inter-tap intervals (ITIs) with double standard errors in three synchronization conditions: (a) tapping with a sequence of clicks whose inter-onset intervals (IOIs) vary according to an 'expressive' timing pattern (T1); (b) tapping with the same sequence of clicks accompanied by music having the same (fairly typical) expressive timing pattern; (c) tapping with the same sequence of clicks while merely imagining the music in synchrony with the clicks. The lag-0 and lag-1 correlations between the IOIs and ITIs are also given (r0 and r1, respectively). Note the increase in r0 and the decrease in r1 in the latter two conditions relative to the first condition. (From the electronic appendix to Repp 2002*b*.)

correction above). Phase correction is the automatic reactive mechanism that causes tracking, whereas period correction is the predictive mechanism. Expectation and active prediction of a learned timing pattern presumably involve an intentional modulation of the period of the internal timekeeper. As learning proceeds, prediction via period correction improves, so that there are smaller asynchronies for phase correction to react to.

Figure 4.3 illustrates the relative accuracy of synchronizing with an expressive timing pattern that is fairly typical for performances of the excerpt from the Chopin Etude. Inter-tap intervals averaged across a number of trials and participants are shown for three conditions: synchronization with (a) a sequence of clicks with 'expressive' timing but without accompanying music, (b) the clicks accompanied by the synchronous music, and (c) the clicks while the music is merely being

imagined. The target timing pattern is shown as the dotted line. Note that the initial underprediction of large deviations is smaller in the second and third conditions than in the first condition, and this is reflected in an increased lag-0 correlation (prediction) and a decreased lag-1 correlation (tracking).

Marching and dancing to music

There have been very few systematic studies of activities other than finger tapping in synchrony with music. It can be safely assumed, however, that the basic principles revealed by finger-tapping studies also apply to other forms of synchronized movement, especially if they involve periodic contacts with a surface. That is true for the feet in both marching and dancing, whereas the arms and the body move more freely. Direct comparisons between continuous (free) and discontinuous (contact) movements in an SMS task remain to be conducted.

In this context, it should be noted that music has been used in a clinical setting to improve the gait patterns of stroke victims and patients with Parkinson's disease (see Thaut *et al.* (1999) for a summary). These patients readily entrained their steps to the music and derived greater benefits from rehabilitation training than did control groups. Thaut *et al.* hypothesized that there is a direct pathway from the auditory system to spinal motor neurons, which enables rhythmic input to drive motor action.

Synchronization of complex movements with simple sequences

Playing music in synchrony with a metronome

Playing music with a metronome is a task familiar to all music students, especially pianists. Surprisingly, however, it has not been studied in detail. In what seems to be the only study in the literature, Repp (1999*c*) asked pianists to play two Chopin Preludes in synchrony with a metronome and compared the results to playing without a metronome but in strict time (i.e. without any expressive timing). The main difference was that the correlation between successive inter-beat intervals was negative when playing with a metronome but positive when playing merely in strict time. The Wing–Kristofferson model predicts a negative lag-1 autocorrelation in self-paced rhythm production. The reason why a positive correlation was obtained instead is that there is residual expressive timing variation in performances intended to be in strict time (Penel and Drake 1998; Repp 1999*b*), and this systematic variation entails positive covariation of successive intervals. The emergence of a negative correlation in the metronome-paced condition was attributed to phase correction in synchronization. In both conditions, the timing of beats was much more regular than in normal expressive performance.

Interestingly, however, the key depressions between beats (i.e. rhythmic subdivisions) showed large deviations from regularity that were hardly affected by either synchronization with a metronome or by the mere intention to play in strict time. Thus, regularity at the beat level does not imply more regular timing at a lower metrical level.

Tapping rhythms in synchrony with a metronome or rhythm template

A recent study (Repp *et al.* 2005) investigated the tapping of 'uneven' rhythms at various tempi. In such rhythms, the inter-beat intervals are not divided evenly. The rhythms included three sets: 2 + 3, 3 + 2; 2 + 2 + 3, 2 + 3 + 2, 3 + 2 + 2; 2 + 3 + 3, 3 + 2 + 3, 3 + 3 + 2. The distinction among the rhythms within each set rested solely on which element was considered as the metrical (down)beat. The rhythms were produced in four conditions: self-paced; synchronized with a metronome, such that the downbeat taps coincided with the tones; synchronized with a precise rhythm template; and synchronized with a rapid isochronous sequence of subdivisions. The last condition served to determine the rate limit of synchronization (see section on Variability above), which was found to be considerably higher than for tapping with every fourth tone of a rapid sequence (Repp 2003), presumably due to the greater cognitive demands of uneven rhythms.

The conditions of main interest here are the other two synchronization tasks. There were four noteworthy findings. First, a characteristic distortion of the 3:2 interval ratios in the direction of 2:1 was equally present in free tapping and in synchronization with a precise rhythm template. In other words, synchronization did not increase the precision of rhythm production. Second, in tapping with a template, the downbeat tap was not synchronized more accurately than the subdivision taps. Rather, the taps generally seemed to be timed so as to minimize the mean asynchrony per rhythm cycle. Third, the asynchronies of the downbeat taps were very different in synchronization with a simple metronome than in synchronization with a rhythm template. In the former condition, they were the only taps that generated asynchronies and thus were the only asynchronies to be minimized, whereas in the latter condition, two or three asynchronies per cycle had to be balanced. Finally, which of the rhythm elements was considered the downbeat had little effect on timing and synchronization. However, the position of a tap in a rhythmic group had a strong effect on its asynchronies with a pacing sequence.

Franêk *et al.* (1988) also found that participants could not synchronize very accurately with cyclically repeated rhythms when they embodied complex interval ratios. Various other studies (e.g. Semjen and Ivry 2001; Semjen

and Vos 2002) have used a metronome to pace bimanual tapping or other periodic bimanual movements having complex interval ratios. However, those studies focused on the bimanual interaction, which is beyond the scope of this chapter.

Synchronization of complex movements with complex sequences

Playing music in an ensemble

One important topic still in need of investigation is synchronization between two individuals, even with a task as simple as tapping simultaneously or in alternation. In such a situation, each participant provides the pacing sequence for his or her partner, and phase correction (as well as perhaps period correction) will occur in both sequences. Preliminary work on such dyadic interactions has been reported by Himberg and Cross (2004) for finger tapping and by Boker and Rotondo (2003) for dancing.

Rasch (1979) measured the mean 'asynchronization' occurring between the players of three professional trios playing classical music. Asynchronization was defined as the 'root mean square of the standard deviation of the onset difference times for all pairs of voices' (p. 123) and was found to range from about 30 to 50 ms. Synchronization was better at fast than at slow tempi. Shaffer (1984) used Rasch's measure to examine the coordination between two pianists in duet playing and found asynchronization of similar magnitude, despite considerable expressive timing variation. Evidently, the pianists were able to predict each other's expressive timing to a considerable extent. In both studies, however, the musicians were able to take advantage of visual as well as auditory cues for coordination.

A recent study (Keller *et al.* in press) examined synchronization accuracy in pianists playing duets with recorded performances of one part of the duet, so that visual cues were not available. The main question was whether pianists would be more accurate synchronizing with performances recorded by themselves than with performances recorded by other pianists. This was indeed found to be the case, although the difference was small. Keller *et al.* attributed it to implicit action knowledge which enables players to predict their own expressive timing patterns better than those of other players.

Friberg and Sundström (2002) measured the relative timing of tone onsets in excerpts from recorded performances by great jazz musicians. They found that the 'swing ratio', a characteristic long–short pattern, was more pronounced in the playing of drummers than in soloists. This implies asynchronies between soloist and drummer. In contrast to the finding by Repp *et al.* (2005) that the mean asynchrony per cycle tends to be minimized when synchronizing a rhythm with a

template, Friberg and Sundström found that soloists lagged behind drummers on the downbeat but were synchronized precisely on the off-beat. This may reflect an expressive strategy of 'playing behind the beat' as well as the structural importance of off-beats in jazz. Other preliminary observations about synchronization in jazz performance have been reported by Prögler (1995) and Schögler (1999–2000).

Ensemble playing requires not only in-phase synchronization with other players but also precise alternation (anti-phase coordination) and other, more complex, forms of rhythmic coordination, as in African drumming or Balinese gamelan. Keller (1999, Keller and Burnham 2005) required percussionists to produce a memorized rhythm concurrently with a different, computer-controlled rhythm in the course of a study of 'prioritized integrative attending' (i.e. attending to one's own part as well as to the integrated rhythm of several parts (Keller 2001)). Synchronization accuracy was assessed only in a qualitative way. More studies of this degree of sophistication and realism are needed to close the gap between laboratory SMS research and actual music performance.

Following a conductor's gestures

Another interesting area awaiting investigation is synchronization of music performance with a conductor's movements, which are often far more complex than a simple beat pattern. Some preliminary work has been conducted by Luck (2002, 2004). He recorded the arm movements of several conductors when they gave a downbeat, reproduced the movement trajectory on a computer screen, and asked participants to make a single tap when they perceived the downbeat as occurring. By manipulating the shape and velocity pattern of the trajectory, he determined that velocity and acceleration were important in conveying a downbeat, but the relative importance of different variables varied from conductor to conductor.

Conclusions

A large number of SMS studies using simple movements and simple auditory sequences has laid the theoretical and empirical groundwork for a more detailed study of the synchronization skills required in music performance, dance, and some athletic disciplines. The SMS research in these latter areas is still very limited. The present chapter (which makes no claim to be comprehensive) has mentioned some relevant studies and has pointed out topics awaiting more careful study. Clearly, here is a potentially rich area for research, the results of which will be of both theoretical interest and of practical relevance.

Part 3

Movement analysis

Chapter 5

Hand movements and musical performance

Thomas E. Jerde, Marco Santello, Martha Flanders, and John F. Soechting

Introduction

Hand movements, like all movements, are subject to biomechanical and neural constraints. Accordingly, not all movements are possible and others are subject to distortions and errors. The design of musical instruments and the structure of musical compositions, as human inventions, undoubtedly conform to these constraints. Nevertheless, musical performance is a skilled and demanding task, often requiring years of practice; thus it may test the limits of these constraints. It follows that the study of motor control in music should provide a unique opportunity for delineating the neural and biomechanical constraints that also govern more mundane tasks and for describing how practice and learning shape and modify these constraints. Unfortunately, however, little is known about movement kinematics in musical performance. In this chapter we will discuss the influence of these constraints by extrapolating from observations on hand movements in other tasks.

Musical performance involves the serial execution of a sequence of notes, and as such it is a specific example of the serial organization of behaviour (Lashley 1930). It has been hypothesized that such complex movements are generated by the concatenation of simpler, basic elements, so-called movement primitives (e.g. Mussa-Ivaldi and Bizzi 2000). With practice, such movement sequences become fluent and almost automatic (cf. Hikosaka *et al.* 1995) and individual elements in the sequence may overlap temporally, a phenomenon termed 'co-articulation'. Here, we will also review some of our results on the extent of co-articulation in highly practiced behaviours such as typing, piano playing and finger spelling in American Sign Language. Finally, we will close with some general observations on the expressive requirements of musical performance and how they may affect motor performance. A schematic overview of this chapter is provided in Fig. 5.1.

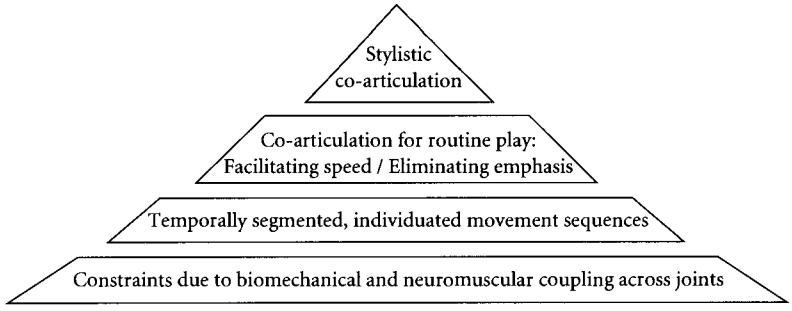

Fig. 5.1 Levels of organization affecting motor execution during musical performance. The influence of each of the levels is discussed in the text.

Biomechanical and neural constraints on hand movements

The major constraint that governs finger movements is that it is virtually impossible to restrict motion to a single finger. This phenomenon has been termed a lack of 'individuation' (Schieber 1995) or 'enslavement' (Zatsiorsky *et al.* 2000). It has been demonstrated in the somewhat artificial situation in which a subject is asked to exert isometric force with different combinations of fingers. However, it is also present during highly practiced movements such as typing, piano playing, and finger spelling (Flanders and Soechting 1992; Engel *et al.* 1997; Soechting and Flanders 1997; Jerde *et al.* 2003*a*).

An example is provided for the kinematics of typing in Fig. 5.2. The traces show the motion of proximal interphalangeal (pip) joints of the four fingers as touch typists typed each of the letters normally typed with the right hand. The heavier traces correspond to the finger actually striking the key (e.g. the *P* for the little finger) and the traces are arranged according to the layout of the keyboard. It is clear that each of the fingers is in motion for each of the keys, irrespective of whether or not the finger actually strikes a key or not. Furthermore, the motion at each of the pip joints had a similar time course, and an amplitude that showed a spatial gradient (largest for the *Y* and smallest for the *P* and the *L* for the little, ring, and middle fingers).

The kinematics of finger movements during piano playing exhibit similar features (Engel *et al.* 1997) although they were not studied in as detailed a fashion. A lack of individuation is also present during finger spelling (Jerde *et al.* 2003*a*). Many of the postures corresponding to the letters of the alphabet in finger spelling are at the limits of joint motion (e.g. one or more fingers fully flexed or extended), to facilitate their visual recognition. That is to say, finger spelling should foster individuation of finger movements. Nevertheless, we found that we could identify, with a high degree of reliability, the letter that was spelled from the posture of only 4 of the 15 measured degrees of freedom of the hand (using

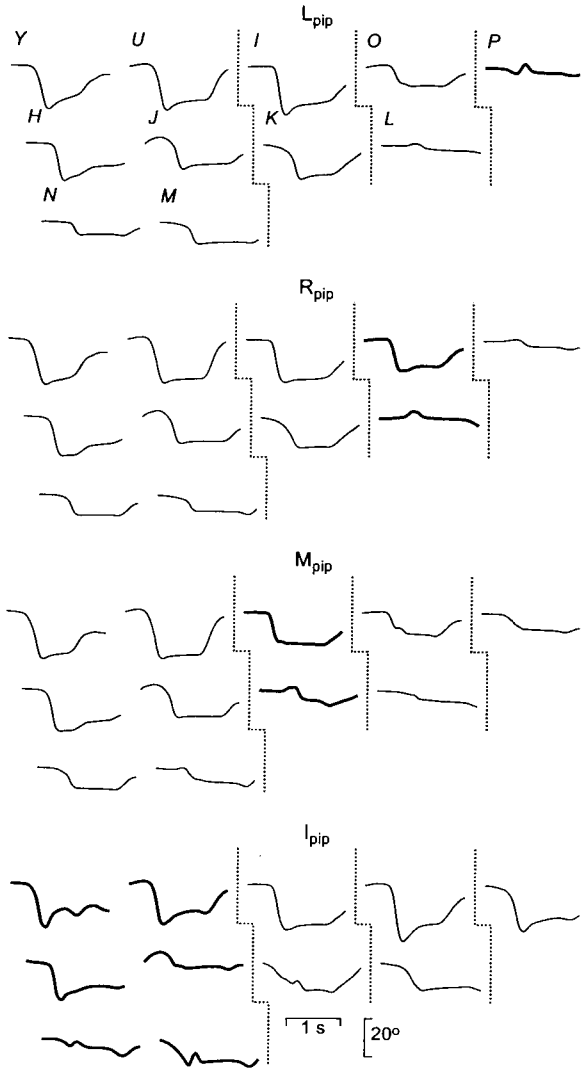

Fig. 5.2 Motions of the proximal interphalangeal joints (pip) of each of the four fingers (index, I; middle, M; ring, R; little, L). Traces depict finger motions spanning the keypresses of each of the letters typed with the right hand, a downward deflection corresponding to extension. Each of the letters was embedded in words in which the surrounding letters were typed with the left hand. Traces corresponding to the finger actually striking the key are emphasized with a heavier line style. Note the similarity in the pattern of motion at all of the joints. (Adapted from Soechting and Flanders (1997).)

one joint of the thumb and one each of the ring, middle, and index fingers). For example, we could differentiate the *I* and the *S* (which ideally differ only in the posture of the little finger, fully flexed for *S* and extended for *I*) on the basis of the postures of the three other fingers and the thumb.

Tasks requiring the use of multiple digits such as whole-hand grasping are also characterized by a few, well-defined patterns of motion regardless of object geometry (Santello and Soechting 1998; Santello *et al.* 1998) and sensory modality used to shape the hand (Santello *et al.* 2002; Winges *et al.* 2003). The predominant pattern underlying all hand postures, independent of the number of digits used

for grasping, consisted of simultaneous flexion/extension of all digits (Santello *et al.* 1998, 2002) resulting from consistent covariations in the angular excursion of the metacarpal and proximal interphalangeal joints. This, in turn, leads to closing and opening of the hand as a unit. However, using a principal components analysis, we showed that higher-order principal components, which accounted for only a small amount of the postural variability, nevertheless contributed a significant amount of information about the object to be grasped. The results suggest fine control of finger movements superimposed on these simpler patterns.

These simple kinematic patterns emerge from a concatenation of mechanical and neural factors. The mechanical factors include the coupling among the muscle compartments and tendons of long flexors and extensors of the fingers (Fahrer 1981; von Schroeder and Botte 1993; von Schroeder *et al.* 1999; Keen and Fuglevand 2003). These muscles also cross several joints within each finger, further increasing the mechanical coupling between movements occurring at these joints. These passive linkages limit the extent to which we can move one finger independently of others in tasks involving the production of individuated finger force (Hager-Ross and Schieber 2000; Zatsiorki *et al.* 1998, 2000).

The neural factors include the organization of inputs to the motor neuron pools of hand muscles. The fibres of a given motor unit can exert force on more than one tendon (Kilbreath *et al.* 2002) and activation of such motor units would inevitably lead to forces being produced by digits that should not be involved in the task. Furthermore, motor units controlling distinct digit compartments of flexor and extensor muscles receive common input during production of individuated finger force (Reilly *et al.* 2004) as well as whole-hand grasping (Winges *et al.* 2003). This also leads to forces being generated at non-instructed digits.

The selective activation of hand muscles to produce motion of single or multiple digits probably plays an even more important role in the dexterous control of the hand. Due to the biomechanical architecture of hand muscles, complex co-activation patterns of many muscles are required to produce individuated finger movement as well as to prevent motion at non-instructed digits (Schieber 1995; Reilly and Schieber 2003). These observations suggest that the neuromuscular architecture of the hand might have evolved to allow the coordinated action of *multiple* digits rather than individuated finger control. Hence it is not surprising that extensive practice is required to attain the exquisite dexterity and individuation of finger movement necessary to play a musical instrument.

Movement sequences and co-articulation

Co-articulation, or the influence of preceding and following movements on posture in movement sequences, is a key aspect of skilled motor planning, and has been demonstrated in speech (cf. Kent and Minifie 1977). We initially sought

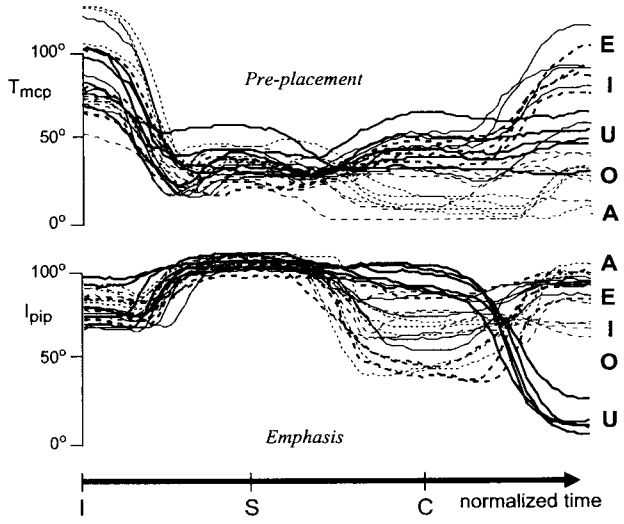

Fig. 5.3 Assimilation (pre-placement) and dissimilation (emphasis) during finger spelling. Traces depict the motions at the metacarpophalangeal joint of the thumb (T_{mcp}) and of the index pip joint (I_{pip}) as a subject finger spelled words containing the letters ISC followed by one of the vowels (e.g. DISCOVER). Note that the posture at the two joints at the time of the 'C' depends on the upcoming vowel. Posture at the I_{pip} emphasizes the distinction between the C and the next letter, while postural changes at the T_{mcp} are minimized. (Adapted from Jerde *et al.* (2003*b*).)

to find evidence for this phenomenon in sequences of finger movements in typing (Soechting and Flanders 1992). However, that task is characterized by a strictly serial organization of movements; the finger movements that characterize one keypress are unaffected by the subsequent letter in the sequence up until the time of the keypress for the first letter. This was true when the next letter was typed with the opposite hand or with the same finger or a different finger of the same hand. In a more recent study of finger spelling in American Sign Language (Jerde *et al.* 2003*b*), we did find that in fluent finger spelling of individual words the hand posture spelling a given letter contains significant information about preceding and following letters (Fig. 5.3). These forward and reverse influences can be characterized as assimilation and dissimilation. In assimilation, the difference in joint angles between succeeding letters is reduced, which we interpret as pre-placing or leaving behind certain fingers. On the contrary, in dissimilation, the difference in joint angles is increased, interpreted as emphasizing the difference in hand shape between the letters. Instances of assimilation and dissimilation occurred in the same movement sequence, at the different joints (emphasizing the fact that individual joints can be controlled independently, the evidence presented in the previous section notwithstanding). Importantly, the joints which showed the greatest dissimilation were those that had been previously shown to

contain the most information about the letter being spelled (Jerde *et al.* 2003*a*). Thus it appears that in finger spelling co-articulation occurs not just as a result of optimization of kinematic profiles but also as a communicative strategy to enhance intelligibility.

Musical performance is another instance of highly practiced, skilled sequential movement in which we might expect co-articulation to play a role. Like speech or finger spelling, a highly practiced task with specific constraints on the timing of execution, the playing of a musical instrument generally involves the assembly of discrete movement units in sequence, in which movements corresponding to specific notes might be adjusted depending on what notes precede or follow. Engel *et al.* (1997) showed that certain manoeuvres in piano playing (such as the thumb-under manoeuvre when an ascending scale is played) do elicit measurable anticipatory modifications in hand kinematics, but only in specific instances, unlike the general phenomenon of co-articulation observed in speech and finger spelling. Thus it appeared that a basic level of music performance may consist of temporally segmented movement sequences (see Fig. 5.1). However, as we continue to investigate organization of movement in musical performance we may better understand the role of co-articulation, and in what ways it may be manifested, by considering more generally how a highly skilled musician translates a musical representation into a sequence of movements according to specific artistic demands.

Motor control and musical expression

To understand more fully the role that co-articulation plays in musical performance, we should first understand its role in the music itself. Music can be defined broadly as temporally organized sounds, where each individual sound draws its significance from its relation to the others preceding and following it. In modal and tonal music, representing the majority of developed music in most cultures, a piece or passage of music is written in a certain key. This means that a specific pitch, called the 'tonic', is the foundation for the scale, and every note derives salience (and significance in analysis) from its relationship with the tonic pitch. With regard especially to the past four centuries of Western tonal music, the strongest function of a pitch is the force with which it leads back to the tonic pitch. This return to the tonic is called a cadence, and is usually perceived with a sense of finality or satisfaction; cadences of various types comprise the harmonic backbone that provides structure to the music. The pitch most predominant in the music immediately before the cadence is typically the fifth note of the scale, also called the 'dominant'; when this pitch is prominent in the underlying harmony, a cadence is usually expected. Other pitches in the scale have similarly

important and distinctive roles: the seventh pitch is the 'leading tone', which usually also leads strongly back to the tonic, several other pitches have similar leading tendencies establishing a complex vocabulary of harmonic progression, and the third pitch, depending on how wide the interval is between it and the tonic, defines the mode of the scale as major or minor, which greatly affects the mood of the music. Besides these harmonic considerations, a melody by its very nature derives its distinct character from the ordering of its pitches, and how each pitch relates to the harmony underlying it. Thus the context relating a note to others surrounding it, and the particular transitions that join them, are fundamental aspects of musical structure.

Because of these interdependences in the roles of individual notes in a piece of music, a sensitive, artistic performance depends on the performer's awareness of each note in the context of others surrounding it—for example, a pitch of C# acting as the third in an A major chord might be played differently from one acting as the leading tone in D major, even in the same passage. This phenomenon can be observed clearly in expressive melodic devices such as appoggiaturas and suspensions, which are notes that form dissonance with expected harmony. A performer can greatly heighten dramatic tension in a musical phrase by emphasizing these unexpected pitches, setting them apart from the surrounding notes by differences in volume, articulation, and timbre. In such cases, a musician must strive consciously to alter the performance of a note to draw attention to its musical role. The effect can be enhanced by altering the surrounding notes as well, to increase contrast with the note to be emphasized.

Several gross movements preceding the altered note may require adjustment to accommodate these alterations: a violinist may need to take more bow, and a wind player may need to draw extra breath several measures in advance. These types of movements represent a kind of reverse influence reminiscent of that observed in co-articulation, but it is hardly surprising that one can predict a horn player is going to play something louder because she takes a large breath. However, more subtle motor co-articulation might be observed in adjustments made on a more local level to facilitate the emphasis of particular notes. For example, a pianist can apply greater force in striking a key if the finger (or the entire arm) is raised, which requires upward movement in advance of the key-press. On a conscious level, the pianist is probably thinking about the note to be accented and the extra force necessary (the stroke), and not the preparation that must be accomplished during preceding notes (the lift). In fact, the pianist Vladimir Horowitz recommended that students attempting to learn to accent one note independently of others in a chord should at first consciously alter their hand and finger position prior to striking the chord, allowing the behaviour to become automatic with practice (Horowitz 1928). If such a technique is indeed

employed in performance, it ought to be possible to measure the modification of posture or muscle activation prior to an accented note.

In contrast to conscious applications of context-dependent nuance, musicians require practice to develop the co-articulation required to eliminate unwanted emphases from a phrase brought about by biomechanical constraints (Fig. 5.1). For example, in playing a simple scale, pianists must perform a 'thumb-under' manoeuvre to reach all the notes in sequence with the fingers of one hand, and the larger movement necessary to accomplish this imparts a natural tendency for these notes to be different from the surrounding ones in timing and in volume. It takes considerable practice to iron out these timing irregularities and unwanted volume changes by anticipatory compensation, so that the musician can play a scale with every note having equal emphasis. It is only from a baseline of smooth, unaccented performance that a musician can employ musical taste with precision, to overlay the basic phrase with nuances of articulation and intensity.

Thus a musician must undergo thorough training to be able, at an automatic level, to eliminate differences between notes, while simultaneously, at a conscious level, to emphasize differences between notes for stylistic effect (Fig. 5.1). In physical terms, both these effects must be achieved by anticipatory adjustments to the movement sequence. In general, the overlapping of multiple layers of nuance over a musical phrase (involving both steadiness and change in volume, articulation, and tempo flexibility) where these expressions are carried out by a kinematically connected physical system subject to biomechanical constraints as well as simple inertia, suggests that even if strict serial ordering of discrete movements were possible in performing a musical phrase, the results would be artistically inferior to what might be obtained were the control of each movement to be tailored to reflect the dynamic musical and muscular context in which it occurs. As Horowitz said: 'So if I play all the notes steadily along, without graduation, or without relating one to another, and without climactic or guiding emphasis, I have said nothing, even though I may have played the notes correctly and in correct time' (Horowitz 1932). Conceivably, the mechanisms used to diminish or emphasize differences in physical execution between notes in a musical phrase might be related to the assimilation and dissimilation demonstrated in finger spelling.

The technical proficiency that is required to play evenly and to layer nuances onto a musical phrase does assume the ability to play the notes in that phrase accurately and in the correct order, but this is in itself no small feat, as anyone who has tried to play an instrument can tell you. From a motor control perspective, the effortlessness with which experienced musicians accomplish this translation from notes on a page to a complicated movement sequence is perhaps even more interesting than the refinements and adjustments that set

apart a truly remarkable performance from a mediocre one. On this basic level, the importance of note-to-note transition movements becomes even more apparent, and is reflected in the standard pedagogy of musical performance. Taking the example of a wind instrument player, step one in learning the technique of the instrument is memorizing which keys must be closed to produce a given note. But mastering these static fingerings is only the lowest level of competence. Serious music students pursue practice routines of technical exercises designed expressly to isolate the most important finger movement sequences. Musicians practice endless varieties of scales and arpeggios, because in Western music if you know them in all 12 keys, you have already trained to automaticity a rather high percentage of all the note-to-note transitions and sequences you might encounter in the repertoire (Wye 2003). It is the systematic overlearning of these transitions that allows effortless fluency in performance, like acquiring a comprehensive vocabulary of note-combination transitions. Musicians also practice these patterns with varieties in tempo, volume, and articulation, attempting to internalize all combinations of conditions that might be required in a performance situation. Linda Gruson notes: 'Musical practising may be viewed as a sequence of transitions from controlled to automatic processing in which larger and larger chunks of musical information are built up from more basic sub-components' (Gruson 1988).

In this sense, musical performance is very similar to speech: the low-level selection of movements must become an automatic process so that it does not interfere with conveying the intended meaning. As an orator does not have to consciously decide how to conjugate an upcoming verb, neither does an accomplished pianist have to waste cognitive resources deciding at what point in a long scale to perform a thumb-under manoeuvre. Like an orator might decide beforehand to use a particularly cogent word or choice of word order, a pianist may consciously pre-select a particularly elegant fingering for a tricky passage. And just as an orator, despite needing command of an enormous working vocabulary, need not have practiced a specific sentence in order to say it fluently, likewise a good pianist can sight-read unfamiliar music by breaking it down into chunks and piecing them together in accordance with a standard syntax of well-studied harmony.

Even the best pianists (as well as orators) do occasionally make mistakes, however. But again, like in language, there is a tendency for musicians to make plausible mistakes that fit within the correct harmonic framework, such as playing the wrong note of a chord, rather than playing a note which is not even a part of the chord (Schaffer 1981). This tendency may be a result of both conscious and unconscious processes. Consciously, if a performer feels hesitation regarding the proper note to play, making a very quick decision is made simpler by having a

constricted range of options, limited to only those that are harmonically acceptable; this reflects an effective cognitive strategy to deal with performance error. However, an alternative explanation may involve not a conscious cognitive strategy but instead reliance on the musician's highly practiced motor programs. In a moment of crisis during performance, it is conceivable that the performer unconsciously reverts to better-established motor programs that correspond with the given harmonic situation.

The facility with which musicians learn movement sequences can also be seen in the tradition of violinists and pianists in particular to play entire recitals from memory. Here, musicians can rely not only on specific motor programs established during practice, but on other forms of memory. Visual memory plays a substantial role for some, both of the printed score and of the hands on the keyboard, and auditory memory as well. But one of the most important techniques available to highly trained musicians is analytic memory. As Aiello and Williamon (2002) describe, 'while inexperienced pianists might strive to remember all the individual notes that occur in the right and left hands in a certain measure, experienced pianists might easily recognize that those notes constituted a cadential formula in a particular tonality. Their knowledge of harmony, together with their advanced keyboard skills, would enable them to play these notes with ease.... This process of chunking allows for rapid categorization of domain-specific patterns and accounts for the speed with which experts recognize the key elements in a problem situation'. They also note several examples of professional pianists who avoid relying on kinesthetic or 'muscle' memory to perform memorized recitals, claiming it is less reliable than analytic memory. This method not only demonstrates the highly developed analytical skills that experienced musicians have available to them, but also underscores the efficiency with which they can assemble units of their musical motor vocabulary into fluent sequences. It appears that for those who have achieved true mastery of their instrument, translation from a musical representation in memory to specific motor sequences does not require conscious attention.

Chapter 6

Movement analysis in pianists

Hans-Christian Jabusch

Introduction

Performing instrumental music at a professional level is arguably among the most complex of human accomplishments. As is the case with other instrument families, playing on keyboard instruments requires movements with highest spatiotemporal precision. Piano music such as that from the late nineteenth century is often characterized by a hypercomplex structure and a high density of notes. In virtuoso Late Romantic music, pianists have to bimanually coordinate the production of up to 1800 notes per minute, as for example in the 6th Paganini Etude by Franz Liszt (Münte *et al.* 2002). Visualization and analysis of movements associated with such virtuoso keyboard playing as well as with simple motor tasks on the keyboard have been conducted for different purposes. Two different principles have been applied: (1) the analysis of motion of the upper extremities of the musician or (2) the investigation of the processes taking place in the instrument such as key movements or hammer movements as indirect parameters describing the musician's actions. In the following section a brief historical overview is given of the development of both directions of study.

Historical overview

Early approaches of visualizing mechanical processes during keyboard playing resulted from attempts in the eighteenth century to record keyboard music. In 1780, Joseph Merlin constructed a so-called Klavier-Cembalo which recorded key movements as graphite lines on a clockwork-driven paper roll (Kopiez 1996). In 1895, Binet and Courtier installed a rubber tube between the keybed and the keys of a piano. Depression of a key resulted in a change in air pressure within the tube which was graphically visualized on a paper roll and indicated the duration and loudness of a tone (Binet and Courtier 1895). The temporal resolution of this system was about 1 ms (Kopiez 1996).

Piano teachers made early attempts to understand the hand motion of pianists in order to find an efficient method for playing the piano. However, the ideas of different teachers were frequently contradictory. As an example, the influential

piano pedagogue and composer Reinecke and his students suggested the principle of a fixed and a quiet hand, the keys being struck by flexion of the fingers applying only minimal motion of the forearm and metacarpus (Schultz 1962). In contrast, based on anatomical knowledge and pianistic experience, Matthay and Breithaupt advocated a touch using the arm weight which should be produced by relaxing the supporting muscles. This was argued to be the best touch for playing on a modern concert piano (Matthay 1903; Breithaupt 1912). The limitation of such statements was the fact that they were based on the teachers' personal experiences rather than on objective data or scientific observations. They did not make a clear distinction between perceptual reality and physical reality.

In the 1920s Ortmann was the first investigator to conduct extensive research on movement analysis of the piano-playing hand using a variety of technical devices which we shall outline briefly (Ortmann 1929). Direct lever recording was applied for assessment of simple motor tasks on the piano: aluminium levers were attached to the fingers closely behind the proximal interphalangeal (PIP) joints and one additional aluminium lever was attached to the metacarpus. The levers created lines on a paper roll of a so-called kymograph, recording movements of the hand as well as movements of the fingers in the metacarpophalangeal (MCP) joints. In order to detect small movements, adjustment of the levers offered three-times magnification. Attaching the levers to different parts of the movement apparatus of the hand allowed for the recording of motion of various joints or parts of the upper extremity, and visualization of their interactions during piano playing became possible. Their reaction to the resistance of the piano key as well as to finger–key–surface impact and finger–key–bed impact could be detected by simultaneous recording of the key movement using an additional lever system. Contraction of large muscles like the pectoralis major was assessed by an apparatus consisting of an airtight chamber and a plunger which was attached to the muscle. Contraction of the muscle resulted in pressure on the air chamber thus moving a piston which was connected to a writing lever. Using a combination of these devices, relationships between the time of muscle contractions and movements as well as the course of contraction and relaxation of different muscles could be illuminated during simple movements on the piano. Ortmann investigated the impact of different tempi and dynamics on muscle contractions in simple motor tasks and demonstrated that the patterns of muscle activation changed with each change of tempo or dynamics. Lateral arm movements were recorded using a pantograph which consisted of a lever system with a tracing point attached to the wrist and a recording point drawing its motion on a plain paper surface. Recording of complex movements was achieved using a photographic plate under subdued ambient light conditions: small electric bulbs were attached to those parts of the finger, hand, or arm, the movements of

which were to be recorded. Long-term exposure during complex movements on the piano allowed photographic recording of these movements. Photographic plates were arranged in two or three different planes and displayed the movements in two or three dimensions. Ortmann documented complex finger and hand movements such as in slow and rapid scales, arpeggios (chords with the individual notes being played subsequently), and other movements, and again he found the crucial impact of speed on the coordination of movements in a given motor task (Fig. 6.1). As a conclusion for piano practice, he recommended that from the beginning each passage should be practiced at that tempo and dynamics at which it is finally to be played. Moreover, Ortmann gave detailed descriptions of hand and finger movements in different conditions such as different touch forms (e.g. legato: notes are played in a smooth, connected manner; staccato: notes are played short and detached), different levels of pianistic ability, and inter-individual anatomical differences, and he gained insights relevant for piano technique, piano pedagogy, and piano practice which are still valuable today.

Bernstein and Popova undertook an impressive study with the aim of finding phenomena that were reproducibly seen in professional pianists and of

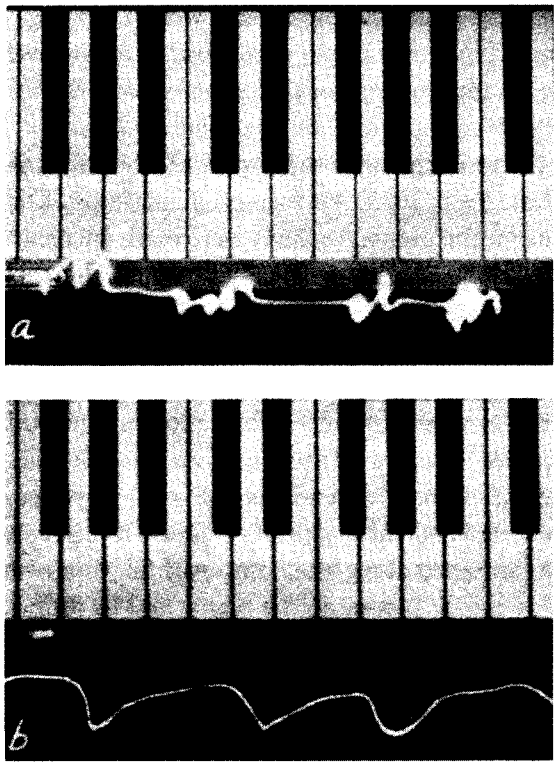

Fig. 6.1 Movements of the metacarpus in a very slow (a) and a rapid (b) C-major scale, played on the piano with the right hand in the upward direction. Movements are displayed as bright lines and were recorded photographically from above with a light bulb attached to the metacarpus. (From Ortmann 1929.)

which were to be recorded. Long-term exposure during complex movements on the piano allowed photographic recording of these movements. Photographic plates were arranged in two or three different planes and displayed the movements in two or three dimensions. Ortmann documented complex finger and hand movements such as in slow and rapid scales, arpeggios (chords with the individual notes being played subsequently), and other movements, and again he found the crucial impact of speed on the coordination of movements in a given motor task (Fig. 6.1). As a conclusion for piano practice, he recommended that from the beginning each passage should be practiced at that tempo and dynamics at which it is finally to be played. Moreover, Ortmann gave detailed descriptions of hand and finger movements in different conditions such as different touch forms (e.g. legato: notes are played in a smooth, connected manner; staccato: notes are played short and detached), different levels of pianistic ability, and inter-individual anatomical differences, and he gained insights relevant for piano technique, piano pedagogy, and piano practice which are still valuable today.

Bernstein and Popova undertook an impressive study with the aim of finding phenomena that were reproducibly seen in professional pianists and of

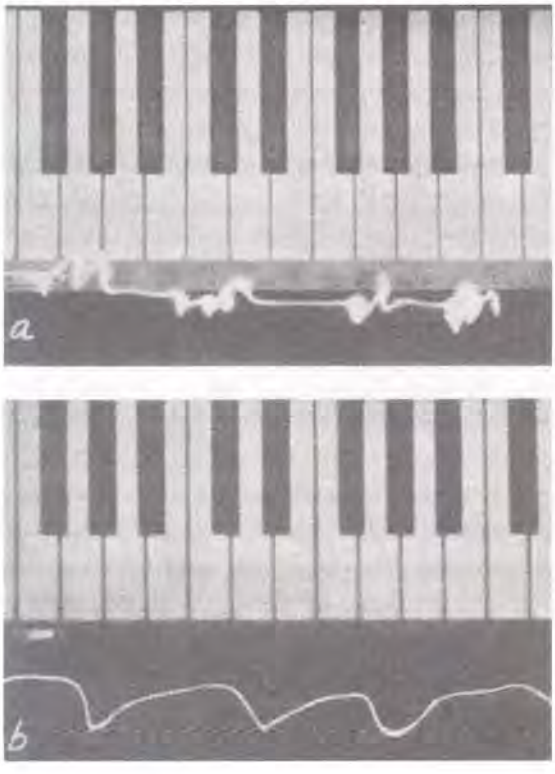

Fig. 6.1 Movements of the metacarpus in a very slow (a) and a rapid (b) C-major scale, played on the piano with the right hand in the upward direction. Movements are displayed as bright lines and were recorded photographically from above with a light bulb attached to the metacarpus. (From Ortmann 1929.)

understanding basic mechanisms underlying pianistic movements (Bernstein and Popova 1929; Kay *et al.* 2003). In order to investigate the influence of the variables of tempo and strike force on the coordination of a certain movement, they focused on one pianistic task which consisted of octave repetitions played with the right hand under standardized conditions. Fourteen professional pianists performed the task several times at different dynamic levels ranging between pianissimo (very soft) and fortissimo (very strong) and in different tempi up to 500 strikes per minute. A kymocyclographic camera allowed visual recording of movements of light bulbs attached to the skull, the shoulder, the elbow joint, the wrist, and the metacarpus according to a principle similar to Ortmann's but as moving pictures and with a temporal resolution of up to 520 images per second. Graphodynamic methods were used to define motions of the centres of mass of the different segments of the upper extremity as well as their accelerations and the inertial forces at these points. Combining these sophisticated methods, Bernstein and Popova described physical laws underlying movements in octave repetitions. During slow tempi, movements consisted of isolated impulses; at medium tempi, movements corresponded to those of a complex pendulum; at the fastest tempi, movements transformed into forced elastic oscillations, similar to those of a simple pendulum with the wrist being kept passively elastic. Concerning the frequently discussed topic of 'arm weight playing', they reported that at very slow tempi falling of the arm purely under its own weight was seen occasionally, whereas at tempi over three strikes per second downward movements of the arm were always accompanied by muscular activity.

In 1932, Seashore conducted experiments with the aim of an 'objective analysis of musical performance' (Seashore 1936, 1938). He focused on patterns of timing and loudness in interpretations on the piano. Analyses were made by recording the hammer movements in the piano using the so-called 'Iowa piano camera' which translated piano tones into a bar code. This was created by light beams which recorded the hammer movements on a film and allowed the analysis of temporal structures of piano playing with a resolution of 10 ms. Additionally, the system recorded the hammer speed, providing indirect information on the loudness of playing. Motion of the upper extremities of the musician was not assessed. Seashore investigated temporal variations within a piece (agogics) played several times by the same pianist. He reported high intra-individual similarities in patterns of timing during repeated performance of a given composition. Moreover, he analysed patterns of loudness of chords played on the piano, and he found that chords were played with an accentuation of the highest note. Much later, these findings were confirmed by computer-based performance research.

During the following decades, no further progress was made in movement analysis in piano playing. Similar to other authors, Gát suggested various principles

of piano methodology based on his anatomical knowledge and pianistic experience (Gát 1956). He underlined his ideas with several series of photos of piano-playing hands. These photos were of accomplished pianists and demonstrated successful movement patterns to piano students and teachers. Beyond visual inspection for pedagogical purposes, however, they did not allow for an identification of general principles of motion on the piano.

In the late 1960s Wagner initiated a new era in the analysis of piano playing by applying the latest technical innovations to his studies. He investigated standardized motor tasks in order to understand basic timing phenomena in piano playing. He used an electronic device which was attached to the mechanics of the piano and produced electrical impulses when a hammer touched a string (Wagner 1968). The measuring error was 1 ms. Wagner recorded the inter-onset intervals in simple scale-playing tasks within a five-tone range under standardized conditions and in different pianists. He described reproducible individual patterns of irregularities in inter-onset intervals (Wagner 1968) and reported on the influence of tempo on the regularity of inter-onset intervals in scale playing. Standard deviations of inter-onset intervals were lowest, demonstrating a low degree of irregularity, for a medium tempo of between 6.1 and 8 strokes per second (Wagner 1971). The irregularity of inter-onset intervals increased in the ranges of higher as well as of lower tempi. In 1973, Wagner and colleagues used a computer-based feedback system in order to provide assistance in the process of piano practice. The pianist was informed about the precision of timing parameters after the performance of different exercises. The inter-onset intervals were used as a primary target variable, and feedback was given, especially with regard to temporal evenness as well as rhythmic precision in playing. Wagner objectified inter-individual differences in the stability of inter-onset intervals (Fig. 6.2) in scale playing and introduced so-called performance diagrams which provided graphical representation of timing precision and its improvement during the process of practising (Wagner *et al.* 1973).

Current development

Since the early 1980s there has been growing interest in the analysis of movements and performance in piano playing, from different perspectives: (1) music psychology focused on performance research and expertise research in piano-playing; (2) in neuroscience, piano playing was chosen as a paradigm for research into sensory-motor control; and (3) in the field of musicians' medicine, movement analysis in piano playing became a promising diagnostic tool and provided insights into the pathophysiology of playing-related disorders. Current developments shall be outlined in the fields of both movement analysis of the upper extremities and analysis of indirect parameters such as key movements or hammer movements.

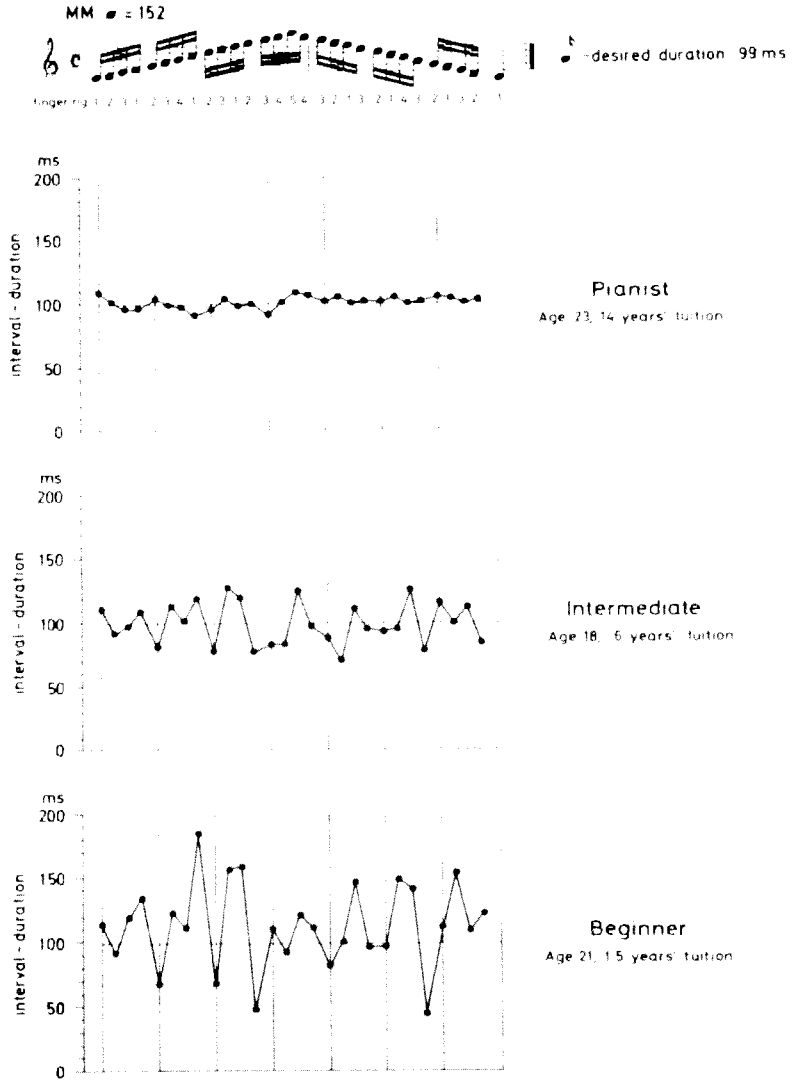

Fig. 6.2 Inter-onset intervals (termed interval duration) of subsequent notes in C-major scales played by a beginner, an intermediate student, and a professional pianist and recorded using a computer-based device attached to a Bechstein piano. (From Wagner *et al.* 1973.)

Analysis of keyboard-related parameters

After the establishment of the 'music instrument digital interface' (MIDI) protocol as a standard of digital processing of music, the first MIDI keyboards were introduced in 1983. MIDI allowed a computer-based analysis of performance parameters such as loudness and timing parameters, the latter with a precision in the range of milliseconds. MIDI keyboards provided information about onset

and offset times of tones, about tone pitch, and about key velocities as an indirect measure of loudness. MIDI became a valuable tool for investigation of topics in music psychology. In the following, several examples are given for this application. Using a MIDI keyboard, Wilson recorded trills and a segment of Chopin's B-minor Sonata played by different pianists. He visualized tone durations and inter-onset intervals and described individual playing patterns (Wilson 1992). Krampe investigated the role of deliberate practice in the acquisition and maintenance of high-level skills in pianists (Krampe 1994). Using a MIDI keyboard, he focused on the repeatability of musical performance in 48 pianists of different ages and levels of skill who were repeatedly playing J. S. Bach's Prelude No.1 in C major from the first volume of the Well-Tempered Clavier. Consistency of interpretation was used as a marker of musical skill. Krampe found that variations of tempo and dynamics were more consistent in professional pianists than in amateurs. There was no age-related decline in the variation of speed and loudness. Additional information was obtained by means of diaries, by retrospective estimates about past amounts of training, and by the analysis of other skill-related tasks. As a result, Krampe described a model based on the relation between intensity of practice during various life phases and performance which explained group differences in skill-related tasks.

MIDI-based analysis was used for the monitoring of practice effects after mental practice (Highben and Palmer 2004), for transfer-of-learning experiments (Meyer and Palmer 2003), and for error analyses (Repp 1996*b*; see also Chapter 3). Several MIDI-based studies with the focus on temporal and dynamic features of piano performance were published by Repp. In two pianists playing Schumann's 'Träumerei' at different tempi he found that major temporal and dynamic features of the performances changed roughly in proportion with the tempo (Repp 1994). In MIDI recordings of 10 pianists playing from the Romantic and Impressionistic piano literature, analysis of note-onset times revealed a pervasive tendency for the highest-pitched notes to lead the lower-pitched notes. Strong correlations were found between average MIDI velocity differences and average lead time (Repp 1996*a*). MIDI recordings were utilized to determine the relation between performance parameters and the structure of the composition. In MIDI recordings of the Classical and Romantic piano literature, timing patterns and dynamic characteristics served to underline the structure of the music (Repp 1990, 1996*c*). Similarly, Shaffer (1995) found that performance both elucidated structure and invented a musical character which reflected patterns of expression. In earlier studies, Shaffer used a modified Bechstein grand piano for examination of timing and dynamics and their relation to the musical structure. The piano was equipped with optical sensors to allow recording of timing and dynamics, based on hammer velocity, with a measuring error of less

than a millisecond (Shaffer 1981). Analysis of timing patterns in a Bach fugue played by an expert pianist led to the assumption that timing was determined by some form of underlying clock system. Timing in polyrhythmic structures of three against four played with both hands in a Chopin etude (No. 1 in F minor from the 'Trois Nouvelles Etudes') was analysed with respect to independence of movement in different hands and fingers. There was great use of rubato (flexible tempo), and there was evidence that the metrical polyrhythm was played under two levels of deformation: one was a rubato common to both hands, the other was a temporal displacement of one hand relative to the other. Shaffer suggested that an abstract representation of motor output is mapped into two command arrays, one for each hand, each having a clock timing with a flexible coupling between both clocks (Shaffer 1981).

MIDI-based analysis of piano performance as an indirect measure of finger motion was reported by Jabusch *et al.* (2004). In a study with 13 professional pianists, the evenness of scale playing in the legato style was investigated, with special focus on hand and finger coordination in the thumb-under movements in the ulnar playing direction as well as finger cross-over manoeuvres in the radial playing direction. The pianists played sequences of 10 to 15 C-major scales over two octaves in both playing directions and with each hand separately. Scales were played using the regular C-major fingering (1–2–3–1–2–3–4–1–2–3–1–2 –3–4–5 and reverse). The tempo was metronome-paced and standardized at 120 beats per minute for a quarter note, and scales were played in sixteenth notes. As an example, scale analysis results are reported for the right-hand tests. Over all scales of all pianists the mean standard deviation of inter-onset intervals was 8.1 ms in the ulnar playing direction and 8.9 ms in the radial playing direction, indicating an extraordinarily high level of evenness in playing. This was achieved by a peculiarity in the coordination of the thumb-under movements (3–1 and 4–1 fingering in the ulnar playing direction) and finger cross-over manoeuvres (1–3 and 1–4 fingering in the radial playing direction). In the preparation phase of thumb-under movements in the ulnar playing direction, there was a consistent finding of significantly shortened tone durations of notes preceding the tones played by the thumb. This resulted in minimal gaps (mean 13.0 ms) between the notes at the 3–1 and 4–1 fingering positions (Fig. 6.3). In the radial playing direction, such significant shortening of tone durations in the preparatory phase of finger cross-over manoeuvres was seen in the 2–1 fingering positions, indicating an early pronation movement of the hand facilitating the 1–3 as well as 1–4 finger cross-over manoeuvres. Impaired auditory perception in the temporal proximity of key strokes due to auditory forward and backward masking phenomena may explain that such irregularities in the note offsets are not perceived and are therefore not a focus for practice (Yost 2000).

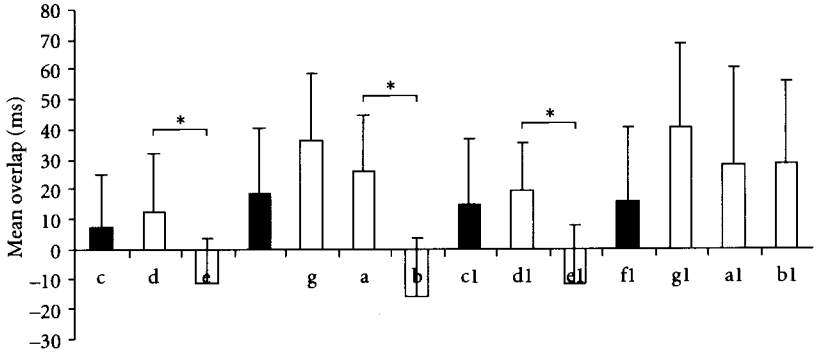

Fig. 6.3 MIDI-based scale analysis (Jabusch *et al.* 2004). Overlaps of subsequent notes of an upward C-major scale played in the legato style with the right hand. Bars display the mean values of repeated performances of 13 healthy professional pianists (error bars: standard deviations). Black bars indicate notes played with the thumb. Negative overlaps indicate short leaps at the positions of the thumb-under movements (*$P < 0.01$).

Upper extremity movement analysis

Technical progress in three-dimensional movement analysis during the 1990s allowed optoelectronic recording of upper extremity motion with a high spatial and temporal resolution. The ELITE system (B.T.S., Milan, Italy), for example, consists of several infrared-sensitive cameras which after illumination by infrared light capture the position of reflective markers. These can be attached to the fingers or other parts of the upper extremity. Three-dimensional coordinates of the markers are traced automatically during motion at a sampling rate of 100 Hz and with a spatial resolution of about 0.3 mm (Engel *et al.* 1997; Sforza *et al.* 2003). Engel *et al.* (1997) used this system in combination with MIDI-based performance analysis and recorded the movements of the right wrist and fingers of pianists. The pianists played scales with identical beginnings and different continuations, either including or excluding thumb-under movements. The aim of the study was to ascertain in which way hand and finger kinematics diverged prior to the depression of the last common note. As a result, playing an ascending scale with the requirement of a thumb-under manoeuvre could evoke an anticipatory modification as much as 500 ms in advance of the last common note as compared with scale playing without thumb-under movement (Engel *et al.* 1997). In view of these findings, it was suggested that a strict serial execution of a movement sequence was favoured as long as this was compatible with the demands of the tasks. Sforza *et al.* (2003) used the ELITE system in order to investigate the repeatability of finger movements during scale playing in different pianists with different experience. Repeatability of movements of different recordings was analysed for each finger by superimposing the traces of the

vertical coordinate of the finger tip of the different recordings as a function of time. Comparison of the areas under these superimposed graphs revealed a repeatability of between 65.8 and 81.4% (mean superimposition) in five different pianists. Repeatability was found to be lower in experienced pianists than in learners and teachers. As a possible explanation, the experts were suggested to be more focused on other aspects of musical performance than hand and finger movements. This might be in contrast to less experienced pianists who might be more focused on the movements required for execution of a basic task such as scale playing (Sforza *et al.* 2003). Palmer and Dalla Bella (2004) used a combination of MIDI and three-dimensional movement analysis using video cameras and passive markers on pianists' hands and fingers to investigate the relation between tempo and movements. Pianists repeatedly performed short melodies with increasing tempi until they made errors. Most tempo-related changes in the variability of finger movements were observed in the plane perpendicular to the keyboard. Peak amplitudes of motion before striking the keys increased as tempo increased. It was concluded that increased movement amplitudes at faster rates may reduce or compensate for trade-offs between speed and accuracy.

Movement analysis in musicians' medicine

Movement analysis in keyboard playing has frequently been reported in the context of musicians' medicine. Pain and overuse syndromes are frequent among pianists, and many musculoskeletal problems in pianists appear to be due to technique, working conditions, or posture (Brandfonbrener 2000). There is an early report by Salmon and Newmark (1989) about the applicability of MIDI in analysing technical aspects of musical skills in the context of musicians' medicine. They suggested using MIDI to assess the impact of hand and finger injuries and to evaluate the effects of rehabilitation programmes. Fry *et al.* (1998) investigated motor control in pianists suffering from musculoligamentous overuse in the arms and hands. They compared parameters such as tone durations, inter-onset intervals, key velocities, and time off the metronome beat in MIDI recordings of pianists with overuse syndromes and a matched group of pianists with no history of overuse. They found more skill-based errors in affected pianists and concluded that a disturbance of coordination could be observed in pianists with an overuse syndrome.

Movement analysis in pianists has been used to find risk factors for overuse syndromes and to identify 'protective behaviour' on the piano with the aim of prevention of overuse. In order to elucidate the influence of finger positions on forces in joints, tendons, ligaments, and muscles, Harding *et al.* (1989) developed a two-dimensional mathematical model of a pianist's finger. Different pianists played on a force-calibrated MIDI keyboard, and recording data were analysed to

determine those finger positions that minimize biomechanical tensions in tendons and joint forces during piano playing. Multiple key strikes played with the same key velocity (loudness) and with different finger positions were analysed. Compared to other positions, the use of a curved finger position with a large flexion angle of the metacarpophalangeal joint was found to reduce tensions in the flexor tendons and resultant forces in the finger joints. It was concluded that the described model might help pianists to minimize tendon tension and joint forces with the particular aim of prevention of injury. In a subsequent study, Wolf *et al.* (1993) used the same method and an additional video system consisting of two cameras. One camera recorded the pianists' hands in the vertical view, another recorded the horizontal view in a sagittal plane. Eight injury-free pianists with different levels of experience were recorded playing a passage from one of Mendelssohn's Songs Without Words (opus 19/2). Data for the force of the key strikes correlated inversely with piano-playing experience. In keeping with Harding *et al.*'s (1989) observation, a curved finger position with an almost perpendicular contact between the distal phalanx and the key resulted in the lowest force coefficients in the distal interphalangeal (DIP) joints as well as in the tendons of the flexor digitorum profundus muscle (Wolf *et al.* 1993). Bejjani *et al.* (1989) also investigated piano playing with this curved finger position and compared it with a flat hand position with extended fingers as well as with a roof-like position characterized by a right-angle flexion in the MCP joints. Using three-dimensional video analysis and surface electromyography of eight muscle groups of the right upper extremity, they found that the curved finger position required a maximum of abduction–adduction movements in the MCP joints, and the flat hand position with extended fingers required the minimum of such movements. The latter position was associated with significantly less activity in the flexor carpi radialis muscle than the other positions. Activity of the anterior deltoid muscle was independent of the hand position. The roof-like hand position with a right-angle flexion in the MCP joints was associated with greatest range of ulnar–radial deviation (Bejjani *et al.* 1989). The impact of playing technique on wrist kinematics was also studied by Chung *et al.* (1992). They examined 'weight playing' pianists who were playing with increased usage of intrinsic hand muscles and forearm rotation and limited use of long flexors and extensors, and compared them with pianists playing in the 'traditional style'. Using a biaxial electrogoniometer, they found that in exercises and in classical music 'weight playing' was associated with less wrist motion than 'traditional playing'. The opposite was found for flexion–extension activity in the wrist during arpeggios and trills. Traditional pianists tended to exhibit increased radioulnar activity (Chung *et al.* 1992).

Biomechanical load in different joints depending on different motor tasks was investigated by Sakai *et al.* (1996) using a passive movement analysis system

(Expert Vision System, Motion Analysis Corp., Santa Rosa, CA, USA) which provided an accuracy to within a 0.1% error of the field of view. Ten pianists were examined during scale playing and during the playing of repeated chords. Specific joints were identified which displayed different biomechanical loads during playing of different motor tasks. In scale playing, flexion was mainly observed in the MCP joints whereas the proximal interphalangeal (PIP) joints were extended. In contrast, playing of repeated chords was associated with repeated flexion, predominantly at the wrist joint. The maximum extension angle of the wrist was significantly larger in chords than in scales; the maximum extension angle in the MCP and PIP joints was significantly larger in scales than in chords. Maximum flexion in the DIP joints was larger in scales than in chords (Sakai *et al.* 1996).

Hand ergonomics and their influence on touch control were studied by Lee (1990). Biomechanical variables such as hand and finger length, hand width, finger span, and ulnar deviation were measured in 13 pianists who played a 'tied-finger' exercise and an arpeggio exercise over more than two octaves. Pianists with greater wrist mobility played the tied-finger exercise with a shorter note duration and in a faster tempo, and they had less sustaining control of the tied finger. No impact of biomechanical variables was seen on arpeggio playing.

Dynamic finger forces in pianists with different levels of skill were investigated by Parlitz *et al.* (1998) using a modified grand piano with an f-scan sensor-matrix foil (Tekscan Inc., Boston, MA, USA) connected to a computer. Two groups of pianists, one amateur and one expert group, played three tied-finger exercises by Dohnanyi with different levels of difficulty. From dynamic force measurements, the mean pulse per touch as well as the mean touch duration were analysed. Playing in a standardized tempo and loudness, amateurs applied significantly higher forces to the keys, with a longer duration. Finger forces and duration increased with higher demands in both amateurs and expert pianists. Since the resolution of force detection was limited, a more sophisticated system was developed. In order to identify 'economy' in piano playing, Tiedemann and colleagues used a grand piano with modified keys allowing for continuous force measurement during all stages of key strike and release (Drescher *et al.* 1999; Tiedemann *et al.* 2000). The keys were constructed as double transverse beams, each with four strain gauge foils which detected the forces acting on different positions of the key and allowed precise force measurement independent of the finger position (Fig. 6.4a). Using this device, forces acting on the keys were obtained before and after onset of the tones in expert pianists, amateurs, and novices. A computer program was developed which provided real-time visual feedback of applied forces (Fig. 6.4b). Novices were playing in a 'force-uneconomical' way,

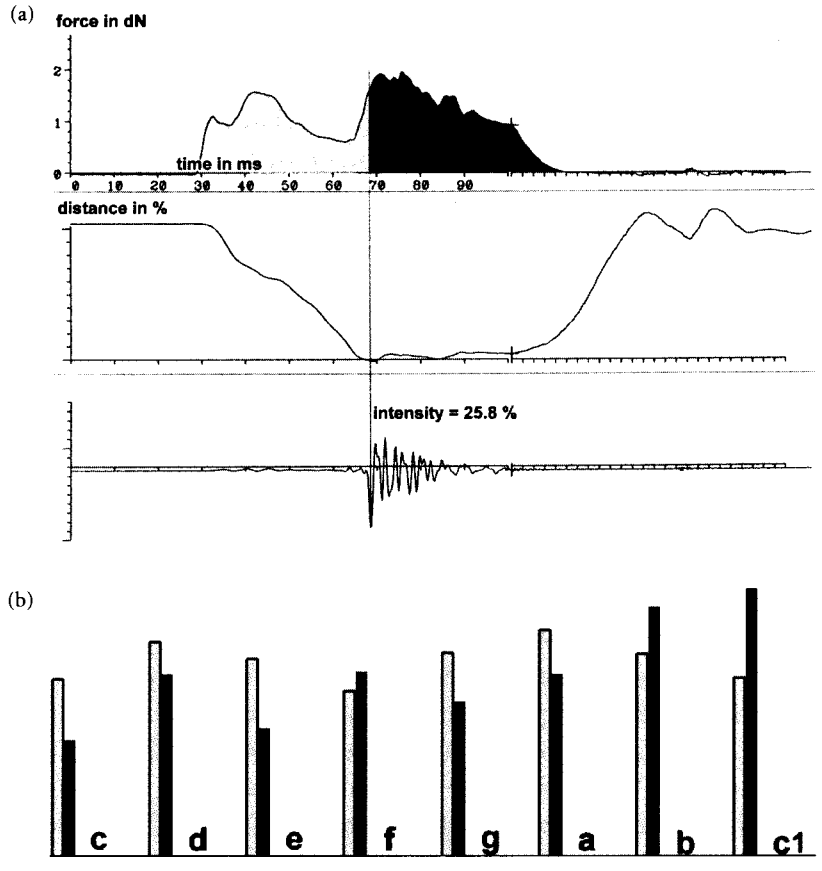

Fig. 6.4 (a) Graphical representation of the force applied to a piano key (upper graph), the distance of key travel (middle graph) and the negative acceleration of the hammer while striking the strings (lower graph) during a single key stroke and release. The force/time area prior to note onset is shaded in grey; the force/time area after note onset is shaded in black. (b) Visual feedback screen after playing a C-major scale. The column pairs indicate force/time areas prior to note onset (grey) and after note onset (black) for all notes of the scale. Especially after onset of the notes f and b and c1, a lot of force was acting on these keys, demonstrating playing with 'uneconomic force'. (Adapted from Drescher 1999.)

applying high key forces especially during the period after onset of the tone and before key release. The forces acting on the key in this period were significantly lower in expert pianists and amateurs and could even be reduced after 5 min of playing with visual feedback of key forces in both groups. Playing *con espressione* (with musical expression) was associated with higher after-onset forces acting on the keys, even in expert pianists. It was concluded that advanced and expert pianists applied strategies to reduce unnecessary forces in piano playing and that

in emotionally intense playing even experts preferred expressive gestures over 'economical' use of forces (Tiedemann *et al.* 2000).

Jabusch *et al.* (2004) described the application of the aforementioned MIDI-based scale analysis for quantification of focal dystonia in pianists. In focal dystonia (see Chapter 17), involuntary flexion or extension of individual fingers fundamentally impairs technical skills on the instrument. Because focal dystonia is task-specific, quantification has to be carried out while the patient is executing the task; thus a pianist has to be evaluated while playing the piano (Altenmüller 2003). Scale playing is affected early during onset of pianist's dystonia. Jabusch *et al.* (2004) conducted MIDI-based scale analysis of standardized and metronome-paced C-major scales in eight patients with pianist's dystonia and eight healthy pianists matched for age, gender, handedness, and pianistic expertise. The individual duration of the disorder in the patient group was between 6 months and 8 years (2.9 $\pm$ 2.5 years) at the time of the study. Mean standard deviations of inter-onset intervals (sIOI) were calculated as a measure of irregularity in scale playing. Consistently, higher values were found for sIOI in affected hands of patients (26.3 $\pm$ 9.9 ms) compared with the hands of the healthy group (9.5 $\pm$ 2.1 ms; $P < 0.001$, Mann–Whitney U-test) displaying a higher level of irregularity in patients' scales. By calculating the mean sIOI plus two standard deviations in healthy reference hands a range of normality was identified (sIOI $<$ 13.7 ms) for the healthy subjects of this study. All sIOI findings in dystonic hands were above this range of normality. Thus, sIOI was found to be a highly discriminative parameter for the playing impairment in dystonic pianists. One patient was treated with injections of botulinum toxin A (see Chapter 17). Treatment effects were monitored by a series of 11 follow-up examinations within a time period of 151 days. After a significant initial decrease of symptoms, on day 32 post-injection, the sIOI value was inside the range of normality yielded in this study. At this time, the patient was able to play technically demanding pieces which had not been possible before treatment. Subsequently, slow fading out of treatment effects could be monitored by gradually increasing irregularities in inter-onset intervals. A second injection of botulinum toxin A on day 147 resulted in significantly lowered sIOI values 4 days later (Fig. 6.5). All subjects were recorded playing scales on audio/video. Three raters blinded to the state of health of the pianists rated the recordings according to the four-step Arm Dystonia Disability Scale (ADDS) (Fahn 1989). Subjective rating scores correlated with sIOI values (Spearman $r = 0.79$, $P < 0.01$). sIOI values, however, provided a higher resolution than the ADDS scores. MIDI-based scale analysis, especially the sIOI parameter, turned out to be a precise and reliable tool for indirect assessment of motor control in pianists with and without movement disorders.

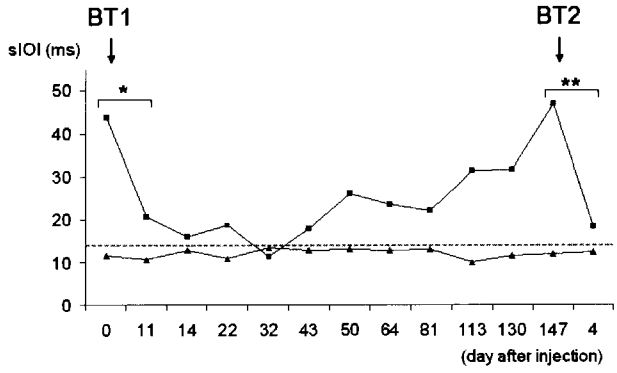

Fig. 6.5 MIDI-based scale analysis results for a pianist with focal dystonia of the right hand during therapy with botulinum toxin A (BT). The degree of irregularity is reflected by mean standard deviations of inter-onset intervals (sIOI). Black squares: sIOI values for the affected hand. Black triangles: sIOI values for the unaffected hand. The area under the dashed line is the range of normality. BT1, date of first injection of BT; BT2, date of re-injection of BT (*$P < 0.01$; **$P < 0.001$). (From Jabusch *et al.* 2004.)

Conclusion

Movement analysis in piano playing has been at the focus of different disciplines such as music psychology, piano pedagogy, neuroscience, and musicians' medicine. Analyses were based on two principles, either the detection of motion of the upper extremity of the pianist or the investigation of keyboard-related parameters indirectly describing the pianist's actions. As early as the 1920s, and with limited technical equipment, physiologists had conducted impressive studies and drawn conclusions about the basic physical principles of pianists' hand movements, some of which are still valid today. Technical progress in three-dimensional movement analysis and in MIDI-based techniques has helped to improve spatial and temporal resolution of movement detection and performance measurements to ranges of millimetres and milliseconds. Other techniques, such as force measurements and electromyography, have been described in order to examine a variety of additional parameters simultaneously. All these sophisticated methods have allowed illumination of the principles of pianists' motor behaviour and motor learning and the role of practice and expertise. For medical problems such as overuse syndromes and focal dystonia these techniques have helped to find risk factors or have served as diagnostic tools.

Although the technical possibilities are great and the numerous studies described above have been performed with high precision and thoroughness, our understanding of movements in pianists is still limited. We have to admit that we are far from understanding the complex phenomena and processes taking place when a pianist masters a piece with maximum demands, such as Franz Liszt's 6th

Paganini Etude. It remains enigmatic how a pianist manages to produce up to 1800 key strokes per minute, every note being played with a temporal precision in the range of milliseconds and every note embedded in a grand musical context which we experience as musical beauty.

Chapter 7

Fingering and bowing in violinists: a motor control approach

Mario Wiesendanger, Andreas Baader, and Oleg Kazennikov

Overview

The degree of motor control required by professional violin players is staggering and derives from many years of continuing practice, typically beginning at a young age. The constraints of the musical score as well those due to the 'handling' of the violin demand continued efforts to master rather awkward positioning and the fast and asymmetric movements of different bowing speeds and the required temporal and spatial precision in fingering. The main aim of our work described in this chapter was to assess the timing of inter-limb coordination during playing of a simple tune on the violin. With an optoelectronic video system, we recorded the trajectories and their time derivatives of individual fingers (left), and bow strokes (right). Fingering was characterized by serial and parallel (anticipatory) mechanisms. Furthermore, timing and pitch (the spatial precision of contact between the finger and the string) were often determined by a combined action of two fingers of the left hand. Surprisingly, we found that synchronization between bow and finger actions could deviate by about 50ms, rarely up to 70 ms, from ideal synchronization (0 ms). This 'error' was, however, not perceptible. We explain this finding as being due to a delayed initiation of the string vibrations and the build-up to a full spectrum of sound after initiation or reversal of bow strokes. A number of delaying mechanisms intervene during playing, such as movements of the whole hand along the fingerboard (position changes), finger changes to another string, bow reversal, and bow-string changes. These irregularly occurring events need extra time (of the order of 20–30 ms), and yet these factors do not disturb the flow of the music. It has also been established that string vibrations occur about 50 ms after the initiation of a bow stroke (the sticking effect). We therefore concluded that the physical properties of vibrating strings allow for a smooth perception of the flow of sound, even with deviations of about 50 ms from perfect bow–fingering synchronization. Music also needs instances of sharp accentuations, e.g. with beat and syncopation. In preliminary

investigations with force gauges we measured bowing forces, i.e. grip force at the frog with the right thumb and the middle finger and the pressure exerted on the bow with the right index finger. These forces control tonal intensity, from the softest pianissimo (*pp*) to the loudest fortissimo (*ff*). Gradual fluctuations in intensity (crescendo and decrescendo), as well as quick changes in intensity for accentuations of the melody are reflected in the kinetics of bowing. In addition the pressure executed mainly by the right index finger also needs to compensate for the ever-changing bow lever: when the bow moves toward the tip of the bow (the down-stroke), the bow pressure has to increase progressively in order to maintain a constant intensity of tone. In the case of an up-stroke, the bow has to be unloaded progressively. We conclude that even relatively simple investigations may provide interesting insights into the rich field of biomechanics and motor control in music performance.

Some history of motor control in music performance

A major emphasis in music research has been on perceptive aspects including rhythm, timbre, harmony, syntax, and semantics, and recently also much on its representation in the brain. Auditory perception is, however, preceded by, and the result of, an extraordinarily high level of skillful motor control. To play virtuoso music, like Paganini's Capricci, requires exceptional skills in bowing and fingering, sometimes combined with awkward postures of the fingering and bowing limbs. Execution implies an exquisite temporal and ordinal precision of finger and bow movements, together with a fine-grained force control. It therefore imposes considerable difficulty for beginners and also advanced players.

Acknowledged violinists typically start their career at a young age, i.e. when the brain has a high plastic capacity (Elbert *et al.* 1995; Münte *et al.* 2002). In view of the complexity and spatiotemporal precision of musical skills it is no surprise that research into music performance lags behind studies of perception, with the exception of rhythm studies (e.g. Palmer 1997; Repp 1999). One of the pioneers in this field was W. Trendelenburg, a physiologist in Tübingen and an accomplished cellist, who published a book (Trendelenburg 1925) on playing stringed instruments from a physiological point of view. Among many aspects of playing stringed instruments, he discovered that the initiation of bow movement precedes the development of string vibration by about 50 ms, a problem that became relevant to our work and to which we will turn our attention below. Nicolai Bernstein, a well-known Russian pioneer of biomechanical studies of natural goal-directed movements, developed sophisticated instrumentation to study and assess the complex biomechanics of motor routines in workers. However, an interest in arts and music led Bernstein, with Popova (Bernstein

and Popova 1929), to embark on an extensive study of 14 concert pianists to explore the kinematics and kinetics of piano key strokes. The task was to play, one-handed and at different metronome speeds, some fragments of piano music. Four light bulbs were fixed to a pianist's arm (including the back of the hand) and one on the head. In addition, one bulb was fixed in the workspace serving as a stationary reference point. By means of a specially designed movie camera and a mirror system placed at an angle from the camera, they managed to obtain three-dimensional coordinates of trajectories and their temporal derivatives (chronocyclography). The movie camera had a rhythmic shutter to sample discrete points on a sensitive film. In addition, load impacts on the keys were also measured. The aim was to calculate the interplay of gravity and inertial forces of arm–hand acceleration as a function of the dynamics of the key strokes and of imposed tempo changes. This was a truly novel way of assessing the biomechanics of music performance. Their paper is now little known, probably because it was published in German in an obscure periodical. Later Braitenberg (1986), a neuroscientist and viola player, had similar reflections about the interactions of passive and active forces in bowing, as well as the learned co-planar arm segments of rectilinear bow strokes and bow tilts for string changes.

The many types of bowing, with the large varieties of tempo, loudness, timbre, and accentuations, can be as demanding as the fingering of the left hand. A challenging problem is the asymmetry and also, to a large extent, the independence of bimanual actions in string players. In contrast to keyboard instruments and the harp (with separate strings for each playable note), the violin has only four strings. This means that the full exploitation of tones requires whole-hand translations along the violin neck (termed position changes) as well as frequent string changes. In order to select a new string, the bow has to rotate around the string–bow contact, mainly effected by shoulder elevations and adductions. As well described by Braitenberg (1986), bow strokes, executed parallel to the bridge and co-planar with the upper arm, are constrained by dynamic adjustments of hand abductions and adductions and flexion–extension of the elbow. Bow strokes result in dynamic changes of the bow leverage and therefore require a parallel 'fine-tuning' of compensatory forces (the bow becomes heavier when the hand is nearing the bridge in an up-stroke). Since the loudness of a tone depends on the pressure exerted on the bow (mainly by the index finger), the production of bow forces must integrate both constraints, leverage and loudness.

String players have to 'catch' the correct spatial intervals on the fingerboard. The spatial intervals, corresponding to half-tone intervals along the fingering board, are non-linear and not marked (in contrast to the guitar). Correct positioning with the fingertips for the intended pitch (also called fingerstops and double stops when two fingers are placed simultaneously on two different

strings) is a major stumbling block for amateur string players and requires intensive learning and memorizing over years of practice for correct intonations. Superimposed on the above technicalities one finally, and most importantly, has to add the musical features, i.e. intentional modulations of tempo, loudness, timbre, and even pitch (vibrato), features that essentially mark the individual artist.

In the following we report on our initial biomechanical study in violinists who were asked to repeatedly play a simple tune on a single string. The primary objective was to assess the temporal features of bimanual coordination, i.e. the synchronization between bowing and fingering. In a second step, we also measured the dynamics of bowing and the consistency of the fingering in more complex tone sequences, requiring changes of string and position. These aspects do not include all the features of 'real' professional music. Nonetheless, it is a basic prerequisite to learn about simpler mechanisms. We observed various mechanisms that were present in all players. In addition it was also clear that subtle differences occur among players in terms of strategies, as will be shown below. Achievement of the same goal with the use of variable strategies is a typical feature of volitional goal-directed movements and reflects the principle of motor equivalence (Lashley 1930; Hebb 1949).

A new approach to assessing the timing of fingering and bowing

We have succeeded for the first time in recording the trajectories of bow and finger movements in violin players (Baader *et al.* 2005). For this we used a movement analysis system with the objective of measuring synchronization of the two limbs. To obtain trajectories of the playing fingers (index, middle, ring, and little), reflecting markers were affixed dorsally, close to the fingertips. With respect to bowing, we did not record the multi-articulate movements of the right arm segments but rather the resulting bow trajectories. Therefore, one marker, or three markers for three-dimensional recordings, were fastened on the bow to obtain bow trajectories. Initially, the reflecting moving markers were recorded with one video camera (Elite, 100 Hz, infrared strobe, example shown in Fig. 7.2); more recently, a three-camera-system (Vicon, 200 Hz) was used for improved three-dimensional recordings of markers (Plate 1 and Fig. 7.3). Unavoidable whole-body movements distort the proper finger and bow trajectories. Therefore, additional reflecting markers were placed on the violin in all recordings in order to transform room-centred coordinates into violin-centred coordinates. We constrained the musical passage to a simple tune played on one string, without position changes of the fingering hand. Each tone was produced by a new *détaché* bow stroke in an ascending or descending sequence. This

enabled us, in a relatively simple way, to approach our goal of assessing bimanual coordination in the context of an asymmetric, skillful, and goal-oriented musical task. Nevertheless, the present task was still based on long-term learning of bowing and fingering and should be distinguished from frequently used bimanual rhythms, such as simple in-phase/anti-phase finger tapping (see Obhi 2004).

Figure 7.1(A) shows the markers on the finger tips providing trajectories of the left-hand fingers, three markers on the bow for bow trajectories, and three markers on the violin for the coordinate transformation. Figure 7.1(B) shows the corrected finger and bow trajectories for a simple sequence played on the D string. The quasi-straight bow strokes and the movements of the fingers, as they tap on the string, are clearly distinguishable.

Figure 7.2(A) illustrates the finger and bow movements of two amateur players who repeatedly played the tune on the D string; the displacement profiles (position versus time) from 10 repetitions were superimposed and aligned at mid-sequence. In an ascending sequence, one can clearly discern when a given finger produced a tone by depressing the string, also termed the fingerstop, i.e. when a short horizontal profile coincides with the horizontal lines indicating the string–fingerboard position. Following the small horizontal bars (below string position), one can easily verify the correct tone sequence corresponding with the musical notation (7.2B). The notes E, F, G and A were played, respectively, by index, middle, ring, and little fingers, whereas tone D was played on the empty D string, i.e. with all fingers lifted (shaded intervals). As in all players, the records of both these players were remarkably consistent, even in the smallest details of the profiles.

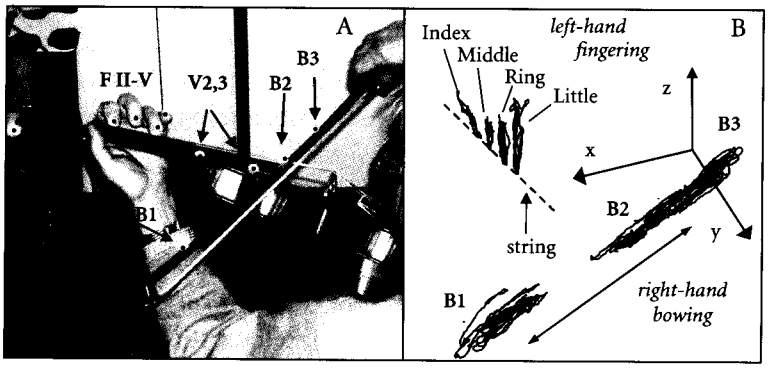

Fig. 7.1 (A) Set-up of reflecting markers for three-dimensional recordings of bow movements (B1, B2, B3) and of finger movements (F II–V). Markers V1, V2, and V3 are used as reference for transforming finger and bow coordinates into violin-centred coordinates. (B) Finger and bow trajectories after coordinate transformation.

enabled us, in a relatively simple way, to approach our goal of assessing bimanual coordination in the context of an asymmetric, skillful, and goal-oriented musical task. Nevertheless, the present task was still based on long-term learning of bowing and fingering and should be distinguished from frequently used bimanual rhythms, such as simple in-phase/anti-phase finger tapping (see Obhi 2004).

Figure 7.1(A) shows the markers on the finger tips providing trajectories of the left-hand fingers, three markers on the bow for bow trajectories, and three markers on the violin for the coordinate transformation. Figure 7.1(B) shows the corrected finger and bow trajectories for a simple sequence played on the D string. The quasi-straight bow strokes and the movements of the fingers, as they tap on the string, are clearly distinguishable.

Figure 7.2(A) illustrates the finger and bow movements of two amateur players who repeatedly played the tune on the D string; the displacement profiles (position versus time) from 10 repetitions were superimposed and aligned at mid-sequence. In an ascending sequence, one can clearly discern when a given finger produced a tone by depressing the string, also termed the fingerstop, i.e. when a short horizontal profile coincides with the horizontal lines indicating the string–fingerboard position. Following the small horizontal bars (below string position), one can easily verify the correct tone sequence corresponding with the musical notation (7.2B). The notes E, F, G and A were played, respectively, by index, middle, ring, and little fingers, whereas tone D was played on the empty D string, i.e. with all fingers lifted (shaded intervals). As in all players, the records of both these players were remarkably consistent, even in the smallest details of the profiles.

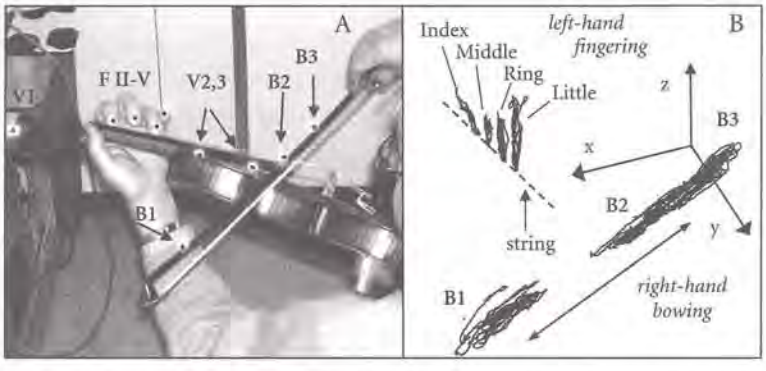

Fig. 7.1 (A) Set-up of reflecting markers for three-dimensional recordings of bow movements (B1, B2, B3) and of finger movements (F II–V). Markers V1, V2, and V3 are used as reference for transforming finger and bow coordinates into violin-centred coordinates. (B) Finger and bow trajectories after coordinate transformation.

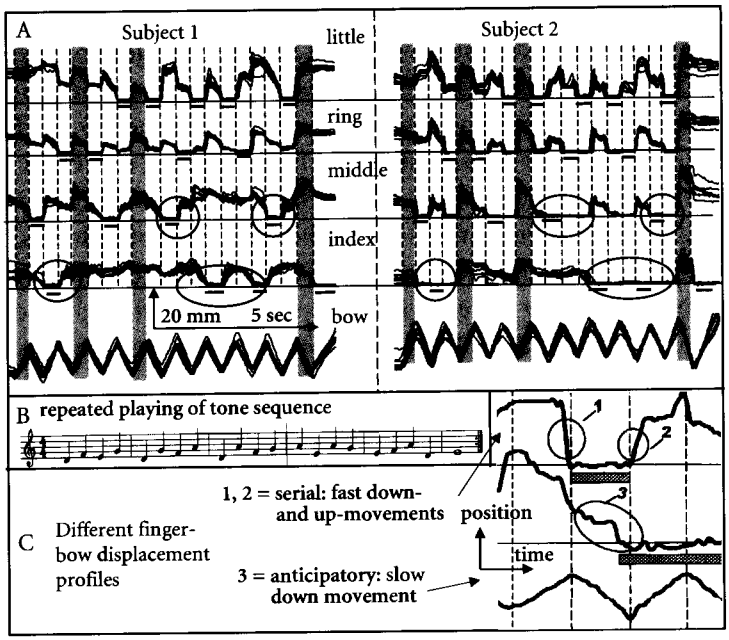

Fig. 7.2 Finger and bow displacement profiles (position versus time) in two subjects playing a simple tune (bottom). All notes are played on the D string; the board/string position is shown separately for each finger as a horizontal line. Fingerstops are underlined (black bars) and allow one to identify the correct sequence of the tune. Horizontal segments of finger displacement traces without string contact reflect the 'enslaving' of neighbouring fingers momentarily not engaged in tone production. The vertical dashed lines mark the sequence of bow reversals and of tone changes, and the vertical grey columns indicate that the bow stroke was on an empty string (note D, i.e. all fingers lifted).

A number of additional features were observed: for example the first two flat intervals of the little finger did not coincide with the string position (Fig. 7.2A), which means that no tone was produced; rather it reflects the tendency of the fingers to move and stop together, especially with the neighbouring tone-producing action finger (in this case the ring finger). This is a common feature, termed 'enslaving' (Zatsiorsky *et al.* 2000), which also occurs in other manipulatory actions.

Whereas there was a considerable consistency in the repeated sequencing of the fingering in a given subject, comparison between individuals revealed differences in strategies, as highlighted in Fig. 7.2A. In contrast to subject 1, subject 2 remained on the string whenever possible when another finger above the string had already occupied the string (see marked index finger). This difference does not affect the tone sequence, but to be prepared on the string for a renewed action is a useful strategy, often required in etudes for string instruments.

Another general feature, illustrated in Fig. 7.2(C), is that, in a step from a higher tone (A, little finger) to a lower tone (F, middle finger), the latter finger is placed in *anticipation*, i.e. before the upper finger is lifted. Thus, it is the *lift* of the

upper finger that determines the timing of tone *onset*, whereas the anticipating finger below controls *pitch*, but not timing. Combined actions of two fingers also occur when, in an ascending sequence on the same string, a tone is followed by a higher tone (e.g. index to middle finger). In this purely serial action, the duration of the first tone is curtailed by the next tone. We concluded that, depending on the sequence, timing and pitch selection may consist of a combination of actions of two fingers and that pure serial organization coexists with parallel anticipatory mechanisms. Serial and parallel anticipatory processes also occur in speaking. Thus, in pronouncing the word '*construe*', the lips become rounded well in anticipation to the uttering of the vowel 'u', a phenomenon that had been called *co-articulation* (Rosenbaum 1991). The intervals between anticipatory placing of one finger and bow reversal were measured separately and were significantly longer than the true synchronization intervals of serial steps (described separately below). The mean synchronization intervals were typically below 50 ms whereas co-articulation intervals (both intervals measured between finger placing and bow reversal) varied much more, and were typically between 50 and 100 ms.

Our principal aim was to assess how well the bow action was synchronized with the tone-initiating finger actions. Since we used one bow stroke for each tone, we could measure the interval between bow reversal and the fingerstop (for a clear detection of the latter event, we used the velocity peak that occurred just at impact of the finger on the board). In short, we found that synchronization did not correlate with the proficiency of a player. The 'error' interval (the time difference between bow reversal and the peak finger velocity for each fingerstop) varied among subjects (-10 ms to $+70$ ms). However, the standard deviation was less variable among subjects and was independent of the mean. It was therefore concluded that the observed standard deviation (SD) of 10–30 ms was an adequate marker of finger–bow synchronization. The SD about each subject's mean time interval, also termed the variable error (VE; see, for example, Schmidt (1988)), was regarded as the time measure of most interest.

What might be the reason for the observed temporal imprecision? Trendelenburg (1925) measured string vibrations by means of a string galvanometer. He observed that onset of vibration lagged behind initiation of the bow stroke by about 40–50 ms. Also, it is noteworthy that the full acoustic spectrum of a tone (responsible for the timbre) generated by a bow stroke takes about 30–40 ms to develop (Deutsch 1985). Synchronization among players in a professional string ensemble was found to deviate by a mean of 50 ms (Rasch 1988). Similarly, when subjects had to tap at a given metronome rhythm, departures from synchronization, up to about 50 ms, were not perceived (Fraisse 1980). Taken together, these observations suggest that, at least in string players, bimanual synchronization errors as small as 50–60 ms are tolerated in terms of auditory perception.

Bowing movements

A short résumé of previous work

The essay of Braitenberg (1986) on the issue of the principles of motor control in bowing has been mentioned briefly above. Nelson (1983) analysed kinematic bowing data from a professional violinist, discussing how velocity data can demonstrate a minimum energy demand in bowing. Other studies were made to serve as a database for overuse syndromes in musicians (Tulchinsky and Riolo 1994; Kihira *et al.* 1995; Turner-Stokes and Reid 1999; Shan and Visentin 2003; Visentin and Shan 2003). Of particular interest are observations made in professional cellists playing short excerpts from pieces by Schubert and Brahms (Winold *et al.* 1994). From bow, wrist, and elbow movements, the authors analysed the temporal derivatives to obtain some dynamic aspects of music execution, such as musical accentuations (*articulations*), which were prominent in the rapid succession of notes in the Schubert piece, and were reflected particularly in prominent acceleration peaks in the elbow and wrist at directional changes of the bow. Interestingly, the slower tempo of the Brahms fragment produced an acceleration peak in the middle of the long strokes. It was suggested that this pulse might be a signal for temporally coordinating the finger action of the left hand. This led the authors to suggest '. . . that some aspects of the coordination and control of cello bowing were constrained by the mechanical and energetic demands of the bowing'. The idea was that temporal coordination of the musical aspects was constrained by dynamic rules.

Principal types of bow movements

Among the vast variety of musical bow strokes, such as forte, piano, *détaché*, staccato, and spiccato, we analysed the strokes for setting the strings into vibration and the tilts for string changes. Plate 1 (A1, A2) illustrate, respectively, the two principal types of bow movements. Three reflecting markers were stuck along the length of the wooden part of the bow, near the frog (grasped by the right hand), at about the middle of the bow, and near the tip. Trajectories of the first two markers (red and green) overlap, whereas the third marker (blue) does not in this case. The trajectories are parallel to the bridge and are the result of a complex, learned coordination of forces acting on the shoulder, elbow, and wrist (see also Braitenberg 1986). The strings are supported by the curved bridge. String changes therefore necessitate a discrete rotational movement around the contact point between the bow and the string. For changing from a lower string to a higher string, the tip end of the bow goes up and the frog end down with the respective movement of the arm (mainly shoulder down in this case until

contact with the desired string). The two principal types of movements are well distinguished in Plate 1: the straight bow strokes (at a right angle to the strings) are best seen from the top (A1), whereas the curved rotational movements, resulting in angular changes of bow strokes around the rotation point, are best seen in a front view (A2).

In Plate 1(B), the kinematics of slow *détaché* bow strokes (i.e. separate strokes for each note) are shown as triangular displacement profiles. Confirming the work of Winold *et al.* (1994), the velocity profiles showed marked oscillations, mainly at bow reversals. Typical frequencies of the oscillations were 6–8 Hz, as revealed by fast Fourier transforms. Note that for these slow bow movements velocity profiles were nearly horizontal, but with fast bow reversals. Correspondingly, in *phase-plane plots* of slow bow movements, the stroke phases were near horizontal (near constant velocity), changing into fast, i.e. near-vertical, reversal phases. With increasingly faster bow strokes, the phase-plane progressively changed into circular profiles (not shown). As concluded by Winold *et al.* (1994), the phase-plane plots characterize rather well the dynamics of bowing. In Plate 1(C1), rotational movement displacements are shown in terms of bow angle versus time. The scales of bow angles were from the highest string E, to strings A, D, and to the lowest G string. The steepness of the slopes was similar (except perhaps for the greatest angle, from string E to string G). The time used for these angular movements was less than 100 ms (C1) and of course was shorter with jumps over fewer strings.

We have mentioned above that a fingerstop was synchronized with the onset of a new stroke (the stroke reversal point). Now the question arises whether coordination of the two hands during playing is also influenced by bow/string changes. Preliminary data show that contact between the finger and the string typically occurred at the middle of the tilt movement, as shown in Plate 1(C2). Perceptually, there was no noticeable auditory sound gap. This is not surprising given the fact that vibrations fade out gradually as the bow leaves the string. The interval at which the vibrations of the previous string stop and those of the next string are initiated was obviously sufficiently short (50 ms or less) not to disturb the flow of the melody. It remains to be seen whether the synchronization between fingerstop and bow reversal is influenced by an additional tilt movement of the bow. Finally, it is worth mentioning that in legato playing (several tones played within one bow stroke), bimanual coordination, as described above, is not taking place. However, peaks of bowing pressure undoubtedly contribute in the accentuation of some of the fingerstops, as suggested by Winold *et al.* (1994). There can be no doubt that kinetic mechanisms of bowing play a considerable role in producing musical accentuations and therefore also in bimanual coordination.

Bow movements and forces

The large variety of finger and bow movements, as well as posture, is driven by a wide range of forces. The fine control of these forces is an important and determining factor of the character of the music. For example, the loudness of tones depends on the pressure exerted on the string by the bow stroke. We have recently developed a kinetic approach to bowing. As alluded to earlier, bowing requires an exquisite force control for the grip exerted at the frog, mainly by the thumb and middle finger. The index finger has the task of adapting the pressure exerted on the bow to modulate the loudness and accentuations, but simultaneously has also to take into account the ever-changing bow lever, demanding compensatory pressure changes by the index finger in front of the rotation point at the frog and by the little finger behind the rotation point (Galamian 1983). For a down-stroke of the bow of constant loudness (from the frog end to the tip of the bow), the index finger has to progressively recruit more pressure on the bow and to diminish the pressure for an up-stroke. The handling of bow forces has been well described (but not measured) from the point of view of motor control by Trendelenburg (1925).

Our aim was to investigate the interplay of the pressure exerted on the bow by the index finger ('*bow pressure*') and the grip force ('*bow grip force*') exerted mainly between thumb and the middle finger. In addition, we introduced electromyographic (EMG) recordings from the first dorsal interosseus muscle of the right bowing hand. Without going into details of our method, the principle of measurement will be briefly summarized. The kinematics of fingering and bowing was processed by a Vicon system (three cameras, 200 Hz). For bow pressure (Bow-PR), we fastened three fine, soft air-filled rubber tubes onto the dorsal bow surface at the frog end. These were tightly sealed and connected to a low-pressure silicon sensor (piezoresistor/Wheatstone bridge), fastened to a small plate on the back of the hand. Another fine rubber tube was wrapped three times around the frog for sensing the grip force (Bow-GF) exerted mainly by the thumb and middle finger. This rubber tube was also tightly sealed at the end and connected to a second pressure-sensitive gauge on the back of the hand. The electrical output signals were led via one flexible tube to the respective inputs for amplification and for half-wave rectification of EMG signals (100–5000 Hz). All calibrated and conditioned signals were processed by an SC/ZOOM interface and special software for signal capture and post-processing (developed at the Physiology Institute, Umeå). The sampling rate was 800 Hz for EMG and 400 Hz for force.

A number of musical passages were tested, varying from slow *détaché* bow strokes on one string to fast and *martelé* strokes over four strings. In Fig. 7.3, part of an Allegro vivace, shown at the bottom of Fig. 7.3, was taken from a violin

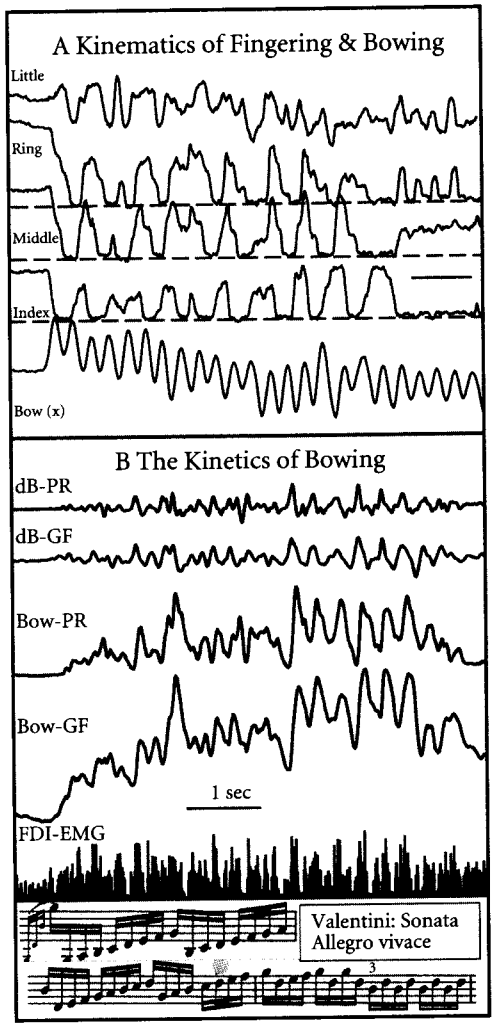

Fig. 7.3 Comparison of the kinematics (A) and the kinetics (B) while playing the initial bars of a Valentini sonata consisting of fast semi-quavers (4 × 4 semi-quavers per bar); all notes played with separate *détaché* bow strokes with string and finger position changes. The instruction is to start piano and to gradually build up the tone intensity (crescendo) to a maximum, i.e. fortissimo. FDI-EMG, electromyogram of the first dorsal interosseus of the bow hand, which contributes to the pressure exerted by the index finger on the bow. Bow-PR, total pressure exerted by index finger on the wooden part of the bow near the frog. Bow-GF, grip force exerted on the frog by the middle finger and the thumb; dB-PR and dB-GF are the rates of the respective forces. Parts (A) and (B) were not recorded simultaneously and are thus not exactly timed equally.

sonata of Giuseppe Valentini (Idea per Camera, *c.*1705) in order to illustrate the kinematics of fingering and bowing (A), as well as the kinetics of bowing (B, recorded separately from A). The musical segment was played repeatedly and consisted of 48 rapid bow strokes and tones, following in groups of 4 × 4

semi-quavers (1/16). The kinematics illustrate the sequencing of fingers and bow strokes. The sequence starts with an up-stroke on the empty string (tone G) and is followed by tones A, B, C, D with, respectively, the actions of the index, middle, and ring fingers. Note that in this initial ascending sequence the index finger remains on the string when the middle finger is already tapping the string. This is again a clear demonstration of serial processing, with a new finger action simultaneously terminating the previous one, and also of an economic strategy to leave the lower fingers on the string (as described earlier). Another example of 'economy' can be observed toward the end when the index finger remains flat on the string while the ring finger goes down and up four times, oscillating between tones B–D–B–D, and so on. It is the ring finger alone that is responsible for the timing of the two tones (this is a similar situation to oscillating between two neighbouring fingers to produce trills). The regular timing of bow strokes contrasts with some irregularities in amplitude that are subtle expressions of accentuations. The little finger was rarely used in this sequence. However, it demonstrates clearly the phenomenon of simultaneous movements without tapping the string, mentioned before as 'enslaving'.

In the kinetics of bowing, there is a slow build-up of force corresponding to the gradual increase from piano to forte. While playing forte, the accentuations of single bow strokes (and thus of notes) were expressed as prominent dynamic peaks. A parallel increased segmentation can be seen in the EMG of the first dorsal interosseus muscle (FDI) that plays a prominent role in adjusting bow pressure for loudness and musical accentuation.

Conclusions and outlook

A biomechanical approach to musical performance is challenging and does not provide quick results. Taking stock of the present results, we nevertheless suggest that even relatively simple musical sequences can reveal interesting principles of motor control, especially about inter-limb coordination and the kinetics of bowing.

A large number of non-musical manipulations, including gestures, are based on the actions of both arms (Wiesendanger and Serrien 2005). With the use of an instrumented drawer manipulandum and weighted objects, we succeeded in obtaining some insight into the construction of bimanual actions. The performance of human skills includes both learned and object-related bimanual operations, like eating with a knife and fork and many other daily actions. This motor behaviour is strongly related to goal achievement (Wiesendanger *et al.* 1994; Perrig *et al.* 1999; Wiesendanger and Serrien 2001*a*,*b*, 2005; Kazennikov *et al.* 2002). We observed the trajectories of individual arms to vary considerably, depending on the constraints (for example the normal light of the workspace versus complete

darkness). However, *goal achievement* was much less variable. Invariant goal achievement is a typical feature of goal-directed behaviour and has been termed *motor equivalence* (Lashley 1933; Abbs and Cole 1987). Progress in understanding some of the rules of bimanual behaviour encouraged us to investigate musical bimanual skills as well.

Playing music, which is deeply rooted in human behaviour, is a particularly interesting, mostly bimanual, sensorimotor behaviour, or rather a higher-order skill, which rests on many years of intensive practice. Three processes are tightly coupled: reading the musical notation, translating it to motor performance, and listening to the resulting music. It is only in advanced players that the three processes 'come together' in an ideal musical experience. Among the frequent and typical shortcomings of amateur players are incorrect intonation, slowing of tempo during difficult fingering, and bad handling of the many bowing characteristics. It is an incredible achievement of the human brain to reach a highly professional level. With the emergence of many technical improvements, the time is ripe for exploring the motor control of musical performance. Thus, we show for the first time the feasibility of assessing the temporal structure of the coordinated, but asymmetric, fingering and bowing of violinists. We also discuss arguments that deviations of up to about 50 ms from ideal synchronization (0 ms) are not perceived. This may well be different in players of other instruments, like drummers.

Another promising start concerned the kinetics of bowing: how do we handle the most intricate control of grip and bow pressure forces? We observed adjustments to the lever changes during bow strokes, as well as the additional controls required for the tonic dynamic adjustments for forte and piano instructions and for the peaks of fast accentuation in the musical flow. Still other basic motor mechanisms may be investigated that may potentially influence the timing, like the translation of left-hand positions along the fingerboard. Understanding music performance in terms of motor control may also be helpful in finding new ways in dealing with the growing number of professional musicians suffering from overuse syndromes. Objective long-term study of motor control in music performance might also be helpful in assessing the therapeutic benefits of treatments for such syndromes.

Chapter 8

Movements and analysis of drumming

Sofia Dahl

Players of percussion instruments strive to acquire playing techniques that can be adapted to the different feedbacks from the various instruments that are played. Analyses of drummers' performances show flexible wrist movements, moving the stick in a 'whiplash' motion. Skilled players appear to maintain their movement strategy consistently for different playing conditions, but how much of the arm that is involved in the movement differs between players. The dynamic level influences both the height to which the stick is lifted in preparation for a stroke and also the timing of strokes. Intervals beginning with accented strokes tend to be prolonged more at soft than at loud dynamic levels.

Introduction

It is not hard to get an object to resonate; one only has to hit it. Compared with the amount of practice necessary to get a reasonable sound out of a trumpet or a violin, the act of striking a drum seems almost trivial. And drumming would be trivial if it were not for timing. Music performance is, after all, considered to be one of the most complex forms of skilled serial actions. If striking something is easy, doing so at the right time is not.

While it is outside the scope of this chapter to compare the playing of different types of instruments to each other, it is worth considering that percussion instruments share some properties that distinguish them from most other instruments (like woodwind or strings). It is these very properties that pose some difficulties for the player.

Diversity—not one instrument but many

Percussion includes a huge variety of instruments, both membranophones (e.g. drums) and idiophones (e.g. cymbals, wood blocks, etc.). Normal percussion playing requires that the player performs the same rhythm on different instruments with differing physical properties (for instance, world-renowned solo percussionist Evelyn Glennie has a collection of 1400 instruments and travels with, on average, 1.7 tons of equipment). A change of instrument changes the kinesthetic

feedback to the player, who must adapt to the conditions at hand. This will lead to many compromises, a single drumstick or mallet may not be equally suitable for all the instruments that are to be played.

Short contact times

Percussion instruments generally produce sounds with impulse-like characteristics. Normally the onset of the note is well defined, the duration is short, and in general the player has little control over the tone, once initiated. The note can be shortened by dampening (e.g. by forcing the mallet to stay in contact with the drumhead after the hit), but it cannot be lengthened. While, for instance, players of wind instruments have close control of the vibrating air column during the full duration of a note, the percussion player's direct contact with the instrument is limited to a few milliseconds. This implies that whatever the resulting striking force and dampening effect the percussionist wants to induce would need to be integrated in the entire striking gesture. The mallet will strike the drumhead (or some other object) with the velocity and effective mass supplied by the player's movement, and the same striking gesture will also determine the duration of contact.

Changing pitch and timbre is awkward

In order to modify the timbre or the fundamental frequency a percussion player can strike at different positions, or choose a mallet with a different mass, hardness, and/or shape. The stiffness and tension of a drumhead can also be adjusted. However, in a normal playing situation there is seldom time for such types of adjustment. A change of timbre or pitch is typically achieved by striking another instrument, with its own specific characteristics and limitations. There is a need to plan ahead in order to reach the instruments that are positioned at varying distances from the player.

Time constraint and need for compromises

The characteristics and properties of percussion instruments can be summarized by three challenges that have to be met. In order to pass as a good, or even acceptable, percussionist a player must:

1. Be able to master the range of expression needed, given the tempo, in terms of dynamics and sound qualities.
2. Strike the right spot at the right moment. This becomes increasingly difficult when there are many different instruments to reach, or when quick changes are necessary between drumsticks and brushes, for example.

3. Be so relaxed that it is possible to maintain the same type of movements for several minutes without fatigue—while still performing with as close control of the stick as possible. For instance, to maintain an illusion of a 'prolonged' tone, a roll, each hand should be able to reproduce close to equal sound levels and timbre.

As for any musician, time constraint is crucial. This can lead to conflicts in several cases, for instance it might not be possible to reach the optimal position in the optimal time. In many respects, percussion playing can be described as a continuous search for a compromise that allows the desired expression within the time given. It could be hypothesized that skilled players could take advantage of the conditions at hand to maximize the desired effects (such as expression, time that can be used for preparation, etc.) and minimize the undesired effects (performance errors, strain, etc.).

Playing techniques

Players of percussion instruments strive to acquire playing techniques that can be adapted to the feedback from the instrument. Most techniques share a common ground regarding the quality of 'efficient' playing. This general consensus can be formulated as three guidelines on how to facilitate playing:

1. Let the drumstick/mallet do most of the work.
2. Take advantage of the rebound that is given by the instrument.
3. Plan stick positions ahead.

All these points rely on the wrist to work as a hinge, relaxed and flexible. The acquisition of relaxed and flexible movements is one of the main issues in learning drumming techniques. The striking movement should be 'like waving goodbye or bouncing a ball' (Cook 1988). With a cramped grip the drumstick does not have enough freedom to move and accelerate. As a result, the command 'relax!' frequently occurs in instruction manuals.

Cracking a whip

The resulting excitation of the instrument ('shock spectrum') is related to the history of the contact force. A high velocity of the mallet at impact results in a high and short force pulse. This corresponds to a high sound level and a rich spectrum with strong high-frequency partials. A wooden stick can help a player to excite an instrument more vigorously by increasing the striking velocity at low physiological cost. At low dynamic levels this is easy enough; there will be a sound just by letting the stick fall. As dynamic levels increase more force is needed, something that can be achieved by providing a sufficient 'runway' during which the stick increases its velocity.

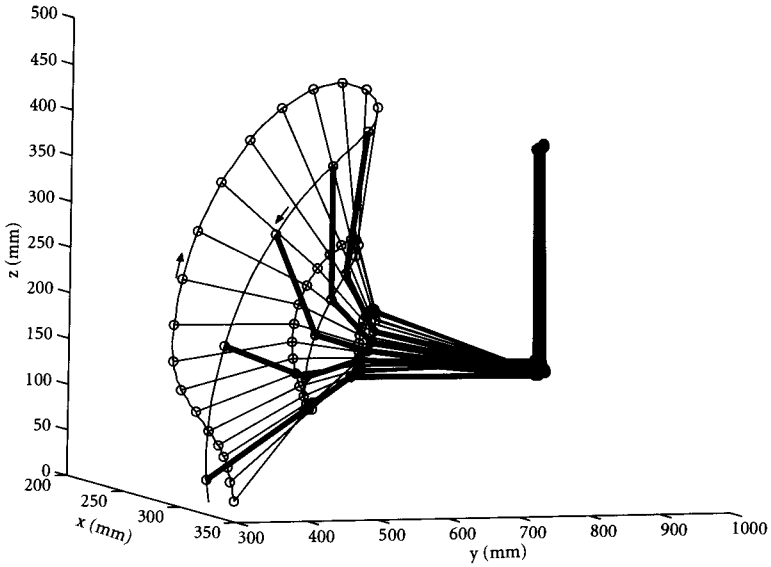

Fig. 8.1 Schematic representation of a player's arm movement during a stroke. The circles mark the positions of five markers on the drummer's stick, hand, wrist, elbow, and shoulder throughout the movement. The leftmost, largest loop describes the trajectory of the tip of the drumstick, while the two inner trajectories represent, respectively, the path of the hand and wrist. The preparation for the stroke starts with an upward movement of the wrist, dragging the drumstick upward. The stick is flicked upward, surpassing the hand and taking a vertical orientation. Also in the actual down-stroke (here indicated by thicker lines) the wrist leads the downward movement. The drumstick follows in a whiplash manner, gaining high velocity from the elongated arc produced by the preparatory motion. (The figure was generated using three-dimensional data from Waadeland (2003). Time separation between the frames is about 25 ms.)

An example of how a single stroke is played is shown by the 'stick figure' in Fig. 8.1. The figure displays the three-dimensional positions of five markers on a player's stick, hand, wrist, elbow, and shoulder during a stroke. The three loops mark the trajectories of the tip of the drumstick (leftmost loop), the hand (middle loop), and the wrist joint (right loop). The figure shows how the hand and wrist lead the drumstick. The preparation for the stroke is initiated by a raising of the wrist with the stick lagging behind, tip pointing down. The stick is first flicked up to a vertical orientation and then flung down to the drumhead, increasing velocity over the full height of the stroke.

The strategy for prolonging the arc during which acceleration occurs can also be found in other contexts. Players of tennis, baseball, and golf all display similar striking movements when they have time to do so (Wickstrom 1983; Abernethy *et al.* 1997).

Letting it bounce

A relaxed grip of the drumstick also opens up the possibility of taking advantage of the rebound from the surface. In drumming, particularly in snare drum

playing, the player tries to take advantage of the fact that a normal drumhead is elastic and therefore will, so to speak, 'send the stick back to where it came from' (Shivas 1957). The rebound vouches for pushing the stick away from the surface quicker than the player would him/herself. By learning control of the rebound it is also possible to play more than one stroke per movement gesture, an energy efficient technique that is used for fast rolls.

The use of the rebound leads to a kind of 'working area' with combinations of tempi and dynamics that are easier to master than others. As when bouncing a rubber ball, certain heights and tempi fit well with the natural periodicity of the ball. However, as one forces the ball closer to the ground it becomes increasingly difficult to maintain a slow tempo. Similarly, at soft dynamic levels, the rebound from the drumhead can be a bit too soft to give the desired 'flow' of movement at some tempi. On the other hand, loud dynamic levels give a rebound which can be too strong to master. Both these cases impose difficulties that have to be dealt with within the given time constraint. At slow tempi, at *pp* level, the drumstick must be held steady and away from the drumhead before it is time for the next stroke, while in the *ff* case, the upward recoil of the stick may need to be restrained if the next downward movement is to begin in time. Therefore very fast playing at loud sound levels becomes difficult. And, as a result, pushing the boundaries to increase the working area of playing demands more control from the player.

Planning ahead

By initiating a transition between one position and another as soon as possible, the player strives to maximize the time between events. One example of how this is done can be found in the playing of accented strokes. In drumming, one of the most commonly used features is to accent a stroke by increasing loudness, and much time and effort is spent mastering the playing of accented rhythm patterns.

Techniques are taught to facilitate the playing of strokes at different dynamic levels by specifying at what height the stick should be *at the end* of the stroke. The terms, tap, up-stroke, down-stroke, and full stroke are commonly used to help the performer plan and carry out the right movements (see, for example, Moeller 1956; Famularo 1999). Soft strokes are generally played just by snapping the wrist without raising the arm ('tapping'). The hand typically stays in a resting position 10–20 cm above the drumhead and the drumstick barely rises above it. 'The tap differs from the stroke in that it is a *wrist* action, and does not involve the arms to any appreciable extent. A large percentage of snare drum music is played using only alternated taps, the strokes being reserved for very heavy sounds and accents. (Holloway and Bartlett 1973).

Prior to a strong blow, the hand must lift the drumstick after the preceding tap. Here the rebound from the drumhead is a welcome assistance when the hand and drumstick need to rise to a higher position ('upstroke' or 'pull-out'), from where the stroke is delivered. When strong strokes are repeatedly played the stick is usually allowed to bounce up to full height ('full' or 'free' stroke). If the following stroke is to be a soft tap the stick must end up in a suitably lower position ('downstroke' or 'control stroke').

Using these basic strokes the player can execute sequential strokes of different heights. This is a prerequisite for playing various combinations of strokes at different dynamic levels, including accents.

Data from empirical studies

Up until recently, the study of drummers' movements has not been a very active area. At present, there are only a few publications available. Nevertheless, those that exist provide information about some of the prominent features of drumming performance and they will be presented here in relation to the guidelines for playing discussed above.

Movement strategies among players

To begin with, there are clear differences between skilled and unskilled drummers. Trappe *et al.* (1998) compared the performances of non-drummers, beginners, students, and professional drummers. The motion patterns of the professionals were found to be flexible and whiplash-like. The students showed similar patterns, but the calculated angles between segments (drumstick, hand, lower and upper arm) showed less control of the stick compared with the professionals. Compared with the drummers, the wrist movements of the non-drummers were stiffer and less flexible. Among the non-professionals there seemed to be a tendency for reducing the degrees of freedom in different joints by co-activating agonists and antagonists.

In studies of interleaved accents for different playing conditions Dahl (2000, 2004) found that players used different movement strategies. The overall patterns of the movement strategies were maintained consistently for different tempi, surfaces and dynamic levels. However, the height to which the stick was lifted in preparation for a stroke and the vertical velocity of the stick marker at impact were both strongly linked to the dynamic level. There was also some influence of the type of surface that was struck; a soft pillow, a runner disk similar to a normal practice pad, or a hard, rigid metal plate (covered with a thin sheet of rubber).

Figure 8.2 shows the movement trajectories for three of the four players in Dahl's study performing a repeated pattern with every fourth stroke accented. The figure displays an excerpt of approximately four measures at *mf*, 200 beats

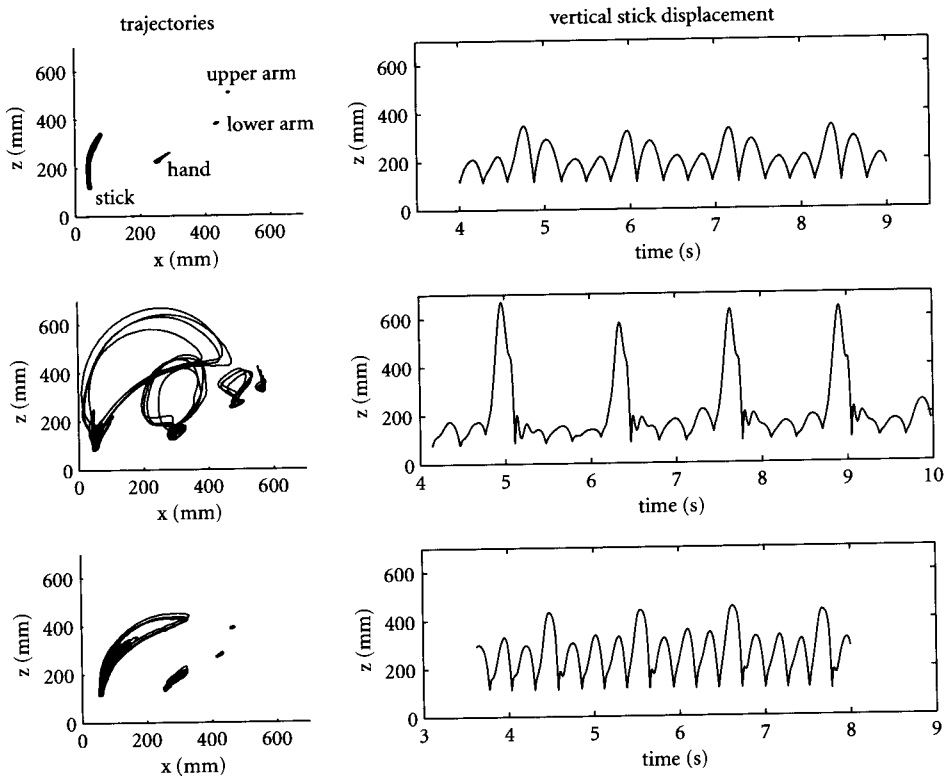

Fig. 8.2 Measurements of movement strategies for playing a repeated pattern of single strokes with interleaved accents every fourth note. The panels in the left column display the movement trajectories for four markers on three players' sticks, hands, and lower and upper arms. The trajectories are viewed from the players' left side, vertical direction (*z*-axis), and horizontal direction (*x*-axis). The accented strokes are initiated from a greater height than are the unaccented strokes. These increased preparatory heights can be seen as larger loops in the trajectories. The right column shows the vertical displacements of the stick marker versus time. The hits are seen as sharp dips in the curves. The increased preparatory heights before every fourth, accented stroke are clearly seen. The three players have their main backgrounds from different musical contexts: symphonic percussion (top row), jazz drumset playing (middle), and military drumming (bottom). The movement strategies of the three players differ, not only in how much of the arm is involved in the accented stroke, but also how high the stick is allowed to rebound after the accented stroke (Dahl, 2004).

per minute (bpm), played on the rubber disc surface. The panels in the left column display the sideways view of the motion trajectories, while the right column panels show the vertical component of the stick trajectory versus time.

The preparation for the accents can be seen both as larger loops in the three-dimensional trajectories and as higher peaks in the vertical component, compared with those of the unaccented strokes. The players' drumsticks, hands, and lower and upper arms are involved to different extents in the movements. The

three professional players have their main experiences from different musical backgrounds: Symphonic percussion (S1, top row), jazz drumset playing (S2, middle), and military drumming (S3, bottom). All the players performed with their right dominant hand.

In particular three things are to be noted from the trajectories:

1. All players initiate the accented stroke from a greater height than the unaccented. However, the interpretation of the accent, in terms of how strongly it should be emphasized, differs between players.
2. The players handle the strong rebound after the accented stroke in different ways. Player S1 (top) allows the stick to rebound fully, incorporating the rebound in the following preparation, causing it to be almost as high as that for the accented stroke. Players S2 and S3 (middle and bottom) let the rebound after the accent be dampened by the hand, resulting in some oscillation. Restraint of the stick is necessary if it is to end up in a suitable position before the subsequent stroke (see 'down-stroke' in the previous section).
3. In order to reach the high position in preparation for the accent, player S2 (middle) actually initiates the upward motion before the preceding stroke. The angling of the stick at the hit before the accent can be seen as an upward shift in the displacement curve. The dip in the curve appears as sharp as for the other unaccented strokes, but because the marker was placed some distance from the tip of the drumstick it becomes evident that the preparation for the accented stroke has already begun.

The technique used with the large preparatory motion of player S2 is sometimes referred to as a 'Moeller stroke' (Moeller 1956; Famularo 1999). Even though the movement involves the whole arm, raising the stick well above the shoulder, the accented stroke is not delayed. By starting the upward movement before the preceding (unaccented) stroke the player ensures that there is ample time to reach the higher position. The player lets the tip of the stick fall down on the drumhead, while at the same time the end of the stick is moved up by the hand. To drag the stick up to such a height may seem elaborate, but it clearly serves a purpose in producing high velocities at impact for the accented strokes. In the vertical displacement, it can be seen how the stick quickly accelerates in the downstroke from the turning point.

Striking velocities

The characteristics of the players' individual movement patterns in Dahl's study (Dahl 2004) were reflected in the measured striking velocity. The heights to which the stick was lifted in preparation for the strokes were highly correlated with the vertical velocity of the drumstick marker at impact (correlation coefficients between 0.92 and 0.96).

The condition with most influence on the movement patterns was the dynamic level, resulting in higher striking velocities at higher dynamic levels. When comparing different striking surfaces, the players tended to increase striking velocity when playing on the soft surface, and to decrease striking velocity for the hard surface.

Both the height from which the strokes were initiated and the striking velocities showed that the main difference between the playing styles of the drummers was the emphasis on the accented stroke as compared with the unaccented stroke. For instance, players S1 and S2 produced similar average striking velocities for the unaccented strokes, but while S1 played the accented strokes on average with a velocity 1.5 times higher than for unaccented strokes, the striking velocity for S2's accented strokes was almost five times that for unaccented.

Figure 8.3 shows a comparison between how players S1 (top) and S2 (bottom) emphasized the accented compared with the unaccented stroke, at different tempi and dynamic levels. The figure shows linear planes fitted to the measured striking velocities for unaccented strokes (bottom plane) and accented strokes (top plane) for the two players performing on the rubber surface. As illustrated by the different inclination of the planes in the figure, tempo and dynamic level have different influences on the players' emphasis on the accented strokes.

One possible explanation for the large differences in the players' interpretation of the accent can be sought in the different backgrounds of the players. Players S1 and S3 are mainly active in the symphonic and military orchestral traditions, while S2 mainly plays drumset in the Afro-American music tradition. In orchestral playing, an accent, although emphasized, should not be *over* emphasized. In contrast, many genres using drumsets often encourage large dynamic differences between accented and unaccented beats. In fact, unaccented notes are sometimes played as soft as possible 'ghost notes' (Dahl 2004).

Relationship to timing

Since the purpose of many of the movement strategies in the playing of percussion is to arrive on time, analysis of the timing performance is an important, but precarious, concern. As in all musical performance, it is difficult to separate the timing variations intended for expressive reasons from unintended variations such as drift in tempo and occasional displacements of individual tones (e.g. Gabrielsson 1999; Clarke 1999).

In analysis of the timing of isochronous tapping sequences performed by three professional drummers, Madison (2000) observed an average standard deviation of 2.8% of the mean inter-onset interval (IOI). Trappe *et al.* (submitted) reported differences in temporal accuracy corresponding to the level of professional expertise. While the standard deviations for the expert players were about 3% (or 6 ms for an IOI of 198 ms), the beginners displayed deviations of more

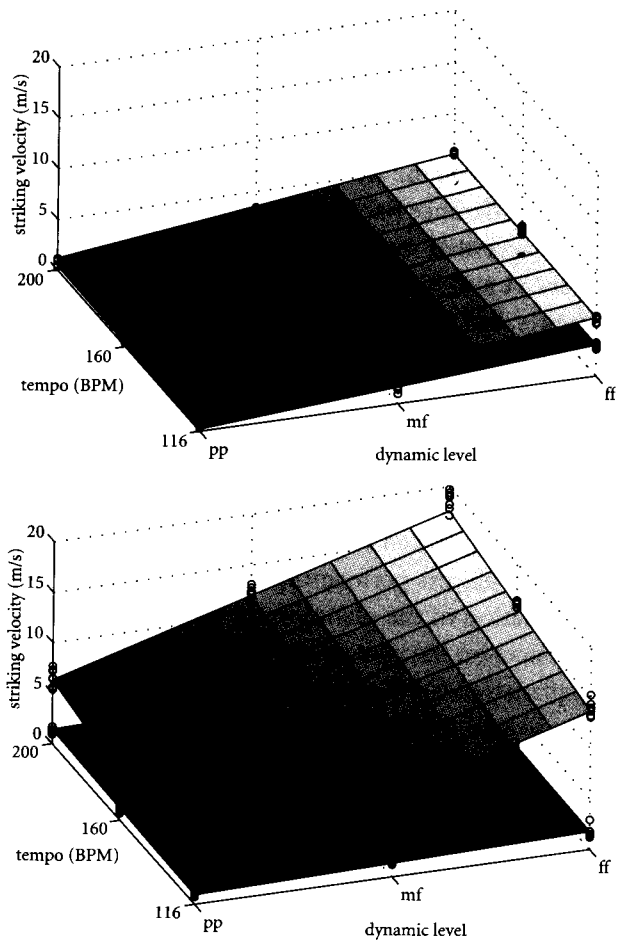

Fig. 8.3 Striking velocities of a marker on the drumstick for player S1 (top) and S2 (bottom panel) playing at three tempi and three dynamic levels on a rubber surface. The graphs show a linear plane fitted to the measured striking velocities for unaccented strokes (bottom plane) and accented strokes (top plane). The measured data points are indicated by circles. The fit of a linear plane to the data is not optimal, but made to simplify comparisons. The velocities are calculated from the displacement data of a marker on the drumstick and, as the marker was placed some distance in on the stick, the velocity at the very tip of the drumstick would be about 30% higher.

than double this figure (7% or 14 ms for the same IOI). Between students and expert players there were only slight differences in the timing performance.

For the playing of accented patterns, Dahl (2004) reported that the timing deviations were generally higher for playing at soft dynamic levels compared with loud playing. Although the accented strokes were initiated from a greater height than unaccented strokes, they arrived 'on time'. Instead, the following stroke was delayed, resulting in a lengthening of the interval beginning with the accented stroke. The average lengthening reached 3% (across all subjects and

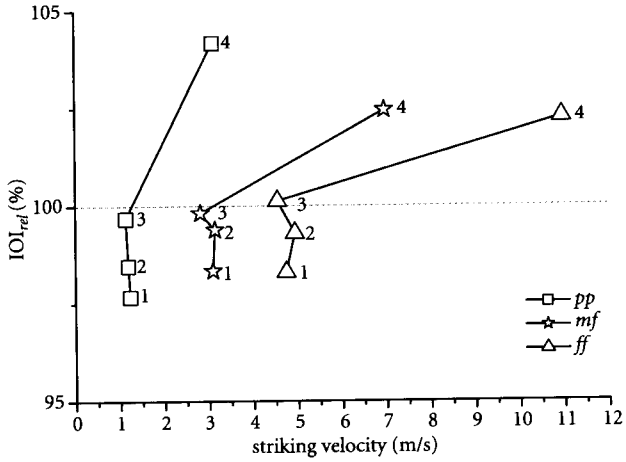

Fig. 8.4 Relation between striking velocity and relative inter-onset interval (IOI_{rel}) for different metric locations and dynamic levels. The figure shows the grand average according to the position of the strokes in the measure (numbered 1, 2, 3, and 4) at *pp* (squares), *mf* (stars), and *ff* (triangles). The data points designated 1 represent all first strokes in each measure averaged across all tempi, subjects, and surfaces, and so forth. The intervals beginning with the accented strokes (4) are lengthened at the expense of the two following, unaccented, intervals. The striking velocity, here used as an indicator of excitation strength (dynamic level), is defined by the motion of the drumstick marker. The actual velocity at the tip of the drumstick would be about 30% higher. The increase in striking velocity for the accented strokes is by about a factor of two for all dynamic levels. The lengthening in IOI_{rel}, on the other hand, decreases with increasing dynamic level (Dahl 2004).

playing conditions). A prolonged interval after an accented note is a common feature in musical performance (e.g. Drake and Palmer 1993; Gabrielsson 1999), but has also been found for accents in finger tapping (Billon *et al.* 1996). For the drummers, the lengthening not only emphasizes the accent but also allows the oscillations of the rebounding stick to decay (cf. Fig. 8.2).

Figure 8.4 illustrates the influence of accented and unaccented strokes on striking velocity and relative inter-onset interval (IOI_{rel}, defined as IOI divided by the mean IOI across eight measures) for different dynamic levels (Dahl 2004). The figure, in which each data point is averaged across 288 strokes, shows the mean IOI_{rel} versus striking velocity of the drumstick marker for the three unaccented strokes (numbered 1, 2, and 3) and the accented stroke (4) at three dynamic levels. As seen in the figure, the lengthening of the interval beginning with the accented stroke is more pronounced at a soft dynamic level. At *pp* (squares) the average lengthening is about 4%, compared with just above 2% at *mf* (stars) and *ff* (triangles). The interval ending with the accented stroke (stroke 3) is of the same length as the mean IOI across the sequence (100%). However, it is played with slightly less striking velocity, an effect of the early initiated upward movement of the stick some of the players use in preparation for the accented blow.

In a preliminary analysis of drummers performing jazz swing patterns Waadeland (2003) reported that the short notes on a cymbal were played using only one striking movement of the hand. Again, this points towards a strategy of letting a loosely held stick rebound and fall back to strike the cymbal again a second time. As tempo increases, the grip of the stick needs to be adjusted so that the time interval between the two strokes decreases, but only to a certain limit. Tones that are played too close after one another 'blur' together and are difficult to perceive as separate events. In measurements of cymbal in jazz recordings, Friberg and Sundström (2002) observed that the inter-onset intervals between the shorter notes in the swing pattern tended to be no shorter than 100 ms, even for very fast tempi (320 BPM).

Conclusion and discussion points

Skilled playing of percussion involves adjusting to and, where possible, utilizing the kinesthetic feedback from the instrument in question. Because the kinesthetic feedback between instruments is different, players seem to settle for a playing technique they can use for a number of playing conditions. The shape of the movement trajectories for a performer is maintained regardless of tempo or struck surface. The dynamic level, however, affects to what extent the arm is involved and also affects the timing of strokes (Dahl 2004). The movement strategies used in drumming can be described as whiplash-like and aim at achieving high stick velocities on impact. The reported values of more than 20 ms^{-1} at the moment just before hit can be compared with the hammer velocity in piano playing, where a striking velocity of 3 ms^{-1} corresponds to loud and 5 ms^{-1} to extremely loud playing (cf. Askenfelt and Jansson, 1991).

In some respects the piano can also be said to be a percussion instrument. Piano players experience short contact times and limited access to timbre and note duration. Many of the challenges and limitations involved in percussion playing are similar to those experienced by pianists. However, in the Western musical tradition there seems to be more well-established and widespread playing techniques for the piano than for percussion. Most commonly, instruction books on drumming do not address the actual playing movements but halt at descriptions of how to hold the stick in a matched grip (both hands gripping the sticks as if just picked up from a table) or traditional grip (left hand playing with the palm up). A lot is left for the teacher to explain, or for the student to find out.

The awareness that students of drumming and percussion have of their own movements is likely to have changed with the inclusion of instruction videos. However, even if the faster movements of the drumstick were visible on a video (standards of 25–30 frames per second give a temporal resolution of 40–30 ms),

the fine-tuned components of a relaxed grip and a flexible movement remain hidden. More importantly, the 'right' feeling cannot be explained if the instructor him/herself is not aware of what strategies are used.

For some musicians too much awareness can sometimes be seen as a threat, something that demands attention and hinders a natural performance. Others believe a greater knowledge of acoustics and human performance helps them expand their understanding of the instrument and that this understanding facilitates playing. Still other musicians merely want to know that their playing technique works and will not cause them injury. We all learn through different channels, some visually (reading, observing), others by hearing (listening, being instructed). For instructors the challenge can be to provide useful knowledge through different means, whichever means best suits the student. The challenge for researchers is then to discover what 'useful knowledge' is. At present, most movement studies of drumming have focused on the playing of patterns with regular single strokes played with one hand. More complicated interactions between the player, stick, and surface (such as how a single playing gesture is used for the playing of many fast strokes in rolls) are yet to be looked into. Hopefully in the future such issues can be dealt with in collaboration between musicians, teachers, and researchers.

Acknowledgements

The author is indebted to Carl Hakon Waadeland for providing the data for Fig. 8.1, and to Anders Askenfelt and Peta Sjölander for valuable comments on the manuscript.

Representation in the brain

Chapter 9

Brain structures of musicians: executive functions and morphological implications

Gottfried Schlaug

For many years researchers have questioned whether the structure of the brain changes in response to long-term stimulation and/or long-term practice of simple and complex skills. While experiments on long-term motor training in animals have provided substantial support for structural plasticity, similar data in humans is still missing. A comparison between musicians and non-musicians is an ideal model for examining whether structural plasticity occurs in the human brain. Musicians learn complex motor and auditory skills as well multimodal skills (e.g. the translation of visually perceived musical symbols into motor commands with simultaneous auditory monitoring of output) in childhood, and continuously practice them into adulthood and throughout their entire professional careers. Several studies have found evidence for structural differences in regions of the brain that may be directly involved in the perception, multimodal integration, motor control, and execution of musical skills. Studies have also found evidence for a correlation between structural/functional brain differences and the intensity/duration of practice as well as the type of instrument played. This chapter summarizes the data on structural differences found between the brains of musicians and non-musicians, with an emphasis on regional differences beyond the primary sensorimotor region and the functional role that these regions might play, particularly regions in the middle and inferior frontal lobes.

Brain differences between adult musicians and non-musicians

Instrumental training is an intense, multi-sensory and motor experience typically initiated at an early age. Playing an instrument requires reading musical notation and translating it into sequential, bimanual motor activity, developing fine motor skills with multi-sensory feedback, memorizing long musical passages, and improvizing music. Studies have explored the basis in the brain of these highly specialized sensorimotor (Elbert *et al.* 1995; Amunts *et al.* 1997;

Hund-Georgiadis and von Cramon 1999; Schlaug 2001; Gaser and Schlaug 2003), auditory (Besson *et al.* 1994; Schlaug *et al.* 1995; Pantev *et al.* 1998; Zatorre *et al.* 1998; Keenan *et al.* 2001; Schneider *et al.* 2002; Gaab and Schlaug 2003), and auditory–spatial (Münte *et al.* 2001) skills. As shown in Plate 2, in a voxel-based morphometric analysis of non-musicians compared with amateur and professional musicians, professional keyboard players have significantly more grey matter in several regions of the brain than amateur musicians or non-musicians (Gaser and Schlaug 2003): these regions include the primary sensorimotor cortex as well as the adjacent superior pre-motor and anterior superior parietal cortex bilaterally, the mesial Heschl's gyrus (primary auditory cortex), the cerebellum, and the left inferior frontal gyrus, and part of the lateral inferior temporal lobe. The differentiation between professional and amateur musicians was based on whether or not a keyboard player's main profession was being a musician (e.g. music teacher, performer). There was also a clear separation between both groups in terms of average practice intensity across their professional life: professional musicians had done about twice the amount of practice as the amateur musicians (Gaser and Schlaug 2003). There are further anatomical differences in musicians' brains. Musicians with absolute pitch have shown greater left-sided asymmetry of the planum temporale (Schlaug *et al.* 1995; Zatorre *et al.* 1998; Keenan *et al.* 2001).

While it may not be as surprising that structural differences are found in those brain regions that subserve skills directly linked to musical training (such as the primary sensorimotor cortex that supports the sequential, independent fine motor skill in both hands or the primary auditory cortex that supports auditory discrimination skills), structural differences outside these primary regions, such as those found in the inferior frontal gyrus, are of particular interest since they may indicate that plasticity can occur in regions that either have control over primary musical functions or serve as multimodal integration regions for musical skills. Functional correlates of differences in music processing between musicians and non-musicians typically take the form of greater functional lateralization and stronger activation of secondary and tertiary auditory brain regions in musicians, whereas non-musicians might have stronger activation of primary auditory regions (Gaab *et al.* 2003). These effects have also been shown in short-term training studies both in adult non-musicians and in young children, using auditory evoked potentials (Besson *et al.* 1994; Trainor *et al.* 1999; Shahin *et al.* 2003, 2004; Bosnyak *et al.* 2004). Furthermore, studies have shown that there is even further functional specialization within the musician group itself. This has been shown in functional experiments by Pantev *et al.* (2001) who found more pronounced cortical responses to trumpet and string tones in the respective players of these instruments, demonstrating that functional brain differences are associated with

the particular musical instrument played. Similarly, when comparing string and keyboard players, Bangert *et al.* (2005) found gross anatomical differences in the pre-central gyrus. The majority of the adult keyboard players had an elaborate configuration of the pre-central gyrus on the left hemisphere, while most of the adult string players had this 'atypicality' on the right (Plate 3). Ongoing work is aimed at determining the frequency this phenomenon also occurs in those not playing an instrument and in children of varying age groups.

There is evidence suggesting that the atypicalities in musicians' brains are not innate but are instead the result of training, since these atypicalities are greater in musicians who began study at a younger age (Elbert *et al.* 1995; Schlaug *et al.* 1995) and who undertook more intense practice (Schneider *et al.* 2002; Gaser and Schlaug 2003; Hutchinson *et al.* 2003). Animal studies also support the view of training-associated brain plasticity (e.g. Greenough and Black 1992; Dawson *et al.* 2000; Anderson *et al.* 2002). Microstructural changes (increases in the number of synapses, glial cells, and capillary density within the cerebellum and primary motor cortex, as well as new brain cells in the hipppocampus) occur after long-term motor training in rats (Black *et al.* 1990; Isaacs *et al.* 1992; Anderson *et al.* 1994; Kleim *et al.* 1996; Kempermann *et al.* 1997; van Praag *et al.* 1999). The sum of these changes could amount to structural differences detectable on a macrostructural level (see Anderson *et al.* 2002).

While these studies suggest that the atypicalities in musicians' brains are due to intense training rather than pre-existing differences, they do not definitively rule out the hypothesis that these differences are innate. The critical test has not yet been carried out. To determine whether the structural and functional differences seen in musicians reflect adaptations due to musical training during sensitive periods of brain development or are instead markers of musical interest and/or aptitude that existed prior to training it is necessary to examine children and/or adults before the onset of instrumental music training and compare them with a group of control subjects not planning to play and practice regularly on a musical instrument. We have some preliminary data to support the practice hypothesis both in a single adult subject as well as in a group of children (see below). Plate 4 shows the results of a voxel-by-voxel statistical analysis to determine a change in volume of both grey and white matter in a single subject who practised a stringed instrument intensely for several months but had not played his instrument for 4 years prior to that. This subject was scanned repeatedly before, during, and after an intense period of practice (1–2 hours per day) for approximately 3 months. The image displays all areas that showed a change in volume over time. The cross-hair is centred on the left motor cortex. Multiple areas within primary motor, pre-motor, parietal, temporal, and occipital regions showed a change in volume over time. There is some overlap between the volume

changes in this single subject and the structural differences between a group of professional keyboard players and controls (Plate 2).

A cross-sectional comparison of 5–7-year-old children prior to instrumental music training

For the past 2 years we have been conducting a pilot longitudinal study of the effects of music training on brain development and cognition in young children (Schlaug *et al.* 2003; Overy *et al.* 2004; Norton *et al.* 2005; Koelsch *et al.* 2005) The major questions addressed were: (1) whether there are pre-existing differences in brain structure/function and/or cognitive skills in children who choose to study a musical instrument compared with those who do not and (2) whether instrumental training initiated at the age of 5–6 leads to cognitive enhancement and stimulates regional brain growth in areas previously shown to be enhanced in adult musicians (Schlaug *et al.* 1995; Schneider *et al.* 2002; Gaser and Schlaug, 2003; Hutchinson *et al.* 2003; Lee *et al.* 2003). We tested 50 5–7-year-old children at baseline prior to music lessons. Approximately two-thirds of the children chose to take piano and one-third string lessons. We also tested a smaller, untreated control group (currently $n = 25$) matched to the instrumental group in age, socioeconomic status (SES), and verbal IQ. Each child underwent a battery of tests including the Object Assembly, Block Design, and Vocabulary subtests from either the Wechsler Intelligence Scale for Children (WISC-III) (for children aged 6 years and older) or the Wechsler Preschool and Primary Scale of Intelligence (WPPSI-III) (for children under the age of 6), the Raven's Colored Progressive Matrices (CPM) and Raven's Standard Progressive Matrices (SPM), the Auditory Analysis Test (Rosner and Simon 1971) as a measure of phonemic awareness, Gordon's Primary Measures of Music Audiation (PMMA) as a measure of musical skill/aptitude, and two motor tests (a finger-tapping test and a finger-sequencing task described in detail by Walker *et al.* (2002)) as a measure of speed and dexterity in both right and left hands.

Children also underwent a structural and functional magnetic resonance (MR) scan of their brain using a child-appropriate magnetic resonance imaging (MRI) protocol. MR images were acquired on a 3 T General Electric MRI scanner. The structural MR sequence had a spatial resolution of $1 \times 1 \times 1.5$ mm. We used a fully automatic technique for computational analysis of differences in local grey and white matter (Ashburner and Friston 2000; Gaser and Schlaug 2003).

We found no pre-existing cognitive, music, motor, or structural brain differences between children that entered the instrumental group and children that entered the control group at baseline (Norton *et al.* 2005), thereby making it

Table 9.1 Morphometric Brain Measures of 5–7 year old Children

	Total brain volume (cm^3)	Grey matter volume (cm^3)	White matter volume (cm^3)	Corpus callosum size volume (mm^2)
Instrumental group	1033 (94)	683 (67)	348 (31)	528 (79)
Non-instrumental group	1032 (116)	681 (88)	344 (32)	512 (75)

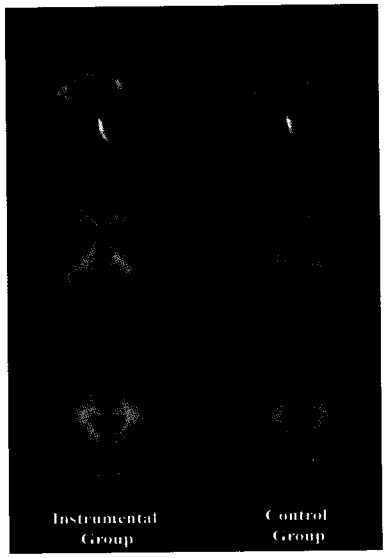

Fig. 9.1 Three views of averaged T1-weighted brains of the instrumental and non-instrumental group.

unlikely that children who choose to learn an instrument do so because they have an atypical brain, and suggesting that the atypicalities seen in the brains of adult musicians are most likely the product of intensive music training rather than pre-existing biological markers of musicality. Table 9.1 shows the mean brain measures. There were no differences in the absolute brain volume, volume of grey matter, volume of white matter, or the size of the mid-saggital corpus callosum. Figure 9.1 shows the averaged brains after spatial standardization for the group of children planning to learn an instrument and the group of children who do not plan to study an instrument. A voxel-based analysis did not show any significant differences in volume of grey matter between the two groups.

In our preliminary analyses of the effects of 1 year of music training (only half of the children have so far completed their second round of testing), we found significantly greater change scores in the instrumental group than in the control group in skills directly linked to music training: fine motor skills (mean of 10% for the instrumental group compared with 5% for the non-instrumental group) and auditory discrimination skills as measured by Gordon's PMMA (1986)

Table 9.1 Morphometric Brain Measures of 5–7 year old Children

	Total brain volume (cm^3)	Grey matter volume (cm^3)	White matter volume (cm^3)	Corpus callosum size volume (mm^2)
Instrumental group	1033 (94)	683 (67)	348 (31)	528 (79)
Non-instrumental group	1032 (116)	681 (88)	344 (32)	512 (75)

Fig. 9.1 Three views of averaged T1-weighted brains of the instrumental and non-instrumental group.

In our preliminary analyses of the effects of 1 year of music training (only half of the children have so far completed their second round of testing), we found significantly greater change scores in the instrumental group than in the control group in skills directly linked to music training: fine motor skills (mean of 10% for the instrumental group compared with 5% for the non-instrumental group) and auditory discrimination skills as measured by Gordon's PMMA (1986)

(9% versus 6%). We have not yet demonstrated transfer effects, although in several transfer domains (e.g. verbal and mathematics) the instrumental group improved more than did the control group (not siginifcant). Brain data also support this trend. There was a non-significant greater increase in volume of grey matter in the instrumental group than in the control group, but no significant change in size of the corpus callosum has yet emerged.

A cross-sectional comparison of 9–11-year-old children (instrumentalists versus non-instrumentalists)

We recently conducted a cross-sectional comparison between a group of 9–11-year-old instrumentalists with an average of 3–4 years of training and a group of non-instrumental children matched in age, handedness, and SES. Preliminary results from this cross-sectional study showed that the instrumentalists had a significantly larger volume of grey matter which was regionally pronounced in the sensorimotor cortex, but also in the occipital lobe bilaterally (Schlaug *et al.* 2004). Plate 5 shows the regional distribution of differences in grey matter volume when the instrumental group was compared with the non-instrumental group on a voxel-by-voxel basis. Table 9.2 shows the average (standard deviation, SD) volume data for total brain, grey matter, and white matter volume.

The instrumental group also outperformed the well-matched control group on the Vocabulary subtest of the WISC-III, a phonemic awareness test (Auditory Analysis), and the Key Math test.

We also investigated whether correlations existed between the performance in music discrimination skills and interindividual differences in grey matter distribution. The composite score of Gordon's PMMA was correlated with the individual grey matter images of all 5–7-year-old children. We found significant associations between the performance score and regional grey matter concentrations in the temporal lobe and the inferior parietal lobe as well as the cerebellum. The same correlation analysis in the 9–11-year-old group including children with significant musical experience revealed a significant change in the maps. Now, there were significant correlations that included the inferior frontal lobe on both sides in addition to the middle to anterior part of the temporal lobe (see Plate 6).

Table 9.2 Morphometric Brain Measures of 9–11 year old Children

	Total brain volume (cm^3)	**Grey matter volume (cm^3)**	**White matter volume (cm^3)**
Instrumental group	1105 (99)	747 (75)	357 (39)
Non-instrumental group	1015 (133)	661 (82)	354 (36)

The functional significance of frontal 'auditory' and 'auditory–motor' regions

Plate 7 shows a comparison between two groups of adults (musicians and non-musicians) and a group of 5–7-year-old children, all performing the same rhythm discrimination task while activity is being measured with functional MR imaging, normal maturational changes in the processing of this information can be seen in the comparison between the adult non-musicians and the children, but additional modulations of these maturational changes can be seen in several regions when the group of adult musicians is compared with both the children's group and the adult non-musician group. Those additional regions include the parietal lobe (mainly around the intra-parietal sulcus), the posterior middle frontal gyrus (Brodmann area 6), and the inferior frontal gyrus (Brodmann areas 44, 45, and 47). In this chapter we will concentrate on the middle and inferior frontal gyrus, since those regions appear to show the greatest difference between adult musicians and non-musicians. The activation of the parietal lobe can be seen in both groups of adults. This activation may indicate that with increased experience (either implicit or explicit), regions in the parietal lobe may become active due either to poly-sensory integration of information or to increased global processing strategies in adults as compared with children who may apply more local processing strategies.

Several studies have found activations or activity changes in a dorsal posterior pre-motor region with purely perceptual discrimination tasks, combined perceptual-memory tasks, and auditory–motor association tasks (Zatorre *et al.* 1998; Ohnishi *et al.* 2001; Gaab *et al.* 2003; Bangert and Altenmüller 2003; Haslinger *et al.* 2004; Hasegawa *et al.* 2004; Meister *et al.* 2004). Across studies, it appears that musicians showed a more pronounced activation of the middle and inferior frontal gyrus regions. It is of particular interest that two independent voxel-based morphometric studies found a larger volume of grey matter in the inferior frontal gyrus in musicians compared with non-musicians (Sluming *et al.* 2003; Gaser and Schlaug 2003; see also Fig. 9.1), although the functional significance of this frontal 'auditory' region is still unclear. It has been speculated that the inferior frontal gyrus might play a role in performing tasks that have to do with the sequencing of behaviourally relevant auditory information (Kölsch *et al.* 2002; Gaab *et al.* 2003; Kölsch *et al.* 2005). Furthermore, they may become active when the integration of information, particularly in the temporal domain, is important for solving a task (Levitin et al., 2004). Research has also shown that these frontal regions are part of the mirror neuron system. The mirror neuron system might be important for associating actions with sounds.

The ability to develop associations between actions and sounds is essential for the production and comprehension of music, or any kind of behaviourally

relevant sound information. Several research studies have implicated parts of the frontal cortex as important regions for integrating information from multiple sensory modalities and brain regions (Bremmer *et al.* 2001; Kohler *et al.* 2002; Keysers *et al.* 2003). It is therefore likely that the frontal cortex plays an important role in developing associations across modalities, including action–sound mappings (Bangert and Altenmüller 2003). Research with monkeys has revealed a neural mechanism that may be responsible for representing associations between actions and sensory stimulation. Rizzolatti and colleagues identified a class of neurons in area F5 of monkey cortex, the presumed homologue of Brodmann area (BA) 44 and BA 6, that is tuned to the actions of others as well as actions of the self (Rizzolatti *et al.* 2002; Buccino *et al.* 2004). These so-called 'mirror' neurons respond both when an action is observed and when that same action is performed. In addition to the sight and performance mirror neurons, a subset of mirror neurons in monkeys also responds to the sound of an action (Kohler *et al.* 2002; Keysers *et al.* 2003). These 'auditory–visual' mirror neurons exemplify high-level abstraction in the representation of action—an identical neural system becomes activated whether a particular action is heard, seen, or performed.

The action representation maintained by mirror neurons has been shown to evolve through learning. The visual stimulus that elicits activity in a particular neuron can change with exposure to new stimuli involving the identical action goal (Rizzolatti and Arbib 1998). It may be inferred that associations between sound and action are similarly malleable. Schubotz and colleagues hypothesized that Hebbian learning drives a somatotopic organization of pre-motor brain activity for processing meaningful temporal sequences (Schubotz and von Cramon 2002; Schubotz *et al.* 2003). They found that for an identical task involving the anticipation of temporal order, stimuli associated with vocal production (sine tones) generated activation of the inferior ventral pre-motor cortex whereas stimuli associated with hand manipulation (circles of varying diameter) generated activation of the superior ventral pre-motor cortex (Schubotz and von Cramon 2002).

This is of immediate relevance for plasticity research using musicians. Music practice and development exemplifies neural plasticity for evolving representations of actions and sounds. Professional singers learn and continuously practice to associate vocal articulation/pharyngeal movements with meaningful patterns in sound. Similarly, professional keyboard players learn and continuously practice to associate hand/finger movements with meaningful patterns in sound. There is some evidence for the second case, since Bangert and Altenmüller (2003) have shown that learning associations between actions and piano tones will lead to changes in activity in the dorsal frontal/pre-motor

cortex. More research is needed to determine whether parts of the frontal/premotor cortex are a general-purpose locus for processing sequences of sound events that are meaningfully related. This hypothesis would certainly explain a majority of frontal activations that have been seen with pure auditory perceptual tasks, auditory memory tasks, auditory discrimination tasks, and auditory–motor association tasks (Zatorre *et al.* 1994; Kölsch *et al.* 2002; Levitin and Menon 2003; Gaab *et al.* 2003; Bangert and Altenmüller 2003). Thus, considering the putative functions of the inferior frontal region, it might not be surprising to see that some of the most pronounced differences between musicians and non-musicians, both structurally and functionally, are in the inferior frontal region.

Acknowledgements

The research mentioned in this chapter was supported by grants from the National Science Foundation (NSF), the IFMR, and the Grammy Foundation. Christian Gaser, Andrea Norton, Katie Overy, Marc Bangert, Karl Cronin, Ellen Winner, D. J. Lee, and Stefan Koelsch have contributed to the research presented in this chapter.

Chapter 10

The motor representation in pianists and string players

Lutz Jäncke

This chapter summarizes current findings about the neuroanatomical and neurophysiological peculiarities of musicians' brains. It is argued that musicians are a paradigm case for studying the functional plasticity of the central nervous system on three levels (function, neurophysiology, and neuroanatomy). Because most musicians start their musical training very early in life and continue to practise throughout their entire life the brain structures involved in the control of musical functions are constantly stimulated and thus shaped.

Introduction

Musicians form an ideal and interesting subject pool for the study of structural and functional adaptations associated with exceptional cognitive and motor performance (several authors have argued this, for example Schlaug (2001) and Münte *et al.*(2002)). In order to understand this, one has to imagine the typical career of a professional musician. One outstanding feature of musically talented children who progress to become outstanding performers is their conscientious approach to practising their instrument at ages which could obviously influence brain development. This was highlighted by Ericsson *et al.* (1993*a*,*b*), who found that accumulated practice time for the best violin students at the Berlin Academy was 7400 h by the time they were 18 years old, and for expert pianists it was 7600 h. This is in contrast to 3400 h for violinists who were student music teachers and to 1600 h for amateur pianists. Ericsson *et al.* also reported that the highest achievers practised regularly at the same time of day and for a consistent amount of time. These findings are supported by those of Sloboda and Davidson (1996), who reported a positive correlation between the amount of practice and grade achievement in the practical examinations of the Associated Board of the Royal Schools of Music. Even with novice musicians, the amount of practice can predict musical outcome, as reported in a study of 7–9-year-old children at the beginning of instrumental training (O'Neill 1997). This author found that performance outcome depended on the amount of practice and general level of

motivation. It was also shown that intelligence and musical aptitude had no influence on the outcome. It is thought that this extraordinary intensity of musical training might shape the brain and its functions. Peculiarities in the brains of musicians have been reported on the grounds of the morphometric analysis of post-mortem brains, lesion data, and neuropsychological tests. In the following, we shall discuss the peculiarities of musicians' motor systems. First we will refer to differences in motor functions and then discuss the anatomical peculiarities of the motor system, and finally the neurophysiological differences. This presentation is mainly based on the peculiarities of the motor system of pianists and string players because the motor functions of brass players or singers have not been examined in detail so far.

Specific motor functions in pianists and string players

Performing music at a professional level is arguably among the most complex of human accomplishments. A pianist, for example, has to bimanually coordinate the production of up to 1800 notes per minute. Similar motor control demands are placed on violinists who additionally have to cope with unusual biomechanical constraints to hold the violin. A further point demonstrating the superiority of the motor system of professional musicians is their extraordinary ability to use both hands (or arms) in a coordinated manner. For example, during piano playing one hand plays the melody (mostly the dominant right hand manipulating the high pitches) while the other hand (the subdominant hand) plays the rhythm. For the violin the case is different. While the left hand is manipulating the strings in a way partly similar to playing the piano, the right arm is swinging the bow. Here the right arm has to generate a fast spatial–temporal pattern coordinated with fast finger movements of the left hand. Thus, both instruments place different demands on bimanual coordination (see Chapter 7). Many researchers have tried to delineate specific motor functions in musicians on the basis of sophisticated behavioural experiments. One of the simplest motor tasks is tapping with the index finger and measuring the *maximum tapping frequency* with one target finger.

To obtain the maximum tapping frequency, subjects are required to tap as fast as possible with one finger (e.g. the index finger) within a pre-determined period (e.g. 20 s). The intertap interval as well as the maximum number of taps is counted using simple computer software and keys registering the taps. The maximum tapping speed has been shown to indicate basic neurophysiological properties of the primary motor cortex controlling the particular finger. It has been shown that the maximum tapping speed with the index finger is significantly faster for the dominant hand. That is, right-handers reveal faster tapping speeds

for the right than for the left hand while left-handers show the opposite pattern. This asymmetry in hand skills is relatively stable during the course of short-term hand-skill training (Peters 1976; Peters and Durding 1978). It is argued that maximum tapping speed is mainly controlled by the hand motor area in the cortex. Several positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) experiments have shown that the rate of finger tapping correlates with the intensity or spatial extent of activation within the sensorimotor cortex (including M1 and S1). In addition to that, single-cell recording studies in monkeys have shown that the discharge activity of M1 motoneurons maximally correlates with the force and velocity of the movement (Hepp-Reymond 1988). Since fast finger tapping requires high movement velocities, one might conclude that fast finger tapping is mainly controlled by M1 motoneurons.

Pianists and string players differ substantially from non-musicians with respect to the fact that they tap much faster (Fig. 10.1). The tapping rate of the dominant hand is increased by about 14% and the rate of the non-dominant hand by about 20% compared with normal controls (right hand; musicians 128 taps/20 s, 6.4 Hz; non-musicians 110 taps/20 s, 5.5 Hz; left hand, musicians 120 taps/s., 6 Hz; non-musicians 95 taps/s, 4.75 Hz). The non-dominant left hand demonstrates a slightly larger performance gain compared with the dominant hand, a fact resulting in a decreased asymmetry between both hands in musicians. Typical hand asymmetry scores are calculated by dividing the performance difference of both hands by the performance sum of both hands, $(R - L)/(R + L)$. The obtained asymmetry score is significantly lower in musicians than in non-musicians (Jäncke *et al.* 1997). Interestingly, there was also a

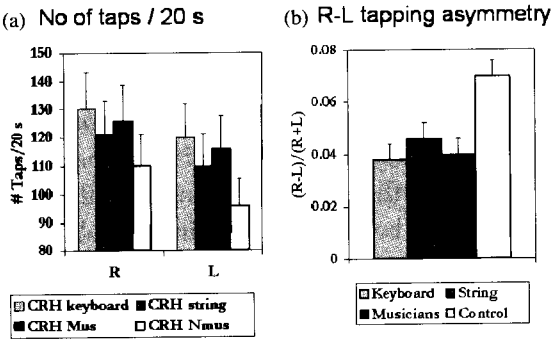

Fig. 10.1 (a) Tapping performance (number of taps/20 s) for musicians and non-musicians and also for string versus keyboard players. Data are taken from Jäncke *et al.* (1997).

for the right than for the left hand while left-handers show the opposite pattern. This asymmetry in hand skills is relatively stable during the course of short-term hand-skill training (Peters 1976; Peters and Durding 1978). It is argued that maximum tapping speed is mainly controlled by the hand motor area in the cortex. Several positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) experiments have shown that the rate of finger tapping correlates with the intensity or spatial extent of activation within the sensorimotor cortex (including M1 and S1). In addition to that, single-cell recording studies in monkeys have shown that the discharge activity of M1 motoneurons maximally correlates with the force and velocity of the movement (Hepp-Reymond 1988). Since fast finger tapping requires high movement velocities, one might conclude that fast finger tapping is mainly controlled by M1 motoneurons.

Pianists and string players differ substantially from non-musicians with respect to the fact that they tap much faster (Fig. 10.1). The tapping rate of the dominant hand is increased by about 14% and the rate of the non-dominant hand by about 20% compared with normal controls (right hand; musicians 128 taps/20 s, 6.4 Hz; non-musicians 110 taps/20 s, 5.5 Hz; left hand, musicians 120 taps/s., 6 Hz; non-musicians 95 taps/s, 4.75 Hz). The non-dominant left hand demonstrates a slightly larger performance gain compared with the dominant hand, a fact resulting in a decreased asymmetry between both hands in musicians. Typical hand asymmetry scores are calculated by dividing the performance difference of both hands by the performance sum of both hands, $(R - L)/(R + L)$. The obtained asymmetry score is significantly lower in musicians than in non-musicians (Jäncke *et al.* 1997). Interestingly, there was also a

difference between pianists and string players, with pianists outperforming string players with a tapping speed approximately 8% faster, although string players are far better than normal controls. Thus, we conclude this performance gain should be due to the extraordinary training musicians (and pianists) get from practising their particular instruments. This argument of use-dependent plasticity is supported by the fact that the tapping asymmetry in musicians is related to the age at which they begin their musical training. Musicians starting their musical training very early in life revealed the smallest tapping asymmetry compared with musicians starting later in life (see Fig. 10.2). Thus, there is strong evidence that this simple motor measure indicating basic motor control mechanisms depends on practice effects and on the age when practising started. Obviously, the motor system (here M1) is tuned to effectively control finger movements.

Besides the fact that pianists and string players tap with a faster speed, several studies have shown that pianists generate the taps with decreased variability; thus, their tapping is more stable. This stability has been found not only for regular beats but also for rhythms generated unimanually or bimanually. From mathematical models, many believe that this timing stability is due to superior peripheral motor implementations (inserting a motor program from central processing centres to the executing organs) and timekeeper executions (e.g. using an internal clock more efficiently) (Krampe 2002; Krampe *et al.* 2002). A further superior aspect of movement control is that with increasing familiarity with a specific piece of music musicians tap more slowly when they are asked to tap along with the rhythm of the music. This slowing of sensorimotor response is

thought to be associated with a different way to integrate motor and sensory functions. In fact, it is thought that with increasing familiarity with the musical piece, musicians tend to synchronize their tapping with the perceived rhythm, relying on higher hierarchical levels (Drake and Ben El 2003). Recent work by Drost *et al.* (2004) uncovered an additional very important peculiarity of the motor system of musicians. These authors found evidence from behavioural experiments that musicians implicitly anticipated a specific motor program when they were required to play a musical chord in response to an imperative visual stimulus congruent with the chord. However, when this association between visual stimulus and motor response was disturbed by a concurrent task (e.g. playing an auditory stimulus which is congruent with the chord) the performance in playing the chords (reaction time) dropped only in the musicians. Thus, the musicians seem to anticipate implicitly the appropriate motor program (playing a chord) when seeing the imperative stimulus and when hearing the concurrent auditory stimulus. Obviously, both stimuli have their own associations with motor programs which might interfere. Taken together, these (and other) behavioural experiments clearly demonstrate that musicians (in particular pianists) have developed a specialized and highly tuned sensorimotor system enabling them to perform at a high level of skill.

An interesting and impressive example of the adaptive nature of the sensorimotor system of pianists has been described by the Harvard psychologists Bruno Laeng and Anne Park (1999). They examined how right- and left-handed novice pianists could adapt to play a reversed piano with the high pitches on the left and the low on the right. Interestingly, left-handers had fewer problems learning on a reversed piano while right-handed learners faced some problems. However, when experienced pianists were tested playing a reversed piano, they were basically unable to play on reversed keyboards even if they were strong and consistent left-handers. Thus, this study demonstrates that pianists acquire strong associations between their motor responses and visual cues (arrangement of keys on the keyboard) which are difficult to rearrange or break when they have been established. Maybe long-lasting and intensive training is required to build up new visual–motor associations.

However, we had the opportunity to study a well-known pianist who is able to play on reversed and regular keyboards (the theoretical arguments about the extraordinary underlying neural mechanisms are given in the theoretical paper by Jäncke (2002)). Interestingly, this pianist started his career by playing on regular keyboards. Simply by accident he noticed that he could also play on a reversed piano. Meanwhile he performs exclusively on reversed pianos, motivated by the subjective impression that he is playing with more emotional emphasis and precision using the reversed keyboard. We believe that he is a rare exception of

a professional pianist exhibiting the capacity to play on both keyboard orientations. Hopefully, we shall uncover the extraordinary organization of his neural network controlling music when he performs in forthcoming experiments.

Anatomical peculiarities of musicians' brains

Since the age of phrenology, neuroscientists have tried to relate extraordinary skills to changes in anatomy of the brain. For example, at the beginning of the twentieth century Auerbach reported that the middle and posterior thirds of the superior temporal gyrus were larger than normal in several post-mortem studies of the brains of famous musicians (Meyer 1977). Modern brain-imaging techniques, such as high-resolution MRI, allow us to study anatomical details in the brains of living humans. Studies in which these techniques have been used have shown in particular that the motor system of musicians is differently structured. The first systematic study demonstrating an anatomical difference in the motor system was published by Schlaug *et al.* (1995). Using MRI they measured the size of the mid-saggital area of the corpus callosum of musicians and non-musicians. Previous zytoarchitectonical studies have shown that this measure correlates with the number and diameter of axons crossing through the mid-line. Thus, the larger the area of the corpus callosum the more efficient is the interhemispheric communication due to more or larger axons crossing through the mid-line. In fact, Schlaug *et al.* found a larger anterior corpus callosum in musicians who started their musical training early in life (before the age of 7). There was no difference between musicians starting later in life and normal control subjects; in addition, there was also no difference between the size of the posterior corpus callosum in either group. The fact that the anterior corpus callosum was larger in musicians starting musical training early in life was taken as evidence for superior interhemispheric communication between the anteriorly located motor areas including the pre-motor and primary motor areas. Although this study was the first to demonstrate a particular anatomical difference in the motor system of musicians, it was unclear whether these findings indeed indicated more efficient interhemispheric communication with respect to excitatory or inhibitory information. On the basis of current research using neurophysiological methods to study functional differences between musicians and non-musicians and current models of interhemispheric communication (Cook 1984), it is assumed that inhibitory influences are more important in coordinating the motor areas of hemispheres. In view of these suggestions, both hemispheres can inhibit themselves more efficiently because of the superior interhemispheric connection. Although this study has elegantly reopened the debate about whether these structural differences are related directly to musical ability, it was only an indirect

indicator of anatomically different organization of motor systems in musicians. At the same time, Elbert *et al.* (1995) published a remarkable paper in which they showed that the cortical somatotopic representation of the left hand was changed in professional violinists. Violinists showed larger cortical representations of the subdominant hand than non-musicans.

Using MRI, Amunts *et al.* (1996) measured the intrasulcal length of the pre-central gyrus, i.e. the depth of the central sulcus (CS), as an estimate of the size of the motor area for the hand. This measure was obtained from horizontal slices of linearly normalized brains. The intrasulcal length of the posterior contour of the pre-central gyrus was measured as an indicator of the size of the primary motor cortex., i.e. Brodmann's area 4 in the hand representation area in a dorso-ventral sequence of 35 horizontal sections. The sections extended from Talairach coordinates $z = 69$ to $z = 35$, thus including the functional hand representation. In summary, these MRI studies revealed the following results:

1. Right-handed males showed a clear left-ward asymmetry of the depth of the CS for the superior horizontal slices from $z = 70$ to about 50 while left-handed males showed a right-ward asymmetry.
2. Professional right-handed keyboard players who had received intensive bimanual training from early childhood were more symmetrical both in hand skill tests and in the sulcal depths.
3. The absolute length of the CS was related to the age of commencement of musical training in as much as those musicians who had started early in life with musical training revealed the largest CS on both sides.

These findings suggest that the anatomical asymmetry in the depth of the CS may depend on handedness and also on the amount or duration of hand skill training (see Fig. 10.3). These findings fit well with data from a magnetoencephalograph (MEG) study analysing dipoles during simple hand and finger movements (Volkmann *et al.* 1998). The authors found larger dipole source intensities in the primary motor cortex of the preferred hand than of the non-preferred hand both in right and left handers. Further studies provide evidence that handedness may have anatomical correlates not only in the asymmetry of the motor cortex for the primary hand but also in the spinal cord (Melsbach *et al.* 1996). There is also evidence for an asymmetric volume of the anterior and posterior cerebellum correlating with handedness (Snyder *et al.* 1995).

Two more recent studies using voxel-based morphometry (VBM) or classical region of interest analysis to detect structural differences between pianists and non-musicians found larger volumes of grey matter in the musician group in the motor network including primary motor (M1), the somatosensory areas (S1), the pre-motor areas (PMC), the superior parietal lobe (SPL), and the left

cerebellum (CB) (Gaser and Schlaug 2003; Hutchinson *et al.* 2003). Thus, with respect to M1 these studies support the previous findings of anatomical peculiarities in the primary hand motor region. The findings with respect to the pre-motor, parietal, and cerebellar regions are new. Motor-related regions such as the pre-motor and cerebellar cortex have been shown to play a critical role in planning, preparation, execution, and control of bimanual sequential finger movements. The cluster of differences in cerebellar grey matter found in these studies are located in the area of the cerebellar finger–hand representation as shown in some functional imaging studies (Grodd *et al.* 2001). Further studies have found activation in this area with auditory–musical tasks and during cognitive learning of skills (Gaab and Schlaug 2003). Thus, these aspects also could contribute to the structural differences in the cerebellum.

A further important finding of one of these studies was that musical status (expressed as level of musical skill) and practice intensity (number of hours a day spent practising the instrument) correlated with the measures of grey matter

cerebellum (CB) (Gaser and Schlaug 2003; Hutchinson *et al.* 2003). Thus, with respect to M1 these studies support the previous findings of anatomical peculiarities in the primary hand motor region. The findings with respect to the pre-motor, parietal, and cerebellar regions are new. Motor-related regions such as the pre-motor and cerebellar cortex have been shown to play a critical role in planning, preparation, execution, and control of bimanual sequential finger movements. The cluster of differences in cerebellar grey matter found in these studies are located in the area of the cerebellar finger–hand representation as shown in some functional imaging studies (Grodd *et al.* 2001). Further studies have found activation in this area with auditory–musical tasks and during cognitive learning of skills (Gaab and Schlaug 2003). Thus, these aspects also could contribute to the structural differences in the cerebellum.

A further important finding of one of these studies was that musical status (expressed as level of musical skill) and practice intensity (number of hours a day spent practising the instrument) correlated with the measures of grey matter

density in the motor areas. Thus, musicians with high musical status or with long practise times showed the strongest changes in the grey matter of the motor areas.

Interestingly, there are only a few findings demonstrating structural differences between musicians and non-musicians with respect to the density of white matter. One study using diffusion tensor imaging (DTI) techniques showed that musicians displayed significantly greater fractional anisotropy (FA) in the genu of the corpus callosum, while significantly less FA was found in the corona radiata and the internal capsule bilaterally. Because FA is thought to indicate the efficiency of white matter tracts, these changes in white matter are thought to reflect the anatomical constraint on increased interhemispheric communication (via the corpus callosum), but reduced intracortical communication (via the corona radiata) (Schmithorst and Wilke 2002).

Overall, the anatomical studies mentioned above provide strong arguments for a relatively strong relation between specialized skills (here motor skills relevant to music) and the size, composition, and shape of particular brain structures (especially the motor areas). Indeed, these studies are correlational in nature; thus, they do not permit direct inference as to whether these relationships are due to innate predispositions or to influences dependent on use. If these structural differences are innate, individuals exhibiting such differences in brain anatomy might be (unconsciously?) drawn or even forced to become musicians and, therefore, face fewer obstacles in mastering a musical instrument. Although self-selection for musicianship by individuals with innate structural differences in their brain cannot be completely ruled out, the strong relationship between structural differences and musical status (as shown in the study of Gaser and Schlaug (2003)), as well as data supporting the relationship between age of commencement of musical training and the size of the motor area for the hand (as shown by the study of Amunts *et al.* (1997)) support the proposal that volumetric structural differences seen in musicians might actually be a consequence of long-term music-related motor training. Maybe these use-dependent influences may reveal their entire strength at early ages (1–6 years), when the human brain increases its size from 400 to 1200 g accompanied by an enormous increase in the capacity for many psychological functions (cognitive and motor functions). However, only future work exploiting longitudinal study designs might help to disentangle the relative contribution of predisposition and practice.

In order to accept the effect of use-dependent influences on brain anatomy one has to refer to findings coming from the animal literature. For example, Anderson *et al.* (2002) have shown regional growth and structural adaptation in cerebral grey matter in response to intense environmental demands during

a critical period of brain maturation. In addition, they have shown microstructural changes in the cerebellum, primary motor cortex, and the hippocampus related to the learning of motor skills and continuous motor activity (Anderson *et al.* 1994). These microstructural changes comprise an increase in the number of synapses per neuron and a greater number of glial cells in cortical areas as well as increased glial volume per Purkinje cell in the cerebellar cortex. Interestingly, these anatomical changes were only found in rats trained to perform acrobatic movements. A further animal group which was required to perform routine exercises only had a predominant increase in capillary density, as well as smaller changes in synapse and glial cell density.

Neurophysiological peculiarities in the sensorimotor system

In the previous sections we have discussed findings from classical behavioural studies and from more recent anatomical studies. Although these studies have considerably increased our understanding of the processes involved in superior musical performance, the possible underlying anatomical changes and the constraints of the musician's brain, the gap between function and anatomy still needs to be bridged. Interestingly, there are only a few studies which have directly investigated neurophysiological functions in musicians during various music-related tasks and which have compared these measures with normal controls. One of the earliest studies examining musicians on the basis of electroencephalography (EEG) measurements was published by Lang *et al.* (1990). They recorded direct current (DC) potentials in 15 musicians before and during the execution of bimanual motor sequences. Unfortunately, they did not examine normal control subjects, thus no direct comparison between musicians and control subjects is possible. The musicians either tapped with their two index fingers in synchrony, or they tapped against triplets ('2 against 3'). Either the right or the left finger started tapping the tapping sequences and after about 4 s the other finger joined in. Ss were free to start the sequences, i.e. to determine the onset times t_1 and t_2. Shifts of cortical DC potentials were averaged twice: (1) time-locked to t_1 and (2) time-locked to t_2. When moving in synchrony (easy rhythm) shifts in DC potential and their likely electrical generators indicated activations of the two primary motor cortices (M1). When bimanually tapping different rhythms, there was not only an activation of M1, but also a very large activation of the mesial, central cortex. It was suggested that this mesial motor area (including the supplementary motor area (SMA)) has the function of controlling the initiation of movements in the difficult sequence which have to fit into a very precise timing plan. However, because there is no direct comparison with normal control subjects, it is difficult to delineate the music-related peculiarity of these findings.

A more recent study using a somewhat similar technique has been published by Kristeva *et al.* (2003). These authors made EEG measurements from 58 scalp positions to investigate the temporal sequence and the time course of activation of the activated brain areas while violin players (two advanced musical students and five professional players) executed or imagined a musical sequence on a violin. Using modern methods to analyse and to cortically map current source densities (CSD), the authors showed that three of seven violinists revealed strong activation bilaterally in the frontal opercular region earlier than the motor areas (M1) while a further violinist showed simultaneous activations in these regions. The frontal opercular regions were also strongly activated throughout musical execution or imagining. The supplementary motor area was involved in both preparation for the sequence and during execution and imagination of the sequence. The left primary sensorimotor area was also involved in the preparation and termination of the musical sequence, both for execution and imagination. The main finding of this study is that the frontal operculum (which is part of the ventral pre-motor cortex) is bilaterally involved in the preparation, execution, and imagination of playing a musical piece with the violin. Thus, the ventral pre-motor cortex, which has been suggested to house the human homologue of the so-called 'mirror neurons', is strongly active during complicated motor actions like playing a violin. This suggestion complements findings obtained from studies conducted with non-musicians in which the ventral pre-motor cortex has been shown to be involved in the preparation and execution of various (non-music-related) complicated motor tasks. Most of these tasks have investigated the observation, imagination, and execution of every-day activities like grasping, squeezing, modelling, and tapping (Jäncke *et al.* 2001; Binkofski *et al.* 1999*a*,*b*; Buccino *et al.* 2001, 2004). The new finding of the Kristeva *et al.* (2003) study is that the ventral pre-motor cortex is also involved in music-related activities which have to be acquired due to long-lasting training. Thus, the ventral pre-motor cortex can be trained to participate in the control of complex movements like violin playing.

Lotze *et al.* (2003) examined professional and amateur violinists during actual and imagined performance of Mozart's violin concerto in G major (KV216) using fMRI. Because it is impossible to use a violin within a fMRI scanner the authors asked their subjects to perform their finger movements on their chests. According to the authors the violinists could easily use this task as a substitute for real violin playing after a short training session. The main finding of this study is that professional musicians revealed focused cerebral activations in the contralateral primary sensorimotor cortex, the bilateral superior parietal lobes, and the ipsilateral anterior cerebellar hemisphere. In addition, they also found that professional musicians exhibited higher activity of the right primary auditory

cortex during execution. Interestingly, a similar pattern of cortical activation was found during the imagination of violin-playing movements. However, there was no activation within the auditory cortex during imagination of movement. These findings support the assumption that musicians execute music-relevant finger sequences with higher motor control economy as amateur musicians. The finding of an absence of activation of the auditory cortex during imagined movements was interpreted as evidence that activation of the auditory cortex is only present if the interconnected motor areas are activated to control real music-relevant movements.

A very recent study employed a similar logic to examine musicians during motor tasks which only musicians can perform (Meister *et al.*, 2004). In this fMRI study, the authors investigated the cortical network mediating music performance compared with music imagery in 12 music academy students. As task, the subjects were required to execute or imagine playing the right-hand part of a Bartok piece. There were two important findings in this study: first, during imagery and execution a similar bilateral frontoparietal network was active comprising the pre-motor areas, the pre-cuneus, and the medial part of the superior parietal lobe (SPL); secondly, during music performance (but not during imagery) the contralateral primary motor cortex and the posterior parietal cortex (PPC) were active bilaterally. Thus, both imagery and actual execution of a musical piece partly evoke activation in a similar cortical network. However, imagination of movement does not activate the primary motor cortex and the PPC; thus these areas are probably more involved in the actual execution of music performance.

As mentioned above, although these three studies have shown that distributed brain areas are involved in the control of playing a musical instrument, they do not directly help us to understand what is different or special in the motor system of musicians. Although this is an interesting question it is not easy to examine, because many motor activities relevant to musical performance are so special that only musicians are in a position to generate them. Thus, one has to find tasks which are very close to musical tasks but which also can be performed (in principle) by non-musicians. Three studies have been published so far in which pianists have been compared with non-musicians during different motor tasks in the context of fMRI measurements. Krings *et al.* (2000) used an overlearned unimanual sequential finger opposition task for the dominant right hand and found significant differences in the extent of cerebral activation between both musicians and non-musicians, with piano players (four right-handed professional piano players with an average 4 ± 8 h of training per day) having a smaller number of activated voxels in the primary motor cortex, the supplementary motor area, the pre-motor cortex, and the superior parietal lobule.

In the Jäncke *et al.* (2000) study two professional pianists were compared with two carefully matched non-musicians in terms of their cortical activation pattern during a bimanual tapping task. The bimanual tapping task was a variant of the so-called 'rubato-task' which comes very close to piano playing (a similar task was used by the early EEG-study of Lang *et al.* (1990)). The subjects are required to tap with one hand while the other hand makes two taps. After a short training session the control subjects were basically able to perform similarly to the pianists; however, the cortical activation pattern in the pianists and non-musicians was considerably different. Non-musicians revealed stronger haemodynamic responses within the left primary (M1) motor area and bilaterally in the SMA proper. However, when the sub-dominant hand tapped at the faster rate non-musicians revealed very strong activations in mesial motor areas including the pre-SMA and the rostral and caudal CMA. There were also stronger activations in the right M1, LPi, and in a posterior paracentral region including the pre-cuneus. In recent studies it has been shown that these motor areas are activated when motor control becomes more complex and unpredictable for both unimanual and bimanual movements. In addition, brain-imaging studies in humans have shown that the region presumably corresponding to the CMA is partly active when a variety of motor tasks require subjects to voluntarily select movements (Koeneke *et al.* 2004). Related to these findings, one may assume that non-musicians rely more strongly on explicit and voluntarily motor control strategies while professional piano players control their movements in a more automatic fashion.

Thus, these two studies suggest that professional pianists use smaller neural networks within the primary and secondary motor areas in order to control unimanual and bimanual movements. If this contention is correct, one might assume that professional pianists or violinists control their movements much more efficiently. One reason for an increased efficiency of motor control might be related to the 'degrees of freedom problem'. According to this theoretical assumption, different muscles are functionally linked together and controlled conjointly. In this context, it is speculated that with increasing levels of motor skill more and more effectors are linked together, thus reducing the number of 'degrees of freedom' to be controlled via motor commands. In this sense, highly trained pianists most likely control fewer 'degrees of freedom' for these tasks, thus enabling them to control uni- and bimanual movements much more efficiently with smaller neural networks than non-musicians. This in turn would increase the control capacity of pianists because they now can control more 'degrees of freedom' or more motor programs with a given network. Considering the fact that highly trained musicians also have larger hand motor areas, this would suggest that they have an efficiently organized neural network as well as a generally larger network at their disposal in the hand motor area.

A study which goes beyond the simple comparison between pianists and non-musicians during different motor tasks is the study published by Hund-Georgiadis and von Cramon (1999). In this study the authors investigated haemodynamic responses in several motor areas during short-term motor learning of the dominant right hand in 10 piano players (PPs) and 23 non-musicians (NMs), using a complex finger-tapping task. In summary they found the following results:

1. All subjects achieved considerable increases in tapping frequency during the training session of 35 min in the scanner.
2. PPs, however, performed significantly better than NMs and showed increasing activation in the contralateral primary motor cortex throughout motor learning in the scanner. At the same time, the involvement of secondary motor areas, such as the bilateral supplementary motor area, the pre-motor, and the cerebellar areas, diminished in relation to the NMs throughout the training session.
3. Extended activation of primary and secondary motor areas in the initial training stage (7–14 min) and rapid attenuation were the main functional patterns underlying short-term learning in the NM group; attenuation was particularly marked in the primary motor cortices as compared with the PPs.
4. When tapping of the rehearsed sequence was performed with the left hand, transfer effects of motor learning were evident in both groups. Involvement of all relevant motor components was smaller than after initial training with the right hand. Ipsilateral pre-motor and primary motor contributions, however, showed slight increases of activation, indicating that dominant cortices influence complex sequence learning of the non-dominant hand.

The very new finding of this study is that experience (motor skill) influences the contribution of secondary motor areas in the motor learning of simple sequential unimanual tasks. In concordance with the studies mentioned above, this study also demonstrates minor involvement of the SMA in the PP group and shows attenuation effects in both groups during motor learning. Modern brain imaging studies have demonstrated that the mesial motor areas (especially the SMA proper and the pre-SMA) are strongly involved in the acquisition and execution of complex unimanual and bimanual tasks. Thus, the stronger the activation in these areas the more complex is the movement control or the more demanding is the movement control. With increasing level of skill the complexity of movement control and the demands of movement control diminish. Therefore with increasing levels of skill fewer neurons in these areas will be involved during the control of unimanual or bimanual movements, as in the case of professional musicians.

The above-mentioned fMRI studies have shown that the motor system of musicians has specifically adapted to the demands of playing a musical instrument. Although these studies have considerably furthered our understanding of these adaptive processes there is one particular disadvantage associated with fMRI data: it is basically impossible to infer from increased or decreased haemodynamic responses whether these changes are due to cortical excitation or inhibition. In order to know more about the particular neurophysiological processes underlying these haemodynamic changes more direct neurophysiological data are needed.

A typical example of this kind of study is the work of Nordstrom and Butler (2002). They studied intracortical inhibition (ICI) and intracortical facilitation (ICF) within the motor cortex ipsilateral to the moving finger in 15 musicians and 15 non-musician controls using transcranial magnetic stimulation (TMS). TMS was used to elicit muscle evoked potentials (MEPs) from left first dorsal interosseous (FDI) muscle at rest and during voluntary abduction of the index finger. A paired-pulse TMS technique was used to test for ICI or ICF. The basic principle is that a subthreshold TMS stimulus is given followed by a TMS pulse evoking a MEP. Depending on the ISI and the neurophysiological condition of the stimulated motor cortex, the amplitude of the MEP will vary in size. For example, if the MEP is evoked shortly after the first subthreshold TMS stimulus (1–5 ms), it is normally lower in amplitude, indicating cortical inhibition. MEPs evoked 8–15 ms after the first TMS pulse are normally enhanced with respect to the amplitude. Thus, this enhancement effect is taken as evidence of cortical facilitation effects. Using this technique the authors found that ICI was less effective in musicians with FDI at rest and during activity, but only with an ISI of 3 ms. In addition, ICF was less effective in musicians under conditions of both rest and activity. The authors argue that the reduced ICI and ICF in musicians could be due to reduced excitability of the neurons responsible for ICI or ICF or to an altered balance of excitatory inputs to corticospinal neurons which favours neurons that are not acted upon by the ICF circuit. The reduced influence of ICI and ICF circuits on the excitability of corticospinal neurons in musicians is likely to reflect a training-induced adaptation. Although this interpretation is somewhat speculative and the underlying neurophysiological aspects are not fully understood, these findings demonstrate that neurophysiological activation within the primary motor cortex is different in musicians.

A further study by the same group (Ridding *et al.* 2000) also using TMS tested for possible differences with respect to interhemispheric communication. Here they used paired-pulse TMS to assess interhemispheric inhibition in six adult professional musicians who began musical training at an early age. Conditioning TMS was applied to the hand area of the motor cortex of one hemisphere,

followed 4–16 ms later by a test stimulus applied to the other hemisphere. Tests were performed at rest, and with the first dorsal interosseous muscle contralateral to the conditioning hemisphere voluntarily active. Conditioning TMS in musicians was 29% less effective at reducing the size of the test MEP at rest, and 63% less effective in the active condition, compared with control subjects. Thus, there is obviously less transcallosal interhemispheric inhibitory influence in musicians than in controls. This finding is quite important for interpreting the anatomical findings with respect to the size of the corpus callosum because this study shows that there is less interhemispheric inhibition in musicians, at least for the hand motor areas. Given that the corpus callosum is larger in musicians and that large areas of corpus callosum normally indicate more and larger myelinated axons crossing through the midline, this study would indicate that more axons support less interhemispheric inhibition. However, although interesting, more work is needed to explain this finding more sufficiently.

The above-mentioned studies have shown that there are peculiar differences between musicians and non-musicians in terms of simple motor measures, macrostructural peculiarities of the motor system, and neurophysiological activation patterns of the motor areas. Whether these differences are due to some kind of pre-wired or genetic prerequisites supporting musical performance or whether these differences are simply a consequence of the use-dependent stimulations associated with learning an instrument is still a matter of dispute. Although many data support the notion that musical training shapes the brain both in terms of anatomy and functional organization (Münte *et al.* 2002; Schlaug 2001) direct evidence for this use-dependent influence is still missing. An interesting contribution supporting the idea that use-dependent stimulation in fact stimulates cortical organization has been published recently by Bangert and Altenmüller (2003). They recorded changes in cortical activation patterns (DC-EEG potentials) induced by short- (20 min) and long-term (5 week) piano learning using auditory and motor tasks. Two groups both new to piano playing were trained. One group was allowed to learn the standard piano key-to-pitch map (the 'map' group). For the other group (the 'no-map' group), random assignment of keys to tones prevented such a map. From the EEG obtained during the training session, the authors calculated the EEG coherence and DC intensity. They found marked changes in the EEG (both for EEG coherence and EEG DC intensity) even after a short training period of only 20 min. This effect was enhanced after 5 weeks of training. The increased DC changes were most prominent in the left central and right anterior regions if the training was conducted with the right hand. The right anterior activation was only present for the 'map' group which was in the position to associate auditory cues (the notes) with a particular motor action. Obviously, the frontal EEG activity captures the

neural activations of pre-motor areas which are known to associate sensory cues with motor programs. Interestingly, these associations are generated very early during motor learning.

Conclusions

As demonstrated in this chapter there are several neuroanatomical and neurophysiological studies supporting the idea that intense practice on a musical instrument stimulates cortical adaptations. These adaptations can be seen at macroanatomical levels, with increased volumes and grey matter densities of many motor and sensorimotor areas. They can also be seen on the level of neurophysiological activation indexed by changed haemodynamic responses or EEG measures attributed to the motor areas. These data show that the entire motor network, including the pre-motor, primary sensorimotor, parietal, and cerebellar regions, acts differently in musicians. Interestingly, these differences can also be found in experimental situations when subjects imagined playing a musical instrument. In addition, several of these studies support the notion that early and/or intensive musical training are the main variables determining the strength and impact of the reorganization of the motor system. Future studies have to show whether these plastic changes are possible during the entire life or are restricted to critical periods of life.

Chapter 11

Brain activation during piano playing

Marc Bangert

The chapter gives an overview of brain imaging in piano playing. Because the piano keyboard, more so than other musical instruments, offers a versatile tool that integrates well into parameter-controlled experimental laboratory set-ups, a large number of studies have been carried out addressing issues not only of instrumental performance but also general questions about music processing, working memory, and learning and neuroplasticity. This chapter examines in detail an electroencephalography (EEG) study covering the topics of auditory–sensorimotor maps and rapid motor plasticity. The last part of the chapter provides a meta-review of research uncovering areas of the brain that contribute to various music-processing tasks. The review speculates on a possible core network for music, and points out its relationship to the network dedicated to speech and language.

Introduction

> Attunement of ears, mind and hands. Most of us possess these pieces of anatomy but sometimes it would seem that they are not 'wired together properly.' Each has an important function to perform by itself, but if each is not attuned to the other two, then one function cannot pass to the next, and we are momentarily out of order. When properly 'wired', the ear will hear something, either in the mind's ear or from an outside source (another member in the group), the aural sensation being forwarded to the mind, where intellectual computations and translations take place. Then the mind issues directives to the muscles of the hands, which hopefully will respond obediently, quickly and cleanly. Now the ears hear the result and coordinately with the mind decide what to hear and play next, repeating the whole cycle again and again.
>
> Coker (1997)

What Jerry Coker, the renowned and inspired jazz instructor, outlines above is (maybe not accidentally) the most precise description of the challenges with which the central nervous system is faced when making music at a professional level. Professional musicians excel in one of the most complex and demanding sensorimotor tasks—music performance requiring high-speed motor control under a rigorous and relentless auditory feedback.

How is this extremely rapid exchange of information between auditory and motor areas coordinated? How is motor control fine-tuned by auditory feedback, and how is the feedback system prepared for what is to be expected?

Brain networks are known to be subject to short- and long -term plastic changes. Changes due to the training of motor skills can occur very rapidly, in the range of minutes (Pascual-Leone *et al.* 1995; Classen *et al.* 1998), and lifelong practice might even alter macrostructural anatomy (Schlaug *et al.* 1995). Highly trained pianists often state that while listening to piano music their fingers feel like they are irresistibly itching to play along, whereas while practising silent drills, e.g. 'tabletop dexterity', these musicians can vividly 'hear' what they are playing.

When playing musical instruments, auditory information has to be processed together with sensorimotor data. Thus, the same music is represented in multiple ways: as sounds, as movements (for example on a piano keyboard), as symbols (notes on a score), and so on.

Brain activation during performance: a distributed network

The production and performance of music is not a matter for professional musicians alone. Almost everyone can sing, hum, and whistle. When it comes to playing a musical instrument, the more natural process of vocal motor control is substituted for by (mostly) hand and finger movement, and now additional areas of the brain have to be recruited. In general, the majority of studies dealing with the production of music in professional musicians reveal a common network, comprising pre-motor areas (PM), the supplementary motor area (SMA), primary motor areas (M1), the dorsolateral pre-frontal cortex (DLPFC) including Broca's area in both hemispheres, and the posterior parietal cortex (PPC).

In one of the early functional neuroimaging studies on piano performance (Sergent *et al.* 1992), positron emission tomography (PET) was used to measure regional cerebral blood flow in pianists during right-handed performance of a sight-read musical score. Among the main findings of this study was the observation that cortical areas distinct from, but adjacent to, those underlying language operations were activated during sight reading. A contribution of areas that have classically been related to speech to instrumental performance has been confirmed many times over the subsequent 12 years, in a variety of paradigms and with several brain imaging techniques.

In professional piano players there are learning-related changes in cerebral motor representation; thus it was found that professional piano players show less cerebral activation in pre-motor and motor areas when compared with non-musicians performing the same movement (Jäncke *et al.* 2000; Krings *et al.* 2000).

Itoh *et al.* (2001) demonstrated that the areas activated during a pianist's performance included the PPC and the primary sensorimotor areas (SM1). Because the paradigm elegantly distinguished performance with the right hand, left hand, or both hands, these authors could disentangle the effector-specific (hand) and task-specific (music) portions of the ongoing brain activity. While unilateral SM1 activation was correlated with motion of the corresponding contralateral hand, PPC activation was correlated with piano performance irrespective of hand modality.

Using functional magnetic resonance imaging (fMRI), Meister *et al.* (2004) compared music performance and music imagery in 12 musicians performing the right-hand part of a Bartok piece. In both conditions they found activation of a bilateral frontoparietal network comprising the pre-motor areas, the pre-cuneus, and the medial part of BA 40. During music performance, but not during imagery, the contralateral M1 and PPC were active bilaterally. This was interpreted to reflect the role of the primary motor cortex in motor execution and the requirements for visuomotor integration during music performance. The only cortical activation with a clear lateralization in their study was found in the left posterior part of the dorsolateral pre-frontal cortex (Meister *et al.* 2004).

A right-sided dominance of the dorsolateral/inferior parts of the frontal lobe was found in several studies. The activation of the right inferior frontal gyrus was suggested to be related specifically to the production of music (Langheim *et al.* 2002). Carter *et al.* (1995) showed activation of this area during selective attention tasks and working memory. An fMRI study conducted by Rao *et al.* (1997) also suggested a role for the right inferior frontal gyrus in the production of music. These results indicate that activation of the right inferior frontal gyrus supports the retrieval and rehearsal of internal non-linguistic auditory representations of time intervals. The right-hemisphere Broca homologue was also shown to be involved in explicit learning of motor sequences and associative motor learning (Seitz and Roland 1992).

Brain activation during imagined performance

It is known that excellent musicians not only rehearse their musical skills by daily practice but also use strategies of mental imagery. For example, Horowitz used to practice mentally before playing in concerts in order to avoid the feedback of a piano other than his own. Rubinstein did so in order to make his daily practice more efficient (Schoenberg 1987).

The main component of mental rehearsal is motor imagery, i.e. a mental simulation of action which involves many parts of the sensorimotor system that are active during execution. It therefore provides a possibility for the central nervous system to evaluate the consequences of future actions and to prepare

properly for the actual execution (Jeannerod 2001). The relationship between motor imagery and motor action can be deduced from the observation that the timing patterns of both processes are similar (Sirigu *et al.* 1995) and that the changes in corticospinal excitability involve the same muscles (Fadiga *et al.* 1999). Functional imaging studies on motor imagery versus performance in non-musicians have shown that imagery and performance activate essentially the same cortical regions (Porro *et al.* 1996; Lotze *et al.* 1999; Gerardin *et al.* 2000), with the exception, however, of the primary motor cortex: the results regarding the involvement of the primary motor cortex in motor imagery differ between studies.

Using fMRI, Meister *et al.* (2004) compared music performance with music imagery in professional musicians (see above). During imagery they found bilateral activation in the pre-motor areas, the pre-cuneus, and the medial part of BA 40. The only missing brain response (when compared with actual execution) was the contralateral M1 and bilateral PPC.

Maps, links, and plasticity

Years of practice may establish a neuronal correlate of an audiomotor connection; this has recently been shown by brain imaging studies for both directions, auditory-to-motor and motor-to-auditory. Professional musicians often report that listening to a well-performed piece of music can involuntarily trigger the respective finger movements. In a magnetoencephalography (MEG) experiment, Haueisen and Knösche (2001) demonstrated that when listening to well-performed piano music pianists exhibit involuntary motor activity involving the contralateral primary motor cortex (M1). To investigate motor-to-auditory processing as a possible feedforward projection, Lotze *et al.* (2003) collected fMRI brain scans of violinists and amateurs as they silently tapped out the first 16 bars of Mozart's violin concerto in G major. The expert performers had significant activity in the primary auditory regions, which was missing in the amateurs.

Using electrophysiological or neuroimaging methods, adaptive changes in the cortical organization similar to those found after stimulation or injury (Merzenich *et al.* 1988; Jacobs and Donoghue 1991; Wang *et al.* 1995) have been found in humans after skill learning and as an adjustment after injury (Seitz *et al.* 1990; Pascual-Leone *et al.* 1994, 1995; Karni *et al.* 1995; Hund-Georgiadis and von Cramon 1999; Charness and Schlaug 2000). Although some studies have pointed out the rapid reversal of representational changes, other studies have found persistent alterations in response to the early acquisition of fine sensorimotor skills such as there being a larger sensory finger representation in the left hand of string players (Elbert *et al.* 1995).

In order to clarify which of the peculiarities of musicians' brains are actually induced by practice, it is necessary to observe plastic processes from the very

beginning of learning to play an instrument. This provides a unique opportunity to disentangle the different parameters that form the network required for playing an instrument. These contributing parameters are sight-reading, visual–auditory transfer (knowing how a musical score will sound), anticipatory auditory imagery, motor planning and execution, audiomotor feedback control, visuomotor control, and analysis of various somatosensory feedback channels.

Pascual-Leone *et al.* (1995) used focal transcranial magnetic stimulation (TMS) to map the motor cortical areas targeting long finger flexor and extensor muscles bilaterally. They showed that as subjects learned a five-finger exercise on the piano over the course of 5 days under auditory feedback, the area of cortical representation for the long finger flexor and extensor muscles enlarged significantly (Pascual-Leone *et al.* 1995; Pascual-Leone 2001). However, this increase could only be demonstrated when the cortical mapping studies were conducted following a 20- to 30-min rest after the practice (and test) session. No such modulation in the cortical output maps was noted when maps were obtained before each daily practice session (Pascual-Leone *et al.* 1999).

Karni *et al.* (1998) provided evidence that a few minutes' daily practice of a finger opposition sequence induced large, incremental performance gains over a few weeks of training, which were associated with changes in cortical movement representation within M1. The authors suggested that these changes reflected the initial set-up of a task-specific motor program, while the subsequent changes indicated the consolidation of this motor program.

Stewart *et al.* (2003) focused on the acquisition of sight-reading skills. They investigated musically naïve participants before and after a period of 15 weeks during which they were taught to read music and play the keyboard. When participants played melodies from musical notation after training, fMRI activation was seen in the superior parietal cortex bilaterally. These authors suggest that reading music involves the automatic sensorimotor translation of a spatial code (written music) into a series of motor responses (key presses).

Sight-reading, however, is not necessarily at the core of music performance—as illustrated by playing by heart or by musical improvisation. In the following, an experiment is presented that sets out to specify the role of the right frontal activity found in several studies mentioned above.

EEG correlates of auditory sensorimotor integration during piano learning

In professional musicians, the cortical activation patterns during performance display widely distributed networks far beyond a simple representation of the modalities involved (audible tones and the digits of the hands; Bangert *et al.* 2005).

Bangert, Altenmüller, and Parlitz at the Institute of Music Physiology and Musicians' Medicine (Hannover, Germany), have investigated the question of how this apparent multimodal and sensorimotor representation is acquired during practice. They invited 17 musically naïve right-handed subjects to be trained twice a week, over a period of 5 weeks, to play the piano with an interactive computer system. They listened to short (3 s) piano melodies and practiced replaying these melodies with the five digits of their right hands as accurately as possible. The system was adaptive: an online performance analysis of the replayed melodies determined the tempo and complexity of subsequently presented targets—the better the performance, the harder the challenge. The subjects' sole feedback on whether a trial was successful was an implicit one: they heard themselves playing.

The EEG acquisition paradigm differed from the practice settings. Whereas the training procedure aimed at sensorimotor binding, for the actual measurement the auditory and motor features of the practiced task were dissociated, as outlined by the basic idea above (Plate 9). The subjects' event-related slow DC-EEG potentials were measured at 30 electrode sites *either* while *passively listening* to short melodic piano sequences (similar to the practice melodies) *or* while arbitrarily *pressing keys on a mute piano keyboard*. The term 'passive listening' refers to the instruction just to 'take the music in', without any attempt to analyse or memorize it.

Automatic co-activation of the cortical representations of 'ears' and 'hands'

Before the first practice (Plate 9), the average non-musician's brain exhibited textbook behaviour: auditory musical processing activated more frontal and central areas, and plain motor execution was accompanied by activity in the left primary motor area. (Note that all the training was performed with the right hand.)

The first signs of plasticity occurred after just 20 min of practice (Plate 9). The passive listening led to a widespread additional activation immediately following the very first session at the piano, but in the vicinity of the central sulcus clearly lateralized to the left (again, the right hand). The subsequent measurements (Plate 9) were collected after five and ten training sessions.

The co-activation of the left sensorimotor cortex was eventually focused in a spatially distinct region. Moreover, in the case of the subjects described here, the frontal activity showed a salient focus of activation at a frontotemporal area of the right cerebral hemisphere (in the following, abbreviated rFTA). The rFTA comprises an anterior part of the superior temporal gyrus (STG) and the inferior frontal cortex. Information has been published on the localization and function of rFTA components using various methods: lesion studies (Samson and Zatorre

1988; 1992; Zatorre and Samson 1991; Zatorre and Halpern 1993; Liegeois-Chauvel *et al.* 1998), PET (Zatorre *et al.* 1994, 1996; Griffiths *et al.* 1998; Halpern and Zatorre 1999), fMRI (Langheim *et al.* 2002), and MEG (Tervaniemi *et al.* 1999).

The right panel of Plate 9 depicts the simultaneous development of cortical activation for the silent motor movement paradigm. Activity in the parietal lobe again increased during the first half of the training period (until week 3), but subsequently decreased by the end of the 5-week session. The most remarkable change can be seen on the side ipsilateral to the moving hand: it looks as if the sensorimotor cortex of the unused left hand had been inhibited during the first session and remained in that state ever after. Again, in addition to these effects, development of some prominent area of activation around the rFTA was observed. Since this area has been demonstrated to be involved in the *perception* of pitch sequences, this effect could provide an explanation for why skilled pianists often state that silent practice creates an apparent auditory impression (or illusion) of the music they are playing.

Two sides of a coin

During data analysis an increasing similarity of the brain activation patterns for the auditory and motor tasks was noticed, until in the expert performers it became hard to tell which was which. The scalar product of two vectors of unit length gives a measure of the similarity of the two activation patterns. Nearly identical patterns would then result in a value close to unity, inverse patterns would yield –1, and differently shaped (orthogonal) patterns would dot-multiply to zero. In contrast to the Euclidean distance, the normalized dot product is robust against non-specific effects with small potentials or differing potentials, and accounts for 'qualitative' similarity in pattern only.

Figure 11.1 illustrates what this method yields when applied to the 'passive auditory'/'silent motor' resemblance. As expected from the appearance of the patterns, the grand average of the beginners' 'auditory-by-motor' scalar product turned out to increase with accumulated practice time (see Fig. 11.2). For the expert performers, perception and action seem to be just two aspects of one integrative skill; in one case, a 38-year-old pianist with 32 years of instrumental practice revealed a staggering value of $d(t) = 0.98$ (average in the time window from 0–2000 ms after onset of music/movement).

Learning a sensorimotor map

The next step set out to clarify the role of the rFTA, which, strikingly, appeared active in the auditory as well as in the silent motor task. Therefore, a control group of another eight naïve subjects was established. They were administered

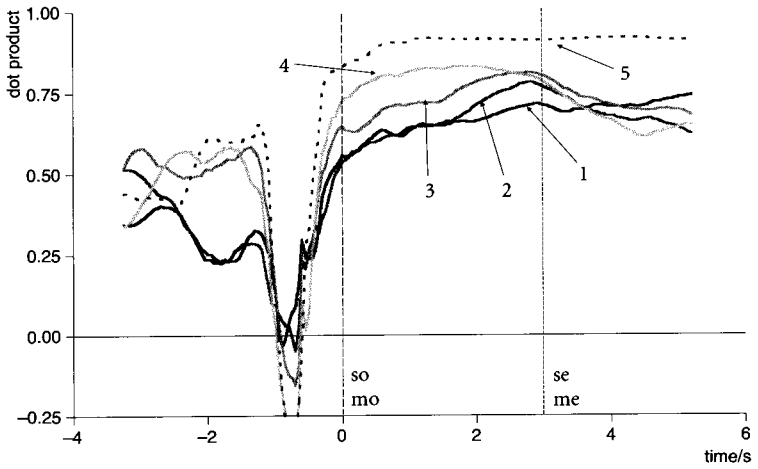

Fig. 11.1 Scalar product of the normalized passive auditory/silent motor brain activation vectors, as a function of time. so = stimulus onset, se = stimulus end, mo = movement onset, me = movement end. Curve 1, novices (n = 9) before the first session; curve 2, novices after 20 min of practice; curve 3, novices after about 21 days of practice; curve 4, novices after about 39 days of practice; curve 5, professionals (n = 3).

the same 5-week training programme (reproducing acoustically presented melodies as precisely as possible with respect to note order, rhythmic timing, and loudness of the piano keystrokes) with one slight modification: the assignment of the five relevant notes (pitches) to the five relevant keys, or fingers, respectively, was shuffled after each single training trial, so that the control group was not given any chance to figure out any coherence between fingers and notes except the temporal coincidence of keystroke and sound. In other words they had no opportunity to establish an internal 'map' between motor events and auditory targets.

Still, the control subjects had to practice proper timing and control of fine finger forces for the reproduction of rhythm and loudness. In fact, as the behavioural data indicated, the control subjects learned to perform these aspects of playing an instrument better than the 'regular learners' (Fig. 11.2a).

Figure 11.2b shows the activation differences between the two groups. We can therefore see a neural vestige of what the regular learners had been trained to make use of, while the control subjects had not.

One intriguing difference can be observed in the localization of the sensorimotor representation of the right hand: whereas a clear co-activation of the sensorimotor hand area (while listening) had developed in the regular learner group, such an effect was absent in the control subjects. In these subjects, no common representation of ear and hand was established. A consistent organization of

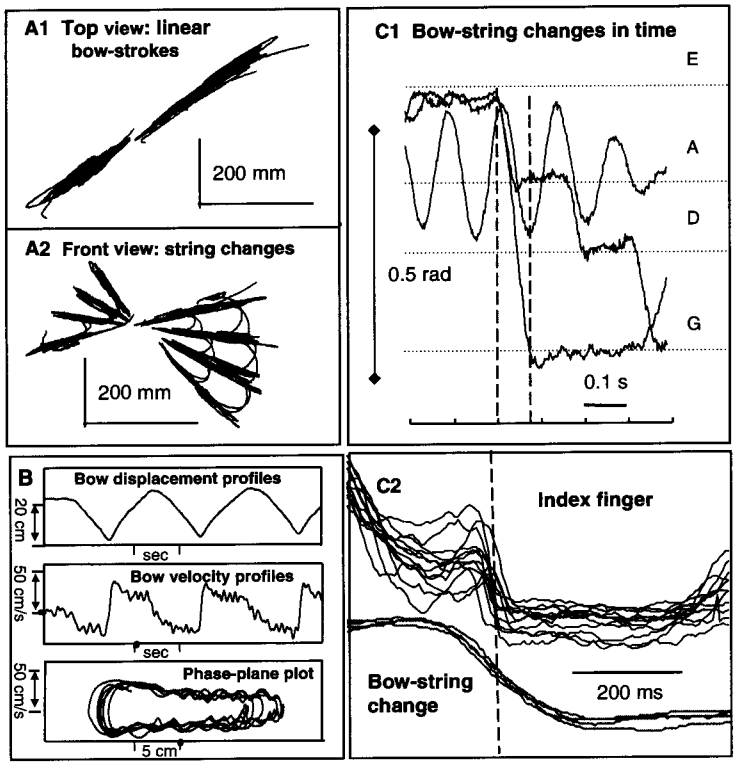

Plate 1 (A1, A2) The two principal bow movements: rectilinear bow strokes and rotating movements during string changes. (B) Slow *détaché* bow strokes: displacement profiles (above), velocity profiles (middle), and phase-plane plots (below). (C1) Bow rotations for string changes (as in A2), but transformed in displacement profiles (1 radian ~57°); bow tilts over one, two, and three strings. The jump from the highest string (E) to the lowest string (G) amounts to about 0.5 radians or ~28° and required about 80 ms in this example. (C2) string change together with displacement profiles of the playing finger. Ten superimposed traces each.

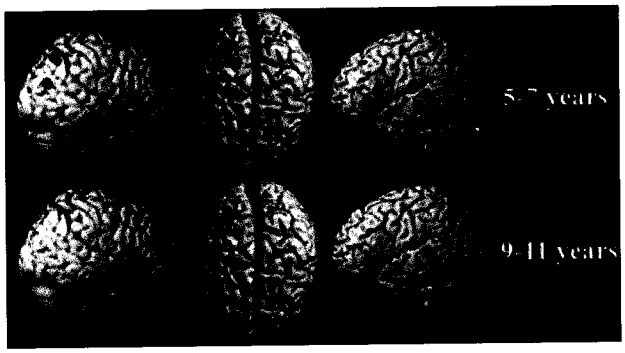

Plate 6 Correlating behavioral performance and gray matter volume differences. The top row shows significant correlations between performance in the Primary Measures of Music Audiation (PMMA) test and voxel-by-voxel grey matter density values in a group of 5–7 year old, musically-naïve children. The pattern shows a bi-hemispheric, temporal lobe dominance. The bottom row shows significant correlations between performance in the Intermediate Measures of Music Audiation (IMMA) test and voxel-by-voxel grey matter density values in a group of 9–11 year old instrumentalists with 3–4 years of instrumental training. Now the pattern shows an anterior temporal and inferior frontal lobe dominance. Statistical results are overlaid on the rendered cortex surfaces of a single subject.

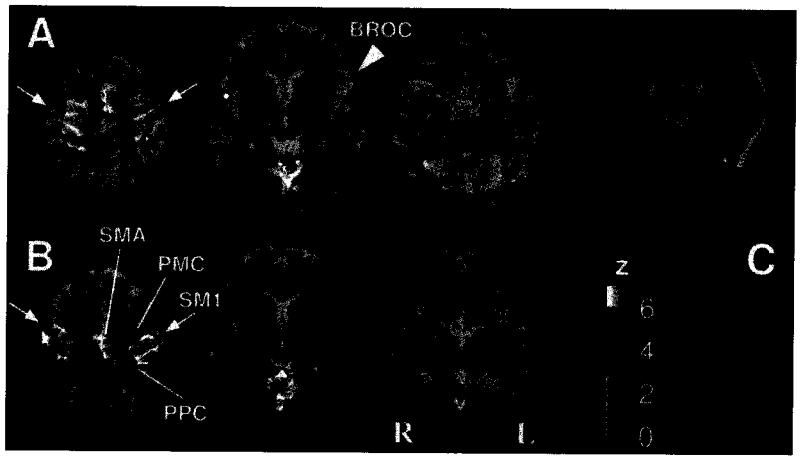

Plate 10 Functional MRI activations: (A) violin playing on a sham instrument (without auditory feedback), (B) bimanually coordinated non-musical reference task (repetitive pulling of a drawer with the left hand, synchronized grip of an object within the drawer with the right hand), (C) whole brain volume and slice angulation. Baseline was the resting state for both tasks. For each task, three oblique slices (slightly tilted with respect to the transverse AC–PC orientation) at the level of the motor cortex, at the level of the frontal operculum, and at the level of the cerebellum, are shown. (A) Prominent bilateral activation is seen in the sensorimotor cortex (SM1; arrows = central sulcus), pre-motor cortex (PMC), supplementary motor area (SMA), posterior parietal cortex (PPC), thalamus and cerebellum. A slight asymmetry with higher activation of the right motor cortex (i.e. contralateral to the fingering hand) can be seen, whereas there is no asymmetry with the bimanual reference task. The main difference in activation between the two tasks was the prominent activation in Broca's area in the violin task (arrowhead), as compared with its lack (in the present slice) or only marginal activation of this region in the reference task. The violin task also produced a weak activation of the right-sided homologue of Broca's area. This asymmetry is opposite to that in the sensorimotor areas and thus most likely related to hemispheric dominance.

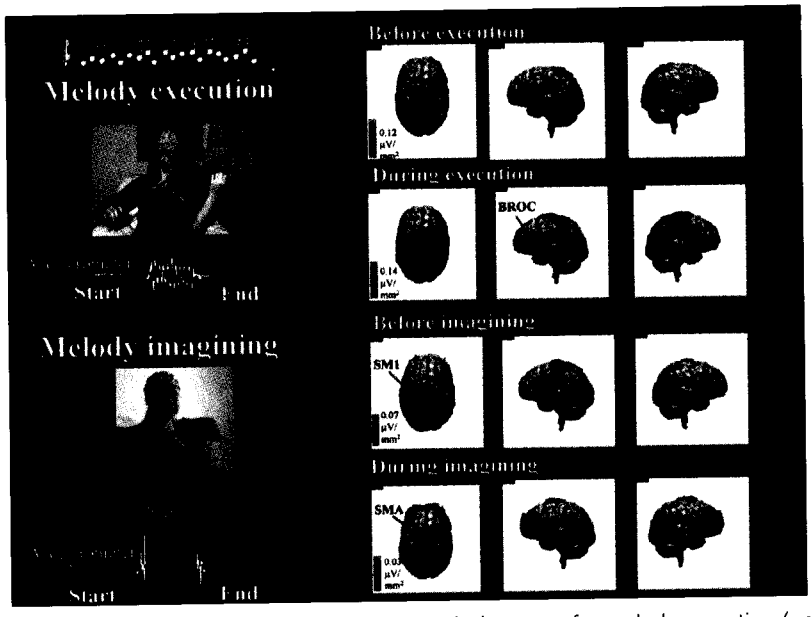

Plate 11 Experimental design and reconstructed cortical sources for melody execution (upper panel, on the right) and imagining (lower panel, on the right) for one of the subjects (S7). The melody is shown at the top of the upper panel (left). High-resolution EEG recorded with an electrode cap from 58 scalp positions during execution of a musical sequence on a violin and during imagining the same sequence (left part of the figure). The start and the end of the musical sequence are defined by recording the accelerogram. The start and the end of imagining the musical sequence are marked by short abrupt movements of the right hand also recorded by accelerogram. The reconstructed CCD maps are superimposed on the segmented brain of the subject (top, left and right view of the brain). The CCD maps, which are displayed with the individual current vectors, show the current flow distribution on the cortex, which can account for the potentials measured on the scalp. Reconstructed cortical sources for melody execution: the CCD maps before the melody execution suggest distributed sources in SM1s, in the SMA, and in the inferior frontal gyrus. During execution activation of networks in the left and right SM1s, in the SMA, in the frontal inferior gyrus, and in the superior temporal gyrus is observed. Reconstructed cortical sources for imagining: before imagining there is activation of SM1s, the SMA, the pars opercularis of the inferior frontal gyrus, and the gyrus occipitalis. During imagining there is activation of the SMA, the gyrus supramarginalis, and the frontal polar areas but no activation of the SM1s and the gyrus temporalis superior. (Modified from Kristeva *et al.* (2003) with the kind permission of *NeuroImage*.)

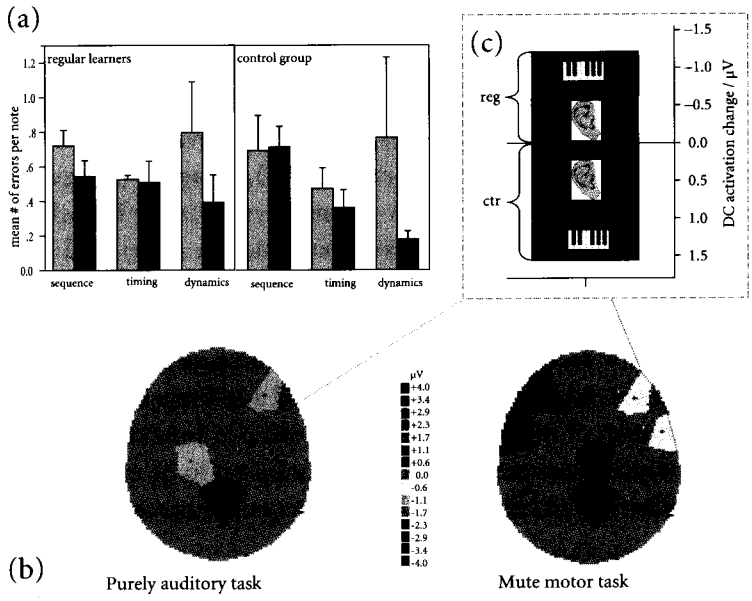

Fig. 11.2 (a) Average error incidences per note of a given melody, split up into sequence, timing and dynamics errors. Regular learner group on the left, control group on the right. Light grey bars, first training session; dark gray bars, last session. (b) Changes of cortical activity induced by 10 sessions of training. Only significant differences between the two groups are shown: red = more negative potential (activation increase), blue = more positive potential (activation decrease), green = no change. (c) Potential changes for a right frontotemporal selection of electrode sites. reg = regular learner group, ctr = control group: green bars, auditory task; red bars, silent movement condition.

perceptual and motor events seems to be a prerequisite for the development of a common sensorimotor representation: It is likely, then, that the sensorimotor map has 'to make sense in order to make synapses'.

Another group difference appeared in the rFTA region (Fig. 11.2b). This was basically due to two mutual effects (Fig. 11.2c). First, in the regular learners, the activity of the area concerned had increased. Second, in the control group, this activity even decreased during training. The subjects had acquired high timing accuracy for the reproduction of fast complex rhythmic sequences and a 'feeling' for the piano keyboard without putting the rFTA into action at all. Obviously, the actual function of the rFTA is to process the sequential order of *pitch patterns* feeding them into working memory, and also to retrieve them from working memory for execution. That means that the rFTA is likely to have properties of a supramodal neural network suitable for translating music into movement, i.e. the rFTA may provide an interface map.

A shared core network?

Recent research on musicians and music processing and performance has repeatedly revealed the following to be involved in musical tasks: motor preparation and execution (Parsons 2001; Hickok *et al.* 2003; Kristeva *et al.* 2003; Lotze *et al.* 2003; Haslinger *et al.* 2004; Meister *et al.* 2004), imagery (Lotze *et al.* 2003; Meister *et al.* 2004), music perception (Ohnishi *et al.* 2001; Kölsch *et al.* 2002; Gaab *et al.* 2003; Hickok *et al.* 2003; Levitin and Menon 2003), and instrumental mirror systems (Hasegawa *et al.* 2004; Haslinger *et al.* 2005).

We have deliberately pooled the aforementioned very different studies covering a whole variety of facets of music perception and production. From the fMRI and PET data these studies provided, we collected and meta-analysed all available Talairach coordinates of the significant task-specific or musician-specific images, and evaluated which areas are most commonly found to be active in this variety of tasks. The following had by far the highest frequency across the studies:

1. In the left hemisphere:
   - frontal operculum (Broca's area/BA 44/46/47) (Kölsch *et al.* 2002; Kristeva *et al.* 2003 (EEG-no coordinates available); Levitin and Menon 2003; Lotze *et al.* 2003; Hasegawa *et al.* 2004; Haslinger *et al.* 2004; Bangert *et al.* 2005);
   - frontal BA 9 (Ohnishi *et al.* 2001; Kölsch *et al.* 2002; Gaab *et al.* 2003; Hasegawa *et al.* 2004; Meister *et al.* 2004; Bangert *et al.* 2005);
   - superior temporal gyrus (BA 22/Wernicke's area) (Parsons 2001; Hasegawa *et al.* 2004; Bangert *et al.* 2005);
   - supramarginal gyrus (BA 40) (Meister *et al.* 2004; Hasegawa *et al.* 2004; Bangert *et al.* 2005).
2. In the right hemisphere:
   - frontal BA 9 (Kölsch *et al.* 2002 (non-musicians); Lotze *et al.* 2003);
   - frontal operculum (Broca's area/BA 44/BA 46) (Kölsch *et al.* 2002; Hasegawa *et al.* 2004);
3. Bilaterally:
   - (SMA/PMA/BA 6) (Gaab *et al.* 2003; Meister *et al.* 2004; Hasegawa *et al.* 2004; Bangert *et al.* 2005);
   - supramarginal gyrus (BA 40) (Meister *et al.* 2004; Hasegawa *et al.* 2004; Bangert *et al.* 2005).

Regardless of whether a music study paradigm involves perception or execution, the ensemble of four main components, resembling Brodmann's areas 9, 44/46, 20–22, and 40, appear to be crucial contributors to a musician's skills—possibly a 'core network' of musicianship. It has to be added, though, that

this network could be related to auditory–sensorimotor co-processing only. The important visuomotor and visuo-auditory aspects of music processing (music notation and sight-reading) seem to employ a substantially different network, with, surprisingly, almost no overlap with any of the audiomotor-focused studies listed above (Stewart *et al.* 2003).

Musical speech or musical language?

It is interesting to speculate why Broca's and Wernicke's areas, though traditionally language-related, should be part of the cortical network dedicated to musical expression in skilled instrumentalists. The concept of language has recently become more and more generalized and is no longer confined to auditory–vocal verbal language. Direct comparison of music and language processing has revealed considerable parallels (Hickok *et al.* 2003) and the small literature review above indicates a substantial role for these areas in music, just as in language. The importance of Broca's area for musicians has recently been shown not only functionally but also structurally by Sluming *et al.* (2002), who used voxel-based morphometry to demonstrate an increased density of grey matter in Broca's area in musicians.

It may be an important distinction to employ the term 'speech' rather than (or additionally to) 'language' when thinking about the function of the Broca–Wernicke network. 'Language' usually rather implies its structure and logical framework, like syntax and semantics, while 'speech' includes the actual process of articulatory execution, and is thereby action-related. The 'language' framework often confines possible interpretations to the peculiarities of logical structure of the experimental paradigm and stimulus material (e.g. musical 'syntax'), although the actual function of Broca's area is much more general, in terms of 'speech' and not only language. Following up on the 'Bach speaks' catchphrase coined by Kölsch *et al.* (2002), we would rephrase this as 'Bach may know the language, but it is rather Gould who does the speaking'.

A bottom-up approach towards the clarification of the functional relevance of the inferior frontal cortex comes from the study of mirror neurons in monkeys. By definition, 'mirror neurons' discharge when a monkey makes a specific action *and* when it observes another individual making a similar action (Rizzolatti and Fadiga 1998). In monkeys, mirror neurons are found in the rostral ventral pre-motor cortex (area F5), originally for the visual domain. However, Kohler *et al.* (2002) recently reported that a population of neurons called audiovisual mirror neurons additionally responds when only the *sound* of the effective action is presented to the monkey. Multimodal neurons have been described in several cortical areas and subcortical centres. These neurons, however, responded to specific stimulus locations or directions of movement. The difference from the neurons described by Keysers *et al.* (2003) is that they do not code space, or some

spatial characteristics of stimuli, but actions when they are only heard. These 'audiovisual mirror neurons' therefore represent actions independently of whether these actions are performed, heard, or seen. Another remarkable property of audiovisual mirror neurons is that about half of them respond with a similar intensity of discharge whether the action is only heard, only seen, or both heard and seen. This finding is important, as it suggests that the neurons code the action in an abstract way, which does not depend on the source of information (auditory or visual) from which the evidence about the presence of the action is taken (Keysers *et al.* 2003). It is not only visual and auditory–visual mirror neurons that have been reported, but also an exclusively auditory responsive domain with high selectivity of these neurons for acoustic stimuli (Romanski and Goldman-Rakic 2002).

Additional support for this physiological finding comes from cytoarchitectural studies (Petrides and Pandya 1999, 2002; Romanski *et al.* 1999). Although the areas in question have a complex multimodal input, they could be differentiated in terms of some of their inputs. In fact, the 'mirror' functionality of area F5 has led researchers to consider this region to be the precursor of Broca's area in the monkey (Rizzolatti and Arbib 1998). Three studies in musicians point towards a musical mirror system in musicians, one using auditory action–observation (Ohnishi *et al.* 2001) and the other two using visual action–observation (Hasegawa *et al.* 2004; Haslinger *et al.* 2005). What makes the hypothesis of an auditory mirror system particularly interesting is that the classic notion of Broca's area being dedicated to language and speech processing has been expanded to include a broad range of stimuli including music.

Conclusions

The cortical structures providing a musician's audiomotor performing skills are always activated together, even when one of the physical aspects of performing (instrumental sound, somatosensory input, movement output) is missing. This substrate of the 'inner ear' ranks among the very first implicit acquisitions during the process of learning to play an instrument. The years of practice provide just the ability to be aware/make conscious use of these neuronal circuits that have already been established. The same structures are likely to be directly involved in musical performance imagery, hence contributing elements of both perception and action to a musician's mental representation of music.

Chapter 12

Brain activation during string playing

Arto Nirkko and Rumyana Kristeva

Introduction

Playing music with any type of instrument requires precise spatial and accurate temporal, mostly bimanually coordinated, motor control. The level of sophistication needed to produce an enjoyable musical performance can only be reached by long-term learning of these specific motor skills, usually over many years. In addition to motor performance, musical perception abilities—consciously or not—are also trained in parallel, as they are necessarily involved in the feedback processes which serve to fine-tune the motor output in the long term: the speed at which music is produced easily exceeds both the central and peripheral conduction times, making closed feedback control impossible. Direct feedback is limited by nerve conduction velocities, already delaying afferent proprioceptive motor input by tens of milliseconds in the periphery. The possibility for closed loop auditory feedback is additionally hampered by the fact that the music must be 'perfect' in the first place during the performance, and cannot be adjusted during the performance until the auditory feedback is perfect. For these two reasons feed-forward control is required (Wolpert and Ghahramani 2000; Wolpert and Flanagan 2001). Continuous mid- or long-term adjustment must rely on both proprioceptive and auditory feedback, especially during the learning phase but also later to ensure stability: even professional musicians need to continue practising.

Thus, the end product of musical performance is based on highly over-learnt sensorimotor skills, which interact with perceptive auditory skills (which are also over-learnt) and continuous adjustment. Further (in terms of temporal coordination) more independent interactions with other sensory, cognitive, and motor systems are evident from the simultaneous requirements for reading notes, watching, and interpreting the conductor (vision and control of eye movement). These processes interact with working memory and the recall of musical sequences from long-term memory, and also with processes such as postural motor control. The latter is not directly involved in producing tone sequences from the musical instrument, but enables the body and instrument to

be kept in a relative position suitable for producing these tone sequences. In addition, a component of actually enjoying the music is likely to be present in the players as well as the listeners. In the player, this is complemented by a probable component of enjoying the playing itself.

With these considerations in mind, it seems quite evident that large parts of the brain must be involved in playing music, many or all of them shared with other tasks, not necessarily of a musical nature. This poses specific problems for the assessment of different components, like 'pure playing' (or 'music production'), as opposed to 'listening' (or 'music perception'), and assessment of some other components involved. Principally, planning and production could be segregated in time from perception, because of the temporal differences between motor preparation, execution, physical tone generation, and auditory perception. This is possible when using methods with high temporal resolution, such as electroencephalography (EEG), which directly assess neuronal activity. The slow negative shifts of the cortical direct current (DC) potential have been shown to reflect activation of the underlying areas. Thus the preparation of a task is accompanied by task-preceding negativity and the execution of a task is accompanied by task-processing negativity. In contrast to EEG, current imaging methods with a high spatial resolution, such as functional magnetic resonance imaging (fMRI), depend on a relatively sluggish haemodynamic response: they are thus biologically limited to an inherently low temporal resolution of the order of several seconds, which is insufficient for direct observation of the temporal sequence of different processes following each other with delays in the range of (tens to hundreds of) milliseconds. An alternative solution to the problem is the segregation of processes related to production from processes related to perception by task design, using a set-up to assess only one component per fMRI experiment. Another intriguing question is whether executing and imagining music involve the same areas of the brain.

In this chapter we attempt to integrate data from both fMRI and EEG to elucidate the activation of the cortical areas in musical performance for both execution and imagination of music.

Stringed instruments and other instruments

Whereas many processes during string playing may be assumed to share similarities with production of music on other instruments, one evident difference is the highly asymmetric quality of the function of each hand in playing a stringed instrument. In many instruments, such as the piano, the fingers of both hands also have to perform asymmetric and intermanually well-coordinated movements, but the functional significance of these movements is similar (selecting or

producing a specific tone) and can even sometimes be performed by either one hand or the other, depending on the spatiotemporal context in the musical sequence. In contrast to this, in string playing each hand has multiple separate, fundamentally different and non-interchangeable functions: one hand (usually the left) has both a postural function in holding the instrument and its main musical function in 'selecting' specific tones, whereas the other hand (usually the right) initiates and sustains production and modulation of the tone. This hand also has a role in selecting the tone on a coarser level (selecting the active strings), but even this selection is fundamentally different from what the left hand does, both regarding different finger, hand, and arm movements and a different musical function. Thus, hemispheric asymmetries have to be specially taken into account in the evaluation of the brain representation during string playing.

The paradigms

In both fMRI and EEG experiments we used the same musical sequence as used by Wiesendanger and colleagues (see Fig. 12.3 and Chapter 7).

Four musicians were investigated in the fMRI experiments. To segregate the production of music from its perception we used pure motor 'music playing' on an MRI-compatible 'sham violin' made of wood, without strings or any other means to produce sound, thus eliminating auditory feedback processes. Further, visual processing was avoided by having the subjects practice and then play the short sequence by heart, with their eyes closed. Due to spatial restrictions in the MRI scanner, both the pseudo-violin and the pseudo-bow were small and were not held in the normal position, but rather were rested on the abdomen when lying in a supine position. The resulting movement excursions were distal, acted from the wrist and not with the whole arm. With this set-up, only a minimum of postural functions were involved and the paradigms focused on motor sequences with direct musical meaning (tone selection with the fingers of the left hand, and bowing with the right hand). To assess regions specifically involved in music production and not only in motor control, the musical task was compared with a bimanual motor sequencing task without musical meaning: the left hand had to repetitively pull a drawer on an MRI-compatible manipulandum, while the right hand had to grip an object in the drawer, in a bimanually synergistic and synchronized manner. Regions known to be mainly concerned with motor execution (the primary sensorimotor cortex, SM1) served as a control region: These regions were not expected to exhibit relevant components specific to music, and were used as an internal control to assess whether the demands of the different tasks on the motor system were similar. A block design with continuous repetition of the same sequence (either with movements executed or only

imagined) was used as the activation task, and with rest (holding the instrument) as the baseline task.

In the EEG experiments we recorded high-resolution EEG data from six healthy right-handed professional violin players (mean musical practice for 15.7 (standard deviation, SD 4.1) years) (Kristeva *et al.* 2003). The EEG was recorded before, during, and after playing single runs of the musical sequence on real violins and were averaged time-locked to the start and to the end of the musical sequence. Averaging time-locked to the start of the musical sequence allowed us to demonstrate the onset of the music-preceding negativity, i.e. the negative slope of the cortical DC potential, which reflected the sequence of activation of the different brain areas during the preparation for execution or imagination of the music. Averaging time-locked to the end of the musical sequence allowed us to show the music-processing negativity, i.e. the sustained negativity which reflected the activation of the cortical areas during execution or imagination of the music.

In both fMRI and EEG experiments, the playing the music was compared with imagining the music. This allowed separation of the areas mainly involved in motor execution from those involved in imagining, planning, and working memory, thus differentiating musical from purely motor areas.

Methods

Functional MRI (fMRI)

Functional MRI was performed as previously described (Nirkko *et al.* 2001): in short, blood oxygenation level-dependent (BOLD) fMRI data were acquired on a clinical 1.5 T scanner (Magnetom Vision, Siemens, Erlangen, Germany) with the standard circularly polarized head coil, using a high-resolution (128×128 matrix, 1.56 mm pixel size) whole-brain (30 slices, one every 4 mm, interleaved acquisition) echo planar imaging (EPI) sequence with a flip angle of 90° and an echo time (TE) of 82 ms, at a rate of one whole-brain volume every repetition time (TR) of 6 s, for a total of 68 volumes in 408 s. The slices were tilted parallel to a line connecting the caudal outline of the genu of the corpus callosum and the occipital protuberance/confluens sinuum. This angulation was found to cover the whole brain including the cerebellum with a minimum of slices, to be more reproducible than the AC–PC line even on slightly non-median scouts, and to reduce susceptibility artefacts due to pneumatized areas below the frontobasis and the thalamic regions (Nirkko *et al.* 2001). Evaluation was performed on a Sun/Sparc/Solaris workstation (Sun Microsystems, Palo Alto, CA, USA) with custom-written software (Nirkko 2000). After motion correction (which was minimal due to fixation of the subject's head with a U-shaped dental plate in

addition to the lateral pads on the head coil), *Z*-score maps selecting clusters of at least 15 pixels size and a peak *Z* score of at least 8 (corresponding to a Bonferroni correction for all acquired pixels in the whole brain volume) were colour coded and overlaid on the original EPI images for evaluation with precise anatomical localization free of the possibilities of misregistration, and on higher-resolution structural spin-echo images with identical positioning parameters for visualization in the figures.

A quantitative measure for activation as a percentage of signal change was measured in structurally defined volumes of interest (VOI), which were manually defined again on the original EPI slices: in addition to the primary and secondary sensorimotor areas described in Nirkko *et al.* (2001), the pre-sylvian frontal opercular area (corresponding to part of Broca's region) and the anterior and posterior insular regions were assessed bilaterally. The mean percentage activation and standard deviation in each region was calculated from the 68 samples per experiment and used for statistical comparison between groups and between regions.

Electroencephalography (EEG)

Electrical potentials (bandpass filter 0–100 Hz; sampling rate 500 Hz) were recorded from 58 scalp positions. An accelerometer was placed on the right index finger to define the start and the end of the musical sequence.

The musical sequence was executed or imagined in a self-paced mode, at irregular intervals of 12 to 24 s, starting from complete relaxation (Bereitschaftspotential paradigm (Kornhuber and Deecke 1965)). Each subject executed or imagined the musical sequence 90 times in total per condition (playing on the real violin and imagining). The analysis time for the potentials time-locked to the start of the melody (for investigating the music-preceding negativity) was set to 5000 ms before to 1500 ms after the start trigger. After that the signal was averaged and baseline-corrected using the time between 5 s and 4 s prior to the start trigger.

The analysis time for the potentials time-locked to the end of the melody (for investigating the music-processing negativity) was set to 8 s before the end trigger to 1 s after it. After that the signal was averaged and baseline-corrected between 8 and 7.5 s before the end trigger.

To describe the start of the preparatory brain activity we measured the time of onset of the music-preceding negativity. To describe the preparatory brain activity at the start of the sequence, we measured the amplitude of the music-preceding negativity calculated as the mean negativity over the time between 89 ms prior to and 30 ms after the start of the musical sequence. To investigate brain activity during the musical sequence, we calculated the mean negativity

over the time between 2000 ms and 1000 ms before the end of the sequence, i.e. of the music-processing negativity.

In one of the subjects we performed advanced source reconstruction analysis, taking into consideration the individual brain morphology from MRI (for more details see Kristeva *et al.* (2003)). Thus we were able to show the cortical sources during *preparation* for execution and imagination of music and during execution and imagination of the music itself.

Brain activation patterns

In fMRI, in both the violin task and the bimanual reference task, a prominent activation pattern corresponding to the previously described sensorimotor network of both hands was seen (Nirkko *et al.* 2001), consisting of the primary sensorimotor cortex around the central sulcus (SM1), the secondary cortical areas of the pre-motor cortex (PMC) and the posterior parietal cortex (PPC), the supplementary motor area (SMA), and the cerebellum. In the violin task only, activation was consistently evident in the pre-sylvian frontal operculum ('BROC', part of Broca's language area) (Plate 10) on standard Z-score maps (six of eight sides in the four violin experiments, as compared with four of 20 sides in the 10 bimanual experiments). Quantitative evaluation yielded significant signal increases of 0.86% ($P << 0.001$, always corrected) in the left BROC during violin playing, and 0.44% ($P << 0.001$) in the right BROC. Conversely, the bimanual reference task also yielded a highly significant, but quantitatively much smaller, signal increase of 0.24% in the left BROC and 0.18% in the right BROC. The violin task thus lead to a 3.6 times higher activation in the left BROC than the bimanual reference task, and the difference between the two tasks was highly significant ($P << 0.001$, corrected).

The SM1 (left and right sides pooled) showed no difference between the tasks (difference 0.10%, not significant). Pooling both sides was necessary because by its very nature the violin task put greater demands on fingering with the left hand, and thus led to significantly asymmetric activation. Notably, this asymmetry during violin playing in SM1 (right more than left) is opposite to the asymmetry in BROC (left more than right).

During the music imagining task, a significant fMRI activation of the bilateral BROC and of the SMA without activation of the left and right SM1 was observed.

In the EEG experiment the execution of the melody lasted 3.2 $\pm$ 0.6 s and imagining the melody lasted 3.1 $\pm$ 0.4 s.

Figure 12.1 (upper panel) shows the music-preceding negativity for two representative subjects for execution and for imagining the sequence. This music-preceding negativity is seen over the left and right BROC, over the SMA, and over the left and right SM1s.

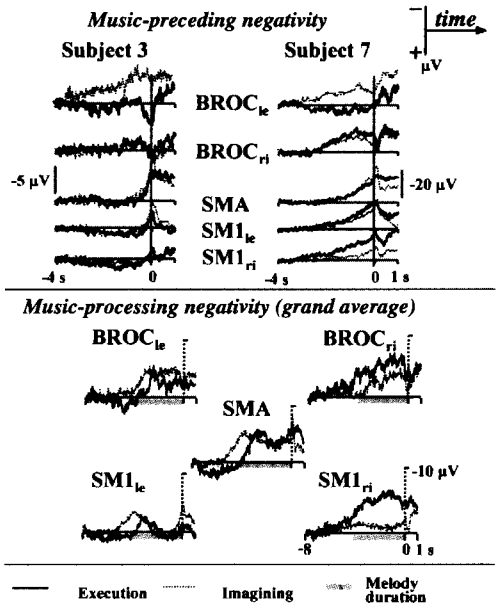

Fig. 12.1 EEG results. Upper panel: Music-preceding negativity (averaged potentials time-locked to the start of execution (solid line) and to the start of imagining (dotted line)). Negativity up. Averaged potentials for Subject 3 (S3, on the left) and Subject 7 (S7, on the right) recorded from electrodes overlying the left and right frontal opercular regions ($BROC_{le}$, $BROC_{ri}$), supplementary motor area (SMA), left primary sensorimotor ($SM1_{le}$), and right primary sensorimotor ($SM1_{ri}$) areas. Averages from 70 trials for execution and 64 for imagining conditions for S3. Averages from 44 trials for execution and 66 for imagining conditions for S7. Note the earlier onset over the left and right frontal opercular regions for S3. The onset times for S7 are similar for bilateral frontal opercular regions and for left and right SM1. Lower panel: Music-processing negativity (grand average curves for potentials time-locked to the end of the musical sequence for execution (solid line) and for imagining (dotted line)) for $BROC_{le}$, and $BROC_{ri}$, SMA, $SM1_{le}$, and $SM1_{ri}$. Negativity up. The duration of the sequence is marked by a grey line. Note the high music-processing negativity over bilateral frontal opercular regions and SMA for both execution and imagining the sequence. Note also that the processing negativity over the right SM1 is very high and it occurs only during execution. Note also that the left SM1 is activated only around the start and the end of the sequence for both conditions. (Modified from Kristeva *et al.* (2003) with the kind permission of *NeuroImage*.)

While the beginning of the preparatory activity of the brain for the SMA, the left SM1, and the right SM1 was very consistent, this was not the case with the preparatory activity of the 'more cognitive' areas, the left and right BROC: in three of the musicians the bilateral BROC became active earlier (about 3 s before the start) than the motor areas (about 1.5 s prior to the start). The music-preceding negativity for one of these three subjects (S3) is shown in Fig. 12.1 (upper panel, on the left). In one of the musicians the bilateral BROC became active simultaneously with the motor areas at approx. 3 s prior to the start.

The music-preceding negativity for this subject is shown in Fig. 12.1 (upper panel, on the right). In the remaining two subjects the music-preceding potential prior to execution and imagining showed a very high variability and the objective criterion for defining the onset time was not met, thus making it impossible to make a numeric statement.

Higher preparatory brain activity at the start of the execution of the melody was found for the right sensorimotor cortex, i.e. contralateral to the fingering hand.

The music-processing negativity reflecting the activation of the different cortical areas during music execution and imagining is shown in Fig. 12.1 (lower panel). Music-processing negativity over the SMA is seen for both execution and imagining. A large sustained music-processing negativity during both conditions can also be seen, as over the left and right BROC with stronger involvement of the left BROC during imagining and of the right BROC during real violin playing.

Large differences between playing and imagining are seen in the activity of the right SM1. During execution of the melody the activity of the right SM1 is characterized by a large processing negativity. During the imagination of the melody, brain activity is observed only shortly preceding the movement marking the end of imagining the sequence. Brain activity in the left SM1 only occurs before the end of the execution and before the end of imagining the sequence.

While the above analysis of the music-specific activity is based on the form and time course of the cortical DC potential recorded from five cortical areas only, Plate 11 shows the reconstructed cortical sources for one of the subjects on the basis of the potential distribution from 58 electrode positions. Before both execution and imagination of the melody, the reconstructed cortical current density (CCD) maps suggest distributed sources in primary sensorimotor areas, the SMA and bilaterally in the BROC. During execution of the melody additional activation is observed in the superior temporal gyrus.

During imagination of the melody a strong activation is present in the SMA, the gyrus supramarginalis, and the frontal polar areas. However, no activation of the superior temporal gyrus or of the primary sensorimotor areas is observed.

Broca's area and its right-hemispheric homologue

Our fMRI and EEG results both indicate that the fronto-opercular part of the Broca language regions is involved in the production of music. This region has already been implicated in motor sequencing and manipulation (Binkowski *et al.* 1999), and our data indeed demonstrate a significant but weak activation with a bimanual reference task as well. However, the fMRI activation during music

production was 3.6 times higher ($P < 0.001$ corrected), suggesting a relevant music-specific contribution.

The stronger involvement of the right BROC during execution of the melody in the EEG experiment is well in line with findings of Bangert *et al.* (1998). Using DC-EEG these authors showed pre-frontal-temporobasal activation during piano playing which was interpreted to reflect audiomotor integration. The results of Rao *et al.* (1997) are also in support of the role of the right inferior frontal gyrus in music production. Using fMRI these authors suggested that the activation of the right inferior frontal gyrus supports the retrieval and rehearsal of internal non-linguistic auditory representations of time intervals.

The EEG results show a considerably larger area of activation than the fMRI results, covering not only the fronto-opercular areas corresponding to the Broca language centres, but also parts of the temporal lobe. This is presumably because the auditory feedback during the EEG experiments with real violins yielded an additional activation of the auditory cortex in the superior temporal lobe, which is adjacent to the frontal operculum as seen from the surface of the skull. The superior temporal gyrus was also shown to play a role in analysing higher-order patterns formed by the features of the individual notes (Griffiths 2001). In contrast, the fMRI experiments were performed without auditory feedback, yielding only areas related to pure motor performance.

Notably, the asymmetry in the motor cortex with preferential activation of the cortex contralateral to the more active hand was opposite to the asymmetry in Broca's area, which was concordant with the dominance of the left hemisphere in the language areas.

Traditionally, the language areas have been functionally divided between the temporal area (Wernicke) for language analysis and understanding, and the frontal area (Broca) for production of speech. Our fMRI results regarding music production, together with other studies assessing musical perception, suggest that a similar division applies to music. Interestingly, contrary to popular scientific belief that music is a more emotionally involved modality which might be represented in the right hemisphere, the fMRI results show that the left hemisphere is also dominant for music production, at least when pure production is assessed in professional musicians. However, our EEG results during real violin playing show that the right hemisphere is more strongly involved if musical perception is included, suggesting that the perception of the music produced is processed mainly in the right hemisphere.

The stronger involvement of the left fronto-opercular cortex during the imagination of music in the EEG experiment and during playing on the sham violin in the fMRI experiment suggest that the hemispheric preponderance of the music-specific activity is related to the presence or absence of auditory

feedback: the auditory perceptive component seems to involve the right hemispheric homologous region to a greater degree, while the performance/production of music alone (without perception) is more lateralized to the left. This interpretation is well in line with studies on musical perception using magnetoencephalography (MEG) (Maess *et al.* 2001), positron emission tomography (PET) (Halpern 2001), or fMRI (Ohnishi *et al.* 2001), where the temporal cortex (including the Wernicke receptive language area) was predominantly involved in the processing or imagination of music.

In the EEG experiment the left and right BROC displayed much larger interindividual differences in terms of beginning of the preparatory activity. This favours the notion that the cortical areas involved in music processing have individually formed patterns of temporal organization during music preparation (Altenmüller 2001). This finding argues against the common opinion that populations of musicians are rather homogeneous in their behaviour. The high variability may result from the high individualization of the musicians' brains during long years of intensive learning of music skills. However, one cannot exclude that the high variability may result from different brain anatomy.

The sensorimotor cortical network

In the fMRI experiments there was no significant difference between musical and non-musical bimanual tasks regarding the activation of the pooled bilateral primary motor cortex (SM1) serving as the control region. This confirms that in terms of motor activation, the two tasks were equivalent. The asymmetry of SM1 activation, with stronger involvement of the right SM1 in the fMRI experiment during the violin task and in the EEG experiment during melody execution, is explained by the inherently asymmetric motor demands of violin playing on each hand and was to be expected. The right SM1 controls the left hand, which performs the more complex sequencing motor task. Further, there is a use-dependent cortical reorganization of the right somatosensory (Elbert *et al.* 1995) and primary motor area which has to overcome 'spill-over' and enslaving to organize the individuated distal movements of the left hand fingers learned during a long practice (Amunts *et al.* 1996; Slobounov *et al.* 2002).

The strong SMA activation and the absence of sources in the left and right SM1s when imagining the melody in both fMRI and EEG experiments is well in line with results of Stephan *et al.* (1995), Seitz and Roland (1992), and Binkowski *et al.* (2000). Functional MRI experiments with imagined movements showed activation of the SMA, especially its 'intermediate' part (Stephan *et al.* 1995). Previous work of ours (Ball *et al.* 1999) has also suggested an inhibitory/disinhibitory function for the intermediate SMA. This would offer an explanation

for its activation during imagination of the melody, because this specific task requires inhibition of overt movements, i.e. suppression of the left and right SM1. Lack of activation of both the left and right SM1 during imagination of a musical sequence was also shown in fMRI experiments (Nirkko *et al.* 2001; Langheim *et al.* 2002). Another explanation for the strong activation of the SMA during the imagining task could be the implication of this area in covert vocalization (Zatorre *et al.* 1996).

The activation of the pre-frontal areas shares similarities with verbal and visuospatial working memory activations as shown by fMRI (Janowsky *et al.* 1989; Milner *et al.* 1991; Wheeler *et al.* 1995; Cabeza and Nyberg 2000; Haxby *et al.* 2000; Fletcher and Henson 2001). It is possible that the activations of the pre-frontal areas seen by us are related to musical working memory.

Conclusions

These observations about bilateral activation of the frontal opercula during preparation for, imagining, and execution of music, and the differences in hemispheric lateralization regarding perception and production extend the hypotheses about the functional role of these regions: The Broca area subserves language production and comprehension (Sasaki *et al.* 1995; Friederici 1998; Bookheimer *et al.* 2000; Caplan *et al.* 2000; Friederici *et al.* 2000; Caplan 2001; Caplan and Dapretto 2001; Fiez 2001; Moro *et al.* 2001; Blank *et al.* 2002; Heim *et al.* 2002; Roder *et al.* 2002; Tettamanti *et al.* 2002), musical syntax (Koelsch *et al.* 2001, 2002; Maess *et al.* 2001), action observation (Galese *et al.* 1996; Rizzolatti and Arbib 1998; Rizzolatti *et al.* 1998; Umilta *et al.* 2001) and imitation of actions (Iakoboni *et al.* 1999; Heiser *et al.* 2003), execution, recognition, and imagery of skilled forelimb movements and generally 'higher-order movement control' (Binkofski *et al.* 2000), selective attention and working memory, as well as acoustic learning (Schäffler *et al.* 1993). Our fMRI and EEG findings indicate that frontal opercular regions also subserve music production and imagining. It would be of interest to investigate how the different subareas of frontal opercular regions differentially contribute to the different functions.

The beginning of the preparatory activity of the Broca areas shows large inter-individual differences. This argues against the common opinion that populations of musicians (violin players) are rather homogeneous in their behaviours.

Our findings also allow some speculations about the important role of the bilateral frontal opercular networks in preparation for and during musical execution and imagining. It is possible that these networks have 'mirror neuron' properties that subserve not only action, observation, imagining, and imitation of other individual's actions, but also observation of one's own performance or

imagining (Kristeva *et al.* 2003), and together with their role in manipulation (Binkowski *et al.* 1999) are thus part of a feedback circuit subserving adjustment and fine-tuning of sequenced motor performance.

Acknowledgements

We thank M. Wiesendanger for the inspiration for this work, and our colleagues who were involved in parts of the reported research: V. Chakarov, J. Schulte-Mönting, J. Spreer, H. Hampel (EEG), K.-O. Lövblad, and S. M. Redmond (fMRI). We gratefully acknowledge financial support received for the EEG part from DFG (grant Kr 1392/7–3) and from the Research Fund of the Albert-Ludwigs-University, and for the fMRI part from Swiss National Science Foundation (SNF grant 4038–044053) and the research funds of the neuroradiology and neurology departments of the University Hospital Berne.

Chapter 13

'Singing in the (b)rain': cerebral correlates of vocal music performance in humans

H. Ackermann, D. Wildgruber, and A. Riecker

Introduction

In the first issue of the 1871 edition of *The Descent of Man, and Selection in Relation to Sex* Darwin suggested that musical vocalizations had evolved into human speech: '. . . some early progenitor of man probably used his voice largely, as does one of the gibbon-apes at the present day, in producing true musical cadences, that is in singing; . . . serving to express various emotions . . . . The imitation by articulate sounds of musical cries might have given rise to words expressive of various complex emotions' (p. 56). By contrast, the nineteenth-century philosopher Herbert Spencer, an adherent of Darwin's theory of natural selection as the driving force of biological evolution, proposed that 'the cadences used in emotional speech afford the foundation from which music has been developed' (Darwin 1981/1871, p. 336). As an alternative to these assumptions of a successive emergence of vocal music performance and speech production, in either direction, other models maintain that both capabilities arose together, from a common ancestral facility ('musilanguage stage of hominid vocalizations'; Brown 2000). In addition to structural similarities between speech utterances and singing behaviour, this suggestion has been based upon functional imaging data: 'the cortical substrates for both language and music depend upon widely distributed networks that in some cases overlap; use both sides of the brain, but are dominated by opposite hemispheres' (Falk 2000, p. 197). So far, the hypothesis of differential lateralization effects of these two modalities of human acoustic communication mainly rests upon data bound to music perception and musical imagery. The present chapter addresses the motor domain of vocal music performance trying to elucidate whether the neural substrates of human singing capabilities show opposite lateralization effects compared with speech and language functions.

A large number of studies addressing the cerebral correlates of motor and cognitive aspects of speech production have accumulated so far. By contrast, considerably fewer investigations of the brain circuits subserving vocal music performance are available. This chapter will review the relevant data obtained in both clinical populations and healthy subjects with a focus on functional haemodynamic imaging as a more recent approach to the study of the relationship between brain and behaviour. Since a close connection has been suggested between human singing capabilities and sound production in other species, especially the 'musical cadences' observed in birds and lesser apes (Darwin 1981/1871; Richman 1993), this chapter begins with a discussion of song-like vocalizations in non-human animals.

Song production in birds and non-human primates: behavioural and neurobiological data

Like humans, birds are highly vocal creatures and acoustic communication plays a central role in their lives (Catchpole and Slater 1995). Songs are defined as 'long, complex vocalizations produced by males in the breeding season' whereas calls tend to be shorter and simpler, pertaining to the behavioural repertoire of both sexes throughout the year (p. 10). However, the line of demarcation between calls and songs is to some extent arbitrary. About 4000 out of a total of 9000 or so avian species known to exist belong to the category of song birds (oscines). Although not undisputed, the two main functions of male song appear to be female attraction and territorial defence.

The syrinx, i.e. the bird's equivalent to the human larynx, contains special membranes set into vibration when air from the lungs is forced over them (Suthers 1999). Some, but not all, oscine species exhibit a functional asymmetry of the innervation of this sound-generating device. In both canaries and chaffinches, transsection of the hypoglossal branches supplying the right half of the syrinx hardly compromises song production whereas the same procedure at the contralateral side severely disrupts singing behaviour. However, other species exhibit right-sided dominance or fail to show any lateralization effects of syringeal innervation.

An elaborate hierarchy of brain structures controls vocal performance in birds (e.g. Nottebohm 1999). Besides the peripheral part of the song control pathway, there is some evidence for functional asymmetries at the cerebral level as well. Thus, unilateral right-hemisphere damage to the higher vocal centre, i.e. a forebrain nucleus giving rise to the principal motor pathway for song production, was found to compromise singing behaviour more than contralateral lesions in the zebra finch. Furthermore, perceptual functions such as song discrimination also seem to be characterized by hemispheric lateralization effects that may, however, vary from task to task (for a review see Catchpole and Slater 1995).

Bird song and human speech production show a variety of striking similarities, for example the shaping of vocalizations by sensory experience and the way in which a critical period of development influences learning abilities (Doupe and Kuhl 1999). It is less clear how far these constraints act upon human singing behaviour as well. To infer any analogies between the neural mechanisms of singing capabilities in birds and humans would, thus, be premature.

Primate species show a rich and elaborate repertoire of vocalizations, subserving a variety of communicative functions such as the display of affective states or the advertisement of predators. Alarm calls even may show a referential signature (Hauser 1996). However, songs in terms of long and uninterrupted vocal bouts have been observed in four primate genera only, *Indri, Tarsius, Callicebus*, and *Hylobates*, characterized by rather distant phylogenetic relationships to each other (Geissmann 2000). As a consequence, singing behaviour appears to have developed several times during primate evolution. Our nearest relatives among the 'singing' primates are the gibbons or lesser apes (*Hylobates*). Among others, these animals show a distinct type of locomotion, called brachiation, and produce loud morning vocalizations of an average duration of up to several tens of minutes, characterized by an inherited stereotypical acoustic structure. Mated pairs of most *Hylobates* species often engage in duets.

It has been proposed that singing behaviour in non-human primates always evolved from alarm or territorial calls because both kinds of vocalizations show commonalities in their acoustic structure and communicative functions. The same developmental pattern has also been applied to production of song within the hominid lineage (Geissmann 2000). However, vocal music performance of humans differs in several significant respects from the alarm and territorial calls of non-human primates. For example, melodies are usually based on a restricted sample of tones and singing is characterized by a steady beat or pulse. Thus, again, any speculations about common brain mechanisms of song production across primate species must be proposed with some caution.

Brain structures subserving singing capabilities: clinical data obtained from subjects with acquired focal cerebral lesions

Preserved vocal music performance in patients suffering from motor or global aphasia

Subjects with severely restricted speech production due to motor or global aphasia subsequent to a left-hemisphere lesion sometimes, nevertheless, show strikingly preserved musical capabilities, being able to sing the lyrics of overlearned songs in a rather fluent and well-articulated manner or at least to hum familiar tunes (e.g. Yamadori *et al.* 1977: 21 out of a total of 24 Broca aphasics). Within

the medical literature, Trousseau (1865), Falret (1867) and Hughlings Jackson (1871) first reported this kind of functional dissociation within the domain of human acoustic communication (references in Edgren 1895). In order to facilitate speech production, melodic intonation therapy, therefore, advises patients with acquired expressive language disorders to impose short phrases on 'simple, non-linguistically loaded melody patterns' (Albert *et al.* 1973). Aphasic syndromes may even be accompanied by compulsive singing and whistling activities (hypermusia; Jacome 1984). The latter behavioural abnormalities seem to occur in parallel with the recovery of verbal skills. Furthermore, even complete removal of the language-dominant hemisphere may fail to compromise a patient's ability to sing (Gott 1973; Burkland and Smith 1977). The right half of the brain has, thus, been assumed to predominantly subserve vocal music performance. As a consequence, damage to that hemisphere must be expected to disrupt singing capabilities.

Cerebral localization of oral–expressive (vocal/motor) amusia: the role of the right-hemisphere fronto-insular cortex

Knoblauch (1888) suggested a classification of the 'disorders of musical capabilities subsequent to brain lesions' in strict parallel to the Wernicke–Lichtheim schema of aphasic syndromes, encompassing a constellation of motor amusia ('Kernamusie'). Benton (1977) called this syndrome oral–expressive or vocal amusia and restricted it to the 'loss of the capacity to sing, hum or whistle a tune'. Instrumental apraxia ('loss of the ability to play one's instrument despite the absence of appropriate motor defects') and musical agraphia ('inability to transcribe a series of heard notes') are considered separate varietes of amusia. In accordance with this taxonomy, more recent case studies have also noted a dissociation between vocal performance, on the one hand, and the ability to play an instrument (McFarland and Fortin 1982) or to write down melodies in musical notation (Brust 1980, case 1), on the other.

Mann (1898) was the first to perform a post-mortem brain examination in a case of 'vocal motor amusia'. The patient had not exhibited any signs of an aphasic disorder. Autopsy revealed a cystic lesion within the posterior half of the right-hemispheric middle frontal gyrus (F2), encroaching upon adjacent pre-central regions. A review by Henson (1985) identified just two further cases of oral–expressive amusia (Jossmann 1926, 1927: ligation of right internal carotid artery, rhythm uncompromised; Botez and Wertheim 1959: deficient intonation and rhythm during singing and whistling subsequent to right-hemisphere tumour, posterior third of F1 and F2). In addition, several clinical studies reported a loss of the ability to (re-)produce melodies subsequent to gunshot or shrapnel wounds associated with a lesion of posterior aspects of F2 and adjacent parts of the

pre-central gyrus as determined on the basis of the skull defect (Mendel 1916; Mann 1917; Foerster 1918; Rohardt 1919; references in Jossmann 1927).

However, Henson (1985) reviewed a further instance of expressive amusia embedded into a more widespread constellation of cognitive deficits (Pötzl and Uiberall 1937). The multiple bilateral lesions detected at post-mortem examination spared right-hemisphere frontal areas but extended to the ipsilateral insula. In line with this observation, more recent case studies of amusia syndromes affecting, among other things, vocal performance also revealed a lesion of opercular and insular areas of the right hemisphere sparing ipsilateral F2. Thus, Peretz *et al.* (1994, case C.N.) observed impaired discrimination and recognition of tunes concomitant with an inability to sing familiar melodies in a patient with bilateral temporal lesions extending to the right anterior insula and, to a limited extent, to the right inferior frontal gyrus (see Patel *et al.* 1998, case I.R., for a further example). And, Griffiths *et al.* (1997) were able to document, among other things, a receptive musical deficit concomitant with normal perception of environmental sounds and speech in a patient who had suffered a right-hemisphere temporoparietal infarction extending to the insular cortex. Most notably, the subject 'felt that his ability to sing had been impaired'. Rather than damage to a circumscript part of F2 and the adjacent pre-central gyrus, lesions within a more widespread network of intra- and anterior perisylvian regions may, thus, give rise to motor amusia.

As a further aetiological variant of oral–expressive amusia, Confavreux *et al.* (1992) observed a patient with focal degeneration of right-hemisphere perisylvian regions, including marked insular atrophy. Initially, the patient's complaints were restricted to a loss of the ability to sing or to hum even highly familiar tunes as well as a low, flat voice. Otherwise, clinical and neuropsychological examinations were, by and large, unremarkable (see Ghacibeh and Heilman 2003 for a further case report).

Besides damage to right-hemisphere pre-motor/opercular/insular cortex, lesions of the ipsilateral temporal lobe sporadically yielded predominant motor amusia (Brain 1941, case 3; Takeda *et al.* 1990). Even a tumour restricted to Heschl's gyrus was found to impair singing capabilities (Russell and Golfinos 2003). As a rule, however, lesions bound to temporal areas of the right or both sides appear to spare vocal performance giving rise to syndromes of 'pure' receptive amusia (see Henson 1985), to more subtle perceptual deficits such as impaired appreciation of timbre and compromised discrimination/recognition of tonal melodies (Zatorre 2003) or, finally, to various syndromes of verbal and non-verbal auditory agnosia (for a review see Ackermann and Mathiak 1999).

Since, as a rule, syndromes of 'pure' motor amusia are bound to right-sided frontal lesions, several authors assume that anterior parts of the 'minor' hemisphere subserve

singing capabilities. However, these deficits more frequently emerge in association with aphasic syndromes subsequent to a left-hemisphere lesion (Edgren 1895; Henschen 1926; Benton 1977). Therefore, Henschen (1926) assigned 'the power of singing' to the left third frontal convolution in front of Broca's area. In line with these suggestions, a recent clinical study found singing of novel tunes to be more severely impaired in patients who had suffered left-hemisphere cerebrovascular events than in subjects with contralateral lesions (Prior *et al.* 1990). By contrast, reproduction of familiar melodies turned out to be compromised in both groups. As an alternative to models of lateralized vocal music performance, either side of the brain has been assumed to mediate the generation of tunes (Kleist 1928).

Summary

A considerable number of patients with motor aphasia subsequent to a left-hemisphere lesion show preserved vocal muscial performance, or at least spared generation of non-lyrical tunes. Nevertheless, oral–expressive amusia in association with right-sided cerebral disorders represents a rather rare event. As a consequence, therefore, singing behaviour must be characterized by less strict lateralization effects at the group level than speech production. Conceivably, the various lesion sites found to be associated with oral–expressive amusia each give rise to different pathomechanisms of disrupted song production. For example, impaired vocal performance could reflect degradation of tonal perception and memory systems in the case of damage to the right temporal lobe (Jellinek 1956, case 2; Ayotte *et al.* 2002). In some instances at least, impairments in musical expression following left-hemisphere lesions might primarily depend upon dysphasic deficits (Brust 1980, case 2) or compromised rhythm processing, a disorder more frequently observed in left-hemisphere dysfunctions (Jellinek 1933; Mavlov 1980). The few available cases of oral–expressive amusia subsequent to right-hemisphere damage must be expected to reflect, in view of the rarity of these constellations, an idiosyncratic rather than a general pattern of functional cerebral organization of human singing behaviour. As a consequence, clinical case studies are inherently limited with respect to any further elucidation of the brain's network underlying vocal musical performance.

Brain structures subserving singing capabilities: experimental behavioural and electrophysiological data obtained from subjects without disorders of acoustic communication

Unilateral transient inactivation of cerebral hemispheres (Wada test)

Application of sodium amylobarbitone (amobarbital) into either internal carotid artery gives rise to rather instantaneous, but transient functional depression of

the ipsilateral cerebral hemisphere for a period of 3 to 5 min (Wada test). By contrast, the contralateral half of the brain remains uncompromised. Besides speech/language functions, this procedure has also been used for the determination of hemispheric lateralization of singing capabilities. In seven out of a group of eight epileptic patients considered for cerebral commissurotomy, Gordon and Bogen (1974) observed monotonous song production 'devoid of correct pitch rendering' following a right-sided Wada test. Subjects had been asked to complete a tune on the syllable 'la' practised prior to the injection of amobarbital. Rhythm turned out to be much less disrupted. In contrast to the production of speech, vocal music performance was found to be largely preserved after left-carotid application of the narcotic drug. Based on these observations, a dissociation of singing and speaking functions with respect to hemispheric lateralization was assumed.

Behavioural laterality measures (time-sharing interference, lip-opening asymmetries) of singing capabilities

Within some limits, functional interference between two concurrent sensorimotor or cognitive activities depends upon the topographic relationships of the underlying cerebral control structures ('time-sharing interference paradigm'). Thus, a task characterized by well-established functional brain asymmetry, e.g. finger tapping, may give some clues about the hemispheric lateralization effects of vocal music performance. Based on this approach, a variety of studies have reported singing to predominantly depend upon the right hemisphere or to be bound to bilateral processes of a rather symmetrical distribution (for a review see Hough *et al.* 1994). Extending these earlier investigations, Hough *et al.* (1994) coupled finger tapping to three vocal tasks, i.e. speaking (continuous repetition of a short sentence), singing a rote song ('Happy birthday to you') as well as ascending/descending production of a diatonic five-note scale ('verbal/manual time-sharing design'). Finger tapping in the absence of any (overt) vocalizations served as a baseline. Comparison of task performance across conditions allows for the calculation of a laterality score of singing and speaking capabilities, respectively. As expected, speaking predominantly recruited left-hemisphere resources whereas, by contrast, singing appeared to involve bilateral interactions of the brain or to be primarily bound to right-sided structures. Most notably, however, performance significantly depended upon gender: females exhibited more pronounced side differences during sentence recitation compared with the two singing tasks whereas rote song elicited the largest lateralization effects in males. In contrast to these findings, a preceding study of exclusively male subjects based on another time-sharing interference paradigm, i.e. balancing a dowsing rod on the left or right finger, yielded discrepant data: humming selectively compromised

the right-handed task, indicating more salient left-hemisphere processing of this kind of vocal performance (Hicks 1975).

Measurements of lip-opening asymmetries by, for example, single-frame photographic analysis provide a further means to assess the hemispheric lateralization effects of motor control. Singing a well-known nursery rhyme as well as reciting its lyrics yielded enlarged right-sided oral movements, indicating predominant left-hemisphere control of these activities ('right mouth advantage'; Cadalbert *et al.* 1994). By contrast, production of the respective melody on the syllable 'ma', i.e. in the absence of the song's words, failed to elicit any mouth-opening asymmetries. Thus, both cerebral hemispheres appear to participate in the generation of tunes.

Electrophysiological recordings during musical tasks

Apart from direct recordings at the cortical surface during, for example, surgical interventions, electro- (EEG) or magnetoencephalographic (MEG) techniques represent the most direct approach available for investigating the neural correlates of distinct sensorimotor or cognitive tasks in humans. Measurements of evoked electrical potentials or magnetic field strengths at the scalp are a widely used approach to the study of the various components of speech and music perception. By contrast, rather few electrophysiological studies addressing singing capabilities are available so far. Among other things, functional lateralization effects give rise to cerebral asymmetries in EEG alpha power in terms of reduced activity within the 8–12 Hz frequency band over the hemisphere more engaged in a given task. Using this approach, McKee *et al.* (1973) first reported lateralization effects towards the right side during music performance. However, a later study failed to detect any EEG alpha asymmetries during production of highly familiar tunes overlearned during childhood on the syllable 'la' (Galin *et al.* 1982). Conceivably, the extent of functional asymmetry during vocal musical tasks depends upon preceding training and, thus, processing strategies: enhanced right-hemisphere activation during whistling the melody of a song (versus recitation of its lyrics) was found to be restricted to musically unsophisticated participants (e.g. Davidson and Schwartz 1977).

Summary

Several behavioural studies point at a predominant contribution of the right hemisphere to vocal music performance in humans. However, these lateralization effects appear to be less robust or pronounced than functional asymmetry of speech production. In addition, right but not left-sided Wada tests, as a rule, interrupt singing behaviour in human subjects. *Actual* vocal music performance, therefore, predominantly must depend upon the 'minor' hemisphere. Persistent

damage to right-sided cerebral structures then could give rise to functional recovery via the contralateral side since the available clinical data indicate that in principle both cerebral hemispheres are able to subserve the generation of tunes (see the last section). By contrast, the time span of the Wada test might be too short for any compensation processes to emerge.

Haemodynamic functional brain imaging of singing capabilities: opposite hemispheric lateralization effects at the level of the anterior insula

Local variations of neural activity give rise to an 'automatic' increase of regional cerebral blood flow (neurovascular coupling). Thus, registration of these haemodynamic effects should provide a feasible means for the identification of the neural structures engaged in distinct sensorimotor or cognitive tasks. The two or so early investigations based on the xenon clearance technique failed to detect any significant inter- or intra-hemispheric changes in cerebral blood flow during singing and/or humming (Ryding *et al.* 1987; Formby *et al.* 1989). Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) represent the two most important brain imaging techniques based on neurovascular coupling mechanisms available today. So far, there has been only a single PET study aimed at the delineation of the cerebral network subserving vocal music performance (Perry *et al.* 1999). Participants were asked to repetitively produce vowel /ä/ across a time interval of 60 s at a pre-specified target pitch, pausing for breath as needed. In contrast to passive listening to complex tones presented at a similar rate and transposed to the same frequency range, this task elicited, as expected, haemodynamic responses of various structures bound to motor control (mesiofrontal regions, bilateral face area of the pre-central gyrus, both sides of the insula, and the cerebellum). Two asymmetries could be noted within these areas:

(1) higher activation of the right pre-central gyrus compared with the contralateral side,

(2) bilateral responses at the level of the intrasylvian cortex, but at slightly different locations.

Repetitive vowel productions at the same pitch address some kind of 'rudimentary singing' (Perry *et al.* 1999) and, thus, do not necessarily represent a valid probe of the cerebral network underlying the generation of melodies. A recent fMRI investigation carried out by our group asked subjects to reproduce a tune drawn from a serenade on the syllable 'la' [1.5 T whole-body scanner (Siemens Vision), echo-planar imaging (EPI) sequence across the complete brain volume, anatomic reference = T_1 weighted 3D turbo-flash sequence, n = 18 healthy

right-handed speakers (nine females) of standard German, age 22–63 yrs; Riecker *et al.* 2000]. Non-lyrical musical material was selected in order to avoid any retrieval of propositional data structures during functional imaging. This task served as a control condition for an experiment that aimed at the determination of the cerebral network mediating speech motor processes based on the continuous recitation of the months of the year (automatic speech; e.g. Ryding *et al.* 1987). Rather than repetition of single lexical items, highly overlearned word strings can be considered a paradigm of fluent verbal output, thus being more similar to melody production. Furthermore, these test materials should elicit a rather monotonous mode of speech production and thus focus on segmental aspects of verbal utterances and avoid the eventual confounding influences of intonational patterns. Since motor imagery has been assumed to provide a 'window' into the mechanisms of action planning, i.e. preparatory activities preceding actual performance of movement sequences (Jeannerod 1994), both overt (loud) and covert (silent) task performance was considered for analysis. Subtraction of the haemodynamic activation patterns bound to these two conditions was expected to allow for the isolation of the brain structures bound to motor execution processes.

Subjects performed speaking and singing at their habitual tempo, and were asked to refrain from verbal thought during the rest periods in between. Each task was applied 12 times in a counter-balanced order (onset-to-onset intervals between activation phases = 24 s). Production rates of speaking and singing had been determined during the training phase (overt generation of the word string 'January–December': mean = 5.6 s, standard deviation = 1.3 s; overt production of part of a serenade: mean = 6.9 s, standard deviation = 1.1 s). Among other things, a cognitive subtraction procedure was performed: overt speech versus overt singing and vice versa. Analysis of the group data revealed rather bilateral activation at the level of the pre-central gyrus and the cerebellum both during speaking and singing concomitant with (non-significantly) higher responses at the right (singing; see above and Perry *et al.* 1999) or left side (speaking). As a new aspect of functional brain asymmetry, opposite lateralization effects emerged within the intrasylvian cortex (speaking aloud = left anterior insula, singing aloud = right anterior insula; Plate 12). This pattern of insular activation turned out to be preserved after subtraction of the respective haemodynamic responses obtained during the silent modes of speaking and singing (overt versus covert speech, overt versus covert singing). Thus, any differences between overt and covert performance do not just reflect threshold effects. Furthermore, the robust double dissociation at the level of the anterior insula was confirmed by the second cognitive subtraction procedure (singing aloud minus speaking aloud and vice versa).

Based on neuroradiological data obtained from a large sample of patients, Dronkers (1996) found the anterior insula to represent the area of maximum overlap of lesion sites in apraxia of speech. This constellation is characterized by effortful and groping articulatory movements, dysprosody, inconsistent distortions of speech sounds across repeated productions, and obvious difficulties initiating verbal utterances. However, non-speech functions of laryngeal and orofacial muscles are found to be unimpaired. Several preceding PET studies documented predominantly left-sided activation of the intrasylvian cortex during naming (line drawings depicting concrete objects), reading, and repetition (auditorily or visually displayed nouns) tasks (e.g. Wise *et al.* 1999; for a review see Ackermann *et al.* 2004). Considering these findings, left-sided intrasylvian structures have been assumed to operate as a centre of speech motor coordination. In a similar vein, activation of the right-hemisphere anterior insula during reproduction of a non-lyrical tune might reflect the sequencing of vocal tract musculature in association with vocal music performance.

Cerebral substrates of musical imagery

Besides listening to a live or recorded performance, music including songs can be re-experienced by imagining it in one's head (musical imagery). Imaginal and perceptual processes show a broad overlap of the respective underlying neural substrates at the level of the central auditory system. Thus, Zatorre and Halpern (1993) performed a pitch discriminaton task in patients who had undergone excision of either the left- or right-sided temporal lobe for the control of medically intractable epilepsy. As a first task, subjects heard a familiar song over headphones, concomitant with a written version of its text on a screen, and were asked to judge whether the second of two capitalized lyrics was higher or lower in pitch than the first one. During a subsequent condition, no song was presentend and the paricipants had to generate an auditory image of the tune, everything else being equal. Most notably, patients with right-sided lesions performed significantly worse on both tasks than subjects suffering from left hemisphere temporal damage or normal controls. Using similar test materials, a subsequent PET study further specified the neural network associated with both music perception and musical imagery: (the bilateral secondary auditory regions, both frontal lobes, the left parietal corex, and the supplementary motor area; Zatorre *et al.* 1996). Subtraction of the haemodynamic responses bound to the two tasks from each other revealed significantly increased activation of bilateral inferior frontopolar regions, the right posterior thalamus, and the subcallosal gyrus during the imagery condition as compared with the discrimination of heard pitch. Conceivably, this circuit is bound to the retrieval of auditory information from memory stores. Using non-verbal tunes as test materials, a subsequent PET study

found lateralization effects towards the right side within the temporal lobe, frontal areas, and thalamus (Halpern and Zatorrre 1999). Functional brain asymmetry, therefore, emerges once words have been removed from imagery tasks.

Besides overt speaking and singing, the fMRI study of our group referred to above also included covert performance of the same tasks, i.e. conditions which also represent some kind of 'auditory imagery' (see Ivry and Fiez 1999). As compared with baseline (rest), activation of two complementary cerebral networks emerged (covert reproduction of a non-lyrical tune = right pre-central gyrus and left cerebellar hemisphere, 'inner speech' = the opposite response pattern). Most notably, no significant activation of the intrasylvian cortex could be detected. These findings are in line with two preceding investigations that included vertical non-speech tongue movements as a control conditions (Wildgruber *et al.* 1996; Ackermann *et al.* 1998). Based on these data, it could be ascertained that frontal haemodynamic activation during silent speaking and singing is bound to vocal tract motor areas (Plate 12).

The studies by Halpern and Zatorre (Zatorre *et al.* 1996; Halpern and Zatorre 1999) addressing the discrimination of melodies had failed to detect significant haemodynamic activity of the sensorimotor cortex during musical imagery. Since our fMRI study focused on the *generation* of 'inner' speech and singing, respectively, areas engaged in motor execution might have been recruited as well or to a larger extent. The cerebral networks bound to processes of imagination might thus depend, within some limits, upon the demands of the task.

Summary: vocal music performance and the right hemisphere

Based on a variety of clinical and functional imaging data, Zatorre (e.g. Zatorre 2003) assumed the right hemisphere to have a higher proficiency in pitch processing. Our fMRI data indicate that lateralized pitch representation 'spills over' to cortical areas engaged in motor control during singing:

1. Reproduction of a familiar non-lyrical tune yielded right-sided activation at the level of the anterior insula concomitant with bilateral haemodynamic responses of the pre-central gyus and cerebellar hemispheres whereas speaking elicited an opposite lateralization effect within the intrasylvian cortex.
2. Silent reproduction of the same tune (musical imagery) resulted in a more limited response pattern, encompassing the right sensorimotor cortex and left cerebellum, but sparing intrasylvian areas (silent recitation of word strings = opposite activation pattern).

Inner speech is considered to be a pre-articulatory, but otherwise fully parsed, representation of sound structure (for further details see Ackermann *et al.* 2004).

Therefore, covertly produced verbal utterances must be expected to have a temporal organization similar to their spoken counterparts. Considering our fMRI data, left motor cortex and right cerebellar hemisphere (both structures are interconnected by reciprocal fibre systems) seem to support these pre-articulatory motor control processes. Based on clinical data obtained from patients with speech motor deficits and on fMRI data registered during syllable repetition and speech perception tasks, this network might support the sequencing of mental syllables into a smooth, i.e. co-articulated, representation of verbal utterances at a speaker's habitual speaking tempo (Ackermann *et al.* 2004). In some analogy to covert speech production, 'inner singing' can be considered a pre-articulatory, but otherwise fully parsed, representation of the tonal and rhythmic organization of a tune. Whereas inner speech requires the sequencing of retrieved mental syllables, the observed right-motor/left-cerebellar network bound to 'inner singing' might underlie the specification of melody templates retrieved from a right-hemisphere storage site with respect to pitch level and duration of its tonal elements.

Haemodynamic activation of the anterior insula was observed during overt task performance only. Thus, the intrasylvian cortex seems to operate 'downstream' of the motor cortex/cerebellar networks bound to inner speech and musical imagery, and might support the transformation of pre-articulatory/pre-phonatory verbal and musical codes into an elaborate spatiotemporal pattern of motor commands driving the muscles of the vocal tract. Insular regions are involved in the coordination of midline musculature (head, neck, trunk) during respiration and swallowing. Conceivably, speaking and singing capabilities have been superimposed during the course of language evolution on these phylogenetically older motor activities via intrasylvian structures (Ackermann and Riecker 2004).

Apart from functional imaging data, a variety of clinical and experimental data indicate singing capabilities to be predominantly bound to the right hemisphere. In comparison with speech production, these lateralization effects are less robust by far (see above). Compared with expressive speech/language functions, vocal music performance must thus be characterized by more 'fluid' hemispheric lateralization effects concomitant with significantly better possibilities of recovery.

Chapter 14

Sensory–motor networks in singing and speaking: a comparative approach

Reyna Leigh Gordon, Amélie Racette, and Daniele Schön

Sheshell ebb music wayriver she flows
James Joyce, *Finnegan's Wake*

Introduction

The comparative analysis of different cognitive functions, using different investigative techniques whenever possible, provides a more powerful means for understanding how the brain processes information and computes operations than studying either domain alone. Indeed, concentration on a single brain region and a single cognitive function with one single investigation method could yield an incomplete view of the functioning of the brain. As noted by Bates (1994), this type of approach most often calls for domain specificity and, as a consequence, assumes a modular explanation of the brain function in question. By coupling the study of differences with the study of similarities, a comparative approach may provide a more complete picture of which computations are specific and which ones rely on more general cognitive principles.

The choice of comparing music and language is far from being arbitrary (see also reviews by Besson and Schön (2001) and Patel and Peretz (1997)). Music, like language, is a universal trait specific to humans. Both require analysis of the spectrum and frequency of sound, streaming, sequencing, extracting regularities, memorization, attentional focus, and learning. It is not by chance that music and language combine beautifully in song!

From perception to production

Most of the literature on music and speech has been centred on perception; production has received much less attention. This can mostly be explained in two ways. First, it is much easier to measure the perception of the listener than the production of the performer. Think, for example, how easily one can measure

pitch or phoneme discrimination (e.g. Is [ba] different from [da]?) but how difficult it is to record, analyse, and quantify the difference between two movements and the sounds they generate. In addition most brain imaging techniques are very sensitive to movements, which tend to cause artefacts in the data.

The second reason is more theoretical. Music and speech performance require the translation of a mental representation into action, such as playing an instrument, singing, or speaking. Moreover, performance is subject to frequent and controlled variations in acoustic parameters, such as intensity, spectral, and temporal changes, from one performance to another. In other words, the plan required to play or speak can be realized in an infinite number of ways. This diversity of outputs, particular to each individual and situation, closely resembles the diversity of input from which a person can recognize the same melody or words.

Even in the case of dissociations between comprehension and production deficits in patients with brain lesions, it is now considered that the two systems are not physically separate; rather, a central system is at work, in which the operations apply at both the access and retrieval levels (Semenza, 1999; Rapp, 2001). Thus, similar constraints apply to theories of comprehension and production (Schön *et al.* 2004).

The study of music and speech production is also conducive to obtaining a better understanding of the essence of musical and linguistic structures. Although it is commonly believed that the structural characteristics of music and language exist independently of the output systems, this is not necessarily the case. On the contrary, the extent to which movements constrain musical syntax and linguistic phonology is considerable. For example, the fact that small intervals are easier to sing (and play on most instruments) heavily influences the melodic structure of music, in that small intervals are extremely frequent while large intervals occur much less often. Similarly, in language, the fact that certain sounds are more difficult to pronounce than others (e.g. /lgma/ versus /ma/), influences the concatenation of different phonemes to form words and sentences. Therefore, the motor systems allowing the production of music and speech enjoy a privileged role in shaping the structure of music and language, and the study of the production of speech and music can thus be important for the study of the origins of music and language.

Why study song cognition?

One approach to comparing the neural bases of language and music is through the use of song, which is a unique combination of these two cognitive domains. In song, language and music are merged into *one* acoustic signal with *two* salient dimensions. By manipulating either the linguistic or the musical dimension of

song, a unitary stimulus, the study of the relationship between these two dimensions may reveal important information about the neural networks underlying language and music cognition. Furthermore, singing is a universal human activity that can be used not only to compare language and music but also to gain insight into the one or the other in diverse contexts.

Despite the fact that song provides an ideal means to compare how the brain processes language and music, it has been relatively little exploited by cognitive neuroscientists until recently (Peretz *et al.* 2004*a*). In this chapter we will cite several studies that have investigated the cognition of song and discuss the findings relevant to the comparison of language and music processing. We seek to show how these studies have addressed the interaction or independence of language and music, the modulation of attention, the functional mapping of brain areas involved in singing, memorization processes, and production of song in patients with language disorders. The intrinsic limits of the model and directions for future research will be discussed in the conclusion.

Relationship between the linguistic and musical dimensions of song

While some studies of the cognition of song use an approach that aims to study the linguistic and musical aspects of song separately by comparing normal speech and vocalises (Gordon and Bogen, 1974; Ryding *et al.* 1987; Riecker *et al.* 2000) or sung language and spoken language (Cadalbert *et al.* 1994; Epstein *et al.* 1999; Jeffries *et al.* 2003; Stager *et al.* 2003), other studies compare how the musical and linguistic dimensions of song are processed, by manipulating these dimensions as they occur in sung language only (Bartholomeus 1974; Besson *et al.* 1998; Bigand *et al.* 2001; Bonnel *et al.* 2001; Lidji 2003; Poulin-Charronnat *et al.* 2005). On the one hand, evidence for independent processing of language and music in song suggests that separate neural substrates are responsible for processing these two different types of information. On the other hand, evidence for interactive processing between the linguistic and musical dimensions provides support for the idea that common neural resources are utilized to process language and music.

For instance, interactions between these two dimensions in song have been observed by Bigand *et al.* (2001), who showed that a subtle change in harmonic processing (from tonic to subdominant) interferes with phoneme monitoring in the perception of choral music, sung with non-words. Similar musical material, this time sung with sentences, was then used to demonstrate that harmonic processing also interferes with semantic priming, measured by reaction time and error rates in a lexical decision task (Poulin-Charronnat *et al.* 2005). These results support the theory that language and music in song are intertwined,

especially in terms of implicit processing, and are thereby interactively processed. Additional evidence for interactive processing between the linguistic and musical dimensions of song has been found for other levels of processing, such as between phonology and melodic intervals in sung non-words (Lidji 2003).

However, evidence for independent processing was found by Besson *et al.* (1998) in an event-related brain potential (ERP) study that aimed to study the relationship of text to music in the perception of opera excerpts, sung a capella. Results showed distinct ERP components for semantic (N400) and harmonic (P300) violations. Moreover, detailed analysis revealed that an additive model of semantic and harmonic processing accounted very well for the observed effects, leading the authors to propose that lyrics and melody in song are processed independently. Further support for independence of semantics and harmony comes from another experiment using the same stimuli, in which a dual-task paradigm was utilized to show there was no decrease in performance when simultaneously attending to language and music in song perception, compared with attending to only one dimension at a time (Bonnel *et al.* 2001).

Attention and levels of processing in song

In view of the number of seemingly contradictory results on the status of language and music in song, it is important to note that since each of these cognitive faculties encompasses several levels of processing (in language: phonology, semantics, syntax, pragmatics; in music: rhythm, melody, harmony, timbre), any experimental results obtained on the relationship between language and music in song may depend on which levels of each system are being examined. While some of the subprocesses involved in the cognition of song may be localized and even lateralized according to the same trends that characterize the perception of speech and music (e.g. spectral characteristics processed in the right auditory cortex and temporal characteristics in the left; see Zatorre *et al.* (2002)), other subprocesses (e.g. working memory) may take place in neuronal networks that are widely distributed. The dynamic combination of all the levels of processing involved in song could therefore account for interactions between certain levels, while other levels may be relatively autonomous.

There is a growing body of evidence indicating that the relationship between language and music in song cognition is intrinsically dependent on attentional processes, as can be seen from the occurrence of task-related effects caused by a modulation of attention between the linguistic and musical dimensions of song.

This point has been illustrated in the past through the use of dichotic listening in order to investigate lateralization effects related to the music or linguistic dimensions of song (Bartholomeus 1974; Goodglass and Calderon 1977). In fact, the allocation of attentional resources to different dimensions of a sung stimulus

could be one of the most important factors in determining the relationship between language and music in song. In addition to ERP evidence for the effects of attentional load on lower-level auditory processing (Alain and Izenberg 2003), an ERP study by Levy *et al.* (2003) further demonstrates the importance of attention and task demands in determining how neural resources are allocated to process musical and linguistic/vocal stimuli. Using an oddball paradigm, listeners were first instructed to respond when they heard a piano tone presented among a series of sustained pitches played by various instruments or sung by different voices, on a neutral vowel. A voice-specific response (VSR) was observed in the ERPs as a positive component, peaking at 320 ms (P320), which was found in response only to sung tones even when subjects were attending a piano sound (Levy *et al.* 2001). Interestingly, the VSR occurred when participants were paying attention to timbre but not when they were paying attention to another acoustic parameter, duration (Levy *et al.* 2003). Since neuroimaging studies have outlined the functional anatomy of human voice-selective areas in the superior temporal sulcus (see Belin *et al.* (2004) for a review), these recent studies by Levy *et al.* indicate that the voice-specific effects observed are task-dependent and partially reflect the allocation of attention in a system that is somewhat specialized in the identification of human voices.

Functional mapping of brain structures involved in song processing

Understanding the nature of the relationship between the linguistic and musical dimensions of song should give an insight into whether music and language are processed by separate or integrated brain structures. Recent brain imaging studies of song production have attempted to shed light on the neural bases of language and music in song; in particular, certain patterns of localization have been uncovered which coincide well with the literature on language and music processing (Tervaniemi *et al.* 2000; Zatorre *et al.* 2002).

Some new evidence for dominance of the right hemisphere in singing comes from studies conducted with transcranial magnetic stimulation (TMS), a technique that provokes temporary reversible lesions of localized cortical zones (Epstein *et al.* 1999; Stewart *et al.* 2001; Lo and Fook-Chong 2004). In accordance with neuropsychological data, speech is inhibited by applying TMS to certain areas of the left cortex; conversely, when TMS is performed on the right hemisphere, some participants are unable to produce melody in song. Speech and non-lyrical melodic singing were also compared by Riecker *et al.* (2000), using functional magnetic resonance imaging (fMRI) to show activation of opposite hemispheres with divergent networks for speaking (left-lateralized) and singing (right-lateralized) (see Chapter 13 for a more detailed discussion). Thus it seems

that, compared with speech, the production of sung vocalises utilizes more right hemisphere resources. However, in this pioneering study a more ecological condition of sung language was not included in the protocol, so it is difficult to assess whether the results obtained can be interpreted in terms of real song.

In contrast, sung language was studied by Jeffries *et al.* (2003) utilizing positron emission tomography (PET), in which non-musicians performed under two conditions: singing an 'overlearned' song and speaking the text of the same song. Opposite lateralization effects were found here as well; the authors concluded that the production of words in song encompasses right-hemisphere-dominant systems known to play a role in the processing of music. Nevertheless, since there was no 'vocalises' condition (non-linguistic melodic singing), it is impossible to determine whether these right-hemisphere activations reflect music processing or linguistic production specific to song, or a combination of the two. In this sense, the use of song to explore music cognition is confirmed, while the status of sung language remains unclear.

The cerebral structures corresponding to different levels of non-linguistic musical processing involved in singing vocalises were differentiated in a recent PET study of song production in musicians (Brown *et al.* 2004). They found that the planum polare (BA38) is more active in complex musical tasks (harmonization and melody repetition) than simpler ones (monotonic vocalization); in addition, the role of the right and left frontal operculum in musical imitation and vocal learning was discussed. However, the phonological and semantic elements of song were not examined, so it is difficult to know if the same musical vocalization network would be mobilized to sing songs with words.

To summarize, studies of the cognition of song have demonstrated that song is a useful model for elucidating the roles of language and music in the brain. Some evidence for left-lateralized language processing and right-lateralized musical processing has been found, but overall it remains unclear as to whether the relationship between these two dimensions of song is of an interactive or independent nature. Task demands and attention modulations seem to have an influence on the results; different results are also observed as a function of which levels of processing are being examined. Furthermore, song perception has not been studied outside the context of a production task with either fMRI or PET. Most importantly, no single study has directly compared spoken language, sung language, and vocalises.

In ongoing research at our laboratory in Marseille, we are conducting a series of experiments (Gordon *et al.* 2004) that aim to determine, first, the cerebral regions involved in the perception of song and, second, the nature of the relationship between the musical and linguistic dimensions of song. In the first experiment the fMRI method was used to establish a functional mapping of the

brain areas involved in the perception of song, compared with speech and vocalises. Thirteen participants (non-musicians) were scanned while listening to stimuli from each of the following three conditions: spoken words (tri-syllabic French words, spoken); sung words (tri-syllabic words sung on three-note melodies); and vocalises (the syllable 'vi' sung on three-note melodies). In all conditions, participants performed a same–different task, in which they responded as quickly and accurately as possible as to whether the two stimuli in the pair were the same or different.

Preliminary results of a random-effects analysis of the data showed tendencies towards left lateralization for spoken words and right lateralization for vocalises and sung words, in agreement with the literature on song production (Riecker *et al.* 2000; Jeffries *et al.* 2003; Brown *et al.* 2004) and language and music processing (Zatorre *et al.* 2002). The contrast between sung words and vocalises (Plate 13) showed left temporal activations most likely reflecting aspects of language processing (e.g. complex phonology, semantics). Conversely, melodic processing was reflected in the contrast between sung words versus spoken words, which revealed bilateral temporal and frontal activity with right-hemisphere dominance.

Interestingly, a comparison of the two main contrasts reveals a greater similarity of activations in the sung words and vocalises conditions than in the sung and spoken words conditions. While the trend of these preliminary results remains to be confirmed by testing additional participants, it could indicate that the perception of song depends more on a musical 'singing voice network' than a linguistic network. However, herein lies the difficulty intrinsic to the study of cognition of song, of creating an experimental design that achieves the delicate balance between linguistic and musical elements. Indeed, the salience of one element or another certainly interacts with the kind of factor, such as task difficulty and allocation of attentional resources, which may modulate brain activity in song cognition, as discussed earlier.

Song memory in healthy musicians and non-musicians and aphasics

As the status of online processing of language and music in song continues to be controversial, this relationship remains complex in terms of how the linguistic and musical dimensions of song are encoded in memory. In particular, the notion that music may serve as a mnemonic device for learning verbal material has a long history. In oral traditions, minstrels transmitted stories through songs. Today, children learn the alphabet as a song, and students try to remember laws of physics sung to popular songs through karaoke (Dickson and Grant 2003).

It is still unclear why music should facilitate word recall. One hypothesis is based on the fact that production of words is slowed down when we sing compared with when we speak. Kilgour *et al.* (2000) have indeed shown that there is no more advantage for word recall in hearing a text sung versus hearing it spoken when a sung text is compressed to be as short as a spoken text. Speed, or syllable duration, would thus be a crucial variable in the effect of music on word recall. Repetition and simplicity of a melody have also been brought forth as explanations of the better word recall of songs (Wallace 1994). Conversely, no more words were recalled when hearing a text on a complex and changing melody than when hearing a spoken text. Another hypothesis originates from studies using recognition paradigms; these results have suggested that the lyrics and melody of the same song are strongly associated in memory (Serafine *et al.* 1984, 1986; Crowder *et al.* 1990; Morrongiello and Roes 1990; Peretz *et al.* 2004*b*). A melody could therefore give access to the words with which it is learned. Finally, it is also possible to argue that there are structural constraints in music, as well as in song lyrics, that can combine to improve recall (Rubin 1995). For instance, the metrical structure of music, or the number of musical notes in a line, limit the possibilities in word recall, as do the rhymes, assonances, and alliterations that frequently characterize the lyrics.

Experimental studies addressing the question of the effect of music on verbal recall have mainly looked at the presence or absence of music at presentation of the text (e.g. Rainey and Larsen 2002), which can only indicate whether music helps to *encode* the words, and not whether music helps to *produce* more words. Only Jellison and Miller (1982) have systematically manipulated the response (sung or spoken) and the presentation (sung or spoken), and found no advantage (and even a disadvantage) of learning words or digits by singing on a simple melody instead of speaking. Although Gingold and Abravanel (1987) did not find any differences in children's performance between texts learned by reciting or singing, they did show that the musical material can interfere with memorization of a text, since bad musical settings disrupted learning of words in song.

In aphasics, there is a classic observation that they can sing words they are not able to produce otherwise (Keith and Aronson 1975; Yamadori *et al.* 1977; Assal *et al.* 1977; Jacome 1984). These kinds of anecdotal reports led to the use of musical support in speech therapy. This is the case for melodic intonation therapy, which is based on an exaggeration of the melodic line of linguistic phrases, accentuating simple pitches and rhythm (Sparks *et al.* 1974). However, recent studies have surprisingly been unable to show an advantage of singing over speaking in brain-damaged patients suffering from speech disorders (Hébert *et al.* 2003; Peretz *et al.* 2004a). These single-case studies have shown that

an equivalent number of words are produced when the same words have to be repeated by singing or by speaking. Moreover, the same types of errors were committed in both modalities. The idea that non-fluent aphasics are able to sing would stem from the observation that their rote memory of automatic material, such as songs, is superior to their performance in generative tasks, such as spontaneous speech. Thus, music *per se* would not explain this difference.

In order to answer the question of whether singing is accompanied by a more efficient memory formation, two studies were conducted, based on oral learning of unfamiliar songs, in three different conditions (Racette and Peretz, in press; Racette *et al.* in revision). In the first condition (sung–sung) participants listened to the sung version of the lyrics and sung them back. In the second condition, the sung–spoken condition, participants listened to the sung version of the lines and recalled only the lyrics by pronouncing them in a natural way. Comparison of these two conditions allowed us to measure the effect of music on response. In the third condition, the divided–spoken condition, the participant listened to the spoken lyrics and recalled only the lyrics. In this condition, the presentation was defined as divided because, as the lyrics were spoken, the corresponding melody was hummed on /la/ in the background. Consequently, when the lyrics were spoken, the context was equivalent to when lyrics were sung, since the melody was presented in both cases. Thus, the divided–spoken condition allowed us to control for the difficulty of extracting text from a song while maintaining the presence of the melody during encoding.

Neurologically intact participants

Thirty-six university students participated in a first study (Racette and Peretz, in revision, a). Half were non-musicians and half were enrolled in the Music Faculty. Participants learned one different song in each of the three conditions following an adaptive procedure. Songs selected for the study were songs that already existed, composed by a folk singer, but that were unfamiliar to all participants. Songs were composed of eight lines. The percentage of correctly recalled words in each condition, as well as musical notes for the sung–sung condition, were calculated when participants recalled the song.

The first surprising finding was that the musicians were no better than the non-musicians in recalling words and musical notes. This might be explained by the fact that musicians usually learn a song with the score. In the procedure used here, participants could only rely on the auditory code of the song, which is also familiar to non-musicians. Therefore, musicians had no advantage over non-musicians in an oral learning procedure in which they were not allowed to use a visual support. When the data for the two groups were pooled together, as

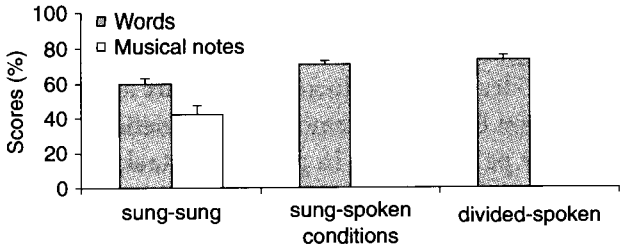

Fig. 14.1 (a) Mean scores obtained by neurologically intact participants while recalling words and musical notes of unfamiliar songs in three conditions.

can be seen in Fig. 14.1, the sung recall was significantly lower than both spoken recalls. This means that music interfered with word recall at response. Moreover, because there were no more words recalled in the sung–spoken condition than in the divided–spoken conditions, there was no facilitation of music at presentation. There was no interference, either. Moreover, there were more words recalled than musical notes when singing. These results suggest that the lyrics and the melody of a song are represented in independent codes in memory. Participants would have to access both the melody and the lyrics, making singing a dual task, at least in the first steps of learning.

Aphasic patients

What happens when one of the codes is altered? It is now known that there is a double dissociation between production of the words (altered in CC (Hébert et al. 2003), spared in IR (Peretz *et al.*1997)) and production of the melody (altered in IR, spared in CC) of songs in patients. Aphasic patients could thus use (spared) music to access words.

In this second study (Racette and Peretz, in revision), eight French-speaking patients were recruited who suffered from a variety of expressive aphasias following left-hemisphere brain lesions. They learned songs in the same three conditions as the university students, but following a simplified learning procedure. The songs were also reduced to four lines. The percentage of words correctly repeated after every line was calculated.

As is shown in Plate 14, there was no difference between conditions. Thus, singing did not improve word production compared with speaking. This was true for the number of words produced but also for the types of errors in the different conditions. Moreover, aphasic patients did not produce more words than notes. The same profile was obtained in subsequent experiments using familiar material. Hence, there were as few words of familiar songs repeated by singing as by speaking. Even if songs are naturally sung with both the lyrics and the melody, there was no cost of producing the lyrics alone. This again suggests that the words

and the melody are accessed separately in memory for songs. In an additional experiment, spoken and sung (on a familiar melody) repetitions of prayers and proverbs again showed that no more words were produced by singing than speaking. These results show that, in equivalent settings, there is no advantage of singing versus speaking the lyrics. This phenomenon applied both to the learning of unfamiliar songs and the production of highly familiar and automatic material.

The only way singing could be more conducive to the production of language than speaking is when patients are asked to sing along, with a slow speed. This is often the first step in speech therapy, where the patient produces words in unison with the therapist. The effect of speed might be magnified by singing, which is also slower than speaking. After extensive training, patients might be able to produce more words when singing along than when speaking in unison. However, they would have to learn to produce words alone at some point, since singing is not a functional way of communication in everyday life. Moreover, when singing along, participants heard what they had to produce at the same time they were producing it. Thus, musical notes might have to be heard to be able to cue recall.

Music and language have to be compared on similar levels to determine if they share the same underlying processes or not. When comparing the production of sung and spoken words, it was suggested that there is a unique code for words, be they sung or spoken. This verbal code would be separated from the musical code for production of musical notes. Therefore, oral production of words and music in both neurologically intact participants and aphasic patients provides additional support for independent representations of music and language in memory for songs.

Discussion

We have seen that the study of song is particularly interesting because it allows us to investigate both musical and linguistic processing as well as their relationship. Indeed, the study of singing is not restricted to musicians, as is the case for instrumental playing, but can be done with so-called non-musicians. In this regard we would like to point out that in Western society the category of 'musician' is defined by very strict criteria, such as musical literacy, extensive theoretical musical education, and instrumental training. However, in doing this we often forget the fact that music, like language, does not necessarily require explicit learning. Indeed, implicit learning takes place for music too (Bigand, 2003), and, as for language, it is not just limited to comprehension. In other words, as most people can speak, most people can sing. This consideration should encourage researchers to better investigate the ability of 'non-musicians' to sing, which may not be so different from the singing abilities of 'musicians' (of course excluding 'singers'!).

The results presented above are not encouraging concerning the effects of musical rehabilitation techniques. However, this null effect might be due to several reasons. First of all, it is important to note that the effect of music training on linguistic or other cognitive abilities has been mostly found with *extensive* musical training (Schellenberg, 2001). In other words, the short-term effects of music, such as the famous Mozart effect, usually seem to be an artefact of mood, arousal, or attentional processes. Therefore, only long rehabilitation procedures may benefit from the use of song or other musical material. Indeed, when possible, the rehabilitation of aphasic patients is a rather long process that takes place over several months. Second, the controversial results of the literature concerning the facilitation of song over speech on aphasic patients might be due to the diversity of the aphasic syndrome. In other words, song facilitation might be effective for only a certain type of aphasic patient, although the study described above did not show any benefit for different types of speech disorder.

This brings us to a more theoretical reflection about the beneficial effect of music in speech disorders. Rather than asking whether music could be beneficial, a first step to progress in this field would be to ask what in music is beneficial to speech production. As already stated above, music has different levels of processing and requires different types of computations that are performed by different neural networks. Therefore, the treatment should put the emphasis on the correct level of processing. For instance, a treatment emphasizing the metric/rhythmic support of speech may improve repetition to a greater degree than using only the intonational elements of melody (Boucher *et al.* 2001). Indeed, a strong metric and rhythmic structure of a musical phrase, if it matches the prosodic structure of the words, may facilitate word retrieval, especially if rhythm in both language and music shares common neural resources (Patel and Daniele, 2003). When music is used as a mnemonic device in learning verbal material, the metric structure constrains the linguistic information, while the melodic structure does so to a lesser degree (although this might be different in the case of tone languages (Chan 1991)). It should also be noted that in song the musical structure takes precedence in determining the realization of a large number of the acoustic parameters, and somewhat dictates, or at least transforms, the linguistic prosody. Since this transformation may heavily influence the intelligibility of the lyrics, one should exercise caution when studying language processing in song.

Additional benefits may be gained from other aspects of music therapy. Since aphasic patients do not necessarily suffer from a music disorder (Hébert *et al.* 2003), producing musical notes alone is still a good way for them to produce vocal sounds. While this would probably not be beneficial to agrammatic aphasic patients, it may help in the rehabilitation process of patients with more vocal/motor dysfunctions (e.g. dysarthria).

Moreover, it seems that most aphasic patients enjoy singing. While this is related to the general effects of music on mood and arousal (Schellenberg 2001; Grape *et al.* 2003), this will engender greater motivation in rehabilitation sessions, which may turn into both greater and more effective participation during the single session and longer endurance over the rehabilitation period.

To conclude, more theoretically driven research is needed to better clarify the intriguing possibility that speech disorders may benefit from musical rehabilitation techniques. With this aim, the clinical research will need to be coupled with fundamental research in order to refine the theoretical basis of the rehabilitation methods in use. Several important questions that also go beyond the issue of rehabilitation remain open: what musical information is most likely to improve word retrieval? For instance, concerning word retrieval, would a strong metric structure play a more important role than melodic structure? Will memory storage in general benefit from any type of musical information or training? Moreover, to what extent is musical practice better than passive listening? Will listening to a song or singing it have similar or different effects on mood or arousal? More action is needed to better understand the relationship between speech and music.

Chapter 15

The role of inhibition in the motor control of finger function

Christian Gerloff and Friedhelm Hummel

Successful performance of music requires contextual modulation of learned motor 'programs', that is, the retrieval or non-retrieval (inhibition) of behavioural elements depending on the situation. This chapter describes recent advances in our understanding of the neural correlates of these elementary aspects of behaviour, as identified with transcranial magnetic stimulation (TMS), electroencephalography (EEG), and functional magnetic resonance imaging (fMRI). Inhibition of pre-learned behavioural programs (e.g. sequences of finger movements) is represented in the brain by a reduction of net synaptic activity in the cerebrocerebellar pathway and by specific modulation of oscillatory activity of the cortical neurons, leading to a suppression of excitability of the motor cortex. The metabolic correlate of this inhibition is a decrease in the blood oxygenation level-dependent (BOLD) signal to below the resting state (negative BOLD). The reverse is true for retrieval (i.e. an increase in the BOLD signal with enhanced excitability of the motor cortex). These data highlight the importance of a finely tuned interplay of excitatory and inhibitory neuronal activities for the successful control of complex motor behaviour as needed for excellent musical performance.

Introduction

The performance of music virtually always requires skilled motor behaviour. Successful motor behaviour depends on learning and the appropriate adaptation of learned actions to different situations or contexts. Adequate contextual control of behaviour requires retrieval and non-retrieval, or suppression, of learned actions, that is, activation *and* deactivation of brain regions representing these actions. For example, in a concert different musicians play their parts at different times, and only if this timing is precise will the performance be good. Precise timing implies that each musician knows exactly when to retrieve the learned motor sequence and when to 'wait'. Waiting, however, can occur in situations that are very similar to situations requiring action, for example in the context of

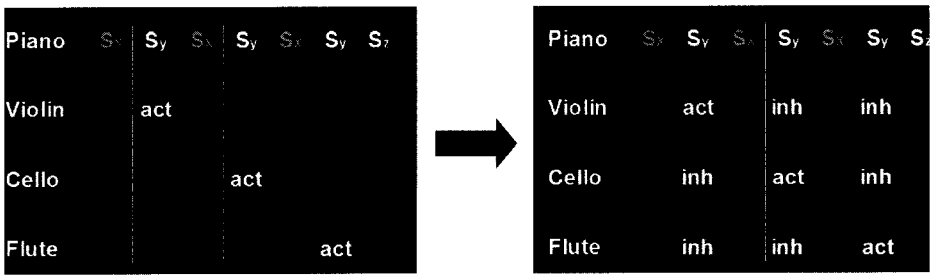

Fig. 15.1 Schematic of the concept of active inhibition in the context of a musical performance. Left: The piano plays three different sequences Sx, Sy, and Sz. On the first Sy, the violin joins in, on the second Sy the cello, and on the third Sy the flute. In each case, Sy is the stimulus triggering the start of the instrument. Commonly, this is interpreted as a series of excitatory events. Right: The same 'concert', but highlighting the fact that the same stimulus (beginning of Sy) prompts the violin first to play and then 'not to play' twice. The same holds true for the other instruments. Each square labelled 'inh' indicates the necessity of inhibiting the retrieval of the learned motor program because the context has changed (although Sy is always identical).

variations of the same theme. In this situation, waiting might be more of an active process than is commonly thought. Waiting might be active inhibition rather than passive 'idling'. Figure 15.1 illustrates this concept.

What are the neural correlates of this 'bidirectional' (excitatory and inhibitory) contextual control? In particular, what is the neural correlate of effective inhibition in the sense of suppression of behaviour? The concept of inhibition is pervasive in human experiments on complex motor behaviour but is commonly ignored. We have studied this question in a paradigm of finger movement sequences which were performed on custom-made MRI-compatible keyboards.

The importance of this aspect of motor control is emphasized by the clinical observation that disturbances of contextual modulation (especially deficient inhibition) can be of pathophysiological relevance in patients who have diseases with known or proposed deficits of inhibitory neuronal circuitry, such as dystonia, Tourette syndrome, or compulsive disorders (Berardelli *et al.* 1998; Greenberg *et al.* 2000; Jankovic 2001). In certain forms of dystonia (e.g. musician's or occupational dystonia, writer's cramp), the occurrence of neurological symptoms depends strongly on the context of the situation (Sheehy and Marsden 1982; Cohen and Hallett 1988; Fahn 1988).

The paradigm

The basic principle of the paradigm used is that identical visual stimuli are presented to prompt the subject to act (condition ACT) or not to act (condition INH), depending on the context (Hummel *et al.* 2002). The motor act consists of finger movement sequences that were learned prior to the actual experiment. In

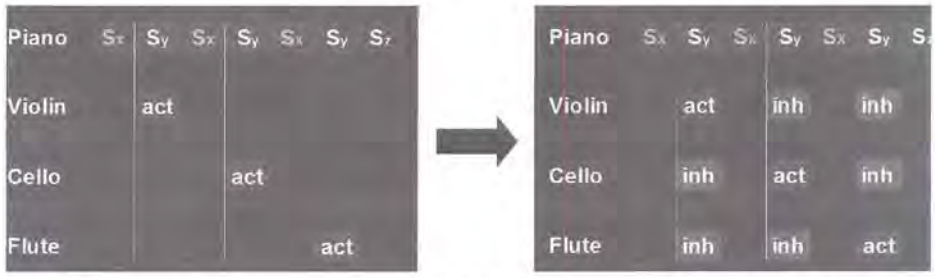

Fig. 15.1 Schematic of the concept of active inhibition in the context of a musical performance. Left: The piano plays three different sequences Sx, Sy, and Sz. What are the neural correlates of this 'bidirectional' (excitatory and inhibitory) contextual control? In particular, what is the neural correlate of effective inhibition in the sense of suppression of behaviour? The concept of inhibition is pervasive in human experiments on complex motor behaviour but is commonly ignored. We have studied this question in a paradigm of finger movement sequences which were performed on custom-made MRI-compatible keyboards.

The importance of this aspect of motor control is emphasized by the clinical observation that disturbances of contextual modulation (especially deficient inhibition) can be of pathophysiological relevance in patients who have diseases with known or proposed deficits of inhibitory neuronal circuitry, such as dystonia, Tourette syndrome, or compulsive disorders (Berardelli *et al.* 1998; Greenberg *et al.* 2000; Jankovic 2001). In certain forms of dystonia (e.g. musician's or occupational dystonia, writer's cramp), the occurrence of neurological symptoms depends strongly on the context of the situation (Sheehy and Marsden 1982; Cohen and Hallett 1988; Fahn 1988).

The paradigm

The basic principle of the paradigm used is that identical visual stimuli are presented to prompt the subject to act (condition ACT) or not to act (condition INH), depending on the context (Hummel *et al.* 2002). The motor act consists of finger movement sequences that were learned prior to the actual experiment. In

this learning session, external stimuli presented at a rate of one per second are associated with the required movements. In the recording session, during ACT these movements are retrieved paced by visual stimuli. During the INH condition, the subject is instructed not to retrieve the movements although the same stimulus is presented. The information about the context (ACT or INH) is given several seconds before presentation of the pacing stimuli. In contrast to the classical go/no-go paradigms, this produces a shift in context without creating time pressure in the millisecond range and it can be applied to highly complex motor acts. Figure 15.2 illustrates the experimental design which was used with TMS, EEG, and fMRI experiments.

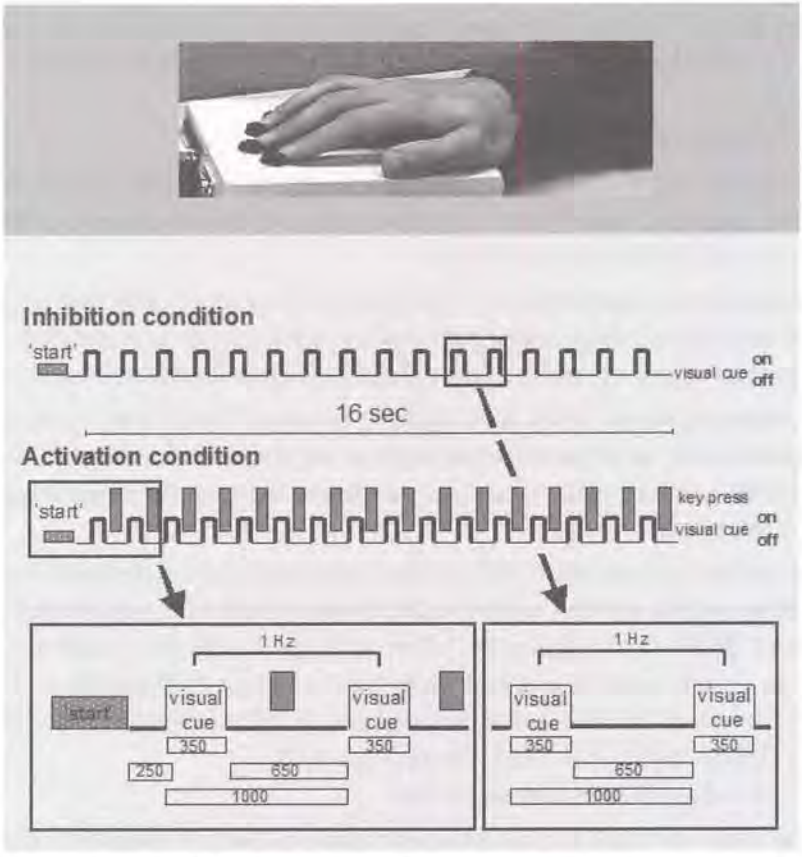

Fig. 15.2 Top: Custom-made keyboard. Bottom: Temporal structure of stimulus presentation. In the inhibition condition, the subjects observed the visual cues but were instructed not to retrieve the learned finger movements. In the activation condition, they responded to visual cues with retrieval of individual finger movements. Solid blocks indicate key presses, high and low on the black line responds to visual cue on and off. The duration of intervals is given in millisecond in the zoomed boxes below.

The following description will focus on the results and their implications for motor control. Methodological information is included where it is considered to be relevant.

Neural correlates of movement retrieval

All subjects overlearned the finger movements during the training session, which was confirmed by their performance (in correct responses) of 97.4 ± 1.4% (mean ± SD) (n = 18 normal volunteers for TMS/EEG) and 98.0 ± 3.7% (n = 6 for TMS/fMRI) during fMRI in the experimental session (ACT condition).

When retrieving the learned movement sequences, TMS documented significant facilitation of the primary motor cortex (M1) contralateral to the moving hand. From a response amplitude during unconstrained rest of 1.4 ± 1.1 mV, the motor evoked potential (MEP) increased to 3.4 ± 2.1 mV during ACT.

The following *TMS methods* were used:

- A 'Magstim rapid' stimulator (Magstim Company Ltd, Whitland, UK) with a peak magnetic field of 2.5 T, a biphasic pulse of 250 ms pulse duration, and a magnetic field rise time of 60 ms.
- A magnetic coil shaped like an 'eight' (inner diameter of each loop 5 cm) was used with the handle pointing backwards and laterally at an angle of about 45° to the sagittal plane in order to elicit MEPs in the first dorsal interosseus muscle.
- For each condition, 20–30 trials (MEPs) were recorded. Based on theoretical considerations and typical latencies of cortical responses to visual stimulation (e.g. P100), a fixed delay of 120 ms was chosen between the visual trigger and the TMS pulse.

The facilitation seen with TMS was accompanied by focal desynchronization of oscillatory EEG activity, in line with previous studies on task-related power decrease (TRPD) in the alpha (7–13 Hz) and beta (14–30 Hz) frequency range. TRPD as a parameter for cortical activation is similar to the well-established concept of event-related desynchronization (ERD) of oscillatory neuronal activity (Pfurtscheller *et al.* 1994; Gerloff *et al.* 1998).

The following *EEG methods* were used:

- Focal TRPD or ERD are accepted surrogate markers of excitatory neuronal activation. Continuous EEG was recorded from 28 (Ag/AgCl) surface electrodes (Fig. 1b), mounted in a cap (Electro-Cap International, Inc., Eaton, OH, USA).
- Impedance was kept below 5 kΩ. Data were sampled at 250 Hz, the upper cut-off was 50 Hz, and the time constant was set to DC (Synamp amplifiers

and software by NeuroScan Inc., El Paso, TX, USA). Linked earlobe electrodes served as reference.

- The analysis in the frequency domain was based on FFT algorithms and normalization as described elsewhere (Gerloff *et al.* 1998; Andres *et al.* 1999). After stabilizing the variance by log transformation, the data were entered into a factorial ANOVA design. The significance level was set to $P < 0.05$ after correction for multiple comparisons.

Topographical EEG analysis revealed activity not only in the contralateral sensorimotor region but also in the central region of the hemisphere ipsilateral to the moving hand (Hummel *et al.* 2002). Bilateral activation of sensorimotor areas during performance of complex finger movements has been a characteristic finding in various studies (Sadato *et al.* 1996; Gerloff and Hummel 2003; Hummel *et al.* 2003). This pattern was confirmed and complemented by the subsequent fMRI experiment. The structures activated during ACT involved M1 (bilateral BA4), secondary motor areas (right dorsal pre-motor cortex, PMd; supplementary motor area, SMA; both BA6), primary somatosensory cortex (S1; left BA3), posterior parietal cortex (i.e. bilateral pre-cuneus and superior parietal lobe, SPL; both BA7), the cingulate cortex (BA24, BA31), and the cerebellum. In addition to these motor-related areas, visual areas (BA19, BA37) were activated—consistent with visual cueing.

The following *functional MRI methods* were used:

- For fMRI data, functional images of the BOLD responses (Ogawa *et al.* 1990) were acquired with a 1.5 T scanner (Magnetom Vision, Siemens, Germany) with a gradient echo planar imaging (EPI) sequence in which one volume is equivalent to 28 axial slices (4 mm thickness, 1 mm gap) with repetition time (TR), 3000 ms; echo time (TE), 39 ms; a 64 × 64 matrix; flip angle 90°; and field of view of 192 × 192 mm. Serving as the anatomical reference were high-resolution images based on a T_1-weighted three-dimensional turbo-flash sequence. The commercially available BrainVoyager (Version 4.9, Brain Innovation, R. Goebel, Maastricht, The Netherlands) was used for fMRI analysis.
- Pre-processing of data included three-dimensional motion correction, slice scan-time correction, spatial smoothing of EPI images with full-width at half-maximum (FWHM) of 4 mm and temporal smoothing with trend removal by temporal fast Fourier transform-based high-pass filtering, co-registration, and transformation of scans according to Talairach and Tournoux. Details of these procedures are described in Trojano *et al.* (2000).
- A general linear model (fixed effect) with predictors for the experimental conditions of ACT and INH and a further predictor for instruction was

computed for multiple regression analysis. This design allowed us to compare the ACT condition and the INH condition with baseline. As our main hypothesis was that some of the same areas involved in activation (excitation) during ACT can be inhibited during INH, a conjunction analysis was computed. With this analysis it is possible to determine areas that are significantly activated during ACT and significantly 'deactivated' during INH (= 'bidirectional modulation of metabolic activity' above and below baseline).

Neural correlates of motor inhibition (non-retrieval)

The key finding prompting us to pursue this line of experiments was a significant reduction in the MEP amplitude when subjects were asked not to move even though the visual cues (learned to be associated with movement) were presented. From a baseline value of 1.4 ± 1.1 mV, the MEP amplitude decreased to 0.8 ± 0.7 mV in the inhibition condition.

Cortical oscillatory activity showed a distinct task-related power increase (TRPI), similar to event-related synchronization (ERS) in the alpha frequency range (maximum 12–13 Hz). As this effect was quite restricted to the alpha frequency, it will be referred to as α-TRPI. As during execution of the motor sequences (ACT), during INH the task-related change in cortical oscillations was not restricted to the M1 contralateral to the moving hand. Also α-TRPI exhibited a bilateral topographic distribution over the sensorimotor regions of both hemispheres (Hummel *et al.* 2002). Previously, alpha power increases had been largely interpreted as correlates of cortical 'idling'. The coincidence of MEP suppression and α-TRPI, however, provides evidence that regional enhancement of alpha oscillations might be operational in down-regulating cortical excitability (active inhibition).

The observed α-TRPI was specific to the situation of previous motor learning. Without prior training and thus establishment of a cue–response association, no α-TRPI occurred. It was also absent if neutral visual material was presented (a video clip without connection to motor performance or other elements of the experimental setting) instead of the visual cues.

We therefore conclude that in this experimental situation α-TRPI is a correlate of contextual inhibitory modulation of a learned motor program. It is tempting to speculate that α-TRPI operates as a mechanism capable of suppressing recently established increases in synaptic gains by long-term potentiation (LTP). Preliminary data on the duration of α-TRPI after a single session support this view, as α-TRPI shows reversibility, which is also one of the characteristics of LTP. Further studies are necessary in order to clarify the exact mechanisms underlying α-TRPI during contextual inhibition. Plate 15 summarizes TMS and EEG results for the ACT and INH condition. The similarity of the topography of

α-TRPI and α-TRPD was one major observation that lead us to assess the fMRI data not only with traditional parametric or differential analyses but also with a conjunction analysis which allows for identification of areas showing both inhibitory *and* excitatory changes.

The fMRI data allowed for a finer anatomical characterization of the neuronal network involved in contextual motor inhibition, including the cerebellum (Hummel *et al.* 2004). We identified as areas with bidirectional modulation of activity the bilateral M1 (BA4), the secondary motor areas (right dorsal premotor cortex, PMd; supplementary motor area, SMA; both BA6), the primary somatosensory cortex (S1; left BA3), the posterior parietal cortex (i.e. bilateral pre-cuneus and superior parietal lobe, SPL; both BA7), the cingulate cortex (BA24, BA31), and the cerebellum. That is, an extended cerebrocerebellar network showed enhanced metabolic activity during ACT but suppressed activity (below baseline) during INH. Besides the implication for motor physiology, this was also one of the first experiments to prove a clear association of inhibition of electrophysiological markers and negative BOLD responses. It is necessary to point out that inhibitory neuronal processes are not well reflected in the neuroimaging literature. For example, a literature search in the international database PubMed in January 2004 revealed 3389 articles for the search terms 'functional imaging' and 'activation', but only 294 for 'functional imaging' and 'inhibition'. In contrast, 30–40% of cortical neurons are inhibitory Golgi type II cells, and the divergence of synaptic connections from one inhibitory interneuron to target neurons is much higher than the one of excitatory neurons. In essence, all the evidence points to a functionally relevant (if not dominant) role of inhibitory neuronal activities in human behaviour. The fMRI results are given in Plate 16.

What does it mean at the theoretical level that the BOLD signal turns negative, i.e. below baseline? This question has been controversially debated for several years now. In the framework of this chapter it is important to note that there are theoretical considerations, modelling data (Tagamets and Horwitz 2001), and recent experimental studies of the visual system of humans and non-human primates (Shmuel *et al.* 2002) that provide grounds for the concept that neuronal inhibition can be reflected by negative BOLD (for a more detailed discussion of this topic see Hummel *et al.* 2004), and that negative BOLD is not merely a consequence of local vascular autoregulation or capillary steal effects.

Implications for the musician's brain

There are two main points which we would like to stress. First, neuroimaging studies on motor physiology in musicians need to take into account the essential role of inhibitory neuronal circuits. In many instances it might make sense to

compute contrasts that allow for the assessment of reductions in activity rather than only evaluating putative excitatory phenomena. Second, the present data might help to further our understanding of neurological diseases frequently affecting professional musicians, such as focal dystonia. To this end, we have studied a group of six patients (five of them with musician's dystonia, one with writer's cramp), and the most striking finding was an absence of the typical inhibitory α-TRPI (Hummel *et al.* 2002). This result extends previous observations of compromised inhibitory circuits in dystonia, because it shows for the first time the absence of proper contextual inhibition during performance of a complex motor task. The multimodal investigation of such phenomena in patients is a promising approach to the pathophysiology of dystonia.

Conclusions

The study described here identifies neural correlates of controlling motor behaviour. We propose the following model for the contextual control of acquired motor behaviour. During acquisition of a sensorimotor program (e.g. association of an external cue with individual finger movements), neural connections between brain areas involved in the processing of motor behaviour are strengthened so as to warrant improved behaviour. The external cues activate not only the visual cortex but also sensorimotor areas. To account for contextual changes, which may require motor behaviour during the appearance of the cue in one situation but not in another, the sensorimotor network must be activated or deactivated (suppressed) depending on these requirements. This *bidirectional* neuronal control is represented by modulation of cortical excitability (TMS), modulation of cortical alpha oscillations, and positive and negative BOLD signal changes in fMRI. These modulations might be controlled by pre-frontal top-down processes.

Acknowledgements

We wish to thank E. Altenmüller for referral of the patients with musician's dystonia. This research was supported by a grant (SFB 550 / C5) from the Deutsche Forschungsgemeinschaft to CG and a grant from the A. v. Humboldt Foundation (Feodor-Lynen) to FH.

Part 5

Apollo's curse—loss of motor control in musicians

Chapter 16

The end of the song? Robert Schumann's focal dystonia

Eckart Altenmüller

Robert Schumann is one of the most prominent composers of the early romantic period. He was born in Zwickau, Saxony in 1810. Early in his adolescence he displayed extraordinary skills in piano playing and attempted to become a concert pianist. After an initial success, increasing technical difficulties hampered his pianistic progress in the years 1831 and 1832. Finally, he developed a task-specific loss of voluntary control of the middle finger of his right hand. By means of a finger-stretching device, Schumann tried to improve the situation. In parallel, he composed the Toccata, Opus 7, a piano work which allowed high-level virtuoso performance without the use of the middle finger of the right hand. However, from 1833, he almost completely gave up playing the piano literature, but continued to improvise. Robert Schumann was suffering from a focal, task-specific dystonia of the right hand, also referred to as pianist's cramp. This disorder is characterized by a painless loss of skilled motor control in a task-specific context. Its neurobiological origin is seen in maladaptive plasticity of neuronal networks with blurring of afferent and efferent receptive fields of adjacent finger representations in the cerebral cortex and basal ganglia. The general basis of such a blurring may consist of a deficient lateral inhibition of synaptic pathways. Risk factors for developing musician's dystonia are male gender, extensive cumulative practice time, extreme motor workload concerning the temporal and spatial quality of the affected movements and personality traits such as proneness to anxiety and perfectionism. All these factors can be demonstrated in Robert Schumann's early life.

Preamble

> I offer up myself to make your son Robert, with his talent and imagination, within three years to one of the greatest living piano players, who will play warmer than Moscheles and greater than Hummel.
>
> Friedrich Wieck in a letter to Johanne Christiane Schumann, Robert's mother, on 9 August 1830, quoted according to Burger (1999, p 87)

Who was this promising young pianist who, according to the judgement of a person with intimate knowledge of the piano world, after only 3 years of diligent study could be better than the great virtuosos of the time, Hummel and Moscheles, who competed with the young piano stars Franz Liszt, Frederic Chopin, and Felix Mendelssohn-Bartholdy. Was he a child prodigy? Had he already made a name for himself with his abilities? Had he been noticed through numerous concerts in the great musical centres of Europe? Not at all—Robert Schumann was a young provincial from Saxony, who had studied law, not music, at Heidelberg. He had been noticed in a few private salons because of his free improvising on the piano, but was completely unknown to the music world outside the area. His only noteworthy public appearance took place on 24 January 1830 in the great hall of the Heidelberg 'Museum'. Robert, then 20 years old, played the 'Variations on the Alexander March' by Ignaz Moscheles, a concert piece which was quite popular at the time and also very demanding. The appearance was a tremendous success, although Robert did not come across as a giant at the keys but rather as a shy young man. He was plagued by stage fright. His school friend Theodor Töpken reported:

> To our relief and because he was used to my presence while playing the piano, he asked me to turn pages for him during concerts, to which I agreed, in spite of my anxiety due to the difficulty of the page turning
>
> Töpken quoted according to Burger (1999, p 74)

His piano playing must have been impressive. The Heidelberger society celebrated him, and the accounts of friends and contemporaries speak for themselves. In December 1829, Schumann noted, in a mix of pride and irony, twenty-one 'collected discussions about my piano playing' in his diary; to mention only a few:

> Music teacher Faulhaber: I recognise in him an extraordinary master.—Music director Hoffmann: Bravo: such a thing makes one glad again.—Professor Morstadt: Superb.—Dr. Wüstenfeldt: Heavenly
>
> Quoted according to Robert Schumann *Tagebücher*, in Eismann (1971)

Obviously, Friedrich Wieck's prognosis was not without foundation, but Robert Schumann's piano-playing career was short. One single public appearance, a few evenings of salon music, passing esteem from Heidelberg and Leipzig society and then—silence at the piano. His falling silent is the subject of our research. Which circumstances led to the termination of his pianistic career? What did it have to do with the puzzling suffering of his hand? What creative solutions did Robert seek? And was it really a silencing, or were his hand ailments a necessary aid in the birth of the composer? The biographical study presented here concentrates on the years 1829 to 1833 and on the development of a disorder of the fine motor skills in his right hand that took place during this time. Schumann's psychological crises of

that time only have a place at the boundaries of the discussion. They have been reviewed in the past by several biographers (Ostwald 1985; Lederman 1999; Steinberg 1999). Finally, Schumann's hand ailment will be more precisely classified than has been possible in earlier writings according to new medical insights.

Childhood scenes

Robert Schumann was born on 6 June 1810 in Zwickau as the fifth child of the bookseller, author, and publisher Friedrich Schumann. His mother, Christiane Schumann, was the daughter of a city surgeon from Zeitz. In the middle-class atmosphere of the home, Robert's musical and literary tendencies were mostly nurtured by his father. At the age of seven, Robert received his first piano lessons from the baccalaureate Kuntsch, who had taught himself to play the organ. Father Schumann purchased a very valuable grand piano and allowed his son to play for him daily after lunch. After only a few years baccalaureate Kuntsch declared himself incapable of giving Robert further lessons, so that as of 1825 Schumann was left to his own devices with regards to his pianistic education. His school friend Flechsig reported:

> I found the young Robert already to be a finished pianist in his 13th year, who also allowed himself to be heard in public concert
>
> Emil Flechsig, *Erinnerungen an Schumann*, around 1875, quoted in Burger (1999, p. 36)

In his 1846 note 'Materials for a Resume', Schumann reported about the years 1820–1826:

> Free improvising (several hours daily) . . . Sick longing for music and piano when I have gone a long time without playing . . . Cello and flute with the city music director Meißner . . . I am strongest at free improvisation . . . entrancing fire of my performance . . . Complete lack of guidance noticeable: Ear training, Technique especially,—Theory
>
> From Eismann (1956, p. 18)

Schumann's great pianistic skill and excellent sight-reading together with his considerable technical shortcomings were noticed by Friedrich Wieck, who, beginning on 1 August 1828, gave lessons to the fledgling law student in Leipzig.

In the beginning, Schumann was required to study scales and finger exercises, much to the chagrin of his roommate Flechsig. The school and college peer made the following remark about this time:

> He took piano lessons from Wieck, who always called him ' "enrage" [maniac] at the piano', and had to do finger exercises like a beginner again, desperately one-sided to listen to
>
> Emil Flechsig, *Erinnerungen an Schumann*, around 1875, quoted in Burger (1999, p. 36)

The readiness for the development of a systematic piano technique was the basis under which Wieck agreed to take on Schumann after his decision to study music in 1831:

> But it is true, that for Robert, the greatest difficulty is the calm, cold, prudent, and lasting conquest of the mechanics as the basis of all piano playing
>
> Letter from Friedrich Wieck's to Schumann's mother 9 August 1832, quoted from Burger (1999, p. 87)

Upswing

In his time at Leipzig and Heidelberg, Schumann was an extremely ambitious piano player, who practised between 6 and 7 hours daily. Wieck knew how to motivate him, and Schumann was certainly also receptive to his praise:

> Piano lesson with Wieck—Scales and praise [20 November 1828]

but on the same day he entrusts this to his diary:

> One says: people wonder how I can still play scales, seeing as how I play excellently otherwise;—I would not want to receive the first mark from anyone, when I cannot give it to myself

It becomes clear that more than the outside encouragement the actual motivating factor is his high self-determination. The work at the piano then took up a large portion of the daily routine. Schumann visited his relatives in Zwickau for Christmas in 1828, made a lot of music and celebrated a great deal. On 12 December, after ample enjoyment of Burgundy, he fell in a ditch while walking home in the dark. At home the carousing continued—this succinct entry followed:

> dislocation of the arm

Then on 27 December 1828, as the first entry:

> The arm hurts,—the sick arm and the toccata

obviously without any substantial hindrance of the piano playing, since he played four-handed variations from Czerny with his friend Josephine Carus on the same day. Incidentally, the toccata mentioned is not the later drafted Toccata Opus 7, rather a work from the composer Charles Mayer (1799–1862), which Schumann was practising during the Christmas season in 1828. The arm injury appears to remain without repercussion, because in the winter and spring of 1829, Schumann worked intensively, without complaint of pain, on the improvement of his technique:

> Finger exercises from Hummel from 7–12 o'clock [18 February 1829]

Also on the programme were the Hummel A minor Concerto and the Alexander Variations by Ignaz Moscheles—a technically very demanding bravura piece. After the move to Heidelberg in May, the systematic finger exercises and the work on the Alexander Variations is carried on even more intensely. It is from this time that the first drafts of the Toccata later published as Opus 7 originate. Whether or not the pain and disturbances in the fine motor skills which appeared in the winter of 1829/1830, as referred to retrospectively in a letter to Agnes Carus, were related to strain from piano playing is questionable, since no entries regarding this can be found in the regularly kept diaries:

> yes, it came to the point, that when I crossed over the fourth finger, my whole body distorted convulsively and after six minutes of finger exercises, I felt the most unending pain, in short, was broken. In summer I magnificently came back, and I have practiced regularly three or four hours every day with good results.
>
> Letter to E. A. Carus, 25 September 1830 in Kross (1978, p. 28)

It is unusual that Schumann would not mention such devastating symptoms in his diary entries. In these years, the diary entries and the contents of letters to relatives and friends differ more frequently from each other, because Schumann omitted his potentially disturbing plans, especially those concerning his lack of motivation in his career, from the letters. It remains unclear, however, which function the dramatic representation to Agnes Carus of the hand ailment in the winter of 1829/1830 fulfilled.

Undeniably, the progress desired at the time was not always attainable:

> 2 hours finger exercises—Toccata 10 times—finger exercises 6 times—variations 20 times myself—and it still didn't work with the Alexander Variations in the evening—frustration over this—deep frustration [4 January 1830]

Schumann did, however, play the same Alexander Variations with considerable effect 3 weeks later, on 24 January 1830, in his first and only larger public appearance on the piano. In a letter addressed to his brother Julius, but not sent, he wrote:

> You can hardly believe how loved and, really without complimenting myself, respected and honored I am. I have been given the Epithet of a 'Favorite of the Heidelberger Public.' The cornerstone for this was lain naturally by—a concert, in which I played the Alexander Variations by Moscheles. The Bravo and Da capo calling would by God take no end and I became quite warm and took on a glow
>
> Unsent letter to Julius Schumann, dated February 1830, quoted from Schumann (1898, p. 102)

Apparently, even that does not go completely without self-criticism:

> my stumbling at the beginning—the last variation played consummately—unending applause [21 January 1830]

Only 2 days later, Schumann notes after an alcohol excess

my numbed finger [26 January 1830]

This singular remark should not be given too much weight, since only 3 days later 'respectable piano studies' and a successful house concert for an English family in Heidelberg with works by Hummel and the Piano Trio in E-flat major Opus 100 from Schubert were noted, and over several months no mention of pain or strange sensation occurs. The representation of his success at the Heidelberg concert in the letter to his brother and the silence about his piano-playing activities in a letter to his mother on the same day indicate that Schumann is trying to gain approval from his brothers and sisters for his decision, which he had most likely made by this point, to pursue a career as a musician. A few months later, his mother gives her consent for what she considered to be a dangerous step, due not in small part to the good prognosis quoted at the beginning with regards to Robert's career as a pianist.

In the Night

Schumann returned to Leipzig for a second time in order to continue his studies, and from the very beginning he encountered many more problems. Robert was under enormous pressure to succeed. In order to pacify his mother, he had agreed to a 6-month trial period, after which Wieck would decide whether or not Robert was suited to a career as a pianist. Financial worries forced him to write ever more desperate letters to his home. He finally moved in to a small apartment in the house of his piano teacher Friedrich Wieck. The proximity to the personality of Wieck probably caused a change in Schumann's perception of his teacher. Schumann discovered, much to his disappointment, that Wieck was less interested in his own training than that of his daughter Clara. It remains unclear whether or not Wieck, as early as the end of 1830, had noticed the physical limitations and especially the diminution of Robert Schumann's fine motor skills, and due to this changed his prognosis. In the diary entries beginning in the spring of 1831 there are a noticeably frequent number of entries concerning playing technique, hand position, and relaxation. It is a mix of frustration mingled with the occasional, ever-diminishing experiences of success at the piano. The month of May 1831 seems to be a key month in this regard, in which the technical difficulties of playing are revealed:

Much piano played, Field's Rondeau, Moscheles' third etude, my middle movement—very relaxed in the etudes. [12 May]

Got up early—My soberness is rewarded; played very well—soft, pearl-like tune and fantasy. [13 May]

Piano playing yesterday was quite satisfactory and made progress. Should Wieck be right about my studies? [14 May]

> Piano bad—the Moscheles Etude timid and unsure—Where does that come from? Been playing on it for fourteen days, attentively and persistently studied. [25 May]
>
> The Chopin is going excellently; today is the fifth day on which I have studied four hours each day. If only there will be no relapses! Protect me, my genius and never disappoint me! [5 July]
>
> My dear Robert, don't lose your courage if it is not flowing and going so well, like in the last eight days; practice patience, lift your fingers quietly, hold your hand still and play slowly: and everything must come back together. [9 July]
>
> The piano didn't want to work yesterday; it was as if someone was holding me by the arm. [13 July]
>
> It has been sincerely miserable on the piano the past several days; I cried yesterday with rage. [21 July]
>
> Now I want to proceed in such a manner with my quiet art since I know where it is, it must also be reachable; if only I had no fingers and could play with my heart for others! [14 August]

Schumann worked on a change in his hand position, which temporarily brings an improvement in his attacks:

> It is going quite well with the piano, excellently in the past few days. The flexibility is shocking and the tunes are flowing and progressing as in old times . . . . I am holding my wrist a little higher, approximately like the Belleville [famous female piano virtuoso], even though the graceful, wavelike line is missing. [13 October]

While Clara Wieck and her father were on a concert tour in Paris from September 1831 until April 1832, Robert developed an apparatus to improve the strength of his middle finger, and questionably that of his index finger as well. The doctor and friend Dr. M. Reuter remembered 10 years later in a letter from 1841:

> He mentioned first in his youth that the pointer and middle fingers had noticeably less strength and flexibility than the other fingers. The long term usage of a machine, with which the aforementioned fingers were pulled closer to the back of the hand, led to a state similar to laming, to the degree that they first, only had a weak sense of feeling and secondly, with regards to movement, could no longer be controlled by will.
>
> Rothe (2002)

Schumann christened this device 'Cigar mechanics'. Later he revealed to friends that he had constructed a sling that was attached to the piano, which pulled the middle finger upwards and held it there. The other fingers remained moveable at the keyboard.

> It is going pretty good with the third finger through the 'cigar mechanic'. [7 May 1832]

Now and then, Robert became hopeful:

> Yesterday I composed and played; the new method is the only one that works; it is the one. [11 May 1832]

But this attempt at self-therapy does not help for long:

> The third finger seems really irreparable. [22 May 1832]
> The third finger is completely stiff. [14 June 1832]

After this entry, there are no more clues to be found about Robert's hand ailment in his diaries. The subject seems to be closed. Apparently, Robert had finally given up the plan to become one of the greatest piano virtuosos of the time. This relieving decision was certainly made easier through the first successes of his compositional work—he had switched from one life's goal to another. He formulates this in a letter to his mother, just 2 years after giving up his piano studies:

> . . . Do not worry about the finger! I can still compose, and I would hardly be any happier as a travelling virtuoso—for that, I was spoiled at home. It doesn't bother me when I improvise. Even my old courage to improvise in front of people came back.
>
> Schumann (1898, p. 176)

A special work for piano accompanies the difficult years from 1829–1833, and was quite possibly inspired by the movement disorder. This is the 'study in double notes', the later Toccata Opus 7 (Fig. 16.1). In the figuration of the right hand, the middle finger can be largely left out. The third passages starting in measure 32 are somewhat uncomfortable, but by alternating the ring and index fingers, the upper voice is quite playable. It is not far fetched to say that this is an attempt to find a creative solution to the movement disorder by avoiding the use of the middle finger. Schumann drafted the piece as an etude, and was proud of

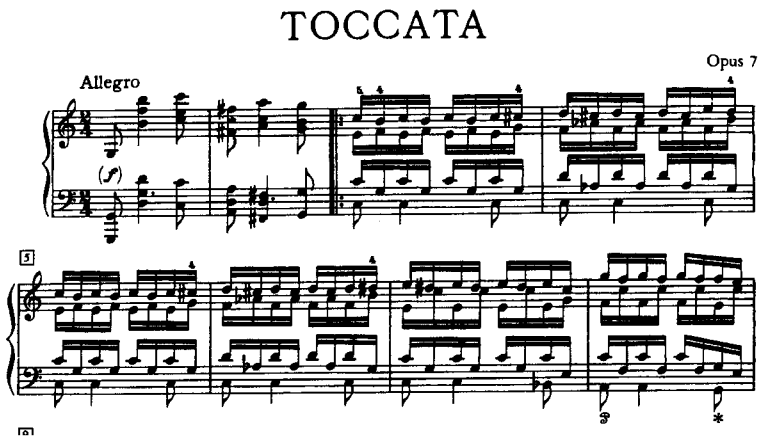

Fig. 16.1 Beginning of the Toccata Opus 7. This extremely difficult piece can be played without the middle finger of the right hand. (From Hallbergers Prachtausgaben der Romantiker, Verlag Eduard Hallberger, Stuttgart, 1890.)

the horrendous difficulties which the Toccata offered. He wrote to his mother on 2 July 1834:

> Take the attached piece (the Toccata) as a proof of my continuing efforts. Anybody in Zwickau will hardly ever make it.
>
> Schumann (1898, p. 240)

The Toccata Opus 7 is probably the most original of Schumann's early compositions. It is closest to the romantic, demonizing style of Liszt and Paganini. The piece had an enormous impact on his contemporaries. In a review of one of Clara Wieck's piano evenings on 9 November 1834 it was said:

> The last piece made a wonderful impression, a Toccata from Schumann—the work is a mold of originality and novelty, and in spite of its strict style, it worked with a deeply gripping magic on all the listeners.
>
> Boetticher (1984)

The end of the song?

Even though Schumann had inwardly distanced himself from virtuosity, he still tried, from the spring of 1832 to the summer of 1833, to improve his situation through medical measures. The treatment included rest, diet, electricity, bathing the hand in animal blood, and homeopathy. All new and expensive treatments of the day that were available were—unsuccessfully—utilized (Neumayr 1989). It is little noticed, however, that Schumann did not become completely silent at the piano. Improvization was still part of his daily musical activities. Even in the spring and summer of 1832, the time of the critical worsening of his movement disorder (6 June 1832 'the finger is completely stiff'), Robert tells about incredible experiences at the piano:

> . . . as I came home, close to nine o'clock, I sat down at the piano and it seemed to me that utter flowers and gods were coming out of my fingers, such was the stream of thoughts. [29 May 1832]
>
> How long and overflowing did I fantasize yesterday. [4 July 1832]

It is surely the freedom of the choice of musical conduits which made it possible for him to compensate for his movement problems while improvizing, similar to the case of the Toccata. Furthermore it can be assumed that the degree disturbance of the fine motor skills varied. Schumann still played the piano literature, mostly to get to know particular works. He preferred to perform his own, in part very demanding, pieces in small private contexts. Hieronymus Truhn describes Schumann's piano playing in the year 1837 as quite impressive:

> He moved his fingers with an almost frightening speed, as if ants were crawling around on the piano; he played his own things—I honestly never heard anything else from

> him—with only very little accentuation, but with lots of usage of both pedals. In the last instance, one naturally must not find a lacking of taste; he only played with as much pedal as needed to help a not so grand piano.
>
> Jansen (1883)

Why?

There has been much speculation about the causes of Robert Schumann's hand problems. Even the finger affected was under discussion. In a letter to Agnes Carus in September 1830, Schumann reveals pain in the ring finger of the right hand in the winter of 1829/1830. In the retrospective report of Robert's friend Dr. Moritz Reuter, the index and middle fingers are discussed. A loss of control in the middle finger of the right hand is described in the diaries beginning in May 1832. On the whole, these precise and repeated diary entries from the critical time period around 1832 speak clearly for an isolated and painless loss of control in the middle finger of the right hand. It is noticeable that the extent of the pain symptoms was overestimated by many biographers. Indications of pain in the hand or arm existed only after an arm injury in December 1828. These were sufficiently explained by a fall after too much wine and did not really affect Schumann after the fact. Several diagnoses are discussed in the literature. Edler (1982/2002) diagnosed a 'complicated tenosynovitis or tendinitis followed by stiffening', Fahrer (1992) an 'augmentation of the extensor tendon of the middle finger through the cigar mechanics', and Franken (1997) the 'result of an arsenic treatment in 1831'. None of these three diagnoses can be applied. A complicated tendonitis would have caused a great amount of pain if it had occurred at close to the same time as the movement disorder. Such pain was not mentioned in the diaries or letters. An augmentation of the extensor tendon due to the 'cigar mechanics' can be eliminated because the causality was reversed: the stretching mechanism was supposed to improve the movement disorder. The completely uncharacteristic symptoms speak against the diagnosis as a result of an arsenic treatment for syphilis. Arsenic poisoning leads to pain, stomach and intestinal cramps, and numbness and paralysis of the feet and hands. A paralysis would also have affected the hand in areas other than piano playing. Neither arsenic treatment nor any symptoms of poisoning were mentioned in the diaries or letters in May 1831, the assumed time frame of infection and potential therapy. After sexual contact with his lover Christel (Charitas), Schumann reports in his diary on 12 May 1831 about a wound on his penis, which could be considered a syphilis infection. It is, however, untypical that the wound hurt, and that treatment with quicksilver or arsenic was not recommended but instead bathing with narcissus water, which was supposed to reduce inflammation. Schumann especially, who tended to be a hypochondriac, would most likely have mentioned a

dangerous arsenic therapy and the resulting side-effects in his diary. Robert Schumann suffered from a task-specific focal dystonia, a musician's cramp. It is the only diagnosis which can sufficiently explain all of the symptoms and the progress of the sickness. Already Merriman *et al.* (1986) suspected a focal dystonia as the underlying pathology, but without providing supporting empirical evidence in detail. Merriman's viewpoint was adopted by Lederman (1999). The entries from his diaries, the attempts to compensate for the disorder by composing piano music extremely well suited for the disorder in question, and the circumstances under which the illness broke out do not leave any doubt concerning this diagnosis. Beyond that, according to new epidemiological studies, Robert Schumann had the typical profile of an 'at-risk patient' (Altenmüller 2003). In summary, Schumann's medical history in the years 1829–1832 is the first convincing documented case of this illness anywhere. Musician's cramp is a neurological disorder characterized by the loss of fine motor control of long-practised skilled movements during instrumental playing. It is related to writer's cramp, but seems to be more frequent in the population at risk. On average, 1 in every 100 musicians in Germany will develop musician's cramp. Men are affected approximately six times more frequently than women. The movement disorder is usually task specific limited to instrumental playing and does not extend to other movements. There are no indications that Schumann's writing skills were affected, even though his editorial and compositional work required many hours' writing each day over a long period of time. There was no pain or

deformation associated with the loss of control. Probably beginning in May 1831, Schumann's middle finger involuntarily drew itself in. In a possibly unconscious attempt to compensate for this, Robert Schumann composed the final version of the Toccata, Opus 7. Figure 16.2 shows just such a hand position with a curling middle finger during the playing of the first measures of the Toccata.

Although the neurobiological origins of this disorder have not yet been completely clarified, it is probable that musician's dystonia is in most cases due to dysfunctional (or maladaptive) brain plasticity. Support for this theory comes from a magnetoencephalographic (MEG) study performed in musicians with focal dystonia. Compared with healthy musicians, the dystonics showed a fusion of the digital representations in the somatosensory cortex, reflected in the decreased distance between the representation of the index finger and the little finger when compared with healthy control musicians (for a review see Münte *et al.* and Chapter 18 (2002) and Chapter 19). Such a blurring of receptive fields of the digits may well result in a loss of control, since skilled motor actions are necessarily bound to intact somatosensory feedback input. The pathological mechanism of the blurring may be based on an impaired lateral inhibition of adjacent neuronal networks processing afferent information from single fingers. With a corresponding genetic predisposition, this disintegration can be accelerated by excessive and intensive practising. The emotions play an important role, since the fixation of incorrect motor programs happens especially intensely under the influence of anxiety and stress hormones (Jabusch and Altenmüller 2004). Musicians with focal dystonia very often suffer from anxiety disorders and from perfectionist tendencies (Jabusch *et al.* 2004; see Chapter 17). These personality traits are present long before the condition becomes manifest, and can also be recognized in Robert Schumann. According to more recent epidemiological studies, the high-risk group is considered to be young to middle-aged men who play classical music, with guitarists and pianists being affected most often. Within the instrumental groups, those who spent the longest time practising their instrument on average during their studies were most at risk. Practice time, professional position, and personality traits are all closely connected (Jabusch *et al.* 2005).

The therapy for focal dystonia remains problematic to this day. In Robert Schumann's case, the result of the treatment with the 'cigar mechanics' and the other attempts at therapy is clear—a career as a pianist remained unattainable for him. On the whole, though, his problems must be seen as a mild and non-progressive form of the condition since he was still quite able to play the piano. Improvization at the piano must have been a return to the roots of music for him, connected to an inner freedom from fear, doubt, and from the extreme pressure of pianistic perfection. The energetic diversion of his creative potential

to composition shows the tremendous will for creation, which had already set him apart as an adolescent. For us, Schumann's decision to follow a career as a composer was a blessing, because it allowed his creative talent be developed to masterful perfection.

Chapter 17

Epidemiology, phenomenology, and therapy of musician's cramp

Hans-Christian Jabusch and Eckart Altenmüller

Introduction

Focal dystonia in musicians, also known as musician's cramp, is a task-specific movement disorder which presents itself as a painless muscular incoordination or loss of voluntary motor control of extensively trained movements while a musician is playing the instrument (Jankovic and Shale 1989; Lederman 1991; Brandfonbrener 1995; Frucht *et al.* 2001; Altenmüller 2003). For those who are affected focal dystonia is highly disabling, and in many cases terminates musical careers. According to estimations, 1% of all musicians are affected (Altenmüller 2003). In this chapter the phenomenology and epidemiology of musician's dystonia are addressed on the basis of data from 144 affected musicians diagnosed and followed-up at the Institute of Music Physiology and Musicians' Medicine of the Hannover University of Music and Drama. Data will be compared with those of other reports and discussed with regard to risk factors for the development of musician's dystonia. Treatment strategies and results will be outlined based on a retrospective inquiry and self-evaluation of affected musicians treated with currently available therapies.

All 144 patients were professional musicians diagnosed with focal dystonia at our out-patient clinic between 1994 and 2001. The diagnostic procedure during their first visit included a complete neurological examination as well as visual inspection while patients were playing their instruments. None of the patients were suffering from secondary dystonias or other neurological disorders. For assessment of the phenomenological and epidemiological data, a retrospective chart review was performed. Data were statistically analysed using χ^2-tests and Fisher's exact tests to identify disproportionate frequencies in the clinical manifestation of subgroups of patients. The level of significance was set at $P < 0.05$.

Demographics, epidemiology, and phenomenology

The patient group consisted of 116 male (81%) and 28 female (19%) musicians. The mean age at onset of symptoms was 33 years (range 17–63 years) and the

mean duration of dystonic symptoms at the time of the first visit was 5.1 years (range 0.1–28 years). At the time of the onset of symptoms, 74 patients (51%) had professional positions as soloists and 24 (17%) were tutti players in orchestras, 25 patients (17%) had teaching positions, and 21 (15%) were students. Concerning the genre, 137 patients (95%) were classical musicians, 2 patients (1%) were jazz musicians, and 5 patients (4%) were pop musicians. Nine patients (6%) had a history of either writer's cramp or musician's dystonia in their family. The distribution of instrument groups was as follows: 22 patients (15%) were bowed string players, 40 patients (28%) were keyboard instrumentalists, 29 patients (20%) were playing plucked instruments, 37 patients (26%) were woodwind players, and 16 patients (11%) were brass players. The distribution of individual instruments is displayed in Fig. 17.1. In order to compare the distribution of instruments among dystonic musicians with that in a normal population of instrumentalists, the respective numbers of members in the German Orchestra Union were used according to the March 2004 statistics of the German Orchestra Union (representing over 90% of German orchestral musicians). In our patient group, 20 high string players (violin, viola) and 2 low string players (violoncello, double-bass) were affected. This ratio was higher than expected according to the distribution of 3810 high and 1464 low string players in the German Orchestra Union ($\chi^2 = 3.81$, d.f. $= 1$, $P = 0.05$). One hundred and twenty-four patients were suffering from focal upper limb dystonias (86%), which presented themselves mostly as hand dystonias in the

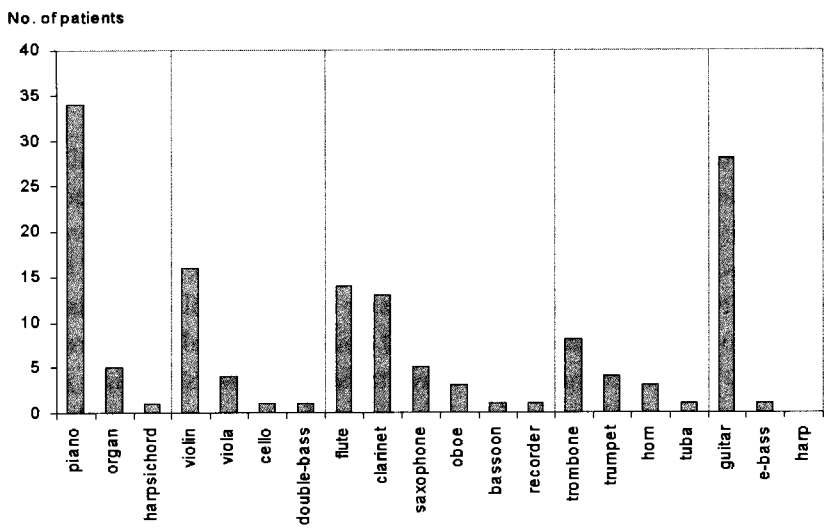

Fig.17.1 The instruments played by 144 patients with musician's dystonia. Instrument families are separated by vertical lines.

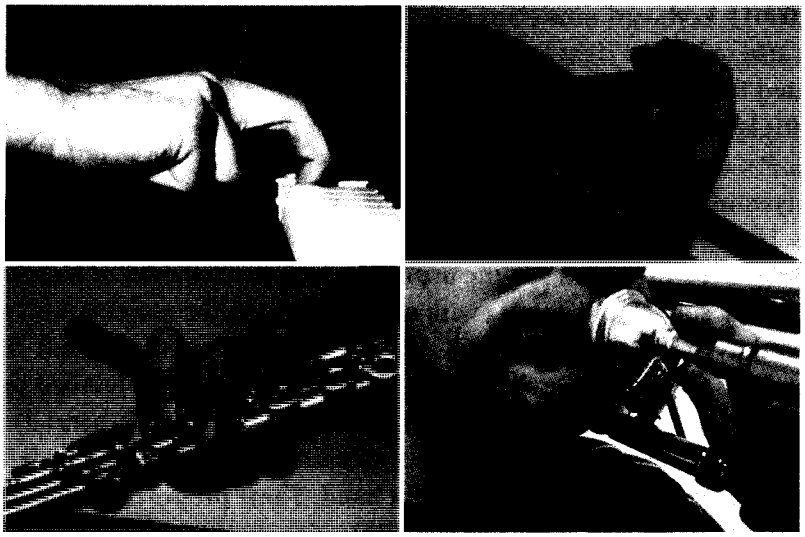

Fig.17.2 Typical patterns of dystonic posture in a pianist, a violinist, a flutist, and a trombone player.

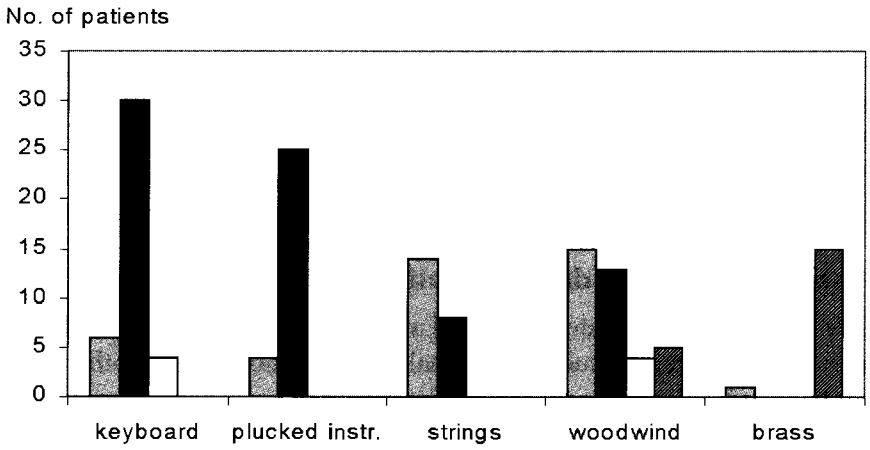

Fig.17.3 Localization of musician's dystonia as distributed in different instrument families: grey bars, left hand affected; black bars, right hand affected; white bars, both hands affected; hatched bars, embouchure dystonia.

typical manner with involuntary cramping of one or more fingers while patients were playing; one trombone player displayed dystonic movement patterns in his left upper arm. Embouchure dystonia was present in 20 patients (14%). Typical patterns of dystonic posture are displayed in Fig. 17.2. Details of the localization of focal dystonia in different instrument families are given in Fig. 17.3. χ^2 -tests of 115 patients with unilateral hand dystonia revealed a different laterality of focal hand dystonia in different instrument families ($\chi^2 = 23.5$, d.f. $= 3$,

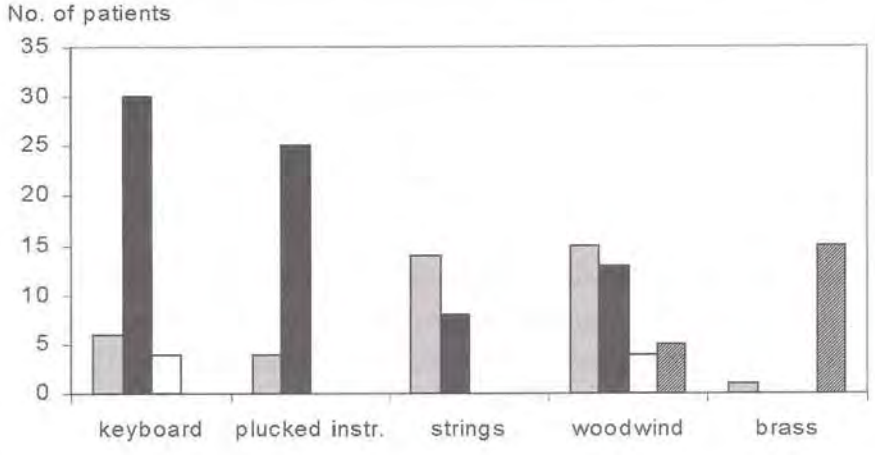

Fig.17.3 Localization of musician's dystonia as distributed in different instrument families: grey bars, left hand affected; black bars, right hand affected; white bars, both hands affected; hatched bars, embouchure dystonia.

typical manner with involuntary cramping of one or more fingers while patients were playing; one trombone player displayed dystonic movement patterns in his left upper arm. Embouchure dystonia was present in 20 patients (14%). Typical patterns of dystonic posture are displayed in Fig. 17.2. Details of the localization of focal dystonia in different instrument families are given in Fig. 17.3. χ^2 -tests of 115 patients with unilateral hand dystonia revealed a different laterality of focal hand dystonia in different instrument families ($\chi^2 = 23.5$, d.f. $= 3$,

$P < 0.0001$): keyboard musicians and those with plucked instruments were primarily affected in the right hand and string players in the left hand (Bonferroni-corrected follow-up χ^2-tests; keyboard vs. string players: $\chi^2 = 13.3$, d.f. = 1, $P < 0,01$; keyboard musicians vs. musicians with plucked instruments: $\chi^2 = 13.6$, d.f. = 1, $P < 0,01$). No such lateralization was seen in woodwind players. Bilateral hand dystonia was seen only in keyboard instrumentalists and in woodwind players. Handedness was categorized as right-handed/ left-handed/ambidextrous according to the preferences in the use of hands in the activities of handwriting, eating with a spoon, and cutting with scissors. Among the patients with unilateral hand dystonia there were 108 right-handed patients and 5 left-handed patients; two patients were ambidextrous. Seventy-five right-handed patients had right-hand dystonia and 33 right-handed patients had left-hand dystonia. This pattern was inverse in left-handed patients: in four of these the left hand was affected and in one patient the right hand. These proportions were significantly different (Fisher's exact test; $P < 0.05$).

Ninety-five patients (66%) had dystonic symptoms only while they were playing their instrument, whereas 49 patients (34%) had additional difficulties in other activities such as writing on the computer keyboard or in everyday activities. Local pain preceded focal dystonia in 13 (9%) patients: 7 patients (5%) experienced local pain only before onset of dystonic symptoms while 6 (4%) patients had pain in the affected region before and after onset of dystonic symptoms. Twenty-five (17%) patients reported local pain only after onset of dystonic symptoms, whereas 106 (74%) patients never experienced pain in the affected region.

Risk factors for the development of musician's dystonia

The demographic data demonstrated a preponderance of male musicians in the sample of the present study, with a male:female ratio of 4:1. In other reports the male:female ratio of patients with musician's dystonia was between 2:1 (Lederman 1991) and 5:1 (Lim and Altenmüller 2003). Since female musicians form the majority of the musicians in Germany, the latter ratio was corrected to 6:1 (Lim and Altenmüller 2003). Similarly, this effect has to be taken into account for the male:female ratio of 4:1 of the present sample of patients, which additionally underlines the increased risk of male musicians developing focal dystonia. A positive family history of dystonia, as seen in 6% of our patient group, has already been described in other reports as a risk factor for development of musician's dystonia (Jankovic and Shale 1989; Altenmüller 2003; Lim and Altenmüller 2003). The mean age at onset of dystonic symptoms (33 years) observed in the present study harmonizes with other studies demonstrating a peak in the fourth decade of life (Lederman 1991; Brandfonbrener 1995; Brandfonbrener and Robson 2002; Altenmüller 2003).

Our results demonstrated a correspondence between the instrument group and the localization of focal dystonia. This is obvious for brass players who suffer predominantly from embouchure dystonia. Additionally, among the musicians with unilateral hand dystonia, the correspondence between the instrument group and the localization of focal dystonia was significant. Keyboard musicians (piano, organ, harpsichord) and those with plucked instruments (guitar, e-bass; no harpists) were primarily affected in the right hand. All these instruments are characterized by a higher workload in the right hand. Correspondingly, bowed string players who have a higher workload and complexity of movements in the left hand were predominantly affected in the left hand. These observations agree with other reports (Tubiana and Chamagne 2000; Brandfonbrener and Robson 2002; Schuele and Lederman 2004). Moreover, focal hand dystonia in both hands was only seen in those musicians with instruments requiring similar movement patterns in both hands (although with a different workload), such as woodwind and keyboard instruments. Within the string family, musicians who were playing the high string instruments (violin, viola) were more often affected than those with low string instruments (violoncello, double-bass). The observed occurrence in high string players was significantly higher than expected according to the overall distribution of high and low string players among German orchestral musicians. The demands on spatial sensorimotor precision required for violin and viola playing are higher than for the low string instruments. Thus, those musicians with instruments requiring highest spatial sensorimotor precision were primarily affected by dystonia. Furthermore, in our sample of musicians with unilateral hand dystonia a context was observed between the handedness and the side affected by dystonia. The majority of right-handed patients was affected in the right hand and the majority of left-handed patients was affected in the left hand. Although the number of left-handed patients was small, this difference was significant and indicated that the hand with a higher total workload tended to be affected. It is noteworthy that there was no string player in the group of left-handed patients. The musical genre of the overwhelming majority of patients was classical music. In contrast to pop or jazz music with improvised structures and great freedom of interpretation, musical constraints are most severe in classical music. The latter requires a maximum of temporal accuracy in the range of milliseconds which is scrutinized by the performing musician as well as by the audience at any moment of the performance. This, as a consequence, combines the situation of public performance in classical music with a high level of social pressure: the gap between success and failure is minimal in this genre.

Taken together, epidemiological findings indicate that the workload of the respective body part, the complexity of movements, and the degree of spatial and

temporal sensorimotor precision as well as the level of social constraints associated with the musical performance were related to the occurrence of musician's dystonia.

Pathophysiological findings

The pathophysiology of focal dystonia remains unclear. Beside of alterations in the circuitry of the basal ganglia (Naumann *et al.* 1998; Preibisch *et al.* 2001) and dysfunctional plasticity in the sensory thalamus (Lenz and Byl 1999; Hua *et al.* 2000), there is growing evidence for abnormal cortical processing of sensory information as well as degraded representation of motor function in patients with focal dystonia (Deuschl *et al.* 1995; Hallett 1998; Elbert *et al.* 1998; Bara-Jimenez *et al.* 1998; Pujol *et al.* 2000). Cortical inhibition was found to be decreased in dystonic patients (Deuschl *et al.* 1995; Toro *et al.* 2000; Hummel *et al.* 2002). In animal studies, repetitive movements induced symptoms of focal hand dystonia and a distortion of the cortical somatosensory representation in monkeys (Byl *et al.* 1996) suggesting that practice-induced alterations in cortical processing may play a role in focal hand dystonia. Recently, behavioural treatment in patients with focal hand dystonia resulted in clinical amelioration and in reversed distortions of the somatosensory map, giving additional evidence for a practice-induced alteration of the cortical map (Candia *et al.* 2003). The importance of practice and the use of the limb in musician's dystonia was additionally underlined by the finding of improvement in symptoms after immobilization of the affected limb in dystonic musicians (Priori *et al.* 2003; see also Chapter 19). An impressive finding was reported by Rosenkranz and colleagues who used focal vibratory input to individual hand muscles to produce sensory input whilst the excitability of corticospinal outputs to the vibrated and other hand muscles was evaluated with transcranial magnetic stimulation (Rosenkranz *et al.* 2005, see also Chapter 18). In musicians with dystonia, focal vibratory input to hand muscles resulted in abnormally suppressed short-latency intracortical inhibition of all other hand muscles examined, independent of their functional connectivity with the vibrated muscles. In healthy non-musicians, such vibratory input increased short-latency intracortical inhibition of neighbouring muscles. In healthy musicians, however, vibratory input resulted in a suppressed short-latency intracortical inhibition only of those neighbouring muscles functionally connected with the vibrated muscles. In patients with writer's cramp, short-latency intracortical inhibition of neighbouring muscles was unchanged. It was concluded that the pathophysiology of musician's dystonia differs from that of writer's cramp. Furthermore, it was hypothesized that long hours of practising complex movements first produce the modulation of

sensorimotor interaction seen in healthy musicians, and that this later progresses into the non-focal pattern of short-latency intracortical inhibition in musician's dystonia (Rosenkranz *et al.* 2005).

The findings of an increased workload and complexity of movements as well as increased spatial and temporal sensorimotor requirements being related to musician's dystonia are in agreement with the hypothesis of a pathomechanism which includes practice-induced alterations. A higher workload in affected musicians might additionally be reflected by the observation of a more perfectionist attitude in dystonic musicians—even before onset of dystonia—compared with other musicians (Jabusch *et al.* 2004*a*) and by the finding of a preponderance of soloists (51%) in our sample of dystonic musicians. A perfectionist attitude as well as an outstanding professional position might point at a different and more intense working behaviour resulting in a higher workload in those musicians who develop focal dystonia.

Local pain and intensified sensory input for various reasons like nerve entrapment or trauma or overuse have been described as potential triggers of dystonia (Jankovic and Shale 1989; Lederman 1991; Charness *et al.* 1996; Altenmüller 2003). The parallels of abnormal cortical processing of sensory information and cortical reorganization in patients with focal dystonia and those with chronic pain have already been reported (Flor *et al.* 1997; Tinazzi *et al.* 2000; Jabusch *et al.* 2004*a*). Local pain preceded focal dystonia in 9% of the patients in the present study.

Possible interaction between predisposition and extrinsic and intrinsic factors

In view of the neurophysiological, epidemiological, and psychological findings in musicians with focal dystonia, predisposing factors have been described, such as male gender (Lederman 1991; Altenmüller 2003; Lim and Altenmüller 2003) as well as a positive family history (Jankovic and Shale 1989; Altenmüller 2003; Lim and Altenmüller 2003) which might constitute a particular vulnerability or susceptibility to musician's dystonia. Additional extrinsic and intrinsic factors may trigger the manifestation of musician's dystonia on the basis of a given susceptibility. Intrinsic triggering factors are physical disorders resulting in local pain and/or intensified somatosensory input (trauma, nerve entrapment, overuse injury) (Lederman 1991; Charness *et al.* 1996; Altenmüller 2003) as well as psychological conditions such as perfectionism and anxiety which were found to be related to musician's dystonia (Jabusch *et al.* 2004*a*). According to Rosenkranz *et al.* (2005), intracortical disinhibition in musician's dystonia might be an acquired, practice-induced phenomenon. Extrinsic triggering

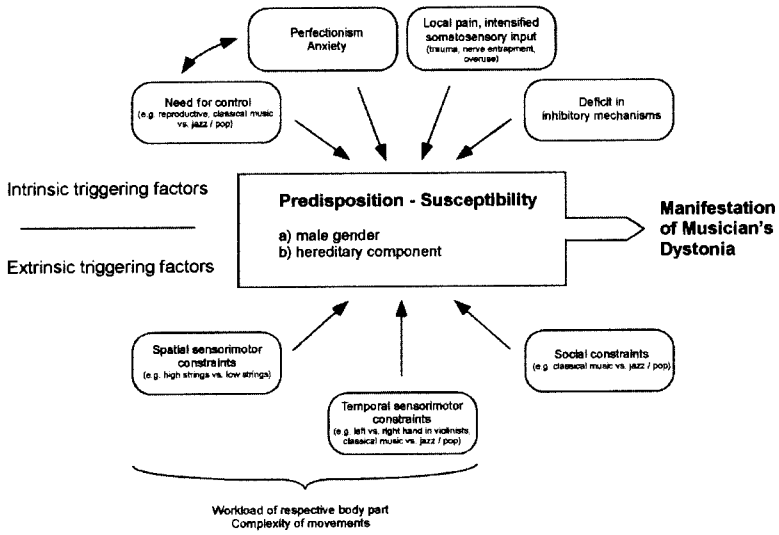

Fig. 17.4 The possible interaction between predisposition and intrinsic and extrinsic triggering factors in the manifestation of musician's dystonia. Further explanations are given in the text.

factors, according to epidemiological findings (Tubiana and Chamagne 2000; Brandfonbrener and Robson 2002; Schuele and Lederman 2004), are spatial and temporal sensorimotor constraints as well as musical and social constraints typical of the performance situation in classical music. The possible interaction between predisposition and intrinsic and extrinsic triggering factors in the manifestation of musician's dystonia is displayed in Fig. 17.4.

Treatment strategies and results

For a survey of treatment results, 160 consecutive professional musicians and music students with musician's dystonia were recruited (Jabusch *et al.* 2005). Treatment strategies included: medication with trihexyphenidyl; injection therapy with botulinum toxin; ergonomic changes; pedagogical retraining; non-specific exercises on the instrument. Outcome data were assessed using a standardized questionnaire which was mailed to patients. Those patients who did not respond were contacted by phone, and a standardized interview was conducted using the questionnaire. Patients were asked to estimate (1) the cumulative treatment response on a four-step scale (free of symptoms, improved, no change, deteriorated); (2) the treatment response to individual therapies (improvement, no effect, deterioration). They were asked about (3) the nature and duration of therapies not applied by the authors (e.g. exercises on the instrument) and (4) their musical activity and professional situation at that time.

Outcome data for the aforementioned 144 patients could be obtained. Data were analysed using χ^2-tests for outcome measures and multiple regression analyses for predictability of treatment responses. Percentage rates were calculated based on the total number of available answers.

Long-term outcome

The mean age at the time of the completion of the questionnaire was 42 years (range 23–69 years). Outcome was revealed on average 8.4 years after onset of dystonic symptoms (range 1–30 years) and 3.4 years after the initial visit (range 1–8 years). At the time of the survey, two patients (1%) were free of symptoms, 75 patients (52%) reported an alleviation of symptoms as compared with the time of their first visit, 50 patients (35%) did not notice any changes and 16 patients (11%) reported a deterioration. Regardless of treatment, a smaller fraction of patients with embouchure dystonia showed an improvement (3 of 20 patients) compared with those with limb dystonia (62 of 123 patients; $\chi^2 = 8.7$, d.f. $= 1$, $P < 0.01$). A change of profession was reported by 35 patients (29%). A larger fraction of music students changed their profession (12 of 21 patients, 57%) compared with those who were already in their professional careers at onset of symptoms (23 of 100 patients; $\chi^2 = 9.84$, d.f. $= 1$, $P < 0.01$) (Jabusch *et al.* 2005).

Trihexyphenidyl

Trihexyphenidyl was given to patients with all kinds of musician's cramps when no contraindication was present. Trihexyphenidyl was administered beginning with 1 mg/day, and the dosage was slowly increased until therapeutic effects were observed. Adjustment of the dosage was made depending on beneficial effects and side-effects. Patients with side-effects and no improvement of symptoms were withdrawn from trihexyphenidyl treatment.

Trihexyphenidyl was applied in 69 patients (48% of all) with an average maximum dosage of 11 mg/day (range 1–30 mg/day). Within 2 months the medication was interrupted in 20 patients due to side-effects or unsatisfactory treatment response. The other 49 patients (34% of all) received trihexyphenidyl on average for 16 months (range 3–67 months). The most frequent side-effects were dry mouth (29 patients; 42% of patients receiving trihexyphenidyl), tiredness (15 patients; 22%), dizziness (13 patients; 19%), agitation (10 patients; 14%), memory impairment (8 patients; 12%), drowsiness (7 patients; 10%), depression (7 patients; 10%), loss of concentration (5 patients; 7%), nausea (4 patients; 6%), hyperkinesia (3 patients; 4%), impaired visual accommodation (2 patients; 3%), and tremor (2 patients; 3%). The average minimum dosage at which side-effects occurred was 9 mg/day (range 1–20 mg/day). Due to

side-effects, 16 patients (23%) were withdrawn from trihexyphenidyl. Side-effects were not related to age or gender. After trihexyphenidyl, an improvement was reported by a total of 23 patients (33%) and by 19 patients with limb dystonia who received trihexyphenidyl for more than 2 months (42% of these; average duration 26 months). Patients' rating of treatment results is displayed in Fig. 17.5. None of five patients with embouchure dystonia showed an improvement after trihexyphenidyl. The occurrence of side-effects was not significantly different in patients who reported an improvement after trihexyphenidyl (side-effects present in 22 out of 23 patients) than in patients with no improvement (side-effects present in 32 out of 44 patients). The average maximum dosage of trihexyphenidyl was 11 mg/day (range 4–30 mg/day) in patients who had an improvement and 11 mg/day (range 1–20 mg/day) in patients with no improvement. Multiple regression analysis revealed a model predicting 49% of the variance of patients' rating of trihexyphenidyl effects (R-square = 0.52; R-square adjusted = 0.49). The following variables predicted a positive rating: limb localization of dystonia (versus embouchure dystonia: $\beta = 0.59$; d.f. = 1; $F = 37$; $P < 0.001$), a high maximum dosage of trihexyphenidyl ($\beta = 0.28$; d.f. = 1; $F = 6.8$; $P = 0.01$), a low number of concomitant treatments ($\beta = -0.35$; d.f. = 1; $F = 11$; $P < 0.01$). The variables age, gender, localized versus non-localized dystonia (localized dystonia affecting one or two fingers versus non-localized dystonia), type of dystonia (flexion/extension/embouchure), task specificity at first visit, and duration of dystonia were not sufficient predictors of the rating of the effects of trihexyphenidyl.

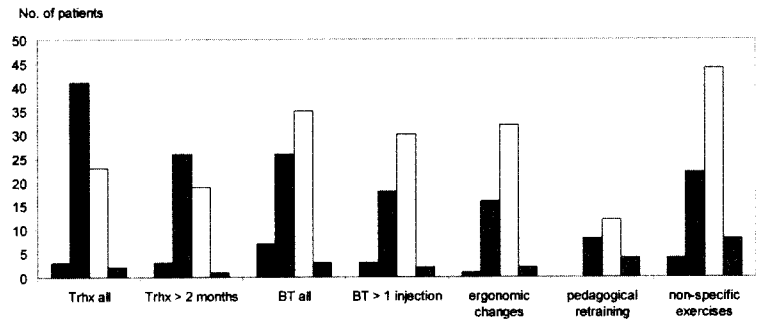

Fig.17.5 Patients' rating of treatment results: black bars, deterioration of dystonic symptoms; grey bars, no change in dystonic symptoms; white bars, alleviation of dystonic symptoms; hatched bars, no answer. Trihexyphenidyl (Trhx): results are given separately for all patients who received Trhx versus for those who received Trhx for more than 2 months. Botulinum toxin (BT): results are given separately for all patients who received BT versus for those who received more than one injection. (From Jabusch *et al.* 2005.)

side-effects, 16 patients (23%) were withdrawn from trihexyphenidyl. Side-effects were not related to age or gender. After trihexyphenidyl, an improvement was reported by a total of 23 patients (33%) and by 19 patients with limb dystonia who received trihexyphenidyl for more than 2 months (42% of these; average duration 26 months). Patients' rating of treatment results is displayed in Fig. 17.5. None of five patients with embouchure dystonia showed an improvement after trihexyphenidyl. The occurrence of side-effects was not significantly different in patients who reported an improvement after trihexyphenidyl (side-effects present in 22 out of 23 patients) than in patients with no improvement (side-effects present in 32 out of 44 patients). The average maximum dosage of trihexyphenidyl was 11 mg/day (range 4–30 mg/day) in patients who had an improvement and 11 mg/day (range 1–20 mg/day) in patients with no improvement. Multiple regression analysis revealed a model predicting 49% of the variance of patients' rating of trihexyphenidyl effects (R-square = 0.52; R-square adjusted = 0.49). The following variables predicted a positive rating: limb localization of dystonia (versus embouchure dystonia: $\beta = 0.59$; d.f. = 1; $F = 37$; $P < 0.001$), a high maximum dosage of trihexyphenidyl ($\beta = 0.28$; d.f. = 1; $F = 6.8$; $P = 0.01$), a low number of concomitant treatments ($\beta = -0.35$; d.f. = 1; $F = 11$; $P < 0.01$). The variables age, gender, localized versus non-localized dystonia (localized dystonia affecting one or two fingers versus non-localized dystonia), type of dystonia (flexion/extension/embouchure), task specificity at first visit, and duration of dystonia were not sufficient predictors of the rating of the effects of trihexyphenidyl.

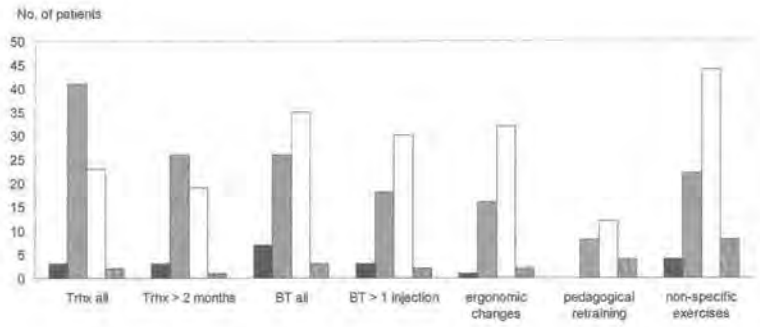

Fig.17.5 Patients' rating of treatment results: black bars, deterioration of dystonic symptoms; grey bars, no change in dystonic symptoms; white bars, alleviation of dystonic symptoms; hatched bars, no answer. Trihexyphenidyl (Trhx): results are given separately for all patients who received Trhx versus for those who received Trhx for more than 2 months. Botulinum toxin (BT): results are given separately for all patients who received BT versus for those who received more than one injection. (From Jabusch *et al.* 2005.)

A limb localization of dystonia, a high maximum dosage, and a low number of concomitant treatments were found to predict a positive outcome of treatment with trihexyphenidyl. The low number of concomitant treatments may be a consequence of a successful treatment with trihexyphenidyl in some patients which limits its value as a predictor variable. A high maximum dosage was a sufficient, but not necessary, condition for an improvement. One patient who tolerated a maximum dosage of 30 mg/day had an improvement, but in other patients an improvement was seen after low dosages. However, there was no patient with high maximum dosages in the group of non-responders to trihexyphenidyl. There was no difference in the occurrence of side-effects between responders and non-responders. All patients with embouchure dystonias were non-responders. As a conclusion, a treatment attempt with trihexyphenidyl appears to be an option for musicians with limb dystonia when no contraindications are present (Jabusch *et al.* 2005).

Botulinum toxin

Botulinum toxin A (BT) injections were recommended only to those patients in whom primary dystonic movements could be clearly distinguished from secondary compensatory movements. A lyophilized botulinum toxin A powder (Dysport®, Ipsen Ltd, Berkshire, UK) was injected using an electromyographic (EMG)-guided technique (Karp *et al.* 1994; Schuele *et al.* 2005). Target muscles were identified by visual inspection of the dystonic movements while patients were playing their instruments. In patients with flexion or extension dystonia of individual fingers, injections in the forearm muscles were preferred. Additional injections in the hand muscles were performed in patients with dystonic flexion in the metacarpophalangeal (MCP) joints and an extension component in the proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints.

Botulinum toxin injections were applied in 71 patients (49%), three of whom had embouchure dystonia. Eighteen patients had only one injection due to unsatisfactory treatment results. Five patients who reported an improvement were not satisfied enough to continue BT treatment. Fifty-three patients (37%) received more than one injection (average 5.7 injections per patient, range 2–25) with an average treatment duration of 16 months (range 1–58 months) and an average interval of 4.2 months (range 1–22 months) between treatment sessions. The average dosage per treatment session was 128 units (range 9–428). The most injected muscles were the flexor digitorum superficialis and the flexor digitorum profundus (50 patients each; 70% of patients treated with BT), followed by the flexor carpi radialis (13 patients; 18%), the flexor pollicis longus, the extensor digitorum and the extensor indicis (7 patients each; 10%), and the interosseus palmaris (5 patients; 7%). The average dosage per muscle group was 112 units

(range 88–150) in the upper arm and shoulder muscles, 38 units (range 5–85) in forearm extensors, 65 units (range 10–175) in forearm flexors, and 26 units (range 5–84) in hand muscles. After BT, an improvement was reported by 35 patients (49%) and by 30 patients who received more than one injection (57% of these; average duration 26 months). Of the latter group, 21 of 33 patients with injections given only in the forearm muscles reported an improvement (64%), and 7 of 13 patients with injections in the forearm muscles and hand muscles (54%) had an improvement: two out of two keyboard players, two of four woodwind players, and three of four guitarists with the right hand affected. No improvement was seen in the affected left hands of one guitarist and two string players after injections in the forearm muscles and hand muscles. Neither of two patients with injections in the upper arm/shoulder muscles experienced an improvement and none of three patients with embouchure dystonia experienced an improvement after BT. Multiple regression analysis did not reveal any of the following variables as predictors of outcome after BT: gender, age, duration of dystonia, localized versus non-localized dystonia, type of dystonia, target muscles, mean BT dosage, task specificity at first visit, number of concomitant treatments. Positive rating of BT effects was correlated to the number of BT treatment sessions (Spearman $r = 0.37$, $P < 0.01$) and the duration of BT treatment (Spearman $r = 0.56$, $P < 0.01$).

According to these results, BT treatment was successful in those patients in whom primary dystonic movements could be clearly distinguished from secondary compensatory movements. This was difficult when compensatory movements were more pronounced than primary dystonic movements. The best outcome was reported after injections in the forearm muscles. Additional injections in hand muscles were useful in patients with a dystonic flexion in the MCP joints and an extension component in the PIP and DIP joints. Botulinum toxin injections in hand muscles appear to be recommendable only in instrumentalists with little lateral finger motion such as in woodwind players and guitarists (right hand). Keyboard players may benefit from this option when they avoid repertoire requiring a wide hand span and extreme lateral finger motion. Botulinum toxin injections in hand muscles were not successful in musicians who needed to perform lateral finger movements such as in the left hands of one guitarist and of two string players. Musicians with embouchure dystonia and with dystonia affecting the upper arm and shoulder muscles did not benefit from BT treatment (Jabusch *et al.* 2005).

Ergonomic changes

Ergonomic changes were recommended whenever applicable. The aim of ergonomic changes was either a blocking of dystonic movements, for example by

attaching splints to the affected fingers, or circumvention of dystonic movements. This was achieved by modifications of the instrument, e.g. the repositioning of individual keys in woodwind instruments or the replacement of ring keys by plateau keys (Altenmüller 2003). Support systems (belts, stands, tripods) were recommended when the dystonic hand had to carry the instrument while playing such as in oboe, clarinet, and bassoon players. Ergonomic changes were made in 51 patients (35% of all), 32 patients (63% of these) experienced improvement and used the ergonomic changes for an average of 35 months (range 3–125 months). Two patients with embouchure dystonia used an ergonomic aid and reported no improvement. As a conclusion, ergonomic changes should be considered in all patients with limb dystonia. They are not helpful in embouchure dystonia (Jabusch *et al.* 2005).

Pedagogical retraining and unspecific exercises

Pedagogical retraining was applied in patients with all forms of musician's dystonia. They comprised a variety of behavioural approaches used under the supervision of instructors and they included elements based on the following principles reported previously (Byl and McKenzie 2000; Boullet 2002; Candia *et al.* 2003; see also Chapter 19):

1. Movements of affected body parts were limited to a level of tempo and force at which the dystonic movement would not occur.
2. Compensatory movements (e.g. of adjacent fingers) were avoided, partially under the application of splints.
3. Instant visual feedback with mirrors or monitors helped patients to recognize dystonic and non-dystonic movements.
4. Body awareness techniques (e.g. Feldenkrais®) were used to increase the patient's perception of non-dystonic movements.

Pedagogical retraining was given in 24 patients (17% of all), 12 patients (50% of these) experienced improvement. Patients reporting an improvement had undergone this treatment for an average of 28 months (range 3–72months). Two patients with embouchure dystonia took part in pedagogical retraining and reported no improvement.

Besides the reported therapies recommended by the authors, patients additionally or alternatively performed unspecific technical exercises on their instruments such as are usually practiced by instrumentalists to improve their technique. Seventy-eight patients (54% of all) were practising such unspecific technical exercises, 44 patients (56% of these) experienced improvement. Six out of 11 patients with embouchure dystonia reported an improvement after practising such exercises (Jabusch *et al.* 2005).

These results provide evidence for the benefit of a behavioural approach, either by pedagogical retraining or by exercises on the instrument. Pedagogical retraining was applied in patients with all forms of musician's dystonia; however, only patients with limb dystonia improved. More than half of the patients who were practising unspecific exercises reported improvement, among them were six out of 11 patients with embouchure dystonia who applied such exercises. It is noteworthy that the results of these exercises were rated better than those of medical therapies. These positive results may be biased by a particular attitude among musicians and the perceived self-control through exercises. On the other hand positive results of retraining and of exercises underline the benefit of active involvement of patients in the treatment process. At present, the existing behavioural approaches are heterogeneous (Byl and McKenzie 2000; Boullet 2002; Candia *et al.* 2003). Instrument-specific retraining programmes ought to be elaborated which include the aforementioned principles. All approaches to retraining therapy require the time and patience of affected musicians which seem to be the limiting factors with these therapies. Behavioural aspects, however, should be included in all treatment approaches, at least as an adjunct.

Findings in the light of the literature

In the overall outcome which was recorded on average 8.4 years after onset of symptoms, 71% of patients managed to stay in the musical profession. In other studies, focal dystonia had led to the end of their musical career in more than half of the patients (Schuele and Lederman 2003, 2004). Outcome measures were conducted 13.8 years (string instrumentalists) (Schuele and Lederman 2004) and 8.5 years (woodwind players) (Schuele and Lederman 2004) after onset of symptoms in these reports. The shorter duration of dystonia might be an explanation for the better outcome of our patients group compared with the report on the string players. In the study on woodwind players, the percentage of patients with embouchure dystonia was 25%; in our group it was 13.9%. The generally worse outcome in embouchure dystonia might explain the different outcome after similar durations of dystonia in both studies. In another report 17 out of 33 musicians with focal dystonia had stopped playing at the end of the follow-up period (Brandfonbrener and Robson 2002). The duration of dystonia and total follow-up time were, however, not mentioned, which did not allow a direct comparison. This was also the case in a report on 145 musicians with an average rehabilitation time of 24 months, after which 35 musicians returned to playing in public (Tubiana and Chamagne 2000).

Instrumental students

The subgroup of instrumental students deserve some additional considerations. Focal dystonia is regarded as incurable at present. Although there are some

patients with encouraging follow-up results, therapy remains difficult and requires years and sometimes decades of patience, effort, and stress. Most patients who are at the zenith of their career have no choice and have to undergo treatment in order to improve their situation. Instrumental students, on the contrary, are young and flexible enough to change their profession. In our group, 12 out of 21 affected students changed their profession during the follow-up period. According to our impression, the results of therapy do not justify keeping students busy with treatment attempts over years in the most flexible and productive period of their lives. We conclude that strategies for students with musician's dystonia should include early support for a change to another profession.

Limitations

Beside of the reported inclusion/exclusion criteria, the choice of treatment was strongly influenced by preferences of patients. The time investment required appeared to influence the choice of treatment. Older patients who desired a quick improvement preferred BT injections. In contrast, several patients found the injection therapy 'unnatural' and preferred a retraining therapy. A major limitation of the study was the lack of objective assessment tools for musician's dystonia which were not available at the beginning of the follow-up. Recently, reliable and precise objective methods have been developed for quantification of musician's dystonia (Jabusch and Altenmüller 2004; Jabusch *et al.* 2004*b*). In future studies such methods will have to be applied for reliable monitoring of treatment effects. Although we were limited in our assessment to a retrospective and subjective rating, several factors may support the validity of our result. Consistent negative results reported by patients with embouchure dystonia after treatment with BT, trihexyphenidyl, and retraining seem to indicate a low placebo sensitivity of musician's dystonia. Most previous studies observed that a significant number of musicians discontinued treatment within a year if they felt the response did not meet their needs. The adherence seen in our study, with an average treatment duration in responders between 2 and 3 years (and up to 10 years), seems unlikely if the result did not improve their instrumental performance significantly.

Conclusion

Focal dystonia in musicians is still the main challenge in the field of musicians' medicine. With the available therapies the majority of patients manage to stay in their profession, many of them, however, with substantial compromises. Therapy of patients with embouchure dystonia remains problematic. The available medical approaches are ineffective, and other options have yet to be developed.

There is a pressing need for novel therapies for musician's dystonia. Several new methods have been described, such as immobilization therapy (Priori *et al.* 2001; see Chapter 19). These have to be investigated in larger numbers of patients in order to confirm beneficial effects. Behavioural therapies and interdisciplinary strategies combining pharmacological and pedagogical methods are promising, but the different approaches need to be evaluated. Since phenomenological and epidemiological data and results from electrophysiological and follow-up studies imply a behavioural component in the development as well as in the treatment of musician's dystonia, future research is required to identify 'beneficial behaviour' on the instrument. This might, possibly, also be of help for finding strategies with the particular aim of prevention of musician's dystonia.

Acknowledgement

We would like to express our appreciation to Werner Linge, Director of Administration of the German Orchestra Union, for providing us with the March 2004 statistics on members of the German Orchestra Union.

Chapter 18

The neurophysiology of focal hand dystonia in musicians

Karin Rosenkranz

Introduction

The classification of musician's dystonia as a form of focal hand dystonia is based on the fact that involuntary abnormal contractions appear that are fairly similar to those observed, for example, in writer's cramp. But compared with the latter there are differences in clinical features that are especially characteristic of musician's dystonia:

1. Musician's dystonia is often highly task specific and highly focal, for example a pianist experiences 'curling in' of the fourth finger while playing scales downwards but not upwards.
2. The age of onset of musician's dystonia is earlier than in writer's cramp—33 years for musician's dystonia (see Chapter 17) versus 38.5 years in writer's cramp (O'Riordan *et al.* 2004).
3. The prevalence of musician's dystonia amongst professional musicians is higher than that of writer's cramp in the general population (Lim *et al.* 2001).
4. The consequences of being affected by focal hand dystonia are, for musicians, often more devastating.

Another distinguishing factor is the clear association of musician's dystonia with excessive practise of complex hand (or mouth) movements. Whereas most patients with other forms of focal hand dystonia, such as writer's cramp, have no history of excessive hand use above that seen in the general population, in musician's dystonia it is often the movements that are practised most that are those where the dystonic symptoms manifest.

As outlined in Chapter 9, there are structural and functional changes in the brains of healthy musicians that have been interpreted as a beneficial adaptation to musical training supporting the development of a unique capacity for skilful performance (Amunts *et al.* 1997; Bangert *et al.* 2001; Münte *et al.* 2002). The interesting question is whether or not practise of a movement and the plastic changes in the brain play an important role in the pathophysiology of musician's

dystonia, therefore distinguishing it from other forms of focal hand dystonia. Over the last decades many studies of focal hand dystonia have been undertaken which have increased our understanding of this condition. However, many studies focused on focal/segmental upper limb dystonia and there is very little information specifically on patients with musician's dystonia.

The intention of this chapter is to give an overview of the neurophysiology of focal hand dystonia in musicians. So as not to miss out on important findings that certainly apply to all forms, several studies done in a more 'general' population of patients with focal hand dystonia are presented. At the end of this chapter we present the results of our own study describing neurophysiological differences between writer's cramp and musician's dystonia and discuss the implications of these findings for the pathophysiology of these two forms of focal hand dystonia. This might be the first step towards an answer to the above question.

Pathophysiology of focal hand dystonia

Most studies of focal hand dystonia reveal abnormalities in three main areas: (1) reduced excitability of inhibitory connections at all levels (spinal, brainstem, and cortical) of the motor system; (2) reduced sensory perception and integration; and (3) impaired sensorimotor organization/integration. However, it should be noted that although each of these alone could potentially be the cause of dystonic contractions—i.e. reduced inhibition could lead to co-contraction of antagonist muscles and overflow of activity to muscle not involved in a task; impaired sensory and sensorimotor integration could lead to poor selection of movement parameters and excess muscle contraction—none are in fact a necessary cause of dystonia. Thus, similar abnormalities are often observed in the unaffected arm if the clinical symptoms are unilateral (Deuschl *et al.* 1991; Ridding *et al.* 1995; Meunier *et al.* 2001). Our hypothesis is that some combination of these factors seems to be necessary for clinical symptoms and the amount of reorganization that is necessary depends on the individual level of abnormalities in inhibitory circuits and in sensorimotor integration.

Excitability of spinal, brainstem, and cortical inhibitory circuits

This has been summarized in the review by Berardelli *et al.* (1998). In brief, spinal inhibition can be probed by testing the excitability of the reciprocal inhibitory circuits between extensor and flexor muscles in the forearm (Nakashima *et al.* 1989; Panizza *et al.* 1989; Chen *et al.* 1995). Brainstem inhibition is tested by examining the recovery curve of the electrically elicited blink reflex (Berardelli *et al.* 1985), and motor cortical inhibition is tested by measuring the duration of

the silent period following a transcranial magnetic stimulation (TMS) pulse (Rona *et al.* 1998). In almost all cases there is less inhibition in patients with dystonia than in healthy controls.

However, two recent studies testing intracortical inhibition using a paired-pulse TMS protocol have shown that in patients with action-induced and task-specific dystonia, who were able to keep their arm completely relaxed during the experiment, the level of intracortical inhibition is normal (Stinear and Byblow 2004; Rosenkranz *et al.* 2005).

More recent studies have examined the time course of excitability in cortical inhibitory systems prior to focal hand movements. The intracortical inhibitory circuits targeted by short-interval paired-pulse TMS decrease the excitability of their projections to the prime moving muscle whereas excitability increases in those that project to nearby muscles that must stay relaxed during the task (Reynolds and Ashby 1999). This is compatible with an organization in which inhibition is normally withdrawn from the focal target muscle and at the same time is increased in muscles that are not involved in the task. Patients with focal dystonia have a deficit in this focusing mechanism (Stinear and Byblow 2004).

Sensory perception, integration, and mapping

Temporal and spatial discrimination, being the ability to perceive two stimuli as temporally or spatially separate, are impaired in patients with generalized dystonia (Tinazzi *et al.* 1999) and focal hand dystonia (Bara Jimenez *et al.* 2000*a*,*b*; Sanger *et al.* 2001). A recent study compared spatial sensory discrimination abilities in patients with primary generalized DYT1 dystonia and other forms of dystonia, especially focal hand dystonia. Interestingly, only the group with focal hand dystonia showed an increased spatial discrimination threshold, pronounced in the dominant hand, whereas no abnormalities of spatial discrimination were found in DYT1 cases (Molloy *et al.* 2003). This finding suggests that altered sensory processing might play a different pathophysiological role in these conditions.

Electrical stimulation of either ulnar or median nerves at the wrist gives rise to SEPs in the sensory cortex. If both nerves are stimulated together, then the SEP is smaller than the expected combined sum of each alone. Tinazzi *et al.* (2000) suggested that this might be due to lateral inhibition between inputs from each source, which might under normal circumstances focus their central effects within the brain. This effect was reduced in patients with focal hand dystonia (Tinazzi *et al.* 2000). As this paradigm gives an indication of a sensory 'between-field' or surround-inhibition, the recovery of SEPs in response to paired median nerve stimuli is an indicator for the 'in-field' inhibition. Frasson *et al.* (2001) showed that this 'in-field' suppression was reduced in dystonia patients.

Mapping studies of the sensory cortex using SEP/magnetoencephalographic (MEG) techniques found that the locus of sensory inputs from individual fingers overlap more in patients with focal hand dystonia than in healthy controls (Bara Jimenez *et al.*1998; McKenzie *et al.* 2003). Similar observations have been made in patients with musician's dystonia in a selective study using MEG mapping. Elbert *et al.* (1998) showed that there is an overlap of the representational zones of the digits in the primary somatosensory cortex for the affected hand of dystonic musicians compared with the representations of the digits in non-musician control subjects. In healthy musicians, an increase in sensory finger representations has been described and interpreted as changes to conform to the current needs and experiences of the individual (Elbert *et al.* 1995). The question arising here is whether these changes develop too far in musician's dystonia, from being beneficial to a being a maladaptation.

However, these mapping studies done at rest might have to be interpreted with care. Braun *et al.* (2003) investigated dynamic alterations in the functional organization of the primary somatosensory cortex (SI) during writing in patients with writer's cramp and healthy controls with neuromagnetic source imaging. Similar to the studies cited above, they found a reduced distance between cortical representations of the thumb and little finger of the affected hand in patients when tested at rest. However, similar to healthy controls, patients showed normal modulation of the functional organization of SI as induced by writing: the cortical distances between representations of the thumb and little finger increased. Thus, despite alterations in the organization of the primary somatosensory cortex in writer's cramp, the capability of SI to adapt dynamically to different tasks is, astonishingly, not impaired (Braun *et al.* 2003).

Interaction of sensory input and motor output

Under normal conditions, motor outflow from the cortex 'gates' sensory input from the moving part of the body. This 'gating' starts before the onset of motion (Shimazu *et al.* 1999). Murase *et al.* (2000) tested SEPs to median nerve stimulation during preparation for and execution of movement in patients with writer's cramp. Differences were found between healthy subjects and sufferers from writer's cramp, especially in the frontal N30, a component that is thought to be generated by sequential processing of sensory input after arrival at the primary somatosensory cortex. Whereas during the pre-movement phase healthy subjects showed a significant frontal decrease of the amplitude of the N30, writer's cramp patients did not. However, during active and passive movements the N30 component was equally attenuated in writer's cramp and healthy controls. During the preparatory period of a movement the sensitivity of cells that respond to afferent input might be altered to allow an undisturbed starting of the

actual movement. This process may be compromised in writer's cramp and contribute to a failure of the motor program before it has even been properly started.

Other authors investigated the integration of sensory inputs and motor outputs with a variety of protocols that use TMS to probe the excitability of the motor cortex. Tamburin *et al.* (2001) showed in healthy subjects that sensory input from one finger has a particular time course of effects on the amplitude of MEPs evoked in hand muscles by the TMS pulse. In addition, the effects are usually spatially segregated, at least to some extent, with the effects being greatest on muscles near the stimulated finger and least on those further away. Both the time course and the spatial specificity are abnormal in dystonia (Tamburin *et al.* 2002). In a similarly designed study, this time using electrical median nerve stimulation, Abbruzzese *et al.* (2001) examined healthy subjects as well as patients with hand cramps, two of them musicians, and patients with torticollis. In healthy subjects the amplitude of the motor-evoked-potential (MEP) in the hand muscles is reduced by preceding peripheral stimulation. This was the case for torticollis patients too. But the patients with hand cramps showed a facilitation of MEPs instead of an inhibition. Thus, the central integration of sensory input evoked from the site of manifestation of symptoms seems to be specifically defective.

Pathophysiological observations in musician's dystonia

In a recent study we compared the sensorimotor organization of the hand in healthy non-musicians, healthy professional musicians in training, and in two groups of patients with musician's dystonia or with writer's cramp (Rosenkranz *et al.* 2005). The protocol employed focal vibration of a single hand muscle to evoke proprioceptive input from the activation of muscle spindles and TMS of the motor cortex to evoke MEPs in three different hand muscles (first dorsal interosseus (FDI), abductor pollicis brevis (APB), and adductor digiti minimi (ADM)) (Rosenkranz and Rothwell 2003). We tested how MEPs and paired-pulse (short interval) intracortical inhibition (SICI) in each muscle was modulated when vibration was applied to each muscle in turn. In healthy non-musicians vibration of one muscle increased the amplitude of MEPs and decreased SICI in the vibrated muscle, whilst having the opposite effect on the non-vibrated hand muscles (Fig. 18.1). This pattern of sensorimotor interaction probably reflects an interaction of the sensory input with intracortical inhibitory circuits in or near to the motor cortical representations of the hand muscles.

Previously we showed that in healthy non-musicians the spatial pattern of interaction between sensory input and motor output could be changed by a prolonged period of sensory stimulation (Rosenkranz and Rothwell 2004). Thus,

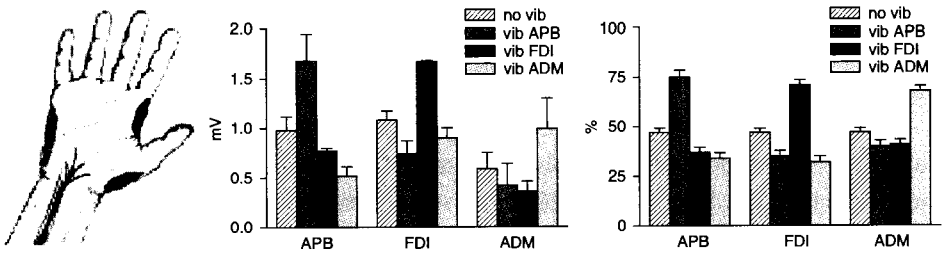

Fig. 18.1 Schematic illustration of the protocol used to test sensorimotor interactions in small hand muscles. EMG recordings are made from three different muscles (APB, ADM, FDI) and low-amplitude vibration is applied to each of them in turn for a period of 1.5 s. The vibration amplitude is such that no tonic vibration reflex is evoked, nor any perceptions of illusory movement. Transcranial magnetic stimulation is applied to the contralateral cortex to evoke MEP in the hand 1 s after onset of vibration. The bar plots on the left show the motor-evoked potentials (MEPs) in each of these hand muscles without vibration, during vibration of APB, during vibration of FDI, and during vibration of ADM. In the vibrated muscle, MEPs are increased and decreased in the non-vibrated muscles. In other trials, short interval intracortical inhibition (SICI) is estimated by using a paired-pulse TMS protocol (Kujirai *et al.* 1993). This decreases the size of the control MEP by about 50%. The bar plots on the right show the results when SICI is evaluated during vibration: it is reduced to about 75% in the vibrated muscle and increased to around 25% in the other muscles (Rosenkranz *et al.* 2005).

15-min continuous vibration of both the APB and FDI muscles led to a situation in which subsequent input from FDI had the same, rather than the opposite, effect on APB. Similarly, after the intervention, input from APB began to facilitate FDI. As expected from previous work in animal experiments, the effects did not occur if the subject did not focus their attention on the input during the prolonged period of vibration. Our conclusion was that a period of training with changed sensory inputs can alter the usual pattern of sensorimotor interaction in the cortex.

In the experiments with musicians we found that in healthy musicians the pattern of sensory–motor interaction was similar to what we had observed in non-musicians after a 15-min sensory intervention (Rosenkranz *et al.* 2005). This would be consistent with the idea that prolonged practice in the musicians had led to a permanent reorganization in the way in which sensory input from individual fingers interacts with motor output. We speculated that this might be advantageous in that it would favour cooperation between finger movements in rapid sequences of movements.

When we examined the patients with musician's dystonia, we observed a pattern that was even further removed from normal (Fig. 18.2): input from any of the three hand muscles facilitated all the other three hand muscles, as if the pattern of spatial organization in healthy musicians had been extended until it led to a situation in which there was no distinction between inputs from any of

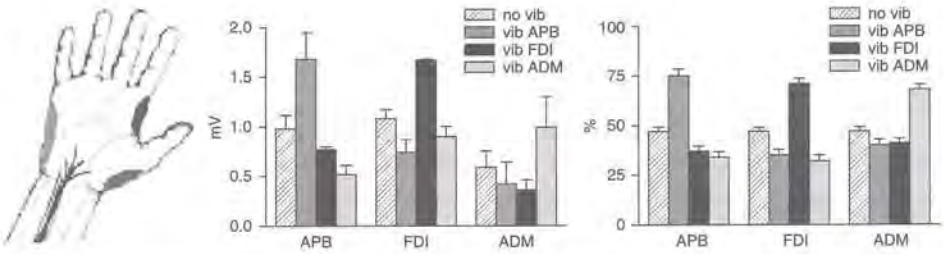

Fig. 18.1 Schematic illustration of the protocol used to test sensorimotor interactions in small hand muscles. EMG recordings are made from three different muscles (APB, ADM, FDI) and low-amplitude vibration is applied to each of them in turn for a period of 1.5 s. The vibration amplitude is such that no tonic vibration reflex is evoked, nor any perceptions of illusory movement. Transcranial magnetic stimulation is applied to the contralateral cortex to evoke MEP in the hand 1 s after onset of vibration. The bar plots on the left show the motor-evoked potentials (MEPs) in each of these hand muscles without vibration, during vibration of APB, during vibration of FDI, and during vibration of ADM. In the vibrated muscle, MEPs are increased and decreased in the non-vibrated muscles. In other trials, short interval intracortical inhibition (SICI) is estimated by using a paired-pulse TMS protocol (Kujirai *et al.* 1993). This decreases the size of the control MEP by about 50%. The bar plots on the right show the results when SICI is evaluated during vibration: it is reduced to about 75% in the vibrated muscle and increased to around 25% in the other muscles (Rosenkranz *et al.* 2005).

15-min continuous vibration of both the APB and FDI muscles led to a situation in which subsequent input from FDI had the same, rather than the opposite, effect on APB. Similarly, after the intervention, input from APB began to facilitate FDI. As expected from previous work in animal experiments, the effects did not occur if the subject did not focus their attention on the input during the prolonged period of vibration. Our conclusion was that a period of training with changed sensory inputs can alter the usual pattern of sensorimotor interaction in the cortex.

In the experiments with musicians we found that in healthy musicians the pattern of sensory–motor interaction was similar to what we had observed in non-musicians after a 15-min sensory intervention (Rosenkranz *et al.* 2005). This would be consistent with the idea that prolonged practice in the musicians had led to a permanent reorganization in the way in which sensory input from individual fingers interacts with motor output. We speculated that this might be advantageous in that it would favour cooperation between finger movements in rapid sequences of movements.

When we examined the patients with musician's dystonia, we observed a pattern that was even further removed from normal (Fig. 18.2): input from any of the three hand muscles facilitated all the other three hand muscles, as if the pattern of spatial organization in healthy musicians had been extended until it led to a situation in which there was no distinction between inputs from any of

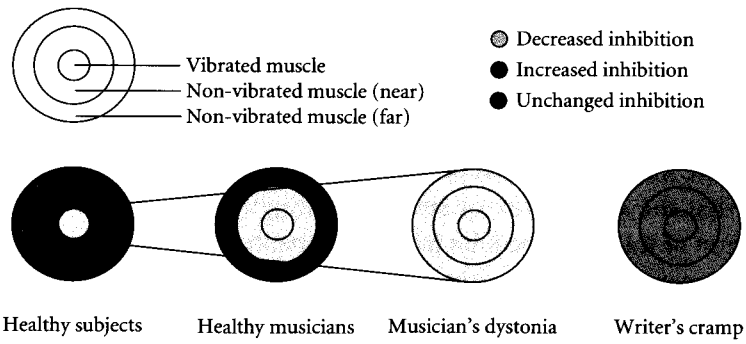

Fig. 18.2 Schematic summary of the effects of focal vibratory input on short interval intracortical inhibition (SICI) in three hand muscles. In this diagram, the hand muscle representations are drawn as circles with the vibrated muscle in the centre, and the 'near' and 'far' non-vibrated muscles surrounding it. This illustration represents the effective functional connectivity between muscles, rather than anatomical distances between muscle representation in the cortex. Shading represents the level of SICI: a reduction of SICI, an increase, and an unchanged SICI compared with the non-vibration condition (see key). In healthy subjects, focal vibratory input to one muscle reduces SICI in that muscle and increases it in other muscles. In healthy musicians, SICI in both 'near' muscles is reduced by vibration applied to either of them, whilst it is increased in the 'far' one. In musician's dystonia, vibration of any muscle reduces SICI in all of them. Patients with writer's cramp show no modulation of SICI by vibration of any muscle; the SICI remains unchanged compared with baseline levels.

the muscles. Interestingly, this was only the case in musician's *hand* dystonia; the two musicians with embouchure dystonia tested here showed a pattern similar to healthy musicians.

In writer's cramp, the pattern of organization differed. In these subjects, input from the muscles failed to have any influence at all on motor excitability. It was as if in these individuals the usual effect of sensory input was completely absent.

The data are consistent with a model in which musical practice in healthy musicians leads to changes in organization of the motor cortex that are probably beneficial to performance. However, in musician's dystonia these progress too far and perhaps they then begin to interfere with movement rather than assist it. This raises the possibility that musician's dystonia is a form of training-induced dystonia comparable to that described in the animal model of Byl *et al.* (1996): in susceptible individuals an initially beneficial adaptation of sensorimotor organization progresses too far and leads to problems in targeting motor commands.

With regard to the epidemiology of musician's dystonia (see Chapter 17), one might assume that those musicians who are known to practise a lot and from an early age might drive their brain's facility for plastic changes too far and exhaust the capacity of regulatory mechanisms, like for example cortical inhibition, that would normally balance the system. Since, fortunately, not all highly performing musicians suffer from dystonia, it could be hypothesized that those who develop

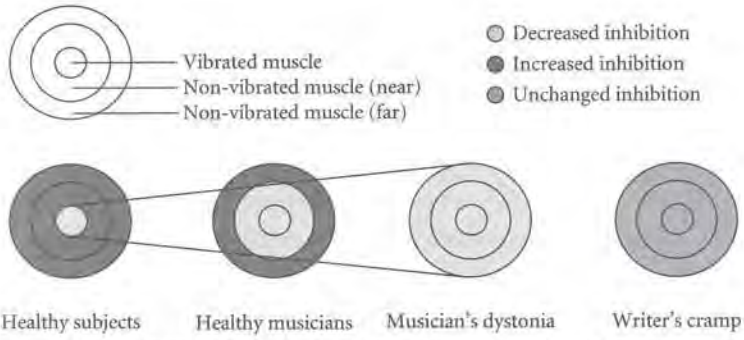

Fig. 18.2 Schematic summary of the effects of focal vibratory input on short interval intracortical inhibition (SICI) in three hand muscles. In writer's cramp, the pattern of organization differed. In these subjects, input from the muscles failed to have any influence at all on motor excitability. It was as if in these individuals the usual effect of sensory input was completely absent.

The data are consistent with a model in which musical practice in healthy musicians leads to changes in organization of the motor cortex that are probably beneficial to performance. However, in musician's dystonia these progress too far and perhaps they then begin to interfere with movement rather than assist it. This raises the possibility that musician's dystonia is a form of training-induced dystonia comparable to that described in the animal model of Byl *et al.* (1996): in susceptible individuals an initially beneficial adaptation of sensorimotor organization progresses too far and leads to problems in targeting motor commands.

With regard to the epidemiology of musician's dystonia (see Chapter 17), one might assume that those musicians who are known to practise a lot and from an early age might drive their brain's facility for plastic changes too far and exhaust the capacity of regulatory mechanisms, like for example cortical inhibition, that would normally balance the system. Since, fortunately, not all highly performing musicians suffer from dystonia, it could be hypothesized that those who develop

it might have a certain susceptibility due to the presence of subclinical deficits in motor inhibition and/or sensory processing that might not even have become apparent had they chosen a different profession.

From a practical point of view, this emphasis on the importance of pre-symptomatic hand training in provoking expression of (sub-)clinical deficits suggests that the appearance of symptoms might be delayed or prevented by modification of training schedules to reduce repetition and increase the variability of the movements that are practised.

Finally, the data show that the situation in the patients with writer's cramp may be rather different since they show a complete lack of any sensory effects on the excitability of the hand area of the motor cortex. In them, we hypothesize that their central nervous system reorganizes in a different way because they don't share the same history of hand movement with musicians and their affected movements do not need to rely on such close interaction between sensory input and motor output to the hand as in musicians. Thus, repetitive sensory input driven by movement practice plays only a minor (if any) role. A primary motor incoordination probably occurs due to an intrinsic deficit of the inhibition mechanisms that subsequently induces a dis-organization of sensorimotor interaction.

Chapter 19

The development of focal dystonia in musicians as a consequence of maladaptive plasticity: implications for intervention

Nancy N. Byl and Alberto Priori

Introduction

Focal dystonia in musicians, or musician's cramp, is a disabling disorder presenting as a painless muscular incoordination or loss of voluntary motor control. This problem most commonly affects extensively trained movements while a musician is playing the instrument (Sheehy and Marsden 1982; Rosenbaum and Jankovic 1988; Lockwood 1989). Involuntary twisting, end-range postures originating from co-contractions of agonists and antagonists interfere with the necessary finely graded, sequenced performance of musical tasks. The aetiology of focal hand dystonia is not completely understood, but it is probably multifactorial (see Fig. 19.1 and Chapter 17). It may develop in individuals with a genetic history of dystonia (Ozelius *et al.* 1997) or physiological dysfunction of the basal ganglia (Black *et al.* 1998) or the sensory motor cortex (Elbert *et al.* 1998). Other aetiologies include a traumatic injury (Jankovic 2001), nerve compression (Charness *et al.* 1996), or a response to excessive, stereotypical, aberrant motor behaviours (Byl *et al.* 1996; Sanger and Merzenich 2000). Interestingly, behaviours that frequently precede the onset of focal dystonia usually include stressful repetitive hand movements (e.g. extensive practice on a musical instrument or overpractice using a new instrument or a new technique) under conditions of high speed, high force, or demanding productivity (Barr and Barbe 2002; Comella *et al.* 2003).

Cortical plasticity in acquisition of skills

The brain is topographically mapped by sensation, motor performance and function (Merzenich *et al.* 1983) (see Fig. 19.2). When learning new sensory and motor skills, functional, topographical, and structural changes occur in the central nervous system (e.g. Jenkins *et al.* 1990). In the acquisition of fine motor

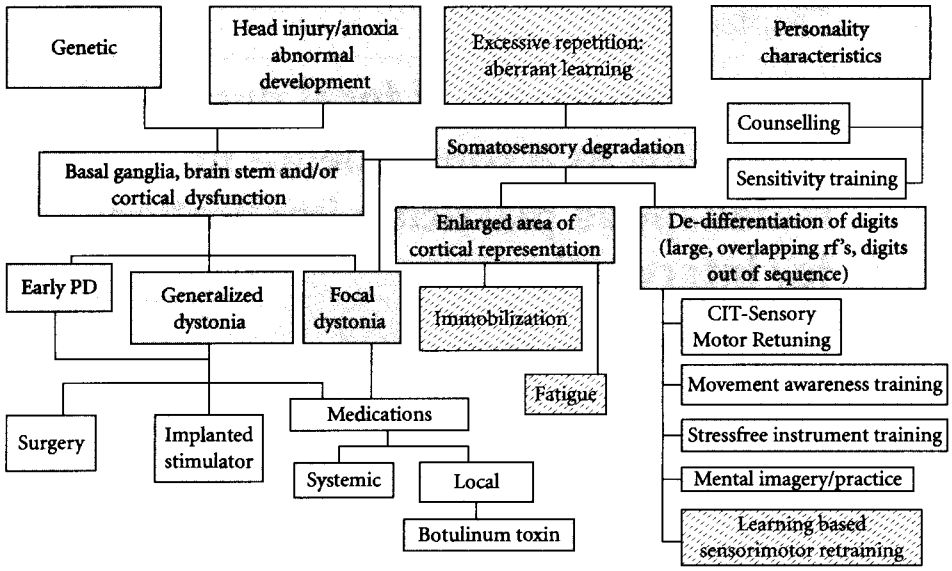

Fig. 19.1 Aetiology pathophysiology ad management of focal hand dystonia. Although focal hand dystonia is considered an idiopathic movement disorder, there are multiple risk factors that are associated with the development of the condition, including repetitive overuse of the hand. There is evidence of degradation of the somatosensory topography of the hand.

skills, such as learning to play an instrument, specific skin locations are stimulated at different moments during the task, engaging competitive cortical processes that drive further differentiation of skin surface representations. Receptive fields in the sensory cortex become smaller, and are represented by more coherent activities generated by smaller populations of neurons (Recanzone *et al.* 1992; Xerri *et al.* 1999). The overall area of cortex representing the skin surfaces used commonly increases, as it is driven by the task to be represented in the cortex in progressively finer grain. Similar competitive training-driven plasticity outcomes apply for proprioceptive, kinesthetic, and motor representations. The overall result is cortical representations become more selective and refined. Time constants and space constants of cortical processes are *specialized* for the task at hand. This progressive, learning-driven specialization, emerging in parallel in multiple cortical areas, *is* skill acquisition (Recanzone *et al.* 1992).

The size of the receptive fields (i.e. the bandwidths of the filters representing information from limited skin regions or specific muscles) of cortical neurons may increase or decrease based on attended, rewarded practice (Xerri *et al.* 1999). The time constants governing dynamic processing of sensory inputs or controlling movement sequencing may be progressively shortened or lengthened, depending on the parameters of the behavioural tasks driving progressive changes

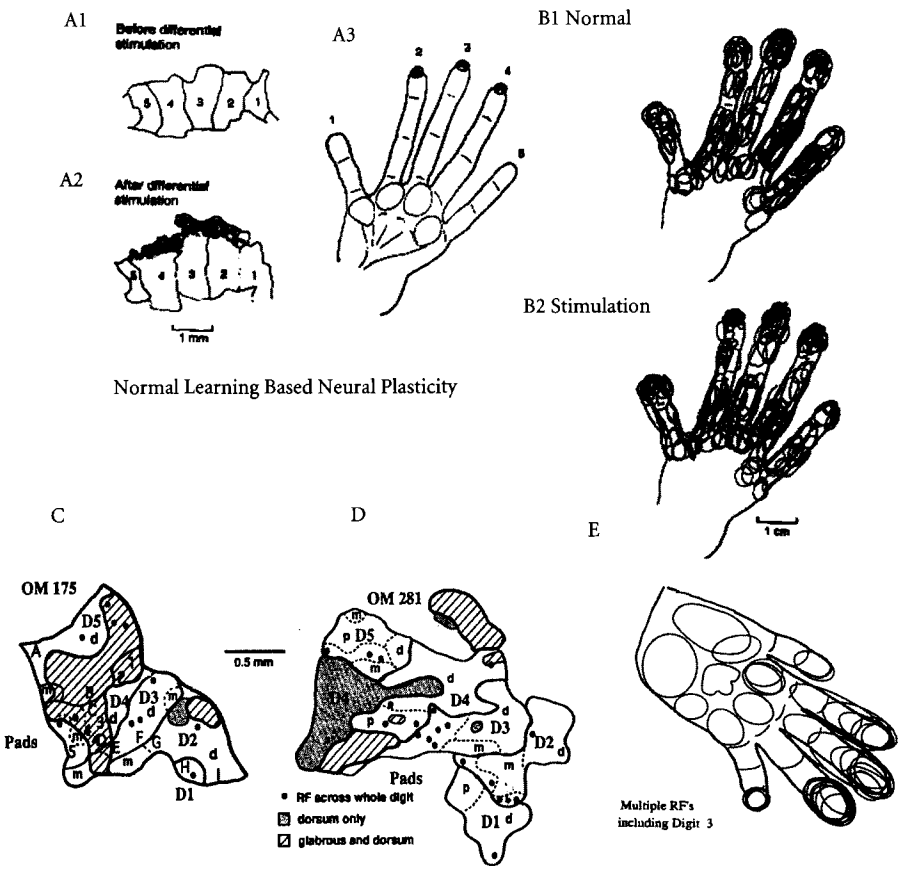

Fig. 19.2 With learning based training, the cortical representation of the hand increases in size (A1 to A2) and the receptive fields on the digits become smaller and more dense (B1–B2). When there is excessive, near simultaneous repetitive movements, the topographical representation of the hand is degraded and the digits overlap with adjacent digits (C). In addition, the representation of the digits overlaps the ventral and dorsal surface overlap(D). On the digits, the receptive fields are large and a single digit has multiple receptive fields on adjacent digits (E).

(Xerri *et al.* 1998). When a skill is well learned, it can be performed automatically without conscious attention. At that point, there is no new learning and there is representational consolidation and a reduction of the size of the area of representation. Also, when stimuli are received near simultaneously or coincident in time, it can lead to a reduction in the size of the topographical representation and a loss of differentiation of receptive fields and overlapping receptive fields across an extended cortical representation, across multiple digits, or across dorsal and glabrous surfaces (Wang *et al.* 1995; Blake *et al.* 2002). These physical neural changes driven by repetitive, attended rewarded behaviours are referred to as 'neuroplasticity' or 'cortical plasticity'.

At least three specific training conditions must be met to drive large-scale cortical plasticity in sensorimotor control systems in the adult brain. First, learning activities must be progressive and repetitive to be enduring (Byl and Merzenich 2001). Physical motor or sensory exercises alone do not drive cortical changes; *learning* is required. Plasticity in the adult brain is strongly modulated as a function of behavioural state and context. Learning also depends on levels of attention and motivation as well as on perceived goal achievement, expectation, and 'reward or punishment'. These behavioural states, which are common conditions in musicians' professional lives, engage the release of modulatory transmitters delivered from cholinergic, dopaminergic, and adrenergic modulatory control system nuclei that regulate the processes of adult cortical plasticity (Juliano and Eslin 1991).

Second, learning must be *progressive*. Given the nature of the competitive plasticity processes in cortical networks, large-scale changes commonly require the use of progressive training exercises, moving from distinctions that an animal or human can achieve (i.e. that its cortical networks can resolve, from strongly correlated activities, in terms of the distribution of spatial and temporal activity), to fine, overlapping steps to ultimately achieve a 'higher' or substantially different level of discrimination or resolution (Kilgard and Merzenich 2001). However, the scale of plasticity is limited in any given cortical zone by the anatomical spread, temporal integration, and combination of inputs (Byl and Merzenich 2001). Processes of change at a given location in a given cortical area are controlled by the strengths and time distributions of inputs feeding that cortical network sector. Because synaptic plasticity is dependent on the coincidence of inputs, or 'Hebbian' (Hebb 1949), the biggest changes are driven by inputs that generate strongly correlated responses in cortical neurons and networks.

Third, enduring, large-scale plasticity of the capacity of the adult cortex to process elements of information requires *repetition and effort*. There is some trade-off between the number of trial repetitions and the strength of the

modulatory control effects that enable plastic change. Efficiently implemented training must amplify the enabling inputs as much as possible. At the same time, large-scale plastic changes in time and space require a heavy schedule of stimulus representation or movement. The strongest neural structural effects are driven by 'paced learning', particularly where the subject is heavily engaged in the same behavioural task over a series of successive days (Recanzone *et al.* 1992).

If the conditions necessary for plasticity are met, specific changes also depend on the precise timing of input events. The Hebb rule is: 'Neurons that fire together wire together'. For example, sensory inputs that arrive in a cortical representational sector at consistently separated moments in time generate separate, segregated, differentiated, competing representations in the cortex (Fig. 19.2). In contrast, sensory inputs that arrive in cortical networks nearly simultaneously in time are mutually co-strengthened, integrated, summarized, and *de*-differentiated; that is combined in representation in the cortex. Based upon this simple principle, cortical plasticity may result in either the refinement or the degradation (de-differentiation) of cortical representations of sensory feedback or movement (Wang *et al.* 1995; Byl *et al.* 1996; Byl and Merzenich 2001).

Models of the origin of focal dystonia based on maladaptive plasticity

Beginning in the mid 1990s, Byl *et al.* (1996) trained monkeys in an attended, rewarded, highly stereotyped behavioural context with a task that simultaneously engaged relatively large hand surfaces with impulsive inputs, analogous to those delivered from a stereotypical power grip similar to that used to manipulate tools. These primates performed a repetitive, daily task over a number of successive months with daily training that demanded rapid opening/closing of the hand or rapid, precise spreading of the thumb and the index finger to make contact with two defined targets. In these experiments, early in the attended repetitive training paradigm, animals developed signs of repetitive strain injury that meant they would not work for a week and behaved as if the hand was painful. Some of the monkeys developed a classic focal hand dystonia, not uncommonly after being nursed through one or more bouts of repetitive strain injury. In the monkeys with dystonic posturing, there was profound degradation of the representation of the skin of the trained hand in the primary somatosensory cortex. The monkey performing the pointing task had an electrode implanted over the hand area, specifically representing digits one and two. This allowed the investigators to map the cortex during training. With the onset of the movement dysfunction, there was an increase in the overlap of digits one and two and the receptive field size increased to 87.68 mm^2 (compared with 8 mm^2

for normal owl monkeys). Signs of cortical columnar substitution were also noted. After 6 weeks, a number of sites could evoke responses from the glabrous skin of the hand and the lower face. At the time of the complete cortical mapping, the implanted electrode was found to be stable and the size of the receptive fields of the first two digits had increased to 101.41 mm^2 (Blake *et al.* 2002).

Degradation of the sensory feedback 'maps' was also seen in the untrained cortical hemisphere. Anatomically, the tendons, ligaments, and nerves were intact; there were no signs of nerve entrapment and no signs of acute inflammation (Topp and Byl 1999). The clinical expressions of focal hand dystonia observed in these monkeys were similar to those described in human patients. They included uncontrollable movements of the digits, co-contractions of flexors and extensors, difficulty releasing the flexed posture of the digits, or inability to perform delicate fine motor movements quickly and accurately. The trained primates who did not develop the dystonic hand postures were those working less intensively with fewer repetitions, more breaks, and shorter work periods.

The animal studies have been substantiated by studies of human subjects where degraded somatosensation has been reported in patients with focal hand dystonia. Patients with focal hand dystonia have poor spatial resolution thresholds over affected hand areas with reduced accuracy of localization (Bara-Jimenez *et al.* 2000). They have less salient sensations evoked by incident stimulation, degraded form perception (Byl *et al.* 1996), reduced kinesthetic and haptic abilities (Sanger *et al.* 2002), and problems with temporal spatial processing (Fiorio *et al.* 2003). All of these deficits are consistent with a *de*-differentiated representation of somatosensory feedback information.

Through cortical response mapping and imaging studies, several studies have also *directly* shown that somatosensory cortical representations of affected hand surfaces are de-differentiated in patients with focal hand dystonia. Representations of the separate digits in these individuals lose their topographic order (Fig. 19.3) and the spread of evoked activities are consistent with highly undifferentiated representations of sensory feedback from affected hand surfaces. There was a significant reduction in the amplitude in the early phase of the somatosensory evoked response when integrated over time for subjects with focal hand dystonia compared with controls (Fig. 19.4). However, within the subjects with focal hand dystonia, the somatosensory parameters were different in severity (Byl *et al.* 2002). It also appears that the somatosensory de-differentiation, excitatory, and inhibitory responses may vary by type of dystonia and, for example, differ in musician's cramp and writer's cramp (Rosenkranz *et al.* 2005). Further, the somatosensory, sensorimotor, and motor fields were all found to be abnormal compared with healthy controls (Lin *et al.* 2005).

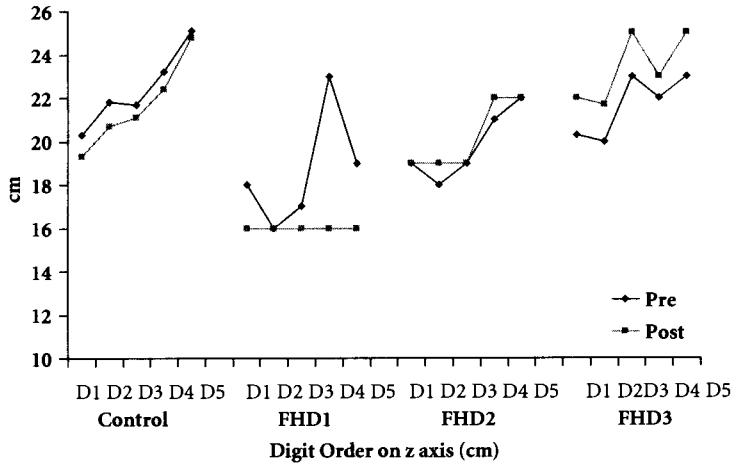

Fig. 19.3 Digit representation in patients with focal hand dystonia (FHD). In healthy subjects, the representation of digits 1–5 as measured by magnetoencephalography should confirm an orderly progression from inferior to superior on the vertical axis (*z*-axis). In musicians with focal hand dystonia, the area of representation of the involved hand is smaller than the uninvolved hand and the precise and orderly differentiation of the digits is compromised. After participating in learning-based sensorimotor training (once a week for 12 weeks), three musicians increased the size of the area of the hand representation, but the digits still remained out of sequence.

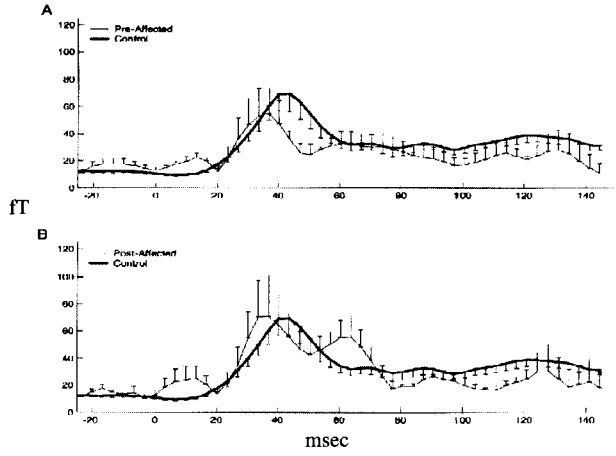

Fig. 19.4 Somatosensory evoked field response: amplitude integrated over time. Based on the somatosensory evoked field response to light touch, the amplitude of the neural firing is reduced in patients with focal hand dystonia compared with controls. After learning-based sensorimotor training, the amplitude of the field response increases (similar to healthy subjects); however, there is some irregular neural firing in the early and late phases of the evoked response.

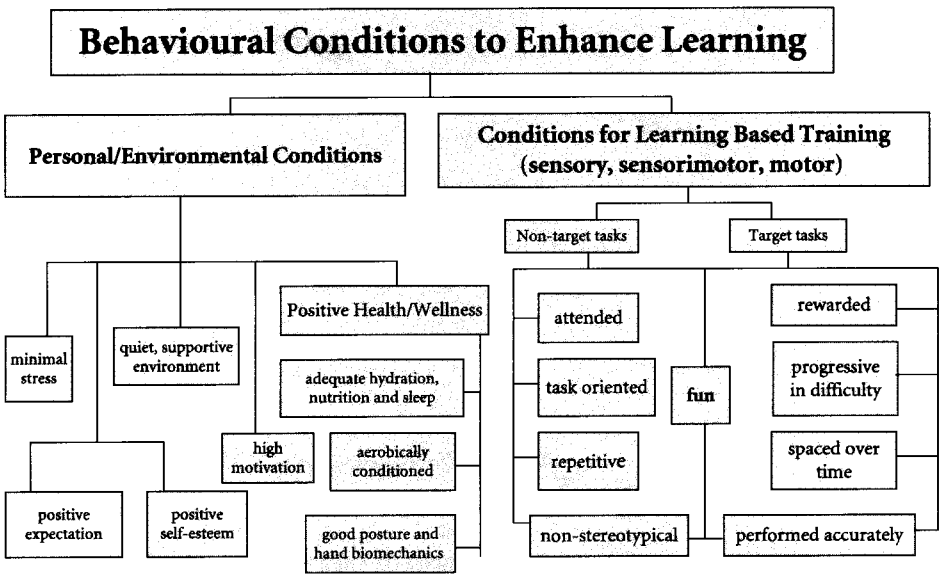
Current treatment strategies for focal hand dystonia

Many of the musicians diagnosed with focal hand dystonia are forced to end their professional careers in music performance (Schuele and Lederman 2004). Although a review of the currently available pharmacological treatments of focal hand dystonia is outside the scope of this chapter, local injection therapy with botulinum toxin in the cramping muscles is only a symptomatic treatment and does not address the central origin of the disorder. Based on the hypothesis of aberrant learning, effective treatment must accomplish a reversal of the degradation of the central nervous system that accounts for one origin and expression of hand dystonia. Any effective therapy must re-differentiate the hand representations. That can only be achieved by intensive, goal-oriented, progressive learning-based training.

Conservative, non-pharmacological interventions such as exercise, retraining on the instrument, desensitization training and counselling, constraint-induced therapy (sensory motor retuning), immobilization, and fatigue and learning-based sensorimotor training have been tried. The first step towards successful rehabilitation is to stop the abnormal movement. The next step is to establish a



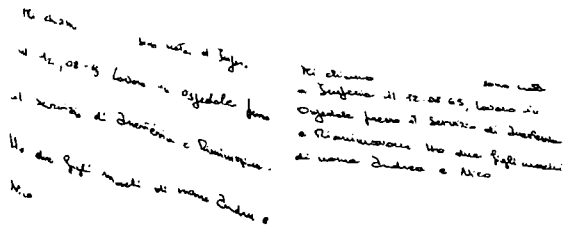


Fig. 19.5 Principles of learning based training to maximize neural adaptation. For patients with focal hand dystonia, the goal is to restore normal fine motor control of the hand. This requires a re-differentiation of the somatosensory representation of the hand. A strong foundation of good health provides a good environment for learning-based training. Learning activities must be attended, repetitive, rewarded, fun, performed normally, progressive in difficulty, and spaced over time.

foundation of positive health and wellness where learning can take place. This includes good nutrition, hydration, stress management, aerobic exercise, good ergonomic hand use, and appropriate instrumental modifications.

The principles of neuroplasticity are most closely aligned to constraint-induced training, retraining at the instrument, immobilization, and learning-based sensorimotor training. In a study (Candia *et al.* 2002) of 11 musicians with focal hand dystonia, the unaffected fingers of the dystonic hands were constrained with splints. For 2 weeks, 2 to 3 hours a day, the patients were trained to use the dystonic fingers on fine motor tasks emphasizing instrumental play. When control of the most involved digits improved, the splints on the less involved digits were gradually removed and practice at the instrument was increased. Eight out of eleven musicians showed an improvement of their motor skills (Candia *et al.* 2002). In another study (Candia *et al.* 2003) patients with focal hand dystonia showed restored cortical organization after treatment.

Based on the evidence that topographical representation of the hand is abnormal in patients with focal hand dystonia, immobilization of the hand has been proposed as an appropriate treatment at the first signs of dystonia. During the past two centuries, neurologists have observed that rest or immobilization might be helpful in treating focal occupational dystonia (Lanska 2002) and several therapeutic devices have been proposed for this purpose. Limb immobilization influences several physiological and anatomical factors from changes in the muscle tissue, tendons, and bone to changes in the cerebral cortex, including effects on spinal motoneurons. In non-dystonic individuals, prolonged immobilization of a limb leads to a shrinkage of the cortical representation of the immobilized limb (Liepert *et al.* 1995). Interestingly, motor fatigue, which transiently reduces and reshapes motor cortical representation in normal subjects, transiently improves motor control in patients with focal task-specific dystonia (Pesenti *et al.* 2001). The transient improvement of focal occupational dystonia after a maximal voluntary fatiguing contraction is specific for dystonia and has been proposed as a diagnostic test (the hand grip test). Thus, the objective of immobilization is to place the finger, hand, wrist, and forearm into a static splint to stop all movement in order to decrease the size of the representational area of the involved hand (Priori *et al.* 2001). In that work the treatment consisted of the application of a static splint that immobilized the finger and the wrist joints on the dystonic side. Patients wore the splint for 24 h a day for 4–5 weeks. Although only a small number of subjects were included in the first trial (eight subjects), after 5–6 weeks of immobilization in a splint for 24 h per day (with the splint being removed only to clean the limb), all of the subjects showed significant improvement (up to 80%) in motor control of the hand in the target task several weeks after the splint was removed (Fig. 19.6). All patients had some transient clumsiness and the

(a) (b)

Fig. 19.6 Writing samples before and after immobilization. Handwriting in a patient with writer's cramp before splinting (a). Handwriting 4 months after splint removal (b). There was improvement in both speed and quality (from Priori *et al.* 2001, with permission).

unusual sensation of being unable to control their hand when the splint was removed (e.g. at 1–3 weeks). Clumsiness prevented them from performing independent finger movements. None of the patients showed a worsening of their dystonia. This gain in function was retained for over 6 months in seven of the eight subjects participating in the study. Specific training activities designed to reorganize the cortical representation were not included in this paradigm to specifically evaluate the effects of limb immobilization without confounding factors.

Pesenti *et al.* (2001) carried out a similar study with a larger group of subjects with chronic focal hand dystonia, including some musicians, taking into account several clinical variables (Priori *et al.* 2003). In one group of patients there was variable improvement ('responders') and in the other group no improvement ('non-responders'). Despite the variability, most of the patients reported that immobilization induced at least some improvement. Immobilization seemed effective in young patients with a recent onset (< 1 year) of severe symptoms related to an overuse syndrome, whose dystonic symptoms improved transiently by more than 20% in the hand grip test. It could be hypothesized that patients with severe, established hand dystonia have more extensive degradation in the representation of the digits. Immobilization alone would not be sufficient to re-differentiate the digits and the integration of other rehabilitation protocols like learning-based sensorimotor training could produce better results

Learning-based sensorimotor training (LBST) is another approach to rehabilitation for patients with focal hand dystonia (Byl *et al.* 2000, 2001, 2002)(Fig. 19.5). The objective of LBST is to redefine spatial and temporal processing capacities in the sensory and motor cortex in order to restore the performance of target-specific skills. This strategy is consistent with repetitive task practice but with an initial concentration on improving sensory differentiation and not just graded, fine motor movement. Sensory conditions are designed to stimulate separate skin locations with non-stereotypical hand engagement trial by trial, in order to drive competitive Hebbian network plasticity to once again shrink the

cortical receptive fields (to give narrow input array bandwidths). Learning-based sensorimotor training is started with the least involved digits on the affected hand and then the most involved digits. If the sensory stimulation causes abnormal muscle contractions, training is moved to the unaffected side or the unaffected digits. Different exercise strategies address subtasks of the target tasks emphasizing different aspects of sensory feedback (i.e. somaesthesia, proprioception, kinesthesia, haptics). The patients initially make relatively simple distinctions about relatively large stimuli, with the difficulty of the task increasing as each patient mastered progressively more difficult distinctions. One set of tasks included reading Braille or embossed letters, making estimations of roughness, and performing discriminations of grating orientation. A second set of sensory tasks included flutter discrimination tasks and the recognition of small surface asperities. Sensorimotor and fine motor tasks designed to activate proprioceptive and sensorimotor feedback as well as cutaneous inputs were included. A series of haptic tasks required the subjects to manipulate and identify surface features and shapes of three-dimensional objects held in their hands.

The tasks are crudely progressive, beginning by using sensory inputs to shape the hand and performing partial tasks using normal movements. Then the sensorimotor training progresses to target fine motor tasks, beginning with tasks similar to the target task and progressing to the target task. The training may even begin in an atypical position (e.g. lying on the back to practice drumming). Initially, the patient simply learns to interface the target task by placing the hand on the instrument and then works at performing simple movements normally (e.g. dropping one finger on a key and maintaining the functional shape of the hand). An attempt is made to sustain the task at a level of difficulty at which errors could be made, i.e. requiring the subject's focused attention. Training stimuli are presented on a heavy, repetitive, daily schedule, meeting general standards for effective 'paced' learning. Feedback is provided by self-observation, verbal comments, auditory feedback from muscle contractions (Deepak and Behari 1999), mirror imagery (Sathian *et al.* 2000) and mental imagery (McBride and Rothstein 1979).

This training protocol has been tested in a series of patients with focal hand dystonia (Byl *et al.* 2000, 2003, Byl and McKenzie 2002). Subjects met a physical therapist for 1–2 h per week, and were trained on multiple tasks designed to engage the broad types of sensory inputs that provide feedback for fine hand motor control. The difficulty of each of these tasks was increased as subjects improved their performances. The task required constant attention. After appropriate instruction and demonstration in the clinic, subjects were instructed to practice the tasks for 30–60 min a day at home. Each patient received a handbook of instructions for home use. As a rule, to achieve effective reversals of the focal hand dystonia to a level at which the trainee could return to work,

training was continued for 6–12 weeks. In the first study, all 12 trained patients showed improvements in performance ability on a variety of tests of sensory discrimination, fine motor accuracy and speed, strength, flexibility, and functional independence. Motor control improved to an average of 70–94% of normal and all but three returned to their usual work.

Summary

In this chapter we have summarized the evidence from animal and human studies suggesting that focal hand dystonia is due to multiple risk factors, one of which may be maladaptive plasticity. There is consistent evidence for somatosensory degradation as well an imbalance between inhibition and excitation at multiple levels of the central nervous system. Given a hypothesis of aberrant neural adaptation, the good news is that the central nervous system is clearly adaptable. Thus, one way to reverse learning-induced, negative behavioural changes underlying focal hand dystonia is for the patient to *learn* their way out of it by retraining the brain.

In the early stages of neural adaptation, when hand dystonia is developing, immobilization of the hand to stop the abnormal movement may shrink the size of the cortical hand representation and be associated with improved function. However, actual cortical mapping studies have not been carried out to confirm this in musicians with focal dystonia. Post-immobilization, the patient should be instructed in healthy biomechanical, stress-free hand-use strategies with learning-based retraining to restore sensory discrimination and fine motor control. In the more established and severe cases of focal hand dystonia, the individual must not only stop the abnormal posturing of the hand, but engage in learning-based sensory and motor retraining.

It is also clear that not all patients with focal hand dystonia are the same. There may be unique cortical changes and responses in musicians that differ from those with writer's cramp. Even those with the same type of focal dystonia may also demonstrate differences in response. Further, those with severe symptoms may differ from than those with mild symptoms. This variability may explain why not all patients respond the same to specific behavioural intervention strategies. Each patient needs to be carefully examined to try and match the intervention to the performance dysfunction.

We could not locate any blinded, large, randomized clinical trials that compared the efficacy of different intervention strategies. The effectiveness of clinical training can be limited by a number of problems. Patient compliance and the behavioural contexts of training-driven plasticity are difficult to monitor. In addition, attentional control is not assured, progressing of task difficulty is variable, and tasks are performed with minimal refined regulation. It is difficult

to deliver consistent and careful behavioural rewards for 'correct' performance trials and tasks can become dull and uninteresting rather than engaging and fun. Thus, research is still needed to determine the most efficient training strategies to maximize the effectiveness of learning. Training programs need to become efficient, possibly automated, where individuals not only have greater control of their own training process but where continuously adaptive challenges of stimulus discrimination/identification can be presented to enable a re-differentiation of cutaneous, proprioceptive, kinesthetic, haptic, and fine motor representations in the brains of affected patients. Despite the limitations of the evidence, recovery has been reported by some highly motivated individuals who are willing to perform the necessary dynamic, repetitive, attended, rewarded, progressive task practice that can sufficiently re-differentiate the sensory and motor cortex to restore the performance of fine motor skills.

Chapter 20

Music performance anxiety

Jürg Kesselring

Definition

Music performance anxiety (MPA) may be defined as 'a state of arousal and anxiety occurring before or while a person is performing non-anonymously in front of an audience producing a valuable or evaluated task touching on his/her self-esteem'. A description by a sufferer is particularly realistic and dramatic: 'my heart is beating up to the neck, I can hardly breathe, my knees are trembling, my hands are wet, I cannot think clearly, I am disorientated, I feel helpless and abandoned. Everybody will laugh at me, they will hate me, even kill me—and they will be right . . . now it is clear that I had completely overestimated myself. What a shame . . . !'. This description (most probably by someone who is not actually performing because this would impede his or her finding the words) contains all the reactions one would expect from heightened activity of the sympathetic nervous system, an adrenergic response which is usually set up in situations of fear and danger which induce 'fight or flight' reactions for survival. Music performance anxiety is a problem of the whole person and cannot be reduced to a disorder of motor control.

Symptoms

Music performance anxiety is a special form of emotional behaviour (Damasio 1999) with aspects of:

1. Motor expressive behaviour: e.g. trembling or shaky voice, hands, arms, knees, or feet; irregular breathing, changes of facial expression (mimics), chewing finger nails, etc.
2. Reactions of the autonomous nervous system (sympathetic as well as parasympathetic): e.g. palpitation (rapid heart rate), sweating, flushing; shortness of breath or hyperventilation (clammy hands), fidgeting, pacing, loss of sensitivity or numbness in fingers, gastrointestinal disturbances (dry mouth, loss of appetite, nausea, vomiting), frequent trips to the toilet, increased urination, diarrhoea, insomnia.
3. Subjective feelings (which may in part be influenced by the motor responses and the reactions of the autonomic nervous system): e.g. feeling tense,

increased irritability and vulnerability, depression, anxiety, feelings of helplessness, being overwrought, panic, loss of control, anguish (feeling faint or dizzy), fear, fright, shock, numbness, feeling inadequate or worthless.

4. Cognitive appraisal (thoughts and reflections concerning feelings and bodily symptoms): e.g. concentration and memory problems (decreased concentration and increased distractibility, mind blanks, blocks, freezes, memory lapses), circular thinking (catastrophizing), confusion, difficulties making decisions, interfering negative thoughts.
5. Behavioural changes: e.g. insomnia, loss of appetite, avoidance reactions, hectic or paralyzed movement, talkative or mute, exhaustion.

Causes of music performance anxiety

Is music performance really a situation so dangerous as to provoke these 'fight, flight and fright' reactions and why does the individual concerned feeling him- or herself to be in such a situation when performing music in public? Music performance anxiety may be present during performance and when not mastered may render it impossible, or it may be present for hours or days or even weeks before a performance. This is clear evidence for the fact that it is the imagined situation of performance which induces the same bodily reactions as does an acute danger in the real world. The imagination of a real frightening situation is apparently equally as effective in producing these bodily reactions as such a situation itself. The changes observed would have an adaptive function in relation to a physical threat but the after effects of the alarm system can, when not overcome before and during the performance, greatly interfere with its accomplishment (Wilson and Roland 2002). What is perceived as the danger leading to the anxiety reactions is mainly a fear of being judged and possibly devalued in one's self-esteem. The activity of the sympathetic nervous system, however, is Janus faced: it acts equally as a positive stimulant increasing alertness and focusing concentration. The quality of arousal is related to arousal with an inverted U-shaped curve: low levels of arousal are insufficiently motivating while excessive arousal interferes with performance because concentration is disrupted, memory blocks occur, and there is loss of steadiness in the hands and voice (the Yerkes–Dodson law; see Wilson and Roland 2002)

Considerable research has focused on MPA and coping strategies (Smith *et al.* 2000) but only a few studies have monitored physiological parameters before, during, and after performance, demonstrating increased heart rate, pulse, and blood pressure (and lower confidence) particularly during auditions (Fredrikson and Gunnarsson 1992). The latter study allowed the differentiation of a high-anxiety (tremor often experienced) from a low-anxiety (no tremor) group, and

importantly performance quality was rated higher in the latter group by an attending expert professor. Interestingly, however, raters blind to group assignment who listened to tape recordings and only had auditory cues made the reverse judgement, suggesting that quality judgement (at least in the tasks that were investigated) made by raters present at the performance was influenced more by factors associated with visual cues than by auditory ones—probably by behaviours like self-confidence and body posture.

Biological reactions such as fighting, fleeing, or avoidance make sense in a strictly biological realm but may become counterproductive in the social context in which one of the most feared situations is the possibility of being laughed at or ridiculed. Stage fright results from an imbalance between self-set claims and expectations and coping capabilities, and it arises particularly in situations which may endanger self-esteem, the affection and sympathy of others, or the continuation of a career.

Musicians perform complex psychomotor skills under conditions of high arousal when outcome is critical, performance is being evaluated, and competition is fierce. A person's appraisal of the demands of a performance, the perceived coping resources (e.g. ability and preparedness), and the 'meaning' or consequences (Smith *et al.* 2000) are all influenced by personality (self-esteem, confidence, auditory style) and motivational factors (perfectionism, practice time).

Music performance as a social situation gains significance by the presence and (mainly silent) participation of spectators and audience. In order to be able to participate the audience expects to encounter fulfilment of norms and standards but equally to be led by the person on stage to novel aesthetic experiences. Performance is an exchange of emotional values. Anxiety in such situations may arise through the suspected expectations of the audience. It is not just the fear of threatening events in nature but the fear of the reaction of other, largely unknown and anonymous, people. A sense of reality and autonomy must be balanced against dependency on expectations of the evaluation and appreciation by others. Pathological MPA may therefore be understood as a form of social phobia (Steptoe and Fidler 1987; Cox and Kennardy 1993). It is a mirror-world in which a person finds themself alone, dependent on the pre-conceived imagined estimations of others without being able to confront them in reality.

Performance is a conflicting mixture of attraction and avoidance: a challenge on the one hand of being heard and seen and on the other hand a fear of being exposed with possible failure. Such fear is more marked when a pre-defined role has to be performed (as is the case in music performance). There is general agreement that auditions are the most stressful performance situations because they combine scrutiny and evaluation with a socially inferior status and may have a direct influence upon career progression (Wilson and Roland 2002). The degree

of anxiety increases in direct proportion to the rigidity of the role, and this has to be taken into account by the person in that role well before the actual performance. The more we specialize and restrict our competence, the more vulnerable we become, and music performance is one of the highest possible specializations with narrowly defined stereotypes of bodily, mental, and emotional functions. The quality of a performance may be described, predicted, and analysed in a three-dimensional model of stress factors interacting with each other: Trait anxiety (susceptibility to stress), situation (environmental pressure), and task mastery (Wilson 2002). Expectations in our fantasy may grow into veritable monsters and become more dangerous than the ones we encounter in real daily life.

Performance anxiety is most often related to a kind of judge or censor, internal or external, real or imagined, a consequence of previous life experiences. Unfortunately, very often the 'inner censor' is critical, doubtful, and cowardly—the very opposite of the qualities we strive for when performing, namely self-confidence, persuasive power, and courage. Reconciliation of these contradictory tendencies is therefore a pre-requisite for coming to terms with MPA. The 'worry-factor' (Wise 1971) leads only to increased self-centredness and is attracting just what we are most afraid of.

Emotional evaluation and self-esteem

At the base of the problem of MPA lies the anxiety of being unmasked in front of the public, to lose value (and power) in failure. It is the conflict between the way by which a person is valued by others, by the values and validations experienced previously, and between the self-given evaluation, i.e. between expectations, the way one would like to be seen, and between self-evaluation. Most importantly this private conflict takes place in public.

Emotions are created by inner engagement and involvement with the task. In MPA, shame, anger, and disorientation predominate. Anxiety is an emotion of the whole person, expressing itself as restlessness, irritability, insecurity, tension, clumsiness, sweating, freezing, etc. The problem in MPA is not anxiety itself but rather our attitude towards it. The narrow boundaries of anxiety may be overcome by courage on the basis of trust, which is the opposite of anxiety. A reason for trust is serious and adequate (not perfect) preparation. Practising means to make the difficult easy (or at least easier). Anxiety about failure most often results from projecting one's own self-destructive views and ideas onto others (the audience, jury, teachers, rivals). Shame is another emotional factor closely related to anxiety and always involved in MPA. Performing inevitably means exposing parts of oneself which are usually protected. The ambivalence of wanting to be heard and seen on the one hand and of wanting to protect intimacy and identity on the other often renders performance so difficult. Anger arises if

we are not able to fulfil the expectations of the inner censor or when perfectionism demands total control, which is never completely possible. Distractibility arises from inadequate concentration and lack of focus on the task and it may influence all cognitive domains even leading to complete disorientation.

Prevalence

In 2002 a survey was conducted in three orchestras in Switzerland: the Zürich Chamber Orchestra (ZKO) (full-time professional musicians), the Glarner Musikkollegium (GMK) (part-time professional musicians), and the Orchester Gesellschaft Zürich (OGZ) (good amateurs) to which 50 musicians responded (for details see the Appendix).

When asked whether they ever experienced anxiety while performing, 25 of the 32 women declared to have MPA sometimes and 6 often; and of the 18 men responding 12 had MPA sometimes and 4 often. Only three amateurs declared that they never experienced MPA.

Stage fright was experienced more often during solo performance than when playing chamber music or in an orchestra concert, as is to be expected (Wilson and Roland 2002). More than half of the responders considered MPA to be disturbing often, 7/50 very much so. Symptoms began with equal frequency long before and shortly before performance, when entering stage and before difficult passages, respectively. These figures correspond well with those found among 155/650 professional orchestral players in The Netherlands who responded in a survey (Van Kemenade *et al.* 1995): in 59% MPA was considered serious enough to affect professional life, in 32% to a slight degree, in 32% to a moderate degree, in 28% it was very distinct, and in 9% of strong intensity. Anticipation of anxiety lasted for days (36%), weeks (10%), and even months (5%) and the conclusion was: 'that their lives would have been merrier, happier, more relaxed and less stressed and more satisfying'. Among the symptoms were (in decreasing frequency) palpitation, intestinal problems, tremor, difficulty concentrating, dry mouth, wet hands, difficulty with intonation, unreliable memory, increased sweating, and irregular breathing.

Similar figures have been found by Krawehl and Altenmüller (2000) with symptoms among 40 music students considered to be very disturbing in 30% and sometimes disturbing in 60%, and by Wesner *et al.* (1990).

When asked about personality type (on a scale from 0–10), 12 considered themselves to be introverted (7 women, 5 men) and 16 (11 women and 5 men) to be clearly extroverted while 22 (17 women, 5 men) ranged in between. Interestingly of those reporting MPA sometimes, twice as many considered themselves as being extroverted versus introverted, whereas those who experienced MPA often were equally distributed. On a scale for emotional stability,

MPA was reported with equal frequency in those who considered themselves to be stable and in those who considered themselves to be unstable. On a scale for curiosity and openness (ranging from hesitant/anxious to open/courageous) MPA occurred twice as often in those who considered themselves to be open and courageous. All of those with a feeling of psychological weakness had MPA.

When asked about the ability to relax, 10 rated themselves as being rather tense (4 women, 6 men) and 20 (11 women and 9 men) to be relaxed. Neither this question nor the questions regarding leisure satisfaction nor whether one would consider oneself as being a nervous person helped to predict the occurrence of MPA. Thirty participants could not agree to 'feel well in (even unfamiliar) society', phobias (height, open spaces, animals) were an issue in 11 women and 3 men, panic attacks occurred in 4, mainly among those who said they had MPA sometimes. This was rarer than in the study by Clark and Agras (1991) in which all participants fulfilled DSM-III criteria for social phobia.

Treatment strategies

Cognitive-behavioural strategies are used by many musicians to cope with MPA: positive thought, visualization and distraction, muscle relaxation, deep breathing, proper nutrition and exercise (Gratto 1998). In our survey, when asked 'What do you do against MPA?' the answers were (in decreasing frequency) relaxation, exercise, autogenous training, sport, beta-blockers, and tranquillizers (only amateurs!). Half of them had the impression that their coping behaviour would be very helpful, a quarter indicated that it would help only a little.

Although the effects of coping behaviours on health and performance are of central importance, little research has been conducted on the efficacy of specific strategies (Smith *et al.* 2002). Experiences in sports medicine suggest that exposure to intermittent stressors may condition the body to respond positively to adrenergic stimulation. Physically fit individuals have a higher threshold for stressor intensity, a more rapid recovery to baseline levels, and an elevated endorphin concentration. Gradual incremental exposure to stressful situations may promote resilience and effort without distress.

Beta-blockers

Beta-blockers block the receptors for the physical effects of the natural fight or flight response mentioned above. The ability of beta-blockers to help anxiety is related only to their blockade of beta receptors outside the brain; they will not help the emotional symptoms of stage fright (e.g. sleep problems or negative inner voices). It is important to find, under medical supervision, the ideal dosage by experimenting several times and under different circumstances before a major performance to get to know the personal effects and adverse reactions.

Beta-blockers are not approved for use in anxiety or stage fright, but they may be prescribed for this purpose because there is scientific literature to support this use. They do not make playing better just by relieving physical problems resulting from the fight or flight response, and some musicians feel that adrenalin helps their performance, giving them an edge that adds intensity to the performance. Beta-blockers do not directly improve emotional states, except to the extent that some musicians feel better when their physical problems are relieved, namely interacting with 'the obligate body-relatedness of feeling' (Damasio 1999). If performance anxiety manifests itself mainly in psychological ways (e.g. negative inner voices), beta-blockers will not help.

Scientific studies clearly show that beta-blockers significantly reduce symptoms that can hinder some people's playing. The musicians in the studies said they felt better about their performance after taking beta-blockers, and music critics consistently judged their performances to be better. There is, however, the danger that beta-blockers only help technical aspects of performance, but may in fact diminish emotional elements. A study of 2122 musicians in major US symphony orchestras showed that 27% reported taking beta blockers (72% of these mainly for auditions, 52% for solo recitals, 50% for difficult orchestral performances, 42% for concerto performances, and 4% before every performance) (Fishbein *et al.* 1988).

Negative self-talk often mediates performance (Wilson and Roland 2002) mostly resulting from fear of failure, of getting worried and tense, of making mistakes such as playing wrong notes, losing the timing, of not being perfect, of disapproval (negative past performance experiences), of losing control, of problems with distraction or memory problems, and lack of confidence in ability (not feeling good enough, believing others are better).

Instead one should try to focus on realistic, positive self-talk with clear, precise goals, perform regular mental rehearsals, and use many performance simulations. A voice of trust must be actively sought ('Whether you think you can do it or whether you think you cannot do it—you will be right!'), and curiosity must be maintained: the pleasure of adventures and discoveries, free from prejudices ('Link to the inner child').

Successful professional performers view anxiety or nervousness before a performance as a normal and even beneficial part of preparation (Wilson and Roland 2002). A very experienced teacher recommends creating a network of channels through which the player can transmit a potential flow of communication, *in spite of* the difficulties surrounding him. MPA does not occur in gypsies because they are not burdened with the responsibilities of our social system; their sole interest is the pleasure of the listener (Havas 1973). A summary of coping strategies with MPA may therefore be: 'Playing is never difficult—it is either made easy or remains impossible' (Havas 1973).

Appendix: Details of survey of MPA in three Swiss orchestras (2002)

Orchestras surveyed: Zürich Chamber Orchestra (ZKO) (full time professional musicians); Glarner Musikkollegium (GMK) (part-time professional musicians), and Orchester Gesellschaft Zürich (OGZ) (good amateurs).

The following abbreviations are used: FS, female, sometimes; FO, female, often; MS, male, sometimes; MO, male, often.

1. Did you ever experience anxiety while performing?
2. How much is stage fright disturbing you?
3. When does music performance anxiety begin?
4. Which symptoms do you experience?
5. What do you do to combat music performance anxiety?
6. Does it help?

ZKO	Women (6)	Never 0, sometimes 6, often 0
	Men (4)	Never 0, sometimes 3, often 1
GMK	Women (9)	Never 0, sometimes 8, often 1
	Men (4)	Never 0, sometimes 3, often 1
OGZ	Women (17)	Never 1, sometimes 11, often 5
	Men (10)	Never 2, sometimes 6, often 2

Stage fright was experienced more often during solo performance (39: FS 21; FO 5; MS 10; MO 3) than when playing chamber music (21: FS 13; FO 4; MS 3; MO 1) or in an orchestral concert (11: FS 6; FO 3; MS 1; MO 1).

Very much (7)	FS 3, FO 3, MS 1, MO 0
Often (31)	FS 19, FO 2, MS 8, MO 2
Not very much (4)	FS 0, FO 0, MS 3, MO 1

Long before (6)	FS 4, FO 2, MS 0, MO 0
Shortly before (18)	FS 8, FO 3, MS 6, MO 1
Entering stage (11)	FS 5, FO 3, MS 2, MO 1
Difficult passages (14)	FS 7, FO 1, MS 4, MO 2

Symptom	Number	Distribution
Palpitation	30	FO 4, FS 18, MO 1, MS 7
Intestinal problems	24	FO 5, FS 18, MO 1, MS 0
Tremor	22	FO 3, FS 14, MO 2, MS 3
Concentration difficulty	15	FO 3, FS 10, MS 2
Dry mouth	14	FO 3, FS 9, MO 1, MS 1
Wet hands	13	FO 0, FS 8, MO 1, MS 4
Intonation	11	FO 0, FS 10, MO 0, MS 1
Unreliable memory	9	FO 1, FS 5, MO 0, MS 3
Increased sweating	7	FO 0, FS 4, MO 1, MS 2
Irregular breathing	4	FO 0, FS 4, MO 0, MS 0

Relaxation exercise (19)	FS 11, FO 3, MS 4, MO 1
Autogenous training (8)	FS 6, FO 1, MS 1, MO 0
Sport (5)	FS 3, FO 1, MS 1, MO 0
Beta-blockers (7)	(only amateurs)
Tranquillizers (3)	(only amateurs)

Yes, a lot (26)	FS 14, FO 3, MS 7, MO 2
A little (8)	FS 4, FO 3, MS 1, MO 0

The motor actions that can be witnessed as a virtuoso musician performs can be so fast, so accomplished, so precise, as to seem somehow superhuman. The musician has to produce the movements, monitor those they have already made and the subsequent result, co-ordinate their hands, fingers, eyes, and perhaps throat and diaphragm. These achievements are of course the product of hundreds, even thousands of hours of practice — playing scales and studies, time and time again. But those hours of practice by no means guarantee that great musicianship will result. This technical prowess has to be combined with a range of other, perhaps less tangible, qualities.

This book explores the secrets of musical virtuosity. It presents a comprehensive account of music and motor cognition, examining the neural basis of music making — our understanding of which is just starting to be enhanced by brain imaging. It considers the effect on our brains of prolonged music making. It explores the motor processes across a range of instruments (vocal, string, wind, percussion) and within different performance situations. It also considers what happens when things start to go wrong — why motor problems occur in so many professional musicians in later life, and the possible therapies for such problems.

Music is a topic of considerable interest within the brain sciences. With contributions from leading psychologists, neuroscientists, and neurologists, this book makes a unique contribution to our understanding of music and the brain.

Los autores

Eric Clarke es profesor de música de la Universidad de Sheffield y ha publicado numerosos trabajos sobre la psicología de la interpretación, la percepción y producción del ritmo, y el significado musical y la relación entre el lenguaje y la música. Es coeditor (junto con Nicholas Cook) del libro *Empirical Musicology: Aims, Methods, Prospects* y ha participado como improvisador en el Lapis String Quartet.

Jane Davidson es profesora adjunta de música de la Universidad de Sheffield. Ha publicado estudios sobre la expresión musical, los gestos, la práctica musical y los determinantes de la excelencia musical; es coeditora del libro *The Music Practitioner* y ha dirigido la revista *Psychology of Music.* Actúa con regularidad como solista vocal, ha dirigido y creado piezas de teatro musical y ha realizado la coreografía de diversas danzas y óperas.

Jonathan Dunsby es profesor de música de la Universidad de Reading. Ha escrito numerosas obras sobre la música de los últimos dos siglos, y entre sus libros se incluyen *Performing Music: Shared Concerns, Structural Ambiguity in Brahms, Schoenberg: Pierrot Lunaire* y (junto con Arnold Whittall) *Music Analysis in Theory and Practice.* Estudió piano con Fanny Waterman, ha ganado premios en diversos concursos internacionales y ha acompañado a muchos artistas distinguidos.

Elaine Goodman es profesora de música de la Universidad de Hull. Consumada violonchelista y pianista, toca con regularidad en diversas agrupaciones

de cámara y orquestas. Su tesis doctoral, presentada en el Royal Holloway College de la Universidad de Londres, trata sobre el ensayo y la interpretación en grupo, y sus campos de investigación incluyen la psicología de la interpretación, el análisis musical, la educación musical y los estudios sobre música popular.

Peter Hill es profesor de música de la Universidad de Sheffield. Entre las obras que ha publicado se encuentran *The Messiaen Companion* y un libro sobre *La consagración de la primavera* de Stravinsky. Como pianista ha grabado más de cien programas para la BBC y un galardonado ciclo de Messiaen. Sus discos recientes incluyen un recital de obras de Stravinsky y las obras completas para piano solo de Schoenberg, Berg y Webern.

Peter Johnson estudió en Cambridge y Oxford y ha publicado obras sobre Webern y diversos aspectos de la interpretación. Los objetivos de sus investigaciones recientes abarcan desde la filosofía de la interpretación hasta su análisis acústico, y ha trabajado ampliamente como director e intérprete de teclados. Es director de los departamentos de estudios de postgrado e investigación del Conservatorio de Birmingham.

Colin Lawson es conocido internacionalmente como intérprete de clarinete histórico y ha tocado con orquestas como The Hanover Band, el English Concert y la Orchestra of the Age of Enlightenment. Ha grabado como solista para muchas compañías discográficas y publicado numerosos escritos en la Cambridge University Press, incluyendo diversas ediciones y manuales. Es pro vicecanciller y rector del London College of Music & Media de la Thames Valley University.

Raymond Monelle ha ejercido la crítica musical durante treinta años y sus reseñas han aparecido en *The Independent, The Scotsman, Scotland on Sunday, Opera* y otras muchas publicaciones. Anteriormente era compositor, pianista y director. Su obra sobre teoría y semiótica musical es conocida internacionalmente y entre sus libros se incluyen *The Sense of Music,* Princeton University Press, 2000.

Stefan Reid es profesor de música de The Forest School de Londres. Estudió en la Universidad de Oxford, la Universidad de Surrey y el Royal Holloway College de la Universidad de Londres, en el que presentó su tesis doctoral sobre el arte de la práctica o estudio. Da conciertos regularmente como pianista y posee una distinguida reputación como director coral y orquestal.

John Rink es profesor de música del Royal Holloway College de la Universidad de Londres. Entre sus libros se incluyen *The Practice of Performance: Studies in Musical Interpretation, Chopin: The Piano Concertos* y (junto con Jim Samson) *Chopin Studies 2.* Es uno de los tres directores de la colección *The Complete Chopin —A New Critical Edition* y es coautor de un catálogo comentado de las primeras ediciones de Chopin junto con Christophe Grabowski. Como pianista, da conciertos y recitales-conferencia con regularidad.

Janet Ritterman ha sido directora del Royal College of Music desde 1993 y fue nombrada Dama de la Orden del Imperio Británico en 2002. Ha trabajado profesionalmente como pianista solista y acompañante, y se ha especializado en la educación y adiestramiento de intérpretes dotados. Sus temas de investigación incluyen el desarrollo del conservatorio, la pedagogía instrumental y la interpretación histórica. Ha publicado obras sobre compositores del siglo XIX y ha participado en numerosas conferencias nacionales e internacionales.

Elizabeth Valentine es profesora adjunta de psicología y directora del Psychology of Music Research Group del Royal Holloway College de la Universidad de Londres. Entre sus campos de investigación se incluye la psicología de la práctica y la interpretación musical, y ha escrito sobre temas como el efecto del canto sobre el estado de ánimo y la música de fondo como ayuda para la memoria autobiográfica en los casos de demencia. Es intérprete aficionada de teclados y flauta de pico.

Peter Walls es profesor de música de la Universidad Victoria de Wellington, Nueva Zelanda. Ha publicado numerosas obras sobre la práctica interpretativa, y su libro *Music in the English Courtly Masque 1604-1640* obtuvo el premio «Outstanding Academic Book» de la revista *Choice* y el «Derek Allen Prize» de la British Academy. Ha dado conciertos como violinista barroco y es director de orquesta y de ópera.

Aaron Williamon es investigador asociado y director del Centre for the Study of Music Performance del Royal College of Music. Su tesis doctoral, presentada en el Royal Holloway College de la Universidad de Londres, estudia cómo aprenden, ensayan y recuperan información los músicos expertos durante el estudio y la interpretación; su obra sobre la evaluación de las interpretaciones memorizadas recibió el premio Hickman de la SRPMME (Society for Research in Psychology of Music and Music Education). Otros objetivos de sus investigaciones son el miedo escénico y las técnicas de colaboración en el aprendizaje y el ensayo musical.

Prefacio

La interpretación musical es una parte fundamental de la vida humana, pero hasta el más experimentado intérprete, maestro o erudito puede no apreciar lo que implica. Todos sabemos que una interpretación en público generalmente representa innumerables horas —incluso años— de aprendizaje y preparación, pero cómo se preparan las interpretaciones, sobre qué base y con qué resultados son aspectos menos conocidos. ¿Por qué algunas interpretaciones resultan «musicales»? ¿Deberíamos intentar respetar las intenciones del compositor? Y, de ser así, ¿cómo se pueden comprobar? ¿Cuál es la relación entre la partitura, la obra musical y las interpretaciones a las que éstas dan lugar? ¿Cómo se puede aumentar la eficacia de las prácticas y los ensayos, y cómo se puede superar el miedo escénico? Preguntas como éstas suelen rondar la mente de los intérpretes, por no mencionar la de sus maestros, pero hasta ahora ha sido difícil encontrar respuestas convincentes. Durante mucho tiempo, los músicos han tenido que recurrir a la tradición y la intuición para buscar las respuestas y, aunque aquéllas son indudablemente importantes, no siempre son suficientes. La creciente literatura académica sobre interpretación que se ha escrito en los últimos años ha ofrecido poco en términos de ayuda práctica: dirigida a lectores altamente especializados y escrita generalmente en un lenguaje un tanto impenetrable, ha tendido a descuidar los intereses de los intérpretes a pesar de que se necesitan obras claras e interesantes sobre asuntos como la práctica, la memorización, el miedo escénico, el análisis musical para la interpretación y las «responsabilidades» históricas del intérprete moderno. El hecho de que hoy en día sean cada vez más las universidades y conservatorios que ofrecen cursos en los que se fomenta la integra-

ción de la teoría y la práctica, en lugar de su tradicional separación, y que cada vez más los intérpretes profesionales se consideren a sí mismos tanto «hacedores» como «habladores» (términos de Joseph Kerman), hace que la ausencia de material adecuado sea aún más lamentable.

Los dieciséis ensayos de este libro tienen como objetivo desentrañar las complejidades de la interpretación y revelar los aspectos del aprender, ejecutar y responder a la música pertinentes a las interpretaciones en todos los niveles. Con un objetivo amplio y un lenguaje accesible, el libro está dirigido a los profesores, estudiantes y eruditos, así como a los amantes de la música, que deseen saber más sobre lo que implica la interpretación musical y no depender únicamente de la tradición y la intuición. Está dividido en cuatro partes, que corresponden a las etapas evolutivas de una interpretación: conceptos y preconceptos, aprender a interpretar, hacer música e interpretar la interpretación. Cada parte consta de cuatro capítulos, el primero de los cuales establece el ámbito de los otros tres. La Parte I comienza con una perspectiva general de la interpretación a través de la historia que sirve de introducción a la presentación de los conceptos básicos de la interpretación histórica, el análisis y la psicología de la interpretación. Los siguientes cuatro capítulos tratan sobre la historia de la enseñanza, el desarrollo de la habilidad interpretativa, la práctica o estudio y la memorización. La Parte III considera cómo se hace música partiendo de la partitura, así como los temas relacionados con la imagen personal, la interpretación en grupo y el miedo escénico. La última parte analiza el acto de escuchar, el legado de las grabaciones, la crítica musical y la opinión de los intérpretes sobre la interpretación.

Todos los autores de este libro son destacados expertos en el campo, y muchos son intérpretes de considerable experiencia y renombre. Ambos factores garantizan una obra vital y convincente, que al mismo tiempo plantea cuestionamientos provechosos. El libro pretende despertar un amplio interés, rehuyendo de las jergas y complejidades innecesarias y evitando concentrarse en un único instrumento o género interpretativo. En cambio, arroja una nueva luz sobre los principios y procedimientos que subyacen en la interpretación y su estudio, al menos dentro de la tradición clásica occidental, que constituye su principal centro de atención, aunque en el transcurso se hacen referencias a otras músicas y repertorios (incluyendo el jazz y el rock).

Existen varios hilos conductores comunes a lo largo del libro. El primero y principal es la importancia de la *experiencia* de la música a través de la interpretación, que transforma la partitura (en caso de haberla) en un evento musical único, reconociendo en todo momento que la partitura no es «la música» y que, aunque uno quiera, nunca se puede ser totalmente fiel a ella. (El libro también subraya que las grabaciones no reflejan «cómo suena la obra», a pesar de que pueden revelar mucho sobre las prácticas interpretativas

históricas y por supuesto sobre las visiones personales.) En varios capítulos se plantea, por consiguiente, la diferencia entre aprender «las notas» y aprender «la música» al desarrollar una visión de la obra —es decir, al construir un sentido del conjunto— que, como señala, es un primer paso vital. Varios autores tratan sobre el papel que desempeña el análisis en la interpretación y su aprendizaje, así como en la memorización y la lucha contra el miedo escénico. Se demuestran varias técnicas de análisis y se discute el papel de la intuición en contraposición a un conocimiento más profundo. De igual manera, al principio del libro se considera la respuesta del intérprete moderno al precedente histórico, particularmente los riesgos de la interpretación «históricamente *des*informada».

La naturaleza de la práctica o estudio —una actividad generalmente solitaria, totalmente opuesta a la interpretación como experiencia sumamente social— es otro tema común que permite considerar la relación entre las imágenes mentales y las representaciones físicas, la repetición en contraposición a la inspiración, la resolución de problemas y el proceso mediante el cual podemos «olvidarnos» de lo que hemos aprendido a medida que la música se hace más nuestra, para recordarlo «automáticamente» durante la interpretación. Varios autores analizan cómo memorizamos la música y ofrecen consejos prácticos para profesores e intérpretes por igual. Dejando atrás la fase preparatoria de la interpretación, los capítulos siguientes consideran los múltiples factores sociales que intervienen en la interpretación, como las relaciones entre los intérpretes y el público o entre los integrantes de un conjunto, así como los temas relacionados con la presentación, el papel que desempeña el cuerpo durante la interpretación y las semejanzas (y diferencias) entre la interpretación musical y la actuación. Dichas consideraciones están dirigidas a una amplia gama de intérpretes, incluyendo cantantes (por ejemplo, los capítulos 9, 11 y 14), pianistas (capítulos 2, 3, 7 y 9), ejecutantes de cuerdas (capítulos 8 y 14) y vientos (capítulo 14). La polémica que existe entre los intérpretes que intentan encontrar instrumentos históricamente «correctos» para tocar un repertorio determinado y los que desean «transcribir» música para tocarla en instrumentos modernos es abordada frontalmente en varios capítulos, al igual que la diferencia que existe entre las percepciones de los oyentes y los «hechos» que revelan los datos empíricos sobre las interpretaciones. Estas consideraciones forman parte de un debate más amplio sobre qué es lo que escuchan los oyentes y cómo lo escuchan, y sobre la manera en que los críticos y los intérpretes mismos han escrito sobre la interpretación —una actividad que para algunos ha sido tan apremiante como lo es para muchos intérpretes la necesidad de interpretar.

Como sugieren estos comentarios, el libro ofrece abundantes consejos prácticos, y la sección de «lecturas complementarias» al final de cada capítulo

ofrece una bibliografía concisa para aquellos que deseen estudiar más profundamente determinados temas. Esperamos sinceramente que este libro inspire a los lectores a investigar más sobre la interpretación, bien sea leyendo detenidamente otros textos generales sobre su estudio (por ejemplo, mi libro *The Practice of Performance: Studies in Musical Interpretation,* la obra de Jonathan Dunsby *Performing Music: Shared Concerns* o la de Colin Lawson y Robin Stowell *The Historical Performance of Music: An Introduction)*, bien ahondando en publicaciones más especializadas. Si realmente este libro ha despertado el interés por la interpretación y ha proporcionado respuestas para al menos algunas de las preguntas planteadas anteriormente, entonces habrá cumplido sin duda su propósito.

Quisiera agradecer a Sarah Smith por elaborar el índice y a Lucy Carolan por su cuidadosa edición de las copias; a Ruth Milsom y Mark Wells por preparar las ilustraciones de los capítulos 9 y 12; a mis alumnos de postgrado del Royal Holloway de la Universidad de Londres por su entusiasmo por el manuscrito, y a Penny Souster por su acostumbrada paciencia y sabios consejos.

Conceptos y preconceptos

1 *La interpretación a través de la historia*

COLIN LAWSON

La interpretación en contexto

En la mayoría de los conciertos clásicos de hoy en día esperamos que el público permanezca callado y absorto, pero ése es un fenómeno social bastante reciente, muy alejado de los eventos musicales anteriores a los comienzos del siglo XX. En el estreno de su Sinfonía «París», en julio de 1778, Mozart estaba encantado con un público respetuoso que, sin embargo, respondía activamente [1]:

> Yo estaba seguro de que iba a gustar un pasaje que se encuentra justo en medio del primer Allegro. El público se entusiasmó bastante, y hubo una tremenda ovación... Como había observado que aquí todos los primeros y últimos Allegros comienzan con todos los instrumentos a la vez, y generalmente al unísono, comencé el mío con dos violines solamente, tocando *piano* durante los primeros ocho compases, seguidos inmediatamente de un *forte*; el público, como yo esperaba, susurró «¡silencio!» durante el suave comienzo, y cuando escuchó el *forte*, comenzó a aplaudir inmediatamente [2].

Más de un siglo después, en 1893, tuvo lugar el concierto inaugural del Queen's Hall de Londres, representado en un cuadro que se encuentra actualmente en los archivos de la Royal Opera House del Covent Garden; el director y la orquesta aparecen en plena actividad; sin embargo, las conversaciones también fluyen libremente en las primeras filas del público [3]. Menos controlado fue el famoso y tumultuoso estreno de *La consagración de la primavera* de Stravinsky, en París en 1913, uno de los últimos ejemplos docu-

mentados de la respuesta activa del público dentro de la tradición concertística occidental.

Hoy en día, el público que responde libremente es más característico de los conciertos de música pop, en los que los intérpretes exhiben sus propias conductas cuidadosamente cultivadas. En las situaciones rituales que no requieren de música escrita hay menos diferenciación entre componer, ensayar e interpretar, y es muy probable que los oyentes y espectadores participen. Aunque la partitura constituye un registro y permite la difusión de la obra musical, también determina una relación más distante entre el compositor y el intérprete. Hasta bien entrado el siglo XIX, se daba por sentado que los intérpretes supieran improvisar, y en efecto lo hacían frecuentemente. Adaptar las partituras a las exigencias de la ocasión era algo rutinario, y también era bastante común insertar arias en una ópera que habían sido compuestas especialmente para los cantantes en cuestión. A principios del siglo XX, Stokowski, Elgar y otros no tenían por qué tener ningún reparo en hacer transcripciones orquestales de la música para teclado de Bach. Aunque la notación original del compositor se encontrara sobre el atril, los intérpretes adoptaban con frecuencia un enfoque libre y creativo. Joseph Joachim, un violinista amigo de Brahms, fue descrito como impredecible por un miembro de su cuarteto: «Tocar con él es sumamente difícil. Siempre con tempos diferentes, acentos diferentes» [4]. La abrumadora supremacía actual de la partitura, que exige fidelidad y exactitud a toda costa, no es de ningún modo característica de la historia de la interpretación en su conjunto. Sin embargo, la literatura musical suele dar la impresión de que el verdadero significado estético reside en la notación, y que la interpretación es, como mucho, una representación imperfecta y aproximada de la obra misma. Se dice que Brahms rechazó una invitación a una representación de *Don Giovanni* de Mozart, alegando que prefería quedarse en casa y leerla, una respuesta que seguramente habría horrorizado a Mozart, que era extremadamente práctico.

Una perspectiva mundial

El estudio de las músicas del mundo pone en duda la mayoría de las hipótesis apoyadas por los intérpretes occidentales, proporcionando por lo tanto un provechoso sentido del contexto. En muchas culturas, la separación convencional entre el intérprete y el público nunca ha existido; mientras el instrumentista o cantante improvisa, los espectadores responden, bien sea dando golpecitos con la punta de los pies o los dedos de las manos, bien dando palmadas, bien cantando o bailando. Los músicos se encuentran tanto en las calles, mercados, ferias o tabernas como en lugares más formales, ya que la mú-

sica se ha mantenido estrechamente relacionada con los rituales como bodas, funerales o eventos del calendario agrícola, y trata sobre temas eternos como las heridas de amor. Los testimonios de la tradición oral se complementan a veces con un material básico más tangible; por ejemplo, en países como China, Corea, India y Japón, existen diversas tradiciones de teoría musical que datan de hasta 5.000 años atrás. Se han conservado grandes colecciones de música china escrita a partir del siglo XII, y muy poco después comenzó a gestarse el repertorio clásico turco.

La invención del fonógrafo, a finales del siglo XIX, contribuyó en gran medida a la investigación de las tradiciones orales y los sistemas musicales existentes. Otro hito fue el desarrollo de los métodos para medir intervalos menores que el semitono, con los que se ha dividido la octava de múltiples maneras desconocidas en Occidente. El análisis técnico de los sonidos musicales y las prácticas interpretativas se ha unido provechosamente al estudio antropológico, de modo que el trabajo de campo abarca generalmente tanto el proceso de creación como el de interpretación. Los instrumentos, melodías y ritmos de la India son desconocidos para los músicos occidentales, y también las ideas que originan su música están estrechamente relacionadas con conceptos filosóficos y religiosos que tienen poco que ver con los enfoques occidentales del tiempo, la materia o la realidad. En esas circunstancias, la música no se aprende de los libros: hay que tener un maestro que proporcione el secreto esencial y el conocimiento esotérico, y enseñe cómo se debe llevar la vida de músico. Desde el principio, el discípulo participa en el escenario observando e interactuando con su maestro. En la cultura hindú, los músicos pertenecen a una casta inferior, no sólo por su condición de comerciantes, sino porque su profesión implica romper tabúes de las clases altas, como tocar la piel de los tambores o tocar con los labios una flauta o una caña que puede haber sido tocada por otras personas. La complejidad rítmica de la música africana y su estrecha relación con la danza están igualmente alejadas de la experiencia occidental. Muchas lenguas africanas ni siquiera tienen una palabra que denote al músico o la música, abstracciones inútiles comparadas con sus términos concretos para significar cantante, bailarín o ejecutante de tambores. En el Extremo Oriente, las ceremonias religiosas y los rituales de la corte imperial de Japón están muy alejados filosóficamente de Occidente. En el elevado y estilizado arte dramático Noh se integran literatura, teatro y danza con una música en la que se combinan tambores con el sonido espiritual del shakuhachi.

El mundo sonoro de la música no occidental comprende muchos instrumentos de diseños y categorías poco conocidas. Un ejemplo antiguo es el qin chino, que se caracteriza por sus expresivos glissandi y etéreas armonías. El gamelán indonés incluye un conjunto de percusión afinada cuyos ejecutantes

participan en una disciplina espiritual vinculada a la danza, la poesía y el teatro cuyo objetivo es alcanzar un estado ideal de calmada ausencia emocional; naturalmente, no hay virtuosos ni solistas en esa tradición, básicamente oral, en la que no existen jerarquías. El sitar indio, con sus característicos glissandi, es un ejemplo de un instrumento que (como el gamelán) se ha dado a conocer en Occidente, especialmente a través de su interacción con la cultura popular.

Grecia y Roma

Hace cuarenta mil años, el hombre hacía música; las pinturas paleolíticas descubiertas en la localidad francesa de Ariège muestran la imagen de un hombre con una máscara de animal rascando un arco musical ante un público formado por renos. Para la época clásica, la música despertaba el interés de los grandes filósofos, al tiempo que invitaba a una amplia participación ritual. Escritores como Platón y Aristóteles consideraban que la formación musical era de gran valor educativo. La relación entre música y poesía exigía respuestas profundas al intérprete y al oyente que hoy en día no se pueden recrear mediante una mera lectura de las fuentes que se han conservado. El canto coral era particularmente importante, con frecuencia incorporaba danzas y siempre estaba acompañado por profesionales que tocaban instrumentos de viento y de cuerdas. El ritual formaba parte esencial de la interpretación, ya que los coros cantaban en honor a los dioses o celebrando a hombres famosos o atletas victoriosos. Aunque es poca la música que ha llegado hasta nosotros, se han conservado tratados teóricos de Aristoxeno (siglo IV a.C.), Ptolomeo (siglo II a.C.) y otros. Podemos conjeturar que la música griega era fundamentalmente homofónica y que las voces cantaban juntas al unísono o a la octava. Los romanos también tenían música litúrgica y otras músicas de carácter público, música militar y canciones de trabajo, asimilando las influencias de los países que conquistaban. Los intérpretes de instrumentos de viento participaban en los rituales de sacrificio, en parte para alejar a los espíritus malignos e invocar a las deidades benignas; fueron representados con frecuencia en relieves y eran muy respetados. Las festividades en honor a los dioses se acompañaban de música procesional, que en el caso de Dioniso podía ser desenfrenada y orgiástica. En la música militar, los trompetistas ejecutaban señales establecidas y tocaban durante las marchas y ceremoniales; en combate, sus sonidos estaban ideados para alentar a las tropas y confundir al enemigo. Las canciones tradicionales proporcionaban un acompañamiento rítmico para ciertas actividades como remar, cosechar y tejer, y se agrupaban en géneros como nanas, canciones infantiles, canciones de cumpleaños y de

bodas. En el teatro cobraron importancia la mímica y la pantomima, un género en el que la música vocal e instrumental acompañaba a un mimo que representaba personajes mitológicos.

La iglesia

Durante siglos, la iglesia ha sido un núcleo importante para el quehacer musical. Los romanos relacionaron la música con todo tipo de vicios e inmoralidades, por lo que las primeras autoridades cristianas se percataron de que podía tanto ennoblecer como degradar la moral del hombre. Una solución inicial al dilema fue ordenar que la música estuviera relacionada con palabras devotas y prohibir los instrumentos. La educación musical ha sido una función importante de la iglesia desde la fundación de la Schola Cantorum, atribuida tradicionalmente a Gregorio Magno (590-604). Allí los niños recibían una formación musical, así como una educación completa en las principales asignaturas académicas, participando igualmente en las festividades profanas y ferias. Esta prolongada tradición no se debe subestimar; cuando se fundó el primer conservatorio moderno en París, en 1795, después de la revolución, la educación musical francesa seguía estando en manos de casi cuatrocientas escuelas de música patrocinadas por la iglesia, en las que se enseñaba canto llano, contrapunto, algo de composición, un poco de francés, mucho latín y algo de aritmética. Aunque los métodos de enseñanza eran anticuados y se descuidaba la música instrumental, cada año unos cuatro mil alumnos iniciaban el seminario teológico o una vida como cantantes u organistas.

Las melodías eclesiásticas no fueron escritas hasta el siglo VI, y sólo en el siglo XII se ideó un sistema para indicar las alturas de los sonidos, aunque no su valor exacto. Una de las principales dificultades de recrear música medieval es que la improvisación y el acompañamiento instrumental no están representados en las notaciones que se han conservado. Los órganos pequeños, las cuerdas frotadas y pulsadas, los vientos y los instrumentos de percusión fueron introducidos en la iglesia, pero la plantilla era seleccionada rigurosamente según la ocasión y los recursos disponibles. Durante varios siglos, la complejidad de la música eclesiástica suscitó reiteradas críticas por parte de las autoridades, por ejemplo del papa Juan XXII en 1323. El Viernes Santo de 1555, el papa Marcelo II ordenó que en lo sucesivo el coro papal interpretara con voces correctamente moduladas y de manera que todo se pudiera escuchar y entender. De tiempo en tiempo, algunos compositores de música eclesiástica trascendieron completamente sus circunstancias profesionales, como es el caso de J. S. Bach. La Alemania luterana produjo muchos directores musicales que componían conscientemente para la mayor gloria de Dios,

satisfaciendo a sus superiores y edificando a la congregación. Bach vivió en una época en que los conceptos de genio y obra maestra aún no se habían formulado; trabajando de semana en semana con una pequeña orquesta de dieciocho a veinticuatro instrumentistas para acompañar a sus cantantes, sin duda le habría asombrado que las generaciones posteriores lo veneraran.

Música profana

Mientras que la música eclesiástica era organizada y coordinada, la música profana se abordaba sin considerar en absoluto que su método u objetivo debía ponerse por escrito. El centro de gravedad de la música pasó de la iglesia a las cortes reales y aristocráticas sólo a comienzos de la época renacentista. Originalmente, la música formaba parte de la tarea de los animadores de la corte, que eran también juglares, acróbatas, bailarines, adiestradores de animales y cómicos. Estos ministriles formaban parte del personal de una casa aristocrática o bien de una compañía itinerante. Acompañados de instrumentos portátiles, no sólo entretenían sino también inmortalizaban gloriosas gestas reales en canciones, al tiempo que versaban sobre los temas habituales del amor, el duelo y la sátira. A medida que se desarrollaban las ciudades en la Edad Media, se formaron asociaciones de trompeteros o *Stadtpfeifer,* originalmente como guardias civiles. Éstas evolucionaron hasta convertirse en bandas locales que tocaban diversos instrumentos y formaban a los aprendices, que trabajaban como sirvientes hasta obtener las calificaciones necesarias. A menudo luchaban por mantener el monopolio de la música ceremonial y social en una ciudad determinada. Los remanentes de este sistema perduraron hasta entrado el siglo XIX, cuando en Leipzig los *Stadtmusiker* llegaron a ser miembros *ex officio* de la Orquesta de la Gewandhaus.

Las cortes renacentistas siguieron un modelo de desarrollo uniforme, con pequeños coros y un grupo de instrumentos para acompañar y hacer música instrumental. Crearon agrupaciones bien instruidas y flexibles para interpretar obras compuestas generalmente en los estilos más sorprendentes y avanzados de la época. El primer libro sobre instrumentos —*Musica getutscht*— fue publicado en Basilea en 1511 por Sebastian Virdung. En él se describen e ilustran mediante grabados el clavicordio, el virginal, el laúd, la viola, la dulcema, el arpa, la chirimía, la flauta, la corneta, la gaita, el trombón, la trompeta y varios instrumentos de percusión y órganos. La impresión de música comenzó a finales del siglo XV, comprometiendo al editor con la noción de que ciertas obras tendrían una larga existencia y creando la idea de un repertorio musical. Un aspecto importante de la clase media isabelina y jacobina fue el desarrollo del placer íntimo de la música de cámara vocal e instrumental.

La época barroca

Durante el período barroco se apreciaba especialmente la espontaneidad en la interpretación. El auge de la música instrumental y la ópera en el siglo XVII produjo un nuevo tipo de músico que hacía especial hincapié en la técnica, demostrando habilidad para improvisar, ornamentar o crear el efecto deseado. Es significativo que las intérpretes femeninas fueron cada vez más aclamadas durante el barroco, no sólo en los escenarios operísticos sino también en conservatorios venecianos como el Ospedale della Pietà, que se hizo famoso por Vivaldi.

Los teatros de ópera fueron importantes por ser los primeros establecimientos independientes en los que se interpretaba música para públicos de diversas clases sociales que pagaban una entrada; el primero abrió sus puertas en Venecia en 1637. Eran relativamente pequeños, siendo el más grande de un tamaño similar al de una sala de cine pequeña de hoy en día. La nobleza alquilaba gran parte de los palcos por un año (a veces de por vida), y los asientos restantes estaban disponibles para los que adquirían una entrada única. El vocabulario sistemático de signos y gestos musicales que desarrollaron Monteverdi y sus contemporáneos llegó a representar las relaciones entre los personajes en escena, ya que a los cantantes se les exigió convertirse en actores. No podemos asegurar que siempre se usaran los mismos recursos para una misma ópera; de hecho, tanto las piezas como la plantilla podían variar en representaciones sucesivas. Entre los tipos de voz actualmente obsoletos, el más importante era el castrato, valorado por su fuerza y flexibilidad. Había muchos aspectos del buen estilo de canto que se escribían de una manera pero que, para ser más elegantes, se realizaban de otra bastante diferente. Desde sus comienzos, la ópera ha generado esa curiosa interacción entre consideraciones comerciales y artísticas que sigue existiendo hoy en día, siendo la interesante carrera de Haendel en Londres un excelente ejemplo del siglo XVIII.

Al igual que la ópera, la música de cámara era dirigida generalmente desde el clave, a menudo por el compositor; las instrucciones interpretativas detalladas eran por lo tanto innecesarias. Los ejecutantes seguían asumiendo un elevado nivel de responsabilidad en una época en la que gran parte del material musical estaba esbozado más que escrito en toda su extensión, especialmente las partes de *basso continuo.* En este aspecto se pueden establecer comparaciones significativas con la técnica del jazz, especialmente en el caso de las *notes inégales* —una sucesión de notas del mismo valor que se tocan desigualmente en el estilo francés según el tempo y el carácter de la música. No fue hasta alrededor del año 1700 cuando la música instrumental alcanzó el prestigio de la música vocal, pues hasta entonces había estado en gran parte confinada a las oberturas de ópera y el servicio del culto de la iglesia. Un fac-

tor importante a este respecto fue que la agrupación dirigida por Lully en la corte de Luis XIV había sido especialmente famosa por su disciplina y unanimidad, y estableció los instrumentos de cuerda como una base para la orquesta. Poco después surgió en Italia un nuevo tipo de escritura virtuosa para cuerdas, ejemplificada por el violinista-compositor romano Arcangelo Corelli.

El período clásico

Durante la segunda mitad del siglo XVIII, la música llegó a difundirse regularmente a través de las ediciones publicadas. Incluso los textos fiables sólo ofrecen una idea parcial de lo que se interpretaba originalmente, ya que los instrumentistas y cantantes seguían aportando una parte importante. Sin embargo, los principales tratados de Quantz, Leopold Mozart y C. P. E. Bach abarcan muchos aspectos de la práctica contemporánea. En ellos se establece un paralelismo cercano entre la música y el lenguaje, y se valora especialmente la habilidad del intérprete para emocionar al público. Las condiciones sociales favorecieron el auge del concierto público, que al principio floreció en lugares pequeños, fomentando un estilo interpretativo claro e íntimo. En las reseñas, las descripciones del nivel de calidad de los conciertos son sumamente difíciles de interpretar. Un ejemplo famoso es la descripción que hace Charles Burney de la orquesta de Mannheim como un ejército de generales, tan capaz de planificar una batalla como de pelear en ella; luego matizó su entusiasmo con una crítica a la afinación de los vientos, cuya aspereza era un problema orquestal universal [5]. Basándose en razones que ahora consideraríamos mezquinas, una reseña notable de 1785-1786 de la orquesta de Lyon señala que el director no tenía inteligencia, ni tampoco un estilo interpretativo preciso, y que había ausencias no autorizadas entre sus colegas. La mayoría de los conciertos (a diferencia de la ópera) generalmente podía contar con un solo ensayo, y a veces no había ninguno. En los programas se valoraban especialmente la variedad y la novedad, y se combinaba música solista, de cámara y orquestal. Por ejemplo, el 25 de noviembre de 1781, el concierto inaugural de la Orquesta de la Gewandhaus de Leipzig incluía una sinfonía de Joseph Schmitt, un himno de Reichardt, el Concierto para violín de Berger, un cuarteto de un autor desconocido actualmente, una sinfonía de J. C. Bach, un aria de Sacchini y una sinfonía de E. W. Wolf.

En su obra *A General History of Music,* Burney describe la sed de música nueva que había en su siglo:

> Tan variable es el gusto en la Música, y tan pasajero el privilegio de cualquier estilo, que su historia es como la de un campo labrado: tal año produjo trigo, tal otro ce-

> bada, guisantes o tréboles: y tal año estuvo sin cultivar. Pero no queda ninguna de sus producciones, salvo quizá una pequeña parte de la cosecha del año pasado y las semillas y malas hierbas que ahora cubren su superficie [6].

Una excepción importante a esta regla general fue, por supuesto, la popularidad que tuvo Haendel en Inglaterra hasta mucho después de su muerte. Para finales del siglo, empresarios como Salomon, quien contrató a Haydn para sus conciertos en Londres después de su prolongado servicio en la corte de Esterházy, hicieron que el éxito fuese juzgado no sólo por la aprobación estética, sino también en términos comerciales. Mozart representaba un nuevo tipo de músico autónomo, presentándose astutamente al público vienés de los años 1780 con sus conciertos para piano en los que desempeñaba el papel tanto de compositor como de intérprete. También escribió papeles operísticos y obras solistas ajustadas específicamente a las habilidades de sus colegas intérpretes. Una generación después, Beethoven plantearía enormes retos a los ejecutantes de orquesta, que tenían que hacer frente a exigencias técnicas y estilísticas nuevas y difíciles en una época en que las condiciones para el ensayo y la interpretación eran desfavorables debido a factores sociales, políticos y también musicales.

Afortunadamente, se ha conservado un documento que retrata la formación musical austríaca del siglo XVIII en forma de un «Musick Plan», un sistema educativo proyectado en 1799 por Anton Stadler, clarinetista de Mozart, en respuesta a un encargo del conde húngaro Georg Festetics. Stadler recomendó una carrera de seis años en la que los alumnos estudiarían aspectos de teoría, interpretación y composición, incluyendo piano, órgano o bajo cifrado, violín e instrumentos de viento, para complementar sus estudios principales. Todos los alumnos de música estudiarían el arte del canto, cualquiera que fuese la calidad de sus voces. Haciendo hincapié en la importancia de una buena educación general, señaló que cualquiera que desee comprender la música ha de tener mucho mundo y saber de matemáticas, poesía, oratoria, arte y muchos idiomas [7].

El siglo XIX

La era industrial trajo grandes cambios, especialmente las posibilidades de transporte que permitieron el florecimiento de las carreras de virtuosos e influyeron igualmente en la vida de los músicos de orquesta. A medida que las partituras se difundían más ampliamente, las indicaciones interpretativas tendían a ser aún más precisas. En la música alemana, la complejidad de los acompañamientos restringió gradualmente la libertad que tenían los cantan-

tes para ornamentar; un compositor advirtió que «las composiciones de Mozart, Haydn, Cherubini y Winter presentan menos adornos que las de Salieri, Cimarosa, Martin y Paisiello» [8]. El establecimiento de conservatorios en toda Europa estaba destinado a fomentar el virtuosismo técnico, especialmente porque es un aspecto de la interpretación que se puede evaluar sin dificultad. Naturalmente, el aficionado comenzó a desaparecer del mundo del concierto público. El piano mantuvo un puesto central tanto en el ambiente doméstico (había arreglos para piano a cuatro manos de casi toda la música orquestal) como en el escenario de concierto, donde Liszt era representativo de un nuevo tipo de virtuoso itinerante. Las innovaciones técnicas de Liszt permitieron una extraordinaria transcripción al piano de las expresiones orquestales, y su destreza virtuosística estaba inspirada en el violinista Niccolò Paganini, una de las figuras más hipnóticas del siglo XIX.

El desarrollo de las orquestas sinfónicas trajo consigo los conciertos públicos financiados por suscripciones y estableció el papel del director. Beethoven fue uno de los primeros músicos que dirigió un concierto en Viena sin tocar un instrumento, desde un atril separado; se dice que estaba especialmente interesado en transmitir la expresión de la música, y no tan sólo un pulso regular. El tamaño de las orquestas era muy variado; más avanzado el siglo, las experiencias de Brahms abarcaban desde su agrupación favorita de Meiningen, de cuarenta y ocho músicos, hasta la Gewandhaus de Leipzig, con una plantilla de noventa y ocho intérpretes. Para su época, el escuchar contemplativa e imparcialmente se había convertido en el objetivo mismo de la interpretación; las revistas y periódicos reflejan bastante bien cómo eran acogidos los conciertos, ya que la crítica profesional se estableció gracias a escritores como Eduard Hanslick y George Bernard Shaw. En Inglaterra, las sociedades corales tendían a relacionar la buena música con la religión, más que con la calidad musical, y el editor Vincent Novello les suministraba enormes cantidades de partituras vocales baratas; dichas asociaciones continúan brindando a los músicos aficionados la oportunidad, actualmente escasa, de aparecer en público. El movimiento de las bandas también formaba parte de una iniciativa de autoayuda y de superación moral y material.

La recuperación de la música antigua comenzó en serio, siendo ejemplos importantes la interpretación que hiciera Mendelssohn en 1829 de la *Pasión según San Mateo* de Bach y el repertorio coral dirigido por Brahms, que incluía obras de Morley, Schütz, Palestrina, Bach y Haendel. Mientras tanto, las ediciones de las obras completas de Bach, Haendel, Mozart y otros establecieron la noción del texto musical definitivo. Sin embargo, aún existía la creencia generalizada de que la música antigua tenía que ser actualizada en la interpretación; en la primera edición del *Grove's Dictionary,* el artículo de Ebenezer Prout sobre «acompañamientos adicionales» sostiene que la inter-

pretación literal de la música de Bach y Haendel no refleja las intenciones del compositor[9]. A la inversa, cada vez más músicos consideraban que los estilos interpretativos contemporáneos no se adecuaban necesariamente a la música de épocas anteriores. Músicos como Arnold Dolmetsch fueron pioneros de la concienciación histórica que tuvo gran aceptación durante el siglo XX. Sus actividades fueron oportunas, ya que la gran influencia de la dirección orquestal de Wagner había hecho que la música de las generaciones anteriores sonara más como la suya propia, reemplazando los elementos verbales de la interpretación por elementos pictóricos.

El siglo XX

El desarrollo de las comunicaciones en el siglo XX permitió a los músicos degustar y asimilar interpretaciones en todo el mundo. Las posibilidades de grabación cambiaron fundamentalmente el carácter de la ejecución musical, y el estudio de grabación originó una nueva veneración por la precisión técnica que a su vez se introdujo en la sala de concierto. La industria de la grabación ha influido enormemente en la comercialización de diversos tipos de músico, tanto en el campo de la música popular como en el de la música clásica.

En el siglo XIX, la música popular aún coincidía parcialmente con el concierto, el teatro y la música doméstica. Después de la Revolución Industrial, el público iba cada vez más a los parques, jardines públicos, salones de baile y teatros de variedades en busca de música, mientras que las melodías más recientes también se escuchaban en los organillos de la calle. Gradualmente, la música seria fue alejada del alcance del público general, ya que la opereta y el teatro de variedades suplían la brecha de accesibilidad que habían creado Verdi y Wagner. Pronto llegaron de América los bailes populares y las marchas de Sousa, y después el ragtime y el foxtrot constituyeron un verdadero descubrimiento. Al principio, el jazz combinaba diversos elementos musicales de África, Europa y América, y encontró rápidamente un lugar en los barcos fluviales y furgonetas publicitarias, así como en los desfiles, funerales, salones de baile y cabarés. La improvisación era una característica esencial que combinaba habilidades individuales y colectivas y se valía de diversos estilos incluyendo la marcha, el rag, el himno y el blues. Los intérpretes de jazz dejaron de verse a sí mismos como meros animadores y empezaron a considerarse cada vez más los defensores profesionales de un arte sutil y complejo.

En el período de entreguerras, Paul Whiteman ofreció una imagen sumamente accesible del jazz, y las comedias americanas más importantes de Kern, Gershwin, Rodgers y Cole Porter alcanzaron una enorme popularidad.

Las barreras nacionales tendieron a desaparecer después de aproximadamente 1940, cuando la música podía ser trasladada y grabada con facilidad y, por lo tanto, formar parte de un complejo mundo comercial y financiero. Entre los estilos importantes se encontraba el swing, con su novedosa instrumentación, su sonido vibrante y su potente impulso rítmico; después, a mediados de la década de 1950, el rock and roll, con una diferencia esencial de sonido, instrumentación e intención expresiva; más tarde, el rock de los años 1960 y 1970, con una variedad y libertad formal y tonal estrechamente vinculadas a los sentimientos políticos y el radicalismo social. Sus textos abarcaban desde lo político hasta las experiencias intensamente personales, combinados con una creciente amplificación y colección de artilugios electrónicos. La importancia artística de la música popular seguía ocupando a la crítica seria, y en 1967 Kenneth Tynan afirmó que la publicación del álbum *Sgt. Pepper's Lonely Hearts Club Band* de los Beatles constituía «un momento decisivo en la historia de la civilización occidental» [10].

En las salas de concierto, los intérpretes debían adaptarse a situaciones nuevas y hacer frente a dificultades técnicas cada vez mayores. Las agrupaciones pequeñas de diversos tipos desafiaban la supremacía de la gran orquesta sinfónica. A principios del siglo XX, obras como *La consagración de la primavera* y *La historia del soldado* de Stravinsky señalaron una mayor complejidad en las exigencias rítmicas. En esa época, uno de los grandes logros educativos del suizo Émile Jacques-Dalcroze fue enseñar a los jóvenes a pensar y sentir diferentes patrones rítmicos simultáneamente. A la mayoría de los músicos de orquesta de 1910 les resultaba muy difícil ejecutar grupos de cinco notas en un compás de 3/4 o 4/4; en cambio, para los que se habían formado con el método Dalcroze eso era un juego de niños.

Además de las influencias del jazz y el ragtime, los cantantes e instrumentistas debían responder a los requerimientos de la composición serial, y a veces se les exigía aventurarse en terrenos aún más desconocidos, como los cuartos de tono. A la mayoría de los instrumentos de orquesta se les exigía abarcar ámbitos extendidos y técnicas nuevas como la producción de acordes en instrumentos de viento-madera. Precisar el límite que separa a los sonidos musicales de los ruidos se convirtió en el objetivo de innumerables experimentos, como las obras de Varèse y el *Ballet mécanique* de George Antheil, escrito en 1924 para diez pianos e instrumentos y máquinas eléctricas, incluyendo hélices de avión. Los recursos electrónicos desarrollados a lo largo del siglo XX amenazaron con usurpar del todo el papel del intérprete. En 1947, Stravinsky condenó la interpretación y exigió un enfoque estrictamente objetivo por parte del intérprete. Sin embargo, la notación musical se extendió incorporando elementos gráficos no convencionales para inspirar la improvisación, mientras que los principios aleatorios (o de probabilidad) también

constituían una fuente de experimentación. La indeterminación surge cuando al intérprete se le requiere elegir el orden del material o se le guía mediante algún proceso hacia un orden evidentemente aleatorio o fortuito. Influido por el budismo zen, John Cage ofreció tales opciones a sus intérpretes en su obra *Variations IV* (1963), «para cualquier número de intérpretes, cualquier sonido o combinaciones de sonidos producidos por cualquier medio, con o sin otras actividades».

En los años subsiguientes, los intérpretes se han beneficiado de las oportunidades que ofrecen la radio, la televisión, los CD y los CD-ROM; parece inevitable que éstos serán complementados por el internet, actualmente preparado para ofrecer nuevas posibilidades para la difusión de interpretaciones individuales. Mientras tanto, la gestión orquestal ha considerado los programas educativos como una manera de llegar a la comunidad y tender puentes entre la vida diaria y la sala de conciertos, reubicando al público como el centro de la actividad musical. Como señaló recientemente el director general de una orquesta londinense: «¿Quizá un siglo de rigurosa etiqueta musical ha reemplazado las emociones, el placer y la comunicación por el mundo académico, el orden social y el aislamiento?» [11].

Aproximaciones a la música de otras épocas

La conciencia histórica estaba suficientemente desarrollada en 1952 como para que Hindemith afirmara que toda música ha de ser interpretada con los medios de producción que se utilizaban cuando el compositor la ofreció a sus contemporáneos. Pero también se percató de las limitaciones de esa aproximación: «Nuestra forma de ser no es idéntica a la de nuestros antepasados, y por lo tanto su música, aunque la recreemos con absoluta perfección técnica, nunca tendrá para nosotros exactamente el mismo significado que tenía para ellos» [12]. En respuesta a la aceptación generalizada de la interpretación histórica, algunos se han preguntado cómo se puede relacionar el conocimiento histórico con la pasión y la convicción personal de un intérprete. Paradójicamente, este aspecto siempre ha sido una importante fuente de inspiración para los compositores.

Richard Taruskin ha sostenido que, de hecho, la responsabilidad absoluta reduce la práctica interpretativa a una lotería, ya que el intérprete no puede ejercer ningún control sobre el estado de la evidencia. Además, la necesidad de satisfacer las intenciones de un compositor (suponiendo que ello fuera posible) demuestra una falta de valentía, por no decir una dependencia infantil [13]. El autor cita a Stravinsky como ejemplo positivo de un compositor que ha cambiado de opinión sobre diversos asuntos interpretativos a lo largo de

su carrera. Taruskin considera que la interpretación histórica se ha ganado su posición actual por su novedad más que por su antigüedad; también considera que es un fenómeno característico de nuestra época. Sin embargo, el estímulo de la historia puede avivar la imaginación musical, lo cual puede ser tan importante como intentar recuperar cada detalle. Recientemente, Margaret Bent señaló que «cada repertorio de música antigua tiene su propia gramática y su propio dialecto. Como ocurre con las lenguas "muertas", esas gramáticas son recuperables, permitiéndonos entender la literatura escrita y saber bastante sobre cómo se realizaban o pronunciaban, incluso sin que sepamos cómo sonaban exactamente» [14].

El hecho de que la articulación separada fuese la norma en la época de Mozart constituye una evidencia histórica tan fundamental que difícilmente podemos ignorarla. El conocimiento también puede complementar el gusto propio de un intérprete en cuanto a la interpretación de ligaduras cortas o la formulación adecuada de una disonancia y su resolución. Es necesario tener en cuenta que antes de 1900, el vibrato en las cuerdas se utilizaba como ornamento y no como un recurso extendido. En efecto, la conciencia histórica puede iluminar la interpretación de múltiples maneras. Recientemente ha habido una sana interacción entre las prácticas moderna e histórica, ya que los principios históricos han comenzado a influir gradualmente en la tendencia predominante del mundo musical. Mientras tanto, las afirmaciones de autenticidad o incluso exactitud histórica («el Beethoven más original que se haya grabado jamás») [15] se han atenuado cada vez más. Los estilos interpretativos apropiados para diferentes épocas serán seguramente uno de los mayores legados del siglo XX, y ciertamente se ha abierto una relación más profunda con la notación. Sin embargo, una obsesión con el pasado ¿no refleja también una terrible brecha entre los compositores modernos y su público? Resulta difícil no coincidir con el gran musicólogo Donald Jay Grout, quien ya en 1957 comentó que si un compositor de música antigua

> pudiera por algún milagro ser devuelto a la vida en el siglo XX para interrogarle sobre los métodos de interpretación de su época, su primera reacción sería indudablemente de asombro por nuestro interés acerca de semejantes asuntos. ¿Acaso no tenemos una tradición musical viva, y debemos intentar revivir una que está muerta? La pregunta puede resultar embarazosa. El arcaísmo musical puede ser síntoma de una civilización en decadencia [16].

Durante el siglo XX, el lugar de la música contemporánea fue, en efecto, sustituido por interminables repeticiones de un repertorio establecido y conocido que entonces invitaba a comparar detalladamente las pequeñas diferencias interpretativas. Los retos del nuevo milenio son, por lo tanto, bastante dis-

tintos de las experiencias descritas en este breve análisis de la interpretación a través de la historia.

2 *La interpretación histórica y el intérprete moderno*

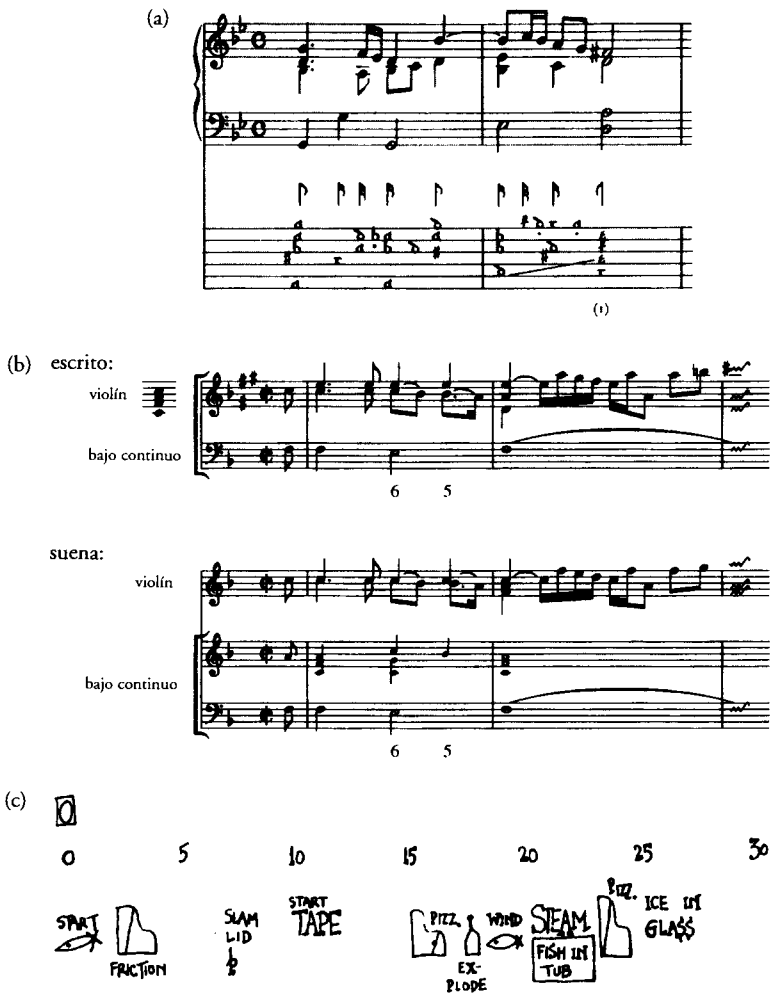
PETER WALLS

«Interpretación»

Este capítulo está dirigido a los «intérpretes modernos», independientemente de que toquen instrumentos históricos o modernos, o canten acompañados de cualquiera de ellos. Podríamos comenzar preguntándonos: ¿Qué es exactamente lo que deberíamos intentar al ejecutar una obra que ha sido compuesta antes de nuestra época? En realidad, la respuesta es esencialmente la misma para la música antigua que para una composición reciente. La mayoría de los intérpretes considerarán que hay que ser fiel a la obra, descubrir su contenido emocional e intentar respetar las intenciones del compositor. Todos valoramos la imaginación y la originalidad de los intérpretes, pero reconocemos que (normalmente) ellas están al servicio de la música que éstos ejecutan, ayudando a descubrir el carácter de la obra o a hacer perceptible su contenido emocional. Por lo general, no nos gusta mucho que la imaginación del intérprete distorsione o disfrace la música que está ejecutando.

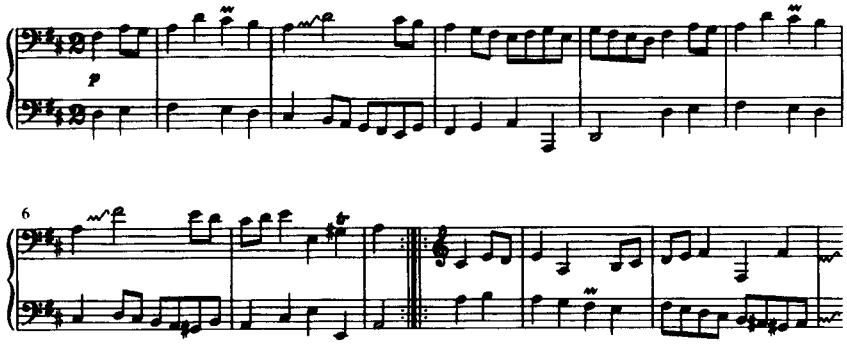
Este proceso de realización sonora de una obra musical se conoce generalmente como «interpretación» —aunque algunos compositores han discrepado mucho en cuanto a su significado. Un caso famoso es el de Ravel, que afirmó: «No pido que mi música sea interpretada, sino solamente ejecutada», una afirmación de la que Stravinsky se hizo eco al escribir: «La música debe ser transmitida y no interpretada, ya que la interpretación revela la personalidad del intérprete en lugar de la del autor, y ¿quién puede garantizar que el ejecutante reflejará la visión del autor sin distorsionarla?» [1]. Se queja-

ban, claramente, de las interpretaciones voluntariosas en las que destacan los caprichos de los intérpretes que no se justifican de ninguna manera en la partitura.



Sin embargo, la palabra «interpretación» debería ser adecuada para expresar lo que deseaban esos compositores. Una de las definiciones del término «interpretar» que ofrece el diccionario de la RAE es: «explicar o declarar el sentido de» una cosa [2]. En este sentido, se puede equiparar a la responsabilidad que tienen los intérpretes de lenguas extranjeras de no tergiversar el significado de lo que traducen.

Considerar la ambigüedad del término «interpretar» constituye una forma bastante útil de distinguir las interpretaciones que son fieles a la música que se está ejecutando de aquellas en las que se interponen otras cosas (como, por ejemplo, la habilidad para presentar algo de manera atractiva). De hecho, podríamos llamar «interpretación» al primer tipo de ejecución (vinculando el término a su significado esencial) y «apropiación» al segundo tipo (ya que, en cierto sentido, la obra musical se convierte en un medio que el intérprete utiliza para su objetivo personal). La interpretación, por lo tanto, puede ser sinónimo de intentar determinar y realizar las intenciones del compositor.



Lectura de la partitura

Toda música escrita requiere de «interpretación». Las partituras musicales aguardan su realización en sonido y, como ocurre con las lenguas extranjeras, la capacidad de leer música es un requisito previo para llevarla a cabo. Esto es algo que todos damos por sentado hasta que nos topamos con una forma de notación que desconocemos, como por ejemplo la tablatura de laúd (Ejemplo 2.1a), la scordatura (Ejemplo 2.1b) o la notación gráfica (Ejemplo 2.1c). Sin embargo, debemos reconocer que, así como la pronunciación y los significados de las palabras cambian con el tiempo, la notación musical aparentemente estándar tiene significados sutilmente diferentes dependiendo de dónde y cuándo fue escrita. De hecho, siempre requiere de una contextualización como parte de este proceso de interpretación. En 1717, François Couperin escribió lo siguiente sobre el problema particular de la música de su propio entorno: «Existen, según mi punto de vista, ciertas deficiencias en la manera en que escribimos la música que están relacionadas con la manera en que escribimos nuestro lenguaje. Se trata de que escribimos algo diferente de lo que tocamos. Ésta es la razón por la que los extranjeros no tocan nuestra música tan bien como nosotros tocamos la suya» [3]. Se refería, específicamente, a que en una serie de corcheas que se mueven por movimiento conjunto, se

EJEMPLO 2.2 *J. S. Bach, Gavota II, «Overture nach Französischer Art» BWV 831, compases 1-10.*

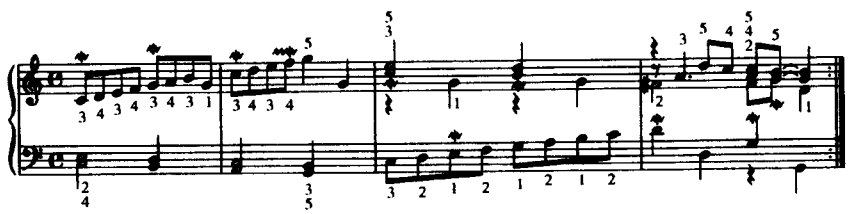
debía alargar sutilmente la primera corchea de cada par *(notes inégales)*, aunque su valor escrito fuese el mismo en apariencia.

Muchos elementos, incluso en una pieza bastante simple de música para teclado, presuponen cierto sentido del contexto. El Ejemplo 2.2 muestra la segunda Gavota de la «Ouverture nach Französischer Art» (Obertura en el estilo francés) BWV 831 de J. S. Bach. Esta Obertura (que en este caso significa Suite) fue una de las pocas obras que Bach publicó durante su vida. Apareció en 1735 en la Parte II del *Clavierübung* (Estudio para teclado), cuya portada especifica que fue escrita para «clave con dos manuales». La indicación *piano* que aparece al principio del primer compás tiene un significado importante, ya que con ella el compositor indica que ha de tocarse en el manual superior, cuyos martinetes pulsan un solo juego de cuerdas afinado a 8′ y cuyo sonido corresponde a la nota escrita. En contraste, la Gavota I (que precede y sigue a la Gavota II, como en la relación entre el minueto y el trío) está marcada *forte,* indicando que se debe tocar en el manual inferior con sus dos juegos de cuerdas, probablemente enriquecido incluso con un tercer juego (a 4′) afinado a una octava por encima. Evidentemente, esta alternancia de manuales crea un contraste dinámico entre las dos gavotas pero, más que eso, produce un cambio significativo de timbre.

En la época, este instrumento habría estado «bien temperado». En otras palabras, no estaba afinado según el «temperamento igual», que constituye la manera habitual de resolver un problema fundamental en los instrumentos de teclado moderno, a saber, que el «círculo» de quintas acústicamente puras no regresa exactamente al punto de partida. En el siglo XVIII, la solución preferida consistía en una gama de temperamentos circulares en los que algunas

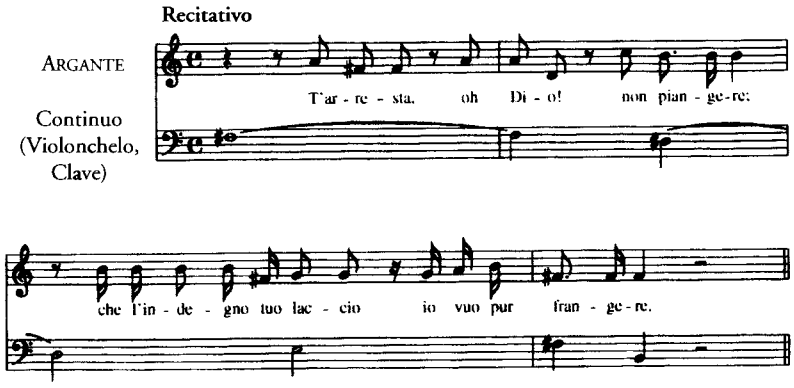
de las quintas (normalmente cuatro o cinco) son ligeramente menores que las acústicamente puras. Esto crea una especie de *chiaroscuro* (un término que empleó Tartini al recomendar uno de dichos temperamentos) [4] entre la agradable consonancia de los acordes más utilizados y el sonido más bien tenso de las armonías lejanas. Como consecuencia, cada tonalidad posee un carácter propio. Existen muchas instrucciones bastante detalladas del siglo XVIII sobre cómo establecer diversos temperamentos circulares. Determinar cuál era exactamente el que Bach prefería es cuestión de conjeturas, pero todos los temperamentos circulares comparten ciertos principios generales. Un método práctico bastante fiable para imaginar el efecto de estas afinaciones es considerar que cada nota del teclado está afinada adecuándose a su forma más simple, es decir, la que sea inferior según el orden de aparición de las alteraciones; de ahí que la nota inmediatamente por encima del Fa en el teclado sonará mejor cuando funcione como un Fa♯ que como un Sol♭, y así sucesivamente. Por lo tanto, el acorde de Re mayor —la tónica de la Gavota II— probablemente sonará más melodioso que el de Fa♯ (dominante de la Gavota I, que está en Si menor). En la Gavota II, un temperamento circular destacará sutilmente los alejamientos y acercamientos a Re mayor [5].

La indicación de que esta obra fue escrita para ser ejecutada en un clave de dos manuales puede considerarse como implícitamente más específica que lo que esos términos sugieren actualmente. No contamos con una información definitiva sobre los claves de Bach (aunque el inventario de su patrimonio señala que tenía cinco cuando murió). En 1719, Bach fue el encargado de comprar un instrumento de dos manuales de Michael Mietke para la corte de Köthen (de la que era Kapellmeister), y al parecer su constructor era muy respetado en Leipzig. Bach también trabajaba con el constructor de claves Zacharias Hildebrandt, radicado en Leipzig. Dos años antes de la publicación de la segunda parte del *Clavierübung,* un periódico de Leipzig había anunciado la reanudación de los conciertos del Collegium Musicum de Bach, que contarían con el atractivo de «un nuevo tipo de clave *[Clavicymbel]* que no se ha escuchado aquí anteriormente» [6].



Independientemente de los modelos, el clave posee características que influyen en la técnica. Las teclas ligeramente más cortas hacen que la digitación pianística ortodoxa sea poco práctica (especialmente el paso del pulgar en los pasajes de escala). Según su hijo Carl Philipp Emanuel, Bach era innovador en sus métodos de digitación y empleaba el pulgar más de lo que había sido normal hasta entonces —aunque aún tenía poco que ver con la digitación pianística moderma. Además, los ejercicios de digitación que incluyó en el «Cuaderno» que recopiló para su hijo Wilhelm Friedemann demuestran que esperaba que practicara las digitaciones de los dedos emparejados que se utilizaban entonces habitualmente (véase el Ejemplo 2.3). Tales digitaciones

se prestan a la sutil prolongación de la primera corchea de un par, produciendo *notes inégales.*



Tal vez las escalas de corcheas del Ejemplo 2.2 deban tratarse como *notes inégales,* ya que la Gavota II es explícitamente una pieza de estilo francés (y Bach era muy versado en la práctica interpretativa francesa). Los signos de ornamentación también son manifestaciones de un rasgo estilístico francés. En efecto, Bach incluyó una tabla de ornamentaciones en el «Cuaderno» de Wilhelm Friedemann que puede ser utilizado para descifrar los signos empleados en esa partitura. Por último, pero no por eso menos importante, es obvio que el hecho de que esta pieza sea una gavota (aunque evidentemente no danzada) influye directamente en el tempo y el carácter rítmico. Johann Joachim Quantz señaló que la gavota es un poco más lenta que una bourrée o un rigaudon, pero comparte el carácter alegre y bien articulado de esas danzas.

El Ejemplo 2.4, un breve recitativo que introduce un aria de Argante en la versión de 1731 de *Rinaldo* de Haendel, muestra un caso en el que es casi imposible leer la notación correctamente sin tener cierto conocimiento de algunos asuntos relativos a la práctica interpretativa. En primer lugar, cualquier cantante experimentado de la compañía de Haendel se habría dado cuenta de que hay que introducir apoyaturas allí donde las notas repetidas sobre un par de sílabas acentuada-no acentuada coinciden con los cambios de armonía y van seguidas de un silencio (en los llamados finales femeninos). Ésta es una manera de tratar debidamente la acentuación de las palabras y tiene una importancia sintáctica (más que decorativa). Dependiendo del gusto del cantante, en la frase «T'arresta» también se podría haber usado una apoyatura. El intérprete del clave continuo habría añadido una suspensión 4-3 en la dominante de la cadencia perfecta para evitar una disonancia desagradable con la apoyatura del cantante. Por otra parte, el violonchelista que toca junto con el clave habría sabido que las notas largas no se han de mantener con todo su valor escrito.

EJEMPLO 2.3 *J. S. Bach,* Klavierbüchlein für Wilhelm Friedemann Bach, *Applicatio BWV 994, compases 1-4.*

EJEMPLO 2.4 *Haendel,* Rinaldo *(versión de 1731), recitativo «T'arresta, oh Dio!».*

¿Cómo aprendían estos principios los intérpretes del siglo XVIII? Los aprendían de sus maestros, sencillamente al escuchar a sus colegas, de los tratados y de los ejemplos escritos. ¿Cómo los asimilamos hoy en día? De manera directa, sólo de las últimas dos fuentes (e indirectamente de dichas fuentes tal y como las interpretan nuestros maestros o intérpretes favoritos). Las apoyaturas de este tipo fueron descritas, por ejemplo, por Francesco Gasparini en su obra *L'armonico pratico al cimbalo* (Venecia, 1708)[7]. Un análisis aún más detallado puede encontrarse en la traducción profusamente comentada que hiciera Johann Friederich Agricola del tratado sobre canto de Pier Francesco Tosi[8]. Alessandro Scarlatti solía escribir exactamente las notas que quería que se cantasen en las cadencias como la que concluye el recitativo del Ejemplo 2.4. El aria que le sigue supone un conocimiento similar de las convenciones —particularmente las relacionadas con la ornamentación. Éstas también son analizadas por Tosi (y Agricola), pero existen algunos fascinantes ejemplos de arias operísticas ornamentadas por el propio Haendel[9].

¿Quién debería cantar esta música? En su producción de 1731, Haendel asignó el papel protagonista de Rinaldo al famoso castrato Francesco Bernardi, conocido como Senesino. Pero la parte de Argante (otro papel masculino) era cantada por la contralto Francesca Bertolli. Actualmente, los papeles masculinos de voces agudas tienden a ser asignados a falsetistas (contratenores). El contratenor operístico es un invento del siglo XX —una solución innecesaria al problema de la ausencia de castrati. Cuando Haendel se encontró en una situación similar (es decir, cuando no encontraba castrati que fueran suficientemente buenos), simplemente asignaba el papel a la mejor

cantante femenina de su compañía. Si queremos ser históricamente exactos, debemos seguir su ejemplo.

Resulta cómodo considerar que la notación es única o esencialmente preceptiva en relación a la altura y la duración de las notas. Sin embargo, los ejemplos de Bach y Handel que hemos analizado nos ayudan a identificar otros parámetros implícitos en la forma en que está escrita la música. Podríamos, por lo tanto, crear una lista de preguntas básicas con el propósito de alcanzar un conocimiento abundantemente contextualizado de la partitura musical:

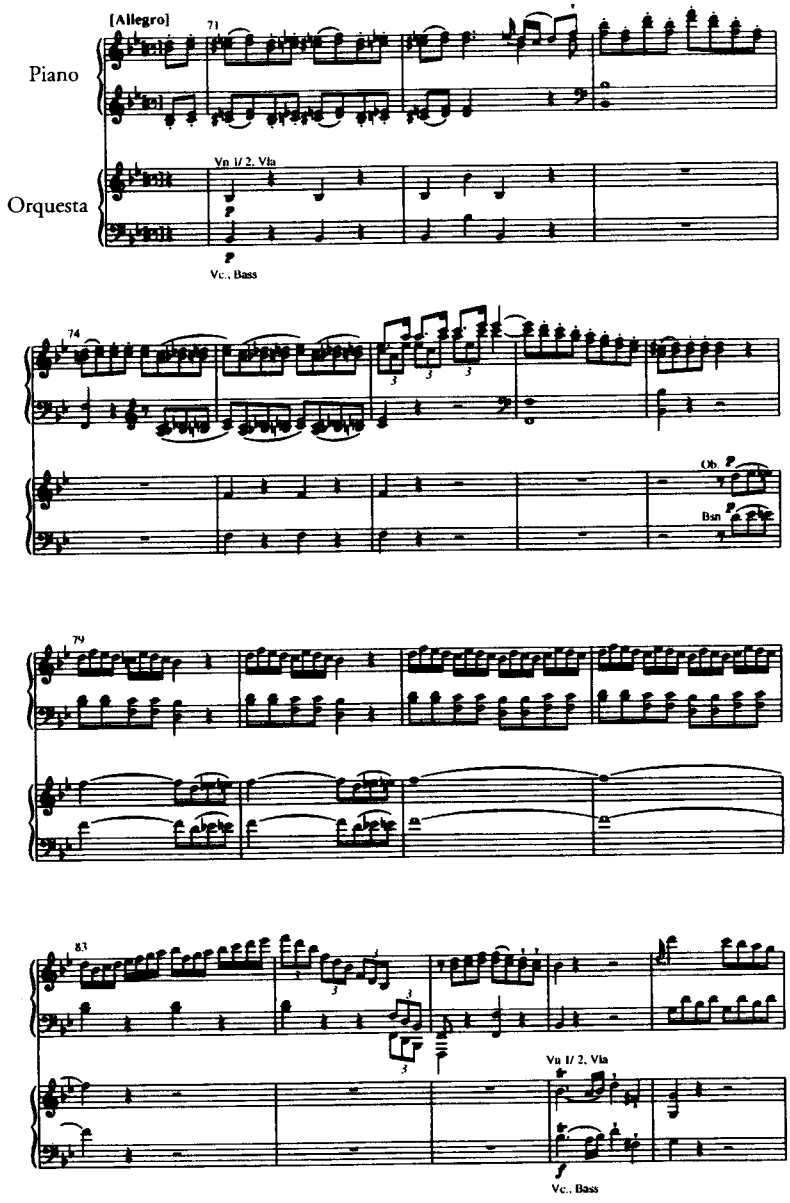
— ¿Para qué tipo de voces o instrumentos fue escrita?
— ¿Cómo se deberán disponer (afinar, etc.) esos instrumentos?
— ¿Qué tipo de técnica se pretende y cuáles son las indicaciones de ésta en cuanto a la articulación, el fraseo, el timbre, etc.?
— ¿Ha supuesto el compositor la existencia de un conocimiento de las convenciones rítmicas o sintácticas no explicitadas en la partitura?
— ¿Qué tipo de ornamentación, si la hay, es la apropiada?
— ¿Existen recursos expresivos que hubiesen parecido usuales cuando la música fue compuesta, pero que ya no forman parte del vocabulario del músico experto?
— ¿Existen aspectos de la expresividad moderna que no son adecuados para este repertorio?

Todas estas preguntas están tan estrechamente relacionadas con el conocimiento de la notación y sus matices, que hasta dudo si considerarlas como aspectos del contexto. Sin embargo, a esta lista (la lista «A») se podrían añadir otras preguntas (la lista «B») que también pueden influir en la manera en que abordamos la ejecución de una obra. ¿Para qué ocasiones fue escrita? ¿Fue compuesta teniendo en mente un tipo de acústica en particular?, etcétera.

Dar con las respuestas «correctas» a todas estas preguntas nunca es fácil, y muchas veces es imposible; además, dichas respuestas no son sustitutos para la imaginación del intérprete. En el mejor de los casos, el campo en el que funciona la imaginación es uno en el que una serie de suposiciones adquiridas es reemplazada por una gama alternativa de posibilidades estilísticas. El proceso de reemplazo puede en sí mismo actuar como estímulo para la imaginación musical. Carl Dahlhaus sostuvo que lo que distingue a una historia de la música —y, por extensión, cualquier historia de las artes— de otros tipos de historia es que se ocupa no sólo de cosas del pasado (hechos, documentos), sino de un presente estético [10]. Podríamos hacer una afirmación similar sobre el papel de los intérpretes. El intérprete, cuya tarea es realizar esa

partitura para un público contemporáneo, está especialmente involucrado en ese acto de mediación entre un pasado histórico y un presente estético.

El instrumento «apropiado»



En este punto, quiero examinar el parámetro más obvio de los descritos anteriormente —la elección del instrumento— y considerar su importancia como parte esencial de un conocimiento riguroso de la música escrita antes de nuestra época. Esto a su vez nos conduce a otra pregunta: ¿Hasta qué punto los intérpretes deberían tener libertad para hacer caso omiso de (o seguir desconociendo) la información históricamente verificable sobre cómo sonaba originalmente la música que tocan?

El interés por los instrumentos históricos se vio impulsado por la convicción de que la mejor manera de tratar la música de épocas anteriores es recreando los timbres instrumentales previstos por el compositor (en la medida en que éstos se puedan establecer). Existe, claro está, un punto de vista alternativo, que encontró su expresión más elocuente en los años 1870, cuando Philipp Spitta afirmó que el pianoforte moderno «flotaba en la mente de Bach» [11]. Spitta, incapaz de apreciar la belleza de un buen clave alemán del siglo XVIII (y que quizá nunca pudo escuchar uno en condiciones), estaba convencido de que la concepción intelectual de Bach iba por delante de la tecnología instrumental —en otras palabras, que sus obras para teclado sólo fueron reconocidas cuando surgió un instrumento digno de ellas.

De hecho, es interesante especular sobre cuál habría sido la reacción, por ejemplo, de Mozart, ante un piano de mediados del siglo XIX, o incluso ante un Steinway moderno de nueve pies. Puede que hubiera pensado (a la manera de Spitta): «éste es el instrumento de mis sueños; es lo que realmente quería para mis conciertos», o en cambio, «si tan sólo hubiera conocido este maravilloso instrumento, habría compuesto alguna música para él». Por otra parte, puede que lo hubiera rechazado como un producto poco refinado y más bien vulgar de una sociedad industrializada. No podemos saber con certeza cuál de estas reacciones (en caso de que fuera una de ellas) es la que habría provocado el piano en Mozart —pero sí sabemos que le entusiasmaron los fortepianos que conoció a finales de la década de 1770. Este hecho en sí mismo debería ser más que suficiente para que cualquier intérprete que quiera tocar las obras de Mozart las tenga muy en cuenta.

Lo primero que uno nota cuando se ejecuta una obra de Mozart en un instrumento de los que él conoció y amó es que la imagen generalizada de su música como una expresión clásica de discreción y elegancia tiende a desvanecerse con bastante rapidez. Incluso una obra como el Concierto para piano

EJEMPLO 2.5 *Mozart, Concierto para piano en Si♭ mayor K. 450, primer movimiento, compases 71-78 (piano y reducción orquestal).*

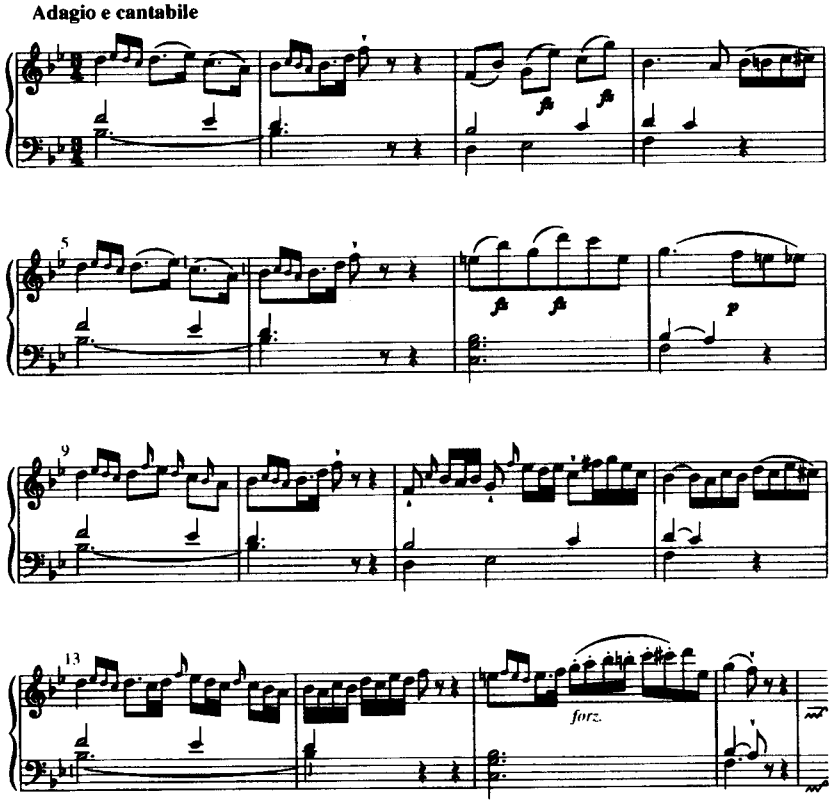
en Sib mayor, K. 450, que parece evocar un mundo de *dramma giocoso* al estilo de *Figaro,* utiliza los recursos del piano al máximo. El Ejemplo 2.5 comienza con el punto en el que el piano expone una idea delineada anteriormente en los compases iniciales en un hermoso diálogo entre los vientos y las cuerdas.

Cuando la parte solista alcanza la cadencia en el compás 86 (donde las cuerdas realizan una transición de un compás a la relativa menor), se expande hasta abarcar el ámbito completo de cinco octavas (Fa_1 a fa''') del instrumento de Mozart. Además, el sonido transparente del instrumento conviene tanto a las dobles terceras, tan predominantes en este ejemplo, como a las ligeras semicorcheas.

El manuscrito autógrafo de la Sonata en Mib mayor Hob. XVI:49 de Haydn asigna la obra al «Forte-piano» —siendo la primera sonata que el compositor describe de esta manera. Además, en tres cartas que le escribió a Maria Anna von Genzinger durante la época en que completó la sonata, en junio de 1790, deja bastante claro que la había compuesto con un instrumento específico en mente:

> He escrito esta Sonata para Vuestra Alteza hace un año, y sólo el Adagio es bastante reciente; recomiendo que preste especial atención a este movimiento, ya que contiene muchas cosas que analizaré para Vuestra Alteza cuando llegue la ocasión; es bastante difícil pero está lleno de sentimiento. Es una pena, sin embargo, que Vuestra Alteza no tenga un fortepiano de Schantz [*sic*], ya que con él podría lograr un resultado doblemente eficaz [12].

En dos cartas subsiguientes explica y reafirma su preferencia, no sólo por el fortepiano, sino por uno de Schanz. En la primera, Haydn insiste en que esta sonata no funcionará muy bien en un clave:



> Es una pena que Vuestra Alteza no posea un fortepiano de Schantz [*sic*], en el que todo se expresa mejor. He pensado que Vuestra Alteza podría traspasar su clave [*Flügl*], que aún está en buenas condiciones, a Fräulein Peperl, y comprar uno nuevo. Vuestras hermosas manos y su habilidad de ejecución se merecen eso y mucho más. Sé que he debido componer esta Sonata de acuerdo con las capacidades de su teclado [*Clavier*], pero me ha sido imposible porque ya no estoy acostumbrado a él... [13].

En la siguiente carta (fechada el 4 de julio de 1790) Haydn explica detalladamente por qué prefiere los instrumentos de Schanz a los de otros constructores vieneses, haciendo hincapié en la ligereza de su respuesta. Es evidente que destaca la importancia que la respuesta del instrumento tenía para él como

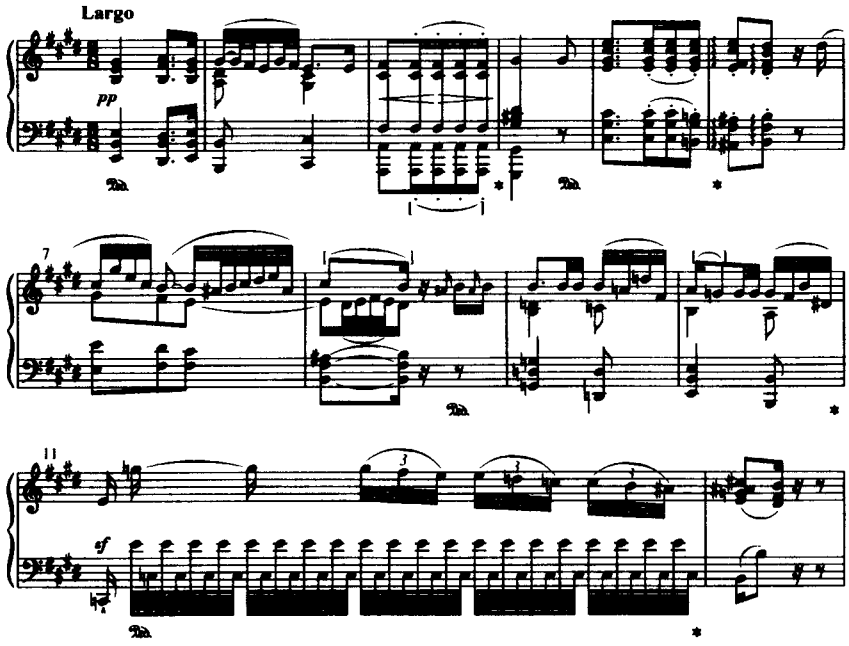
compositor: ya no estaba acostumbrado ni siquiera a un buen clave, y por ello se le hacía «imposible» escribir de una manera que conviniese a Maria Anna Genzinger. Como consecuencia, la mejor manera de *interpretar* esa obra era reproduciendo no sólo el sonido, sino también la respuesta del instrumento que tenía en mente.

Hay varios puntos en esta sonata en los que Haydn utiliza indicaciones que parecen presuponer la utilización de un fortepiano. Los movimientos primero y último tienen un solo *crescendo*, mientras que el Adagio e cantabile presenta varios *sforzando* y cambios dinámicos dentro de una frase (que no podían realizarse de manera convincente mediante un cambio de manual).

EJEMPLO 2.6 *Haydn, Sonata en Mi♭ mayor Hob. XVI:49, segundo movimiento, compases 1-16.*

Sin embargo, casi todas las características específicamente pianísticas son más sutiles —cuestiones del tipo de fraseo cantabile en el que destacaba el fortepiano (véase el Ejemplo 2.6). No obstante, para una persona suficientemente decidida, esta sonata podía tocarse en un clave.

Como hemos visto, Haydn le recomendó a la buena amiga para quien había escrito la Sonata en Mi♭ que adquiriera un instrumento más apropiado (en este caso, uno más moderno). Podríamos imaginarnos a Haydn adaptando su carta y su recomendación a nosotros. Al fin y al cabo, se justificaría igualmente que le señalara a los pianistas del siglo XXI que un instrumento ligero como los de Schanz le vendría mejor a la sonata que un Steinway, cuyo mecanismo es mucho más pesado. Y, como en el ejemplo de Mozart citado anteriormente, el sonido más transparente de un fortepiano vienés de finales del siglo XVIII es mucho más conveniente para las terceras que predominan en esta sonata. A. Peter Brown comenta:



> las diferencias entre el clave y el *fortepiano* del siglo XVIII no son, ni con mucho, tan pronunciadas como la disparidad entre un Steinway o Bösendorfer moderno y el antiguo *fortepiano* Stein o Walter. Los instrumentos fabricados en Alemania y Austria durante el siglo XVIII tenían una articulación brillante y seca que poco tiene que ver estéticamente con los grandes pianos ingleses, de sonido grueso y oscuro, que son los verdaderos antecesores del instrumento moderno [14].

Podríamos señalar argumentos similares sobre el instrumento «correcto» en relación a las músicas posteriores. En el Tercer Concierto para piano, op. 37, de Beethoven, las indicaciones de pedal de los compases iniciales del movimiento lento (Ejemplo 2.7) son incomprensibles y hasta imposibles en un Steinway de concierto moderno, pero constituyen un recurso tímbrico evocativo en el instrumento para el que fue escrito [15]. Carl Czerny, alumno de Beethoven, dijo que el comienzo «debe sonar como una armonía sagrada, distante y celestial» [16].

El incremento del ámbito y del poder sonoro del piano durante los primeros treinta años del siglo XIX redefinió la relación entre el solista y la orquesta en los conciertos para piano. Schumann era muy consciente de ello. No recomendaba que los pianistas buscasen instrumentos antiguos para interpretar conciertos de Mozart o Beethoven, pero sí opinaba que los compositores debían descubrir una nueva manera de abordar el género. En un artículo de 1839 titulado «Das Clavier-Concert» (El concierto para piano) publicado en el *Neue Zeitschrift für Musik* (la revista que había fundado en 1832), escribió:

> Esta ruptura de la relación con la orquesta, como hemos visto, se estaba preparando hace tiempo. El arte pianístico moderno quiere retar a la [orquesta] sinfónica y so-

EJEMPLO 2.7 *Beethoven, Tercer concierto para piano op. 37, segundo movimiento, compases 1-12 (sólo la parte de piano).*

> bresalir mediante sus propios recursos; ello puede explicar la reciente extinción de los conciertos para piano... Sin duda sería una pérdida, en caso de que el concierto para piano y orquesta llegara a ser completamente obsoleto; pero, por otra parte, difícilmente podemos contradecir a los pianistas cuando afirman: «No necesitamos ninguna ayuda, nuestro instrumento puede bastarse por sí mismo». De manera que debemos esperar con confianza al genio que nos mostrará una forma nueva y brillante de combinar la orquesta y el piano, de modo que el autócrata al teclado pueda revelar la riqueza de su instrumento y su arte, mientras la orquesta, más que una mera espectadora, incrementa el conjunto artístico con sus numerosas capacidades expresivas[17].

A los que escuchan por primera vez un piano antiguo les resulta muy fácil advertir que es incapaz de hacer lo que un gran cola de nueve pies hace maravillosamente. Ver más allá de esto, sin embargo, proporciona grandes recompensas —escuchar su flexibilidad dinámica, sus gradaciones tonales y su brillante agilidad, que explican el entusiasmo que sintieron Mozart, Haydn y Beethoven por el instrumento.

Otros instrumentos pueden requerir inicialmente el mismo tipo de adaptación. En el caso del violín, vivimos la absurda paradoja de que, aunque Antonio Stradivari es reconocido popularmente como el mejor constructor de violines de todos los tiempos, en la práctica no confiamos en que supiera lo que estaba haciendo. Ninguno de los instrumentos de Stradivari que utilizan los virtuosos hoy en día conservan los ajustes que tenían cuando salieron del taller de Cremona. Sus barras armónicas han sido reforzadas, se les han insertado almas más gruesas, les han cambiado los puentes, se les ha recolocado el mango con otro ángulo, les han cambiado el tipo de cuerdas y se les han añadido barbadas. Por lo tanto, su sonido ha cambiado significativamente de diversas maneras que seguramente favorecen la ejecución de los conciertos del siglo XIX, pero perjudican a la música de la época de Stradivari.

El arte de lo posible

Una vez que hemos aceptado que las intenciones de Haydn (o cualquier otro compositor) se realizarán probablemente de la mejor manera en los instrumentos para los que fueron concebidas sus obras, existe otra pregunta práctica y pertinente que debemos confrontar como músicos del siglo XXI: ¿hasta qué punto deberíamos esforzarnos por adaptar los instrumentos a los repertorios? Después de todo, Haydn recomienda no sólo un fortepiano vienés, sino los instrumentos de un constructor en particular. Sin embargo, para la época en que compuso su siguiente y maravillosamente exuberante Sonata en Mi♭ mayor Hob. XVI:52 en 1794, le habían cautivado los instrumentos que había conocido en Inglaterra de John Broadwood y sus contemporáneos, que eran más robustos, con mecanismos más pesados y de sonido más rico. Cuando Haydn regresó a Viena en 1795 después de su segunda visita a Inglaterra, trajo consigo un nuevo «Grand piano Forte» de Longman y Broderip (cuyo ámbito se extendía hasta el do′′′′). De modo que, ¿debemos suponer que las tardías sonatas «inglesas» le estaban vedadas a Maria Anna von Genzinger (muy poco después de haber convencido a su marido para que invirtiera en un Schanz) y debían ser evitadas por los fortepianistas que no tuviesen acceso a un piano de estilo inglés de finales del siglo XVIII? En realidad, las últimas tres sonatas de Haydn no sobrepasan el ámbito de los instrumentos vieneses (aunque lo explotan al máximo), de modo que quizá Haydn quería asegurarse de que esas obras, por más que hubiesen estado inspiradas en la sonoridad del piano inglés, siguieran siendo accesibles para sus compatriotas.

Beethoven proporciona una interesante analogía, ya que sus composiciones para piano abarcan el período de mayores cambios de la historia del ins-

trumento. Las sonatas tardías sencillamente no pueden tocarse en el instrumento para el que fueron concebidas sus primeras obras. Entonces, los pianistas que deseen interpretar todas las obras para piano solo de Beethoven ¿deberán adquirir media docena de instrumentos para hacerlo?

En casos como éste, se debe distinguir entre una solución ideal (a la que frecuentemente se puede acceder en los proyectos de grabación comerciales) y una en general más práctica. Resulta interesante reflexionar sobre los testimonios históricos del pragmatismo que, para la mayoría de los músicos, constituye la única alternativa a verse confinados a un segmento cada vez menor del repertorio para su instrumento. Todos los compositores analizados en este ensayo combinan unas preferencias instrumentales muy precisas con una disposición a reconocer las exigencias de las circunstancias interpretativas reales.

La historia de la creación y revisiones de numerosas obras de Bach demuestra su voluntad de adaptarse a las circunstancias, cambiar de idea o explorar otras alternativas. En la *Pasión según San Juan,* por ejemplo, los laúdes y las violas d'amore de «Erwäge, wie sein blutgefärbter Rücken» son reemplazados por el órgano y los violines con sordina en la tercera y cuarta versiones. Los siete conciertos para clave solo (BWV 1052-1058) son considerados transcripciones de obras que fueron compuestas originalmente para otros instrumentos. Sin duda, dos de ellos —el Concierto en Re mayor BWV 1054 y el Concierto en Sol menor BWV 1058— son arreglos de los conciertos para violín en Mi mayor BWV 1042 y en La menor BWV 1041, respectivamente.

Sabemos que a Mozart le encantaban los clarinetes. Después de visitar Mannheim en 1778, le escribió una carta a su padre en la que expresa un gran entusiasmo por la eficacia de los clarinetes en un grupo orquestal: «¡Ah, si tuviéramos además clarinetes! No puedes imaginar el glorioso efecto de una sinfonía con flautas, oboes y clarinetes» [18]. Mozart continuó, claro está, escribiendo para el instrumento de manera memorable. Pero estaba preparado para contemplar las sustituciones en circunstancias en las que, como le acababa de ocurrir en Salzburgo, no había clarinetes disponibles. En 1786, al enviar las partes del Concierto para piano en La mayor K. 488 que iban a ser utilizadas en la casa del príncipe von Fürstenberg, escribió:

> Hay dos clarinetes en el concierto en La mayor. En caso de que Su Alteza no disponga de ningún clarinetista en su corte, un copista competente puede transportar las partes a las tonalidades adecuadas, en cuyo caso la primera parte ha de ser tocada por un violín y la segunda por una viola [19].

Igualmente, Beethoven propuso el violín como una alternativa al clarinete en su Trío en Si♭ mayor op. 11 (1798), y, como ocurre con las de Haydn, las

portadas de muchas de sus sonatas para piano indican piano o clave como alternativas (aunque eso se debe más bien a las prioridades comerciales del editor que a una sincera flexibilidad por parte del compositor).

La evidente disposición de estos compositores a adaptarse a las circunstancias debería ser un incentivo para los intérpretes modernos. Al menos en ciertas ocasiones, ellos estaban preparados para contemplar sustituciones cuando el instrumento que tenían en mente para una obra en particular no estaba disponible. Sin embargo, esa actitud realista no es lo mismo que la indiferencia, y no puede utilizarse para justificar un incumplimiento total de las intenciones del compositor en cuanto a las alternativas instrumentales. Además, sería una locura, ya que para participar de la esencia de las obras del pasado es fundamental que nos acerquemos —literalmente— lo más posible a su mundo sonoro. (Por desgracia, los límites de este ensayo no nos permiten considerar la falacia de que para lograr algo parecido al efecto original habría que aumentar los decibelios y timbres para los oídos acostumbrados a los espectaculares conciertos actuales.)

Conclusión

En este punto podemos regresar al concepto de «interpretación» tratado al principio del capítulo. Si es responsabilidad del intérprete realizar las intenciones del compositor, entonces el primer paso es, sin duda, intentar comprender plenamente la música. Algunos aspectos de esa comprensión no implicarán directamente (o al menos no conspicuamente) un sentido histórico. El análisis, obviamente, es una parte esencial de ese proceso. Pero son muchos los aspectos de la comprensión de la música (que en esencia es lo mismo que leerla correctamente) que requieren una perspectiva histórica.

Como he indicado antes, esa perspectiva puede verse simplemente como leer una partitura correctamente con el mayor conocimiento posible de sus matices. He definido esto como una lectura abundantemente contextualizada. Sin embargo, debemos refinar el concepto de contexto histórico, ya que al abordar prácticamente cualquier pieza musical tenemos que juzgar musicalmente cuáles son los aspectos históricos pertinentes a nuestra comprensión de la partitura y cuáles pueden ser desechados por irrelevantes o innecesarios. En otras palabras, debemos decidir cuáles son las preguntas que pertenecen a las listas «A» y «B», mencionadas anteriormente, y cuáles pueden relegarse a una «lista C», formada por características de las interpretaciones históricas que, por más interesantes que sean, nunca emularíamos [20]. El primer paso del juicio musical es decidir cuáles son los elementos históricos que no incorporaremos para preservar el aspecto estético de la música. Sin

embargo, el límite entre el «mero» contexto y los detalles que consideramos esenciales no es inalterable. Debemos permanecer abiertos a la posibilidad de descubrir la relevancia de detalles que parecen poco importantes.

El punto de vista sustentado en este ensayo se ha descrito frecuentemente como una búsqueda de la autenticidad histórica. Ese concepto, sin embargo, está rodeado de escollos. Como han señalado Peter Kivy y otros, es imposible en la práctica satisfacer las diversas facetas contenidas en una autenticidad absoluta —o, al menos, sería poco realista esperar una conformidad general con respecto a la autenticidad de un caso específico [21]. Así que, olvidémonos de la autenticidad, un término que ha creado más polémica de la que merece. Entre las diversas alternativas que se han sugerido, la «interpretación históricamente informada» es la que ha encontrado más aceptación. Pero también ésta ha sido cuestionada. Según Richard Taruskin, es inaceptable porque no supera el «test del antónimo», y resulta de poca ayuda para describir alternativas válidas [22]. No obstante, la objeción de Taruskin presupone que todo intérprete tiene la libertad de elegir entre adoptar o rechazar un enfoque que toma en cuenta lo que se puede demostrar de las intenciones del compositor. Esto sólo es cierto si aceptamos igualmente que el intérprete también puede elegir entre tocar las notas correctas o no. Por último, podríamos argumentar que es inaceptable tocar Bach en un instrumento apropiado para Brahms y sin tener en cuenta sus expectativas en cuanto a ciertos asuntos como la articulación y la ornamentación. Quizá deberíamos afrontar el hecho de que los intérpretes que pretenden tratar debidamente el aspecto estético de la música haciendo caso omiso de las implicaciones históricas de la partitura no merecen ser considerados como «diversamente capacitados» sino «históricamente desinformados».

Notas

1. Respectivamente, Maurice Ravel, citado por Marguerite Long, *At the Piano with Maurice Ravel,* Londres, Dent, 1973, p. 16; Igor Stravinsky, *Autobiography,* Nueva York, Simon and Schuster, [1936]; Nueva York, Norton, 1962, p. 75. Long también cita el siguiente diálogo entre Ravel y Toscanini: Ravel —«Ése no es mi tempo»—, Toscanini —«Cuando toco su tempo, la pieza resulta ineficaz»—, Ravel —«Entonces, no la toque»—, *op. cit.*, p. 18.

3 *Análisis y (¿o?) interpretación*

JOHN RINK

La confusión y la controversia tienden a reinar cada vez que se utiliza el término «análisis» en relación con la interpretación musical. Algunos estudiosos consideran que el análisis «está implícito en lo que hace el intérprete», por más «intuitivo y asistemático» que sea [1], mientras que para otros, los intérpretes *deben* emplear el análisis teórico riguroso de los «elementos paramétricos» de la obra para poder sondear su «profundidad estética» [2]. Indudablemente, la interpretación musical requiere la toma de decisiones —conscientes o no— en cuanto a las funciones contextuales de determinadas características musicales y la manera de proyectarlas. Incluso el pasaje más sencillo —por ejemplo, una escala o una cadencia perfecta— estará formulado según la manera en que el intérprete considere que dicho pasaje encaja dentro de una pieza determinada y las prerrogativas expresivas que le conceda. Tales decisiones no son necesariamente intuitivas y asistemáticas: la mayoría de los intérpretes examinan meticulosamente cómo «funciona» la obra y cómo superar sus diversos retos conceptuales. Ese proceso es analítico en muchos sentidos, pero es necesario explicar en qué consiste.

El objetivo de este capítulo es examinar la dinámica que existe entre los pensamientos intuitivo y consciente que caracteriza potencialmente al proceso analítico en relación con la interpretación. Después de examinar algunos escritos en torno a este tema, describiré un método de análisis que puede beneficiar a los intérpretes en lugar de constreñirlos [3]. Dicho método será ilustrado en un estudio de caso del Nocturno en Do♯ menor op. 27 núm. 1 de Chopin.

Perspectivas sobre el análisis y la interpretación

En un fascinante ensayo escrito en 1985, Janet Schmalfeldt le da voz a dos personalidades —la del analista y la del intérprete— para considerar la influencia mutua de sus respectivas interpretaciones de dos Bagatelles de Beethoven. Su diálogo es ingenioso pero cuestionable: el analista se expresa con mucha más autoridad que el intérprete, que parece subordinado a los mandatos teóricos de su contrario; además, la división en dos personalidades antagónicas apenas refleja cómo actúan la mayoría de los músicos. Sin embargo, la conclusión de Schmalfeldt parece acertada: «no existe una sola y única decisión interpretativa que pueda ser dictada por una observación analítica» [4]. Esta conclusión se hace eco del comentario que hizo Edward Cone en su clásica obra *Musical Form and Musical Performance,* «toda interpretación válida [...] representa, no una aproximación a un ideal, sino una decisión: ¿cuáles son las relaciones implícitas en la pieza que han de ser destacadas o explicitadas? [5].

Se han hecho comentarios similares en otros escritos, pero, como he señalado, también existe una escuela de pensamiento más doctrinaria que prácticamente exige a los intérpretes basar su interpretación en los resultados de un análisis riguroso. Uno de sus representantes es Eugene Narmour, quien en 1988 insistió en que «los intérpretes, como cocreadores [...] deben adquirir capacidad teórica y analítica [...] para saber cómo interpretar», y que se producen «muchas consecuencias negativas si las relaciones formales no son analizadas correctamente por el intérprete» [6]. Wallace Berry señaló igualmente que «la interpretación musical debe estar basada en un profundo análisis»; a diferencia de Schmalfeldt y Cone, Berry opina que «todo hallazgo analítico tiene una consecuencia en la interpretación» [7].

En 1989, Jonathan Dunsby cuestionó la legitimidad de tales preceptos, afirmando que «entender y tratar de explicar una estructura musical no constituye el mismo tipo de actividad que entender y comunicar la música. Estos polos de actividad se solapan indudablemente, pero no pueden superponerse completamente». Según Dunsby, un enfoque más deliberadamente analítico puede ayudar a los intérpretes a enfrentarse a los pasajes difíciles, pero sus enfoques generalmente pragmáticos excluyen el rigor metodológico asociado normalmente al análisis [8]. En una respuesta a su planteamiento, argumenté que «los intérpretes emplean continuamente un proceso de "análisis", sólo que es diferente del que se emplea en los análisis escritos. Este tipo de "análisis" no es un procedimiento independiente que se aplica al acto de interpretar», sino más bien «un componente del proceso interpretativo». Refiriéndolo como «análisis del intérprete» (es decir, «el estudio esmerado de la partitura, prestando especial atención a las funciones contextuales y la manera de proyectarlas»), destaqué que la «forma» musical es más importante que la estruc-

tura en la conceptualización que hace el intérprete de la música —una noción escurridiza pero esclarecedora cuya concepción es más temporal que la de la estructura. La temporalidad de la música es fundamental a este respecto, un factor que se ignora o subestima en algunos tipos de «análisis riguroso» [9], con consecuencias negativas cuando los resultados de dichos análisis se utilizan directamente en la interpretación. También propuse el término «intuición instruida», que reconoce la importancia de la intuición en el proceso interpretativo, y también reconoce que generalmente implica bastante conocimiento y experiencia —en otras palabras, que la intuición no necesariamente surge de la nada, ni tampoco es necesariamente caprichosa [10].

Objetivo y método

A pesar de las muchas discrepancias entre los estudios publicados, el análisis relacionado con la interpretación puede dividirse en dos categorías principales:

(1) análisis previo a una interpretación determinada (que probablemente servirá de base para ésta),
(2) análisis de la interpretación misma.

El primero, bien sea riguroso o de carácter más pragmático, es potencialmente *preceptivo* con respecto a la interpretación, mientras que el segundo tipo de análisis es *descriptivo.* El análisis post facto no es mi objetivo principal en este capítulo, aunque hay que destacar su importancia. Los gráficos de tempo y dinámica de la Figura 3.1 (basados en interpretaciones grabadas y en directo, respectivamente) ofrecen un ejemplo [11]; además, los músicos normalmente analizan (es decir, descomponen y evalúan) sus interpretaciones posteriormente, intentando encontrar diferentes y mejores maneras de comprender la música para sus futuras ejecuciones en un proceso de constante evolución.

He delimitado en otra ocasión los problemas relacionados con algunas «prescripciones», y la conclusión es que los intérpretes quizá hacen bien oponiéndose a todo intento *sistemático* de correlacionar los resultados de los métodos analíticos rigurosos con la verdadera interpretación. Por ejemplo, las demostraciones analíticas de una unidad motívica pueden ser fascinantes sobre el papel, pero generalmente son más para ver que para escuchar; por otra parte, destacar obstinadamente cada aparición de un motivo importante en la interpretación podría producir resultados absurdos, aun cuando el conocimiento del desarrollo motívico de una pieza determinada pueda resultarle útil al intérprete (por ejemplo, para formular la música con respecto a los

timbres o la dinámica). Igualmente, aunque un análisis schenkeriano puede ilustrar elegantemente la complejidad jerárquica de una estructura tonal, sería cuestionable hacer que la interpretación se corresponda e intentar recrear el análisis en sonido, por más valioso que pueda ser el conocimiento de los procesos y relaciones implícitas en ese análisis para estructurar la interpretación.

No obstante, un estudio analítico riguroso puede ayudar a los intérpretes a resolver problemas conceptuales o técnicos (como he señalado antes), así como a memorizar y a combatir el miedo escénico. Los capítulos 8 y 12 tratan respectivamente sobre los dos últimos asuntos, mientras que en este capítulo se demostrará que el análisis es una herramienta para resolver problemas y se incluirán ejemplos de una concepción paralela del análisis con la cual planteo que los intérpretes frecuentemente entienden la música de un modo similar a los que realizan un «análisis riguroso» pero en términos diferentes —un paralelismo que ignoramos por nuestra cuenta y riesgo.

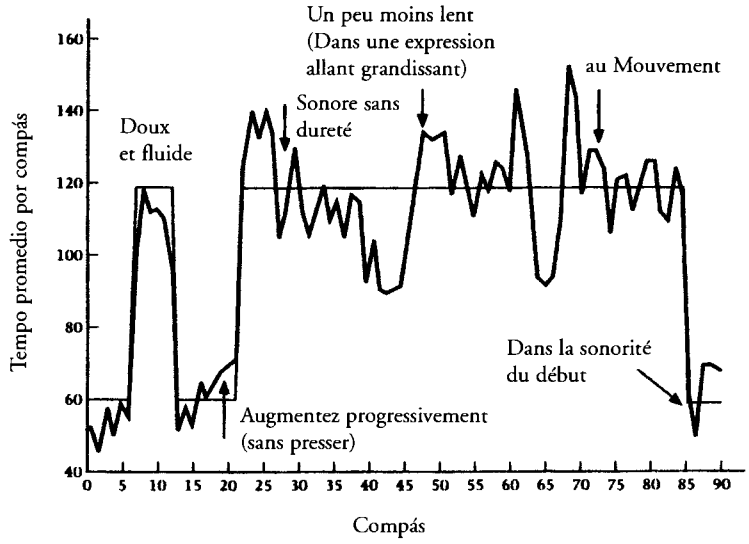

FIGURA 3.1 *(a) «Gráfico del tempo» de la interpretación de Claude Debussy, grabada en un cilindro de pianola (1913), de «La Cathédrale engloutie»; reproducido con autorización de Oxford University Press de José A. Bowen, «Finding the music in musicology: performance history and musical works», en Nicholas Cook y Mark Everist (eds.),* Rethinking Music, *Oxford, Oxford University Press, 1999, p. 440.*

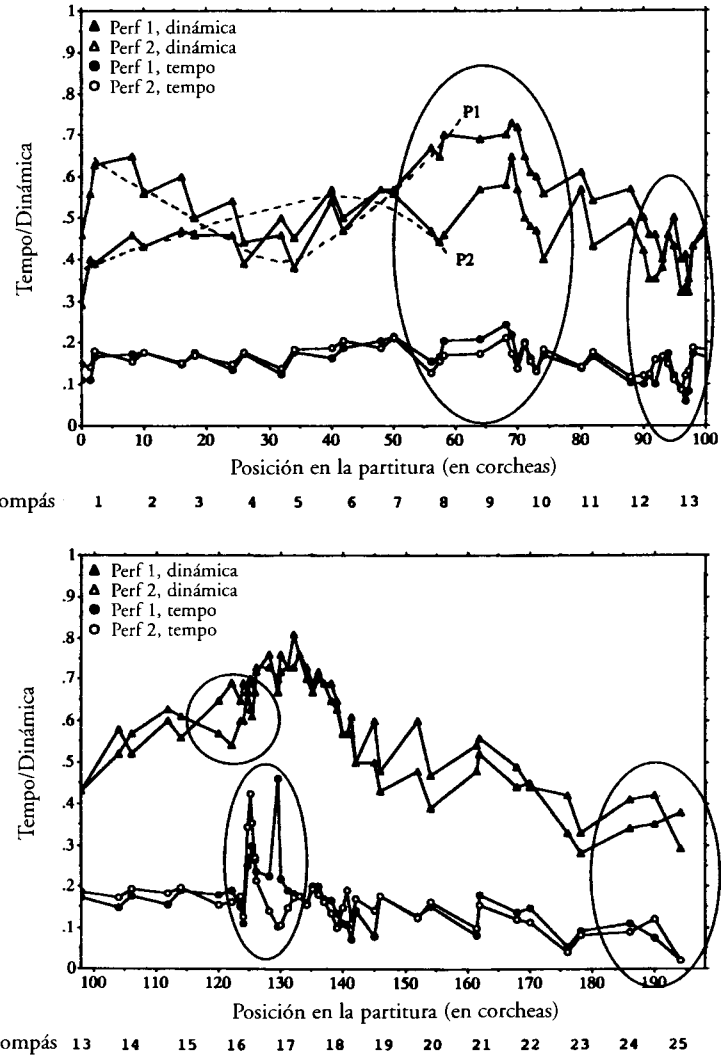

FIGURA 3.1 *(b) Gráficos de las fluctuaciones de dinámica y tempo en dos interpretaciones del Preludio en Mi menor op. 28 núm. 4 de Chopin (sólo la mano derecha; las unidades del eje vertical son arbitrarias pero parten de un cero real), reproducido de Eric Clarke, «Expression in performance generativity, perception and semiosis», en John Rink (ed.),* The Practice of Performance: Studies in Musical Interpretation, *Cambridge, Cambridge University Press, 1995, p. 32.*

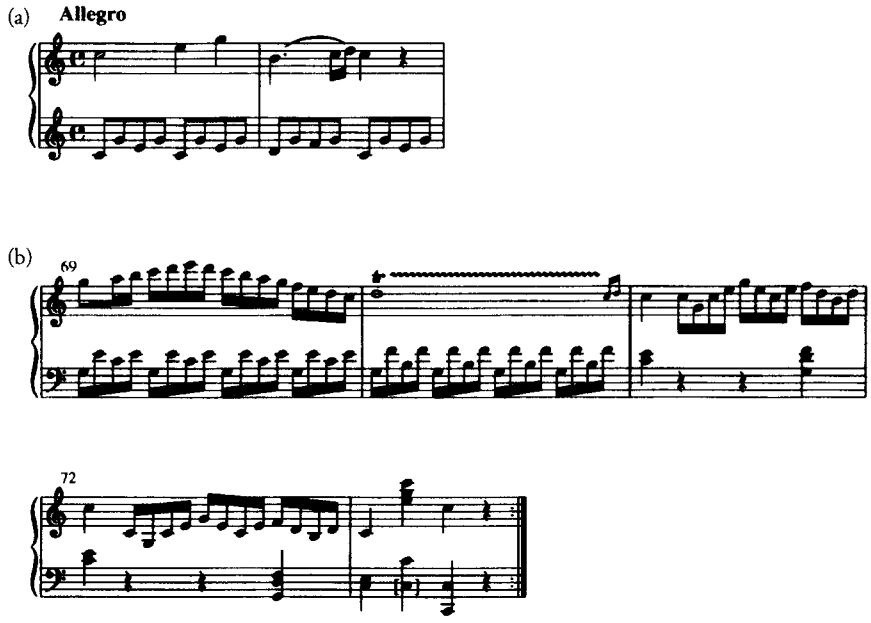


Para comprender ese paralelismo (un tema central de mi estudio de caso), es necesario que consideremos lo que el «análisis del intérprete» puede entrañar. La argumentación anterior se puede resumir en cinco principios:

(1) La temporalidad es inherente a la interpretación y por lo tanto es fundamental en el «análisis del intérprete».
(2) El objetivo principal de dicho análisis es descubrir la «forma» de la música, en oposición a la estructura, y la manera de proyectarla.
(3) La partitura no es «la música»; la música no está confinada a la partitura.
(4) Todo elemento analítico que repercuta en la interpretación será incorporado idealmente dentro de una elaboración más extensa en la que influyen consideraciones de estilo (en sentido amplio), género, tradición interpretativa, técnica, instrumento, etc., así como las capacidades artísticas del intérprete. En otras palabras, las decisiones que resultan del análisis no se deben priorizar sistemáticamente.
(5) La «intuición instruida» guía, o al menos influye, al proceso del «análisis del intérprete», aunque un enfoque analítico más deliberado también puede ser útil.

Hay que destacar que el «análisis del intérprete» se realiza principalmente durante la formulación y posterior reevaluación de una interpretación —es decir, mientras se está practicando, más que interpretando. Ello no excluye su posible influencia en la propia interpretación, ni que puedan surgir nuevos descubrimientos durante ésta. En general, sin embargo, el proceso analítico tiene lugar durante la fase (evolutiva) de diseño, y sus resultados son asimilados por el corpus de conocimientos que subyace en todo acto interpretativo.

Este tipo de análisis se puede ilustrar observando los primeros dos compases de la Sonata para piano en Do mayor K. 545 de Mozart (Ejemplo 3.1a). El pasaje consiste en un acompañamiento en forma de «bajo de Alberti» que apoya a una melodía en la mano derecha: una tríada arpegiada y un final cadencial ornamentado y de registro más limitado. La cadencia es débil: la séptima de dominante en la mano izquierda del compás 2 no está en posición fundamental, y el patrón rítmico de corcheas se mantiene uniforme. Además, la cadencia tiene lugar justo al comienzo de la pieza y carece de finalidad. Independientemente de que el intérprete conciba el pasaje en esos mismos términos, no hay duda de que estará al tanto de esas características y que ellas influirán correspondientemente en su interpretación. Por ejemplo, la mayoría de los pianistas destacarán mucho menos la cadencia en Do mayor del compás 2 que la cadencia que aparece al final del movimiento en los compases 69-71, mucho más definitiva y estructuralmente significativa

EJEMPLO 3.1 *Mozart. Sonata para piano en Do mayor K. 545, primer movimiento, (a) compases 1-2; (b) compases 69-73.*

(Ejemplo 3.1b) [12]. Tocar la cadencia del compás 2 con el mismo peso y la misma determinación sería difícil de justificar (¡aunque un Glenn Gould podría lograrlo!). En resumen, el conocimiento que tenga el pianista de la función contextual de cada cadencia determinará su formulación —el grado de dilatación del tempo (en caso de haberlo, en el compás 2), los niveles dinámicos de los elementos constitutivos en relación a ellos mismos y a la música en su conjunto, el tipo de articulación (pedales, pulsación, timbre), etc.

Se deberán tomar decisiones similares en cuanto a la melodía inicial del compás 1, que la mayoría de los pianistas articularán con un pequeño *crescendo*, destacando sutilmente, y quizá manteniendo, la primera corchea de cada grupo de cuatro en la mano izquierda. La tradición estilística y otros muchos factores influirán naturalmente en sus decisiones, pero en primer lugar el pianista debe reconocer explícitamente la tríada ascendente y arpegiada en la mano derecha y el acompañamiento en forma de «bajo de Alberti» en la izquierda —y cuando digo «explícitamente» no me refiero necesariamente a que deba hacerlo en esos términos. La cuestión es que si no se examinan de-

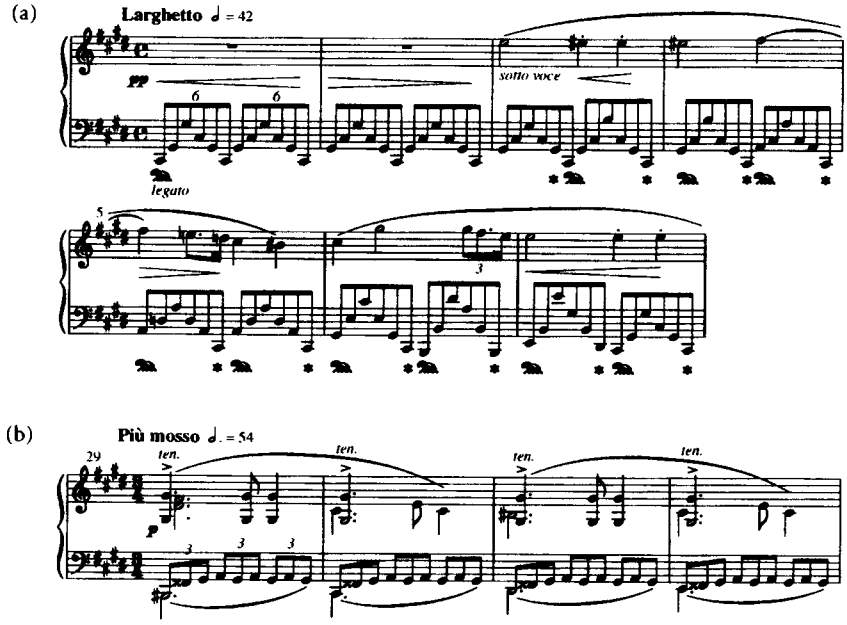
talladamente estos compases, ni se identifica la función de cada elemento dentro de su contexto inmediato como del contexto general, difícilmente se podrá concebir una interpretación viable.

El examen detallado y la identificación de las funciones —esencia de todo proceso analítico— se pueden efectuar a primera vista, como probablemente lo hará el músico experimentado, sobre la base de la «intuición instruida» mencionada anteriormente (es decir, sirviéndose de sus conocimientos sobre sintaxis, estructura melódica, patrones rítmicos, etc.). Sin embargo, la comprensión inmediata no excluye de ningún modo una reconsideración posterior y más deliberada de la manera en que funcionan diversos elementos en una pieza, y en esa fase es posible que se requiera de algo más que intuición.

Una de las maneras en que los músicos pueden satisfacer su «sed de conocimiento musical» [13] es aprendiendo técnicas más rigurosas, no tanto para aplicarlas posteriormente a la interpretación como para asimilar terminologías y conceptos que puedan mejorar su capacidad para explicarse a sí mismos y a los demás (alumnos, maestros, etc.), lo que está ocurriendo en la música. No es tanto al conocimiento a lo que temen algunos intérpretes como a los posibles *requerimientos* relacionados con él: comprensiblemente, a los intérpretes no les gusta que los eruditos les digan lo que deben hacer empleando un lenguaje dictatorial que coarta su libertad musical. No obstante, ser capaces de emplear un vocabulario más sofisticado, además del «arcano sistema de signos, gestos y gruñidos» [14] utilizado frecuentemente en los ensayos, y de comprender mejor las diversas maneras en que la música puede estar organizada, puede resultar provechoso para los músicos que se esfuerzan por alcanzar una intuición más instruida, un pensamiento consciente más profundo y una mayor capacidad de expresarse verbalmente.

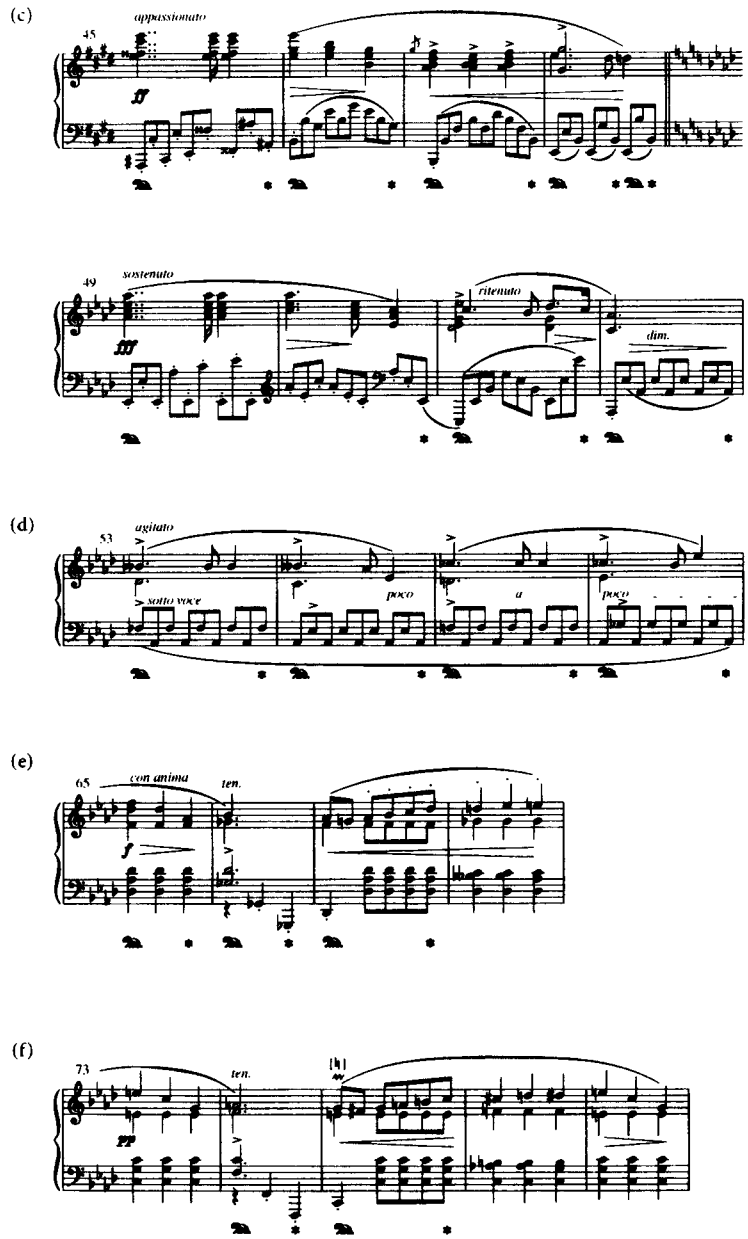
Dichas técnicas incluyen las siguientes:

(1) identificar las divisiones formales y el esquema tonal básico,
(2) representar gráficamente el tempo,
(3) representar gráficamente la dinámica,
(4) analizar la línea melódica y los motivos/ideas que la componen,
(5) elaborar una reducción rítmica,
(6) reescribir la música.



Describiré estas técnicas y el papel que desempeñan en la preparación del Nocturno op. 27 núm. 1 de Chopin, advirtiendo en primer lugar que su aplicación no está limitada a la música para piano solo. En principio, a cualquier músico le podrían resultar útiles estas técnicas, siempre y cuando no las considere como un objetivo en sí mismas, sino como un medio para mejorar su sentido del proceso musical. De nuevo, la temporalidad y la «forma» son

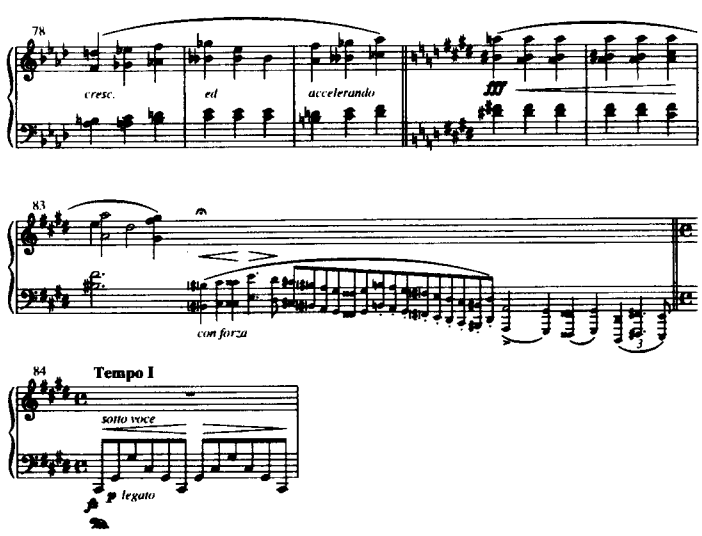
fundamentales para esta tarea analítica, como lo es igualmente reconocer la necesidad de una síntesis más extensa.



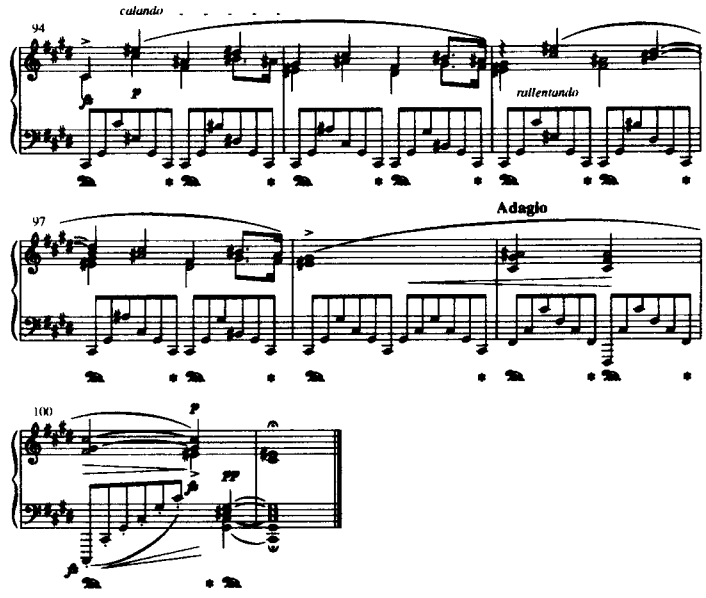
«Análisis de intérprete» del Nocturno en Do♯ menor de Chopin

Chopin compuso los Nocturnos op. 27 en 1835. El comienzo del primero es tenue (Ejemplo 3.2a), pero a la larga la música comienza a tomar cuerpo hasta alcanzar un poderoso clímax, después del cual se retrae tan sólo para volver a crecer (Ejemplo 3.2b-d). Entonces entra una melodía triunfal (Ejemplo 3.2e), seguida de una retractación casi inmediata (Ejemplo 3.2f) y un repentino colapso, culminando con una cadencia catártica que conduce al regreso de la fútil melodía inicial (Ejemplo 3.2g). El ánimo se torna más esperanzador en la coda en Do♯ mayor (Ejemplo 3.2h), que anticipa la lírica tonalidad de Re♭ mayor del segundo nocturno [15].

EJEMPLO 3.2 *Chopin, Nocturno en Do♯ menor op. 27 núm. 1; (a) compases 1-7; (b) compases 29-32; (c) compases 45-52; (d) compases 53-56; (e) compases 65-68; (f) compases 73-77; (g) compases 78-84; (h) compases 94-101.*



EJEMPLO 3.2 *(Continuación)*



EJEMPLO 3.2 *(Continuación)*

(g)

(h)

El primer reto técnico que se le presenta al pianista es controlar el acompañamiento, *pianissimo* y de registro muy amplio, del principio y la repetición, así como la figuración más vehemente, también en la mano izquierda, que aumenta su intensidad y extensión a medida que se acerca el clímax. Entre los desafíos más sutiles se encuentran el mantener la energía de las secciones «tenues» y controlar el dramatismo de la sección central para poder realizar expansiones graduales y contracciones abruptas. Algunos de los siguientes recursos analíticos pueden contribuir a alcanzar esos objetivos.

Identificar las divisiones formales y el esquema tonal básico

Una de las primeras tareas analíticas «deliberadas» que puede abordar el intérprete es determinar la forma de la música y su base tonal. La mayoría de los músicos saben lo que es una forma binaria o ternaria, la forma sonata, la forma rondó, etc., y puede ser útil analizar una obra en esos términos desde el principio, seguido quizá de una descripción más detallada y personal que destaque las principales secciones y subsecciones, el esquema tonal y otras características. Sin embargo, este tipo de diagrama no tiene más valor musical que un circuito eléctrico impreso, a no ser que uno comprenda sus símbolos arquitectónicos en términos diacrónicos, es decir, en términos de tiempo y proceso (sucesión de hechos en el tiempo). Esto es especialmente importante para el intérprete por las razones expuestas anteriormente.

La estructura del Nocturno de Chopin es relativamente sencilla, como demuestra la Figura 3.2. Está en forma ternaria, A-B-A′ más coda, con una división de la sección B en dos partes, definida por la melodía «con anima» en Re♭ mayor, el equivalente enarmónico de la tónica mayor (véase el Ejemplo 3.2e). La tonalidad de Re♭ mayor se ha alcanzado mediante una modulación desde Do♯ menor (sección A) pasando por Mi mayor a la dominante (escrita como La♭ mayor en el Ejemplo 3.2c), que actúa como un pivote importante en la sección B y la pieza en general. Después de una melodía nueva que aparece en el compás 65, y de la ruptura de los compases 78-80, regresa brevemente la dominante, que se mantiene hasta la repetición abreviada [16] de la sección A.

Una vez más, la manera en que los intérpretes conciben el Nocturno no debe corresponderse necesariamente con esta descripción «rigurosa». Los pianistas tienden en cambio a *sentir* las diversas áreas tonales como centros de gravedad que atraen o repelen el flujo de la música —áreas que serán subrayadas según su importancia, mereciendo menos énfasis (en la dinámica y la extensión temporal) la tonalidad transitoria de Mi mayor, por ejemplo, que la consecutiva dominante, que aparece en el clímax.

Compases	1-28				29-64	65-83		84-94	
Sección	A				B			A′	
Subsección	intro	A_1	A_2	'coda'	B_1	B_2	cadenza	intro	A_2'
Compás	1	3	19	27	29	65	83	84	86
Tonalidad	Do♯ menor				---Mi—La♭	Re♭---Sol♯		Do♯ menor	
	i				---III–V	= I V		i	

FIGURA 3.2 *Chopin. Nocturno en Do♯ menor, op. 27 núm. 1: esquema formal y tonal.*

Igualmente, los pianistas no considerarán la forma A-B-A′ como una secuencia de bloques seccionados, sino como un desarrollo diacrónico —posiblemente como una interacción entre fases estables e inestables o estáticas y dinámicas— o como una exposición seguida de una sección contrastante y un regreso [17]. Aunque ninguna de estas formulaciones reproduce exactamente lo que ocurre en la pieza, al menos representan nuestra sensación básica de la música durante la interpretación cuando se expande y contrae, se mantiene fija o avanza, etc. Un *sentido* de la «forma como proceso» es lo que realmente importa al intérprete, aunque para lograrlo sea necesaria cierta experiencia práctica y no tan sólo una asimilación intuitiva. Los diagramas como el de la Figura 3.2 pueden ayudar en ese respecto a pesar de su aspecto rígido.

Representar gráficamente el tempo

Aunque los gráficos de la Figura 3.1 proporcionan una valiosa imagen de la fluctuación del tempo durante la interpretación, es probable que ni los intérpretes ni los oyentes perciban tales fluctuaciones en un sentido literal: los «hechos» de la interpretación expresados por los datos sólo revelan una verdad parcial y un tanto engañosa [18]. Sin embargo, aunque lo anterior pueda repercutir en el análisis post facto de la interpretación, representar gráficamente la fluctuación del tempo puede resultar provechoso para los intérpretes como un análisis *previo a* la interpretación, es decir, mientras se prepara una interpretación. Una de las maneras de hacerlo es determinar las divisiones de tempo más generales de la obra y después delinear a mano el contorno de los tempos predominantes, teniendo en cuenta las pequeñas aceleraciones y ralentizaciones que ocurren durante una interpretación. Aunque este método a mano alzada carece del rigor de los diagramas de la Figura 3.1, puede

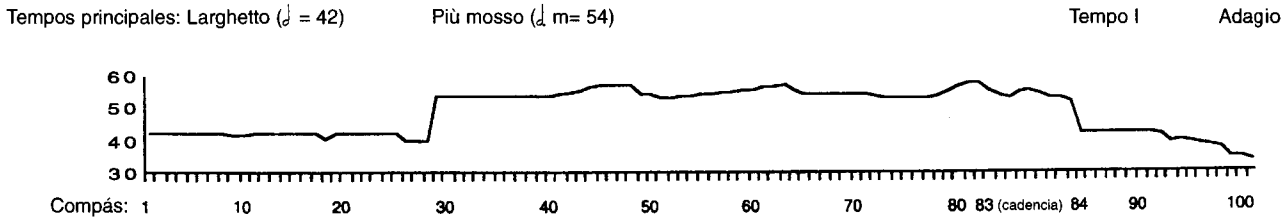


FIGURA 3.3 *Fluctuaciones de tempo en el Nocturno en Do♯ menor op. 27 núm. 1 de Chopin.*

representar más acertadamente la manera en que el intérprete «oye» la música, además de producir una imagen esclarecedora del proceso temporal.

Estos diagramas son mucho más fáciles de trazar cuando el compositor especifica las indicaciones metronómicas, y casualmente los Nocturnos op. 27 fueron las últimas obras en las que Chopin incluyó tales indicaciones. En el op. 27 núm. 1, la sección A está indicada «Larghetto 𝅗𝅥 = 42», y la sección B, «Più mosso 𝅗𝅥 = 54» (siendo la blanca y la blanca con puntillo, respectivamente, las unidades del pulso básico de cada sección). El tempo inicial regresa en la repetición, y los últimos tres compases se tocan Adagio (después de una ralentización gradual en los compases 93-96). Por lo tanto, la pieza puede verse como tres niveles de tempo que se suceden, seguidos del Adagio. Como en el caso anterior, los intérpretes no considerarán estos niveles como entidades, sino como una sucesión continua de pulsos predominantes que están sujetos a ajustes circunstanciales. He representado esa sucesión en la Figura 3.3 con un gráfico que simula los análisis post facto que hemos visto anteriormente, pero trazando el contorno del tempo de la música tal y como transcurre en el oído interior del intérprete. Además de ofrecer una imagen sincrónica, el gráfico también debe leerse de principio a fin, en otras palabras, como progresa el Nocturno. La interacción dialéctica entre el proceso diacrónico y el conjunto sincrónico es, de hecho, característica de la manera en que los intérpretes conciben la música en general —un punto importante al que regresaremos más adelante [19].

Representar gráficamente la dinámica

Podemos mejorar nuestro conocimiento del proceso musical elaborando un gráfico de los niveles dinámicos de la obra en cuestión, de nuevo como en la Figura 3.1 pero con un objetivo potencialmente preceptivo. Para ello trazaremos un diagrama como el de la Figura 3.4, en el cual las principales indicaciones dinámicas aparecen en el eje vertical, mientras que el horizontal indicará la progresión de los compases según las indicaciones dinámicas señaladas por Chopin. Uno de los puntos débiles de este método es su enfoque limitado del contexto, que generalmente influye en el significado de una indicación dinámica. (Por ejemplo, una indicación *piano* puede tener un significado diferente según se encuadre en un *fortissimo* o en un pasaje *pianissimo*.) Sin embargo, aunque las indicaciones dinámicas se interpretan nominalmente, y aunque también carezca del rigor de la Figura 3.1b, el gráfico proporciona una excelente perspectiva general del terreno dinámico, así como la oportunidad de percibirlo a medida que avanza. Esa percepción se puede obtener imaginando que la primera parte de la pieza procede más o

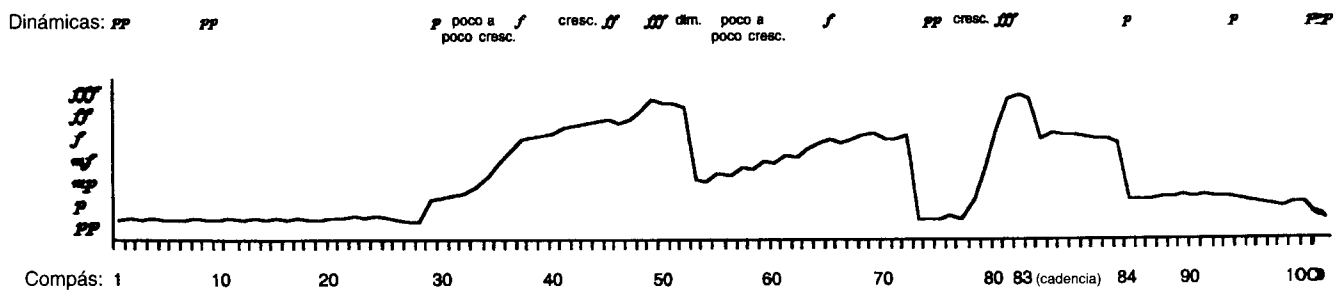

FIGURA 3.4 *Dinámicas del Nocturno en Do♯ menor op. 27 núm. 1 de Chopin.*

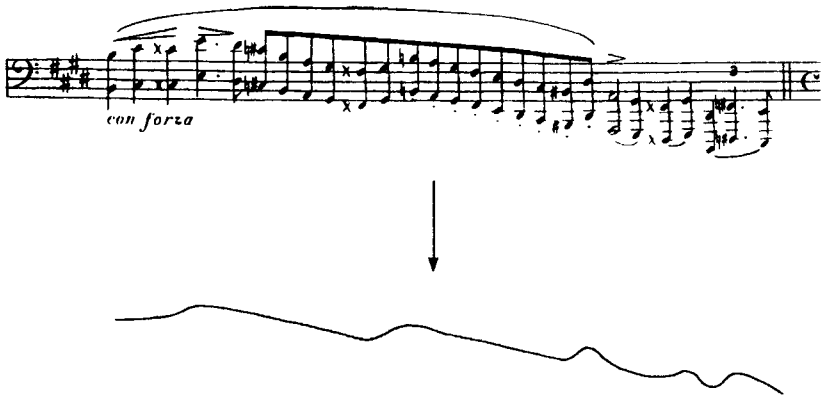
menos horizontalmente sobre un nivel básico, seguido de un rápido ascenso y un empinado descenso, después un ascenso más gradual hacia otro descenso abrupto y finalmente una tercera fase de ascenso y descenso que regresa más escabrosamente al nivel horizontal en el que comenzó la pieza. En mi opinión, Chopin vierte toda la energía potencial del Nocturno en la dinámica, o al menos representa ese flujo de energía en miniatura con las indicaciones dinámicas. En cualquier caso, el diagrama de las fluctuaciones dinámicas viene a ser una «curva de intensidad» de toda la pieza —es decir, «una representación gráfica de los altibajos de la música, de su "contorno" en el tiempo» [20]—, y si intentáramos plasmar la manera en que el intérprete siente el Nocturno, probablemente surgiría un diagrama como éste, cuya representación, una vez más, es importante tanto diacrónica como sincrónicamente.

Analizar la línea melódica y los motivos/ideas que la componen

Aunque resulta difícil idear una metodología general para el análisis melódico, puede ser instructivo trazar contornos melódicos en un papel sin las figuras de las notas, sus plicas, cabezas y otros elementos que distraen nuestra vista de la subyacente trayectoria de los tonos. En general, como se ha sugerido antes, la representación de la música en el oído interior del intérprete se asemeja poco a su apariencia en la partitura: a medida que se desarrolla la interpretación, la notación se transforma en una serie de acciones físicas correspondientes a imágenes mentales de diversos tipos, incluyendo las auditivas (analizadas en el capítulo 4). Los intérpretes suelen concebir la melodía como una línea (continua o no) que cantan para sí mismos mientras hacen música, y un gráfico literal del contorno melódico, que abarque pasajes breves o extensos (que en este último caso probablemente representen sucesivas alturas), se puede parecer más a esa imagen auditiva que la notación original. La Figura 3.5 traza el contorno melódico de la cadencia del Nocturno, cuya ondulación y propiedades gestuales se hacen mucho más evidentes cuando se destaca de esta manera [21].

El conocimiento de los patrones importantes dentro de una melodía, así como de los más generales, también influirá en la manera en que los intérpretes proyectan la música, aunque su objetivo principal no es demostrar la unidad motívica. Dichos patrones pueden sugerir un timbre o una articulación característica, así como texturas, ritmos y otros elementos recurrentes que influyen en la forma de la música. En el Nocturno de Chopin, las secciones A y A′ —caracterizadas por un registro reducido y un movimiento melódico predominantemente conjunto y monódico— presentan una evocadora contramelodía en los compases 20-26 y 89-93 (en forma abreviada) que



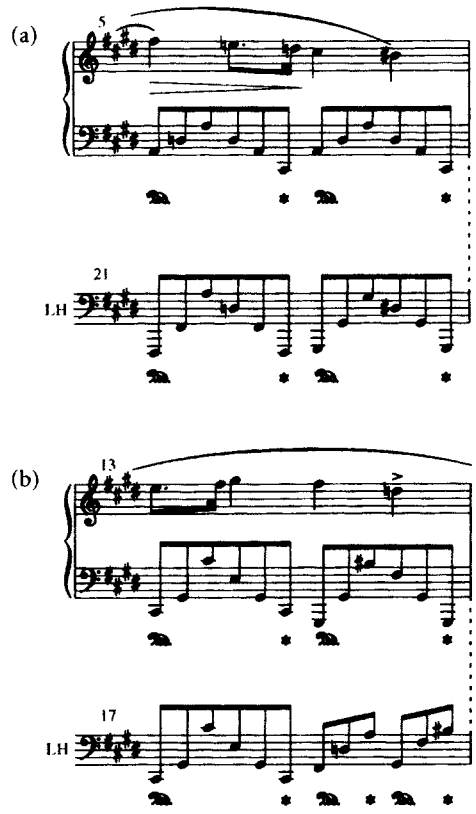


FIGURA 3.5 *Chopin. Nocturno en Do♯ menor op. 27 núm. 1: contorno melódico de la cadencia (partitura reproducida de la primera edición alemana: Breitkopf & Härtel, 1836).*

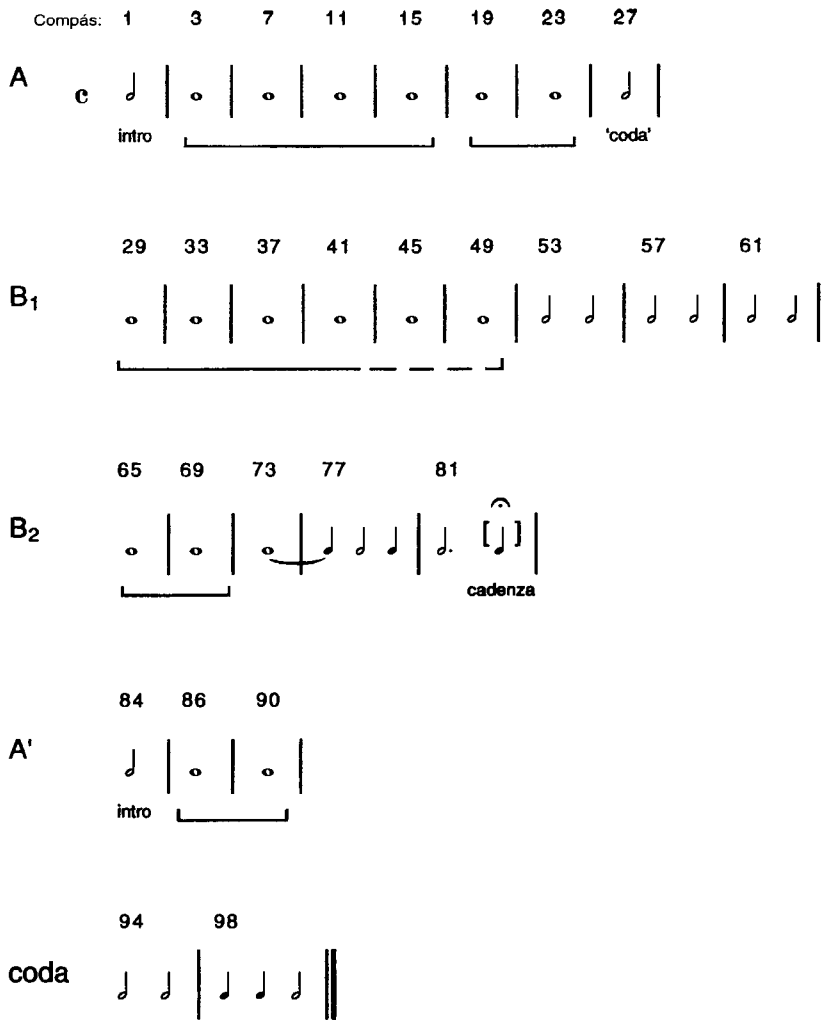
puede tocarse «nostálgicamente», es decir, con una pulsación pesada, aunque separada, y con una dinámica menos reticente que la tenue melodía a la que hace contrapunto, especialmente en los dos pasajes cadenciales (compases 25-26 y 92-93), el primero de los cuales se deja en suspenso, mientras que el segundo concluye el bloque principal de la pieza con su expresiva indicación «con duolo».

El poder expresivo de esas cadencias se debe en parte al sugerente Re♮ dentro del descenso melódico, que se repite a lo largo de A y A′ en dos disposiciones armónicas diferentes. La primera (Ejemplo 3.3a) emplea un Re mayor napolitano por encima de un insistente pedal de tónica, seguido de una cadencia. La segunda (Ejemplo 3.3b) contrapone la armonía de dominante al Re♮, que esta vez constituye un sustituto disonante del esperado Re♯ diatónico.



De nuevo, la terminología no es lo que importa: se trata de un técnica analítica pertinente para el intérprete —que en este caso implica extraer todas las apariciones del Re♮ de la partitura, yuxtaponerlas en papel para compararlas y después considerar sus respectivos roles dentro de la concepción de la interpretación. En mi opinión, los Re♮ proporcionan una clave para comprender las secciones A y A′; su proximidad a la tónica sugiere de alguna manera futilidad (particularmente cuando está armonizado con el acorde napolitano), mientras que la disonancia modal de los compases 13 y 17 parece arcaica y elegíaca, contrastando claramente con la belicosidad y el triunfo de la sección central.

EJEMPLO 3.3 *Chopin, Nocturno en Do♯ menor op. 27 núm. 1: Re♮ melódico en las secciones A y A′; (a) compases 5 y 21 (véanse también los compases 9-10, 25, 26-28, 88, 92 y 93); (b) compases 13 y 17.*

Elaborar una reducción rítmica

Cada sección del Nocturno posee un carácter rítmico particular, y si analizamos e identificamos la función de los principales elementos rítmicos descubriremos el papel que desempeñan en la generación, mantenimiento o suspensión del impulso rítmico. Por ejemplo, el invariable acompañamiento de corcheas de las secciones A y A′ y la coda produce la cualidad estática mencionada anteriormente; la figura con puntillo (♩. ♪ ♩) utilizada prácticamente

𝅗𝅥 = un compás en la notación

c indica un hipercompás de cuatro compases

FIGURA 3.6 *Chopin, Nocturno en Do♯ menor op. 27 núm. 1: reducción rítmica de la estructura de las frases.*

en toda la sección B_1 conduce la música hacia un clímax en dos fases; y las figuras de tres negras repetidas y de una negra y cuatro corcheas de la sección B_2 (𝅗𝅥 𝅗𝅥 𝅗𝅥 y ♩ ♫ respectivamente) ayudan a crear la sensación de triunfo pasajero.

Sin embargo, la reducción rítmica referida anteriormente no está relacionada con detalles rítmicos como ésos, sino con propiedades rítmicas en un nivel superior, a saber, la estructura de la frase. Los escritos sobre análisis describen diversas técnicas de reducción rítmica [22], aunque la más valiosa y accesible desde el punto de vista del intérprete podría ser representar cada compás (u otra unidad) como un valor rítmico proporcionalmente menor, como una negra, y combinar esos ritmos de acuerdo con las frases que se perciben en la música. El siguiente paso es discernir la forma dentro del diagrama resultante, es decir, las instancias de truncamiento, extensión, contracción, elisión, etc., en el nivel de la frase o superior. Esta técnica reductora funciona especialmente bien con Chopin, cuya predilección por las frases de cuatro compases es bien conocida, aunque la estructura de las frases de nuestro Nocturno no carece de impulso. En la Figura 3.6, cada redonda representa una frase de cuatro compases (o «hipercompás») [23], mientras que las blancas representan unidades de dos compases, y las negras, un compás. El diagrama revela que la sección A está formada por un patrón regular de frases de cuatro compases, exceptuando la introducción y la coda (de dos compases cada una), y, al igual que en la sección A', esa regularidad contribuye al carácter deliberadamente estático mencionado anteriormente. En la sección B_1, que comienza con una disposición de 4 + 2 destacando los compases culminantes 45-52, el ritmo de la frase se acelera en los compases 53-64 con seis unidades de dos compases en rápida sucesión. Ello forma una extensa anacrusa a la sección B_2, en la que el patrón de frases de cuatro compases, inicialmente equilibrado, se interrumpe en el compás 77, y las irregularidades resultantes en la estructura de la frase provocan el colapso en ese momento crítico. Aunque los intérpretes podrían intuir todas estas características, éstos comprenden un nivel estructural superior que puede resultar difícil incluso de sentir. Un diagrama como el de la Figura 3.6 ayuda a mostrar que en este Nocturno de Chopin la estructura de la frase y la forma de la música son dos caras de la misma moneda.

Reescribir la música

La notación convencional no capta toda la complejidad de la música, como todo intérprete sabe. Las sutilezas rítmicas son especialmente difíciles de plasmar, al igual que los matices dinámicos, las pequeñas variaciones de altu-

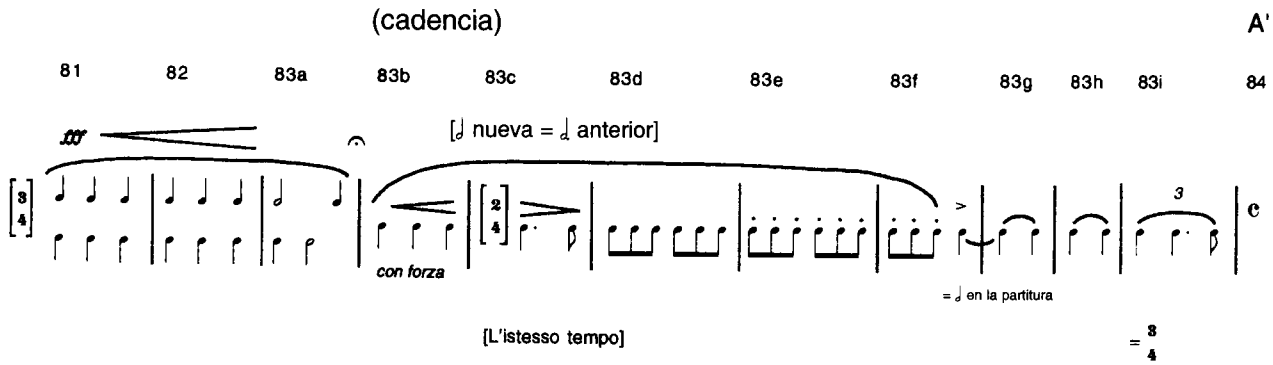


FIGURA 3.7 *Chopin, Nocturno en Do♯ menor op. 27 núm.1: reescritura de los compases 81-84 (con las dinámicas y ligaduras de Chopin).*

ra y la amplia gama de articulaciones que emplean los músicos. Reescribir la música puede reducir las insuficiencias de la notación original al arrojar luz sobre ciertas características ausentes o confusas en la partitura. Por ejemplo, podemos descubrir un esquema métrico alternativo, latente en el original, reescribiendo las partes relevantes de la música en el nuevo compás (o compases) y reagrupando las barras de compás cuando sea necesario para mover los tiempos fuertes y patrones de acentos que de otro modo estarían ocultos [24]. Ello no significa que la notación nueva capte totalmente «la música»: de hecho, la diferencia entre la versión original y la nueva es posiblemente lo más interesante para el intérprete, quien ha de reconocer que «la música» no se ajusta a ninguna de las dos, sino que existe, por así decirlo, en los intersticios entre ambas.

La reescritura también permite representar características como la ejecución rítmica a un nivel inferior, los estratos contrapuntísticos que pueden estar especialmente ocultos en la música para teclado, la distribución de las voces entre ambas manos o entre los miembros de una agrupación, etc.

La Figura 3.7 presenta una reescritura de los compases 81-84 del Nocturno de Chopin, elaborando particularmente las características métricas de la cadencia. Este diagrama surgió como respuesta a mi incertidumbre sobre cómo dar forma a la cadencia en una interpretación real: es producto de un análisis deliberado que emprendí porque la mera intuición era incapaz de resolver un problema muy difícil. El hecho de que el pasaje no esté dividido en compases en el original dificultó la ubicación de los acentos métricos, así como la organización rítmica interna del grupo de quince corcheas (véase Ejemplo 3.2g), factores que influyen en la dinámica, el *rubato* y la articulación y por lo tanto pueden extender o comprimir el contorno melódico de la Figura 3.5. En mi análisis, que desempeñó el referido papel de recurso para solucionar problemas, el compás 83b mantiene el 3/4 de los compases 81-83a, pero en el compás 83c se sugiere un 2/4, manteniendo constante la duración de los compases al equiparar la blanca con la blanca con puntillo (de modo que, retrospectivamente, el compás 83b parece un tresillo de negras). El grupo de quince corcheas se divide en los cuatro tresillos de los compases 83d-e, seguidos de un último tresillo en el compás 83f que impulsa la música hacia la octava sincopada sobre La (escrita como blanca en la partitura). A continuación, un ritmo más lento y regular conduce al tresillo de negras del compás 83i (el 3 que aparece por encima de la ligadura es de Chopin), que implícitamente reestablece el compás de 3/4 de los compases 81-83b al tiempo que prepara el regreso del ¢ (compás común) de la sección A′.

Resulta interesante considerar si Chopin tenía en mente este tipo de esquema organizativo cuando compuso el Nocturno. Indudablemente, sus ligaduras e indicaciones de dinámica y fraseo sugieren esa posibilidad, como

quizá también la estructura de las frases de ocho compases, que coincide con su práctica habitual. Sin embargo, si los pianistas «deben» o no tener en mente este tipo de esquema al interpretar el Nocturno es otro asunto. Crear un diagrama como el de la Figura 3.7 tampoco implica que haya que atenerse a él durante la interpretación; de hecho, yo toco esta música mucho más libremente de lo que sugiere esta nueva notación, por más reveladora que haya sido en un momento dado [25]. Los frutos de este tipo de ejercicios deben ser asimilados como cualquier otro conocimiento adquirido durante el proceso de elaboración de una interpretación —tal vez para que a partir de entonces los olvidemos y, sin embargo, los recordemos inconscientemente cada vez que la música se hace realidad.

Hacia una síntesis

He subrayado a lo largo de este capítulo que los conocimientos adquiridos mediante el análisis —bien sea intuitivo o deliberado— no son más que un factor que influye en la concepción de la música por parte del intérprete. Tanto el intérprete como el público valorará el éxito de una interpretación, no tanto por su rigor analítico, su fidelidad histórica o incluso su exactitud técnica (al menos en ciertos círculos) como por la medida en que logra una «resonancia» al unir los elementos constitutivos en algo mayor que la suma de esas partes, en una síntesis musicalmente convincente y coherente. El análisis puede estar «implícito en lo que hace el intérprete», y también puede ser abordado explícitamente empleando estas u otras técnicas. Sin embargo, es importante no elevar el análisis por encima de la interpretación que produce, o utilizarla como una manera de subyugar y encadenar a los músicos. En cambio, debemos reconocer su utilidad al igual que sus limitaciones, con lo cual quiero decir sencillamente que «la música» trasciende el análisis y cualquier otro intento de comprenderla. Proyectar «la música» es lo más importante, y todo lo demás no son sino medios para ese fin.

Notas

1. «La interpretación de una pieza musical es [...] la actualización de un acto analítico —aunque dicho acto haya sido intuitivo y asistemático— [...] el análisis está implícito en lo que hace el intérprete», Leonard Meyer, *Explaining Music,* Chicago, University of Chicago Press, 1973, p. 29.
2. «Los intérpretes no pueden sondear la profundidad estética de una gran obra sin examinar detalladamente sus elementos paramétricos.» Eugene Narmour, «On the relationship of analytical theory to performance and interpretation», en Eugene Narmour y Ruth A. Solie (eds.), *Explorations in Music, the Arts, and Ideas,* Stuyvesant, Pendragon, 1988, p. 340.

3. Cuando hablo de «intérpretes», me refiero principalmente a solistas, en oposición a los músicos de orquesta o agrupaciones, aunque las técnicas analíticas propuestas aquí pueden utilizarse para preparar interpretaciones de dos o más músicos. También pueden aplicarse a otros repertorios, a pesar de que este capítulo se centra en la música tonal de la tradición clásica occidental.

Para un resumen más detallado de la bibliografía sobre análisis e interpretación, véase Nicholas Cook, «Analysing performance, and performing analysis», en Nicholas Cook y Mark Everist (eds.), *Rethinking Music,* Oxford, Oxford University Press, 1999, pp. 239-261.
11. Véanse también los capítulos 11 y 14 de este libro (especialmente las Figuras 11.1-11.3 y 14.1-14.3). Se utilizaron técnicas bastante diferentes para elaborar los diagramas de la Figura 3.1. Para crear un gráfico de las fluctuaciones de tempo en una grabación en CD, se puede utilizar un ordenador que tenga lector de CD-ROM, pulsando una tecla para marcar el comienzo de cada pulso o compás; después el ordenador une las marcas sucesivas con líneas, como en la Figura 3.1a. Otra alternativa son los programas informáticos como «Sforzando», que permiten trazar las fluctuaciones de tempo y dinámica en las interpretaciones grabadas. En cuanto a las interpretaciones pianísticas en vivo, la información digital obtenida mediante un Yamaha Disklavier define las propiedades expresivas (i.e., duración, dinámica y articulación) de cada nota, que puede representarse gráficamente como en la Figura 3.1b (véase también las figuras 11.2 y 11.3). Obtener dicha información digital de la voz y otros instrumentos es más difícil, lo cual explica en parte por qué predominan en estas publicaciones las investigaciones sobre música para piano.
12. La breve coda de los compases 71-73 refuerza esa cadencia.
13. Jonathan Dunsby, *Performing Music: Shared Concerns,* Oxford, Clarendon Press, 1995, p. 46.

4 *Comprender la psicología de la interpretación*

ERIC CLARKE

Introducción: qué hacen los intérpretes

La interpretación musical en su nivel más alto requiere una extraordinaria combinación de habilidades físicas y mentales. No es inusual para un pianista concertista tocar a velocidades de diez o más notas por segundo en ambas manos simultáneamente, distribuidas sobre el teclado en patrones espaciales complejos que cambian constantemente y con diversos patrones de ritmo, dinámica y articulación. Además, el intérprete debe conocer y comprender la estructura inmediata y general de la música, contar con una «estrategia» expresiva para realizarla y tener resistencia para enfrentarse a los requerimientos físicos y las tensiones psicológicas que plantean la interpretación en público. Habilidades como ésas no se desarrollan de la noche a la mañana, y para el momento en que los mejores intérpretes llegan a la edad de veintiún años generalmente han pasado más de 10.000 horas practicando su instrumento [1], bastante más que el tiempo dedicado a otros aspectos de la educación musical formal y a los componentes más informales de lo que puede llamarse «culturización musical». Incluso observaciones tan sencillas como éstas revelan que la interpretación musical representa un logro humano asombroso y es el resultado de una enorme inversión de tiempo y esfuerzo.

¿Qué es, entonces, lo que hacen los intérpretes? En un nivel, la respuesta a esta pregunta es obvia: producen realizaciones físicas de ideas musicales, independientemente de que dichas «ideas» hayan sido registradas por escrito, transmitidas oralmente (como en las culturas analfabetas) o inventadas en el momento (como en la improvisación libre). El requerimiento más básico es

que el intérprete debe producir las notas, ritmos, dinámicas, etc. (más o menos) correctos de una idea musical —en caso de que exista una referencia (escrita o conceptual) con respecto a la cual se puede medir la «fidelidad». Sin embargo, además de eso, se espera que los músicos den vida a la música, que vayan *más allá* de lo que proporciona explícitamente la notación o la transmisión oral —que sean «expresivos». Por lo tanto, no es de extrañar que una parte sustancial de la investigación sobre la psicología de la interpretación haya estado de alguna manera centrada en cuestiones de interpretación y expresión.

Este capítulo tratará sobre tres aspectos de la psicología de la interpretación: las habilidades físicas y mentales que intervienen en la interpretación, la expresión en la interpretación y el cuerpo durante la interpretación. Los tres temas serán considerados principalmente desde la perspectiva de la tradición concertística occidental, ya que hasta ahora se han hecho muy pocas investigaciones acerca de la psicología de otros tipos de interpretación —aunque posiblemente muchas de las habilidades y características que se pueden identificar y estudiar dentro de la tradición occidental también se emplean en otras tradiciones interpretativas, permitiendo al menos cierta extensión hacia otros contextos culturales. También existe una amplia literatura etnomusicológica sobre diversas tradiciones interpretativas, parte de la cual hace referencia directa a la teoría psicológica [2].

Habilidades interpretativas

Como habilidad física, la interpretación musical ha despertado el interés de los psicólogos que estudian complejas habilidades relativas a los movimientos y el tempo. Los orígenes de ese interés se remontan a la obra de Carl Seashore [3], quien fue el primero en desarrollar técnicas para grabar las características detalladas del tempo y la dinámica de las interpretaciones. Seashore se dedicó principalmente a la precisión y reproductibilidad de la interpretación y a analizar la producción y control de sonidos en interpretaciones instrumentales, excluyendo los teclados. Henry Shaffer [4] y Caroline Palmer [5] desarrollaron esos objetivos de diversas maneras. Por ejemplo, Shaffer se centró en tres asuntos principales: el control del movimiento, los mecanismos del tempo en la interpretación y la coordinación e independencia de ambas manos en la interpretación pianística a solo y entre ambos ejecutantes en las interpretaciones a dúo. Su obra explora la manera en que la imagen mental de una pieza se traduce en los movimientos de la interpretación, y sostiene que el control del movimiento es bastante abstracto y conceptual hasta una fase relativamente tardía del proceso. Expone, por ejemplo, el caso de un intér-

prete que, leyendo a primera vista una fuga de Bach, no se fijó en un cambio de clave entre una página y la siguiente, de modo que produjo una serie de errores que, sin embargo, mantuvieron la armonía subyacente en el pasaje y no fueron simplemente las notas que habrían resultado de leer erróneamente la clave [6]. En cuanto el intérprete se dio cuenta de que algo iba mal, improvisó con un ritmo y una armonía apropiados mientras corregía el error. La presencia de información sobre la estructura musical dentro del programa mental que controla los movimientos es lo que permite una improvisación de emergencia como ésa.

Una de las maneras en que el control abstracto del movimiento ha de concretarse es en términos del tempo. El tempo es particularmente importante en la interpretación musical, ya que es un aspecto importantísimo de la estructura musical y también un medio de expresión. Shaffer y otros [7] han demostrado que los intérpretes expertos tienen un extraordinario control del tempo de la interpretación a niveles que abarcan desde una nota aislada hasta secciones o piezas enteras. Los intérpretes tienen la capacidad de juzgar y establecer el tempo absoluto de una interpretación con diversos grados de certeza y reproductibilidad, y se cree que algunos de ellos poseen un tempo equivalente al oído absoluto (es decir, la habilidad de establecer un tempo metronómicamente exacto sin necesidad de ninguna referencia externa). No existe una explicación generalmente aceptada del sentido del tempo, aunque se han sugerido varios tipos de «reloj interno» u oscilador interno [8]. Se ha propuesto que la formulación temporal a un nivel superior a la nota o el pulso es controlada por la representación (o imagen) mental que tiene el intérprete de la música. La estabilidad (o no) del tempo a un nivel superior puede por tanto atribuirse directamente a la estabilidad de la representación de la música que tiene el intérprete: los intérpretes que poseen una concepción clara y definida de una pieza musical, así como las habilidades técnicas necesarias, probablemente están mejor capacitados para tocarla de manera controlada y reproductible.

Una característica obvia de la interpretación de teclados es la coordinación entre ambas manos —y también el tema análogo de la coordinación entre los intérpretes de una agrupación. Shaffer demostró la considerable independencia entre ambas manos que pueden alcanzar los pianistas, bien sea porque lo exigen los polirritmos de la música, bien por razones expresivas [9]. También en este caso la independencia y coordinación de ambas manos se derivan de la estructura de la imagen mental. Es imposible lograr la independencia necesaria para tocar incluso un simple polirritmo flexiblemente si no se tienen imágenes o representaciones separadas de las partes de cada mano. Igualmente, la coordinación entre los dos pianistas de un dúo no depende (o tal vez no debería depender) de que uno de ellos siga rigurosamente al otro:

el análisis que hizo Shaffer de la interpretación de dos pianistas expertos tocando obras para cuatro manos de Beethoven indicó que implica un importante elemento de predicción por parte de ambos pianistas en cuanto al transcurso ulterior de la interpretación expresiva de cada uno [10]. Ello se puede explicar mediante la suposición de que los dos pianistas compartían una representación de la música y la utilizaban como punto de referencia a partir del cual podían anticipar mutuamente sus formulaciones expresivas. A pesar de la evidente importancia de escuchar y estar conscientes de la respiración, los movimientos corporales, los gestos faciales, etc., de cada uno como canales de comunicación, el papel de las respuestas auditivas y visuales en este proceso prácticamente no se ha investigado [11].

La lectura y la memorización son dos habilidades esenciales dentro de la tradición concertística occidental. A mediados de la década de 1970, Sloboda llevó a cabo un importante programa de investigación sobre la psicología de la lectura musical [12] para el que utilizó el «trayecto vista-mano» como indicador principal —una medida de la antelación con la que un músico procesa la notación durante la lectura. En sus experimentos, Sloboda midió dicha antelación pidiendo a los pianistas que siguieran tocando después de que se les retirara la partitura, repentinamente y sin previo aviso, utilizando cualquier imagen de la notación que perdurase en su mente. Sloboda descubrió que los lectores expertos tenían un «trayecto vista-mano» de unas siete notas, y que en los lectores más expertos esa medida se expandía y contraía coincidiendo con los límites de las frases de la música, lo que sugería que un factor importante en la lectura musical experta es la conciencia de la estructura musical. Los errores en la notación musical también demostraron la existencia de esa conciencia estructural. Sloboda demostró que los lectores expertos generalmente no se dan cuenta de los errores de imprenta aislados y tocan inconscientemente la nota «correcta». En efecto, en lecturas sucesivas de una pieza con errores de imprenta deliberados el número total de errores disminuía (como era de esperar), mientras que el número de «correcciones» inconscientes *aumentaba,* probablemente porque los lectores se familiarizaban con el material y hacían más suposiciones sobre su estructura. Cabe destacar que la lectura musical experta no es simplemente una habilidad visual: un estudio [13] ha demostrado que la capacidad de leer a primera vista está relacionada con la capacidad de hacer coincidir la notación con el sonido —en otras palabras, la habilidad de escuchar la música en el «oído interior» a partir de la notación.

Los estudios sistemáticos sobre el proceso de memorizar música para la interpretación a partir de la notación son sorprendentemente escasos [14], y se sabe relativamente poco acerca de los procesos que tienen lugar durante la memorización y la diversidad de estrategias que pueden utilizar los intérpre-

tes. La habilidad para memorizar música para la interpretación posee un valor cultural particular, aunque algunos podrían argumentar que hay tanto que decir en su contra como a su favor. En un estudio que evalúa el efecto de la memorización en las percepciones del público, Aaron Williamon halló ciertas pruebas de que mejora la comunicación musical [15], aunque sólo para los espectadores/oyentes con formación musical. Otro estudio [16] demostró que el enfoque visual es más eficaz (en cuanto al tiempo que se tarda en memorizar) que el auditivo, que, a su vez, es más eficaz que el enfoque cinestésico (la «memoria muscular»); también demostró que los que tienen más habilidad para memorizar son mejores leyendo a primera vista. Un estudio ulterior investigó el caso de un hombre autista (N. P.) que tenía una memoria musical auditiva excepcional [17] y demostró que a pesar de no haber visto nunca la partitura, este individuo era capaz de recordar y reproducir una pieza para piano de Grieg, de sesenta compases, prácticamente a la perfección después de haberla escuchado tan sólo cuatro veces, mientras que un pianista igualmente experimentado que participó como «factor constante» sólo pudo memorizar un fragmento de la pieza después de la misma cantidad de audiciones. Esta proeza evidentemente notable dependía de un conocimiento estilístico: cuando se realizó el mismo experimento con una pieza de Bartók, mucho más breve y estilísticamente desconocida por N. P., su memorización fue considerablemente peor, mientras que el pianista obtuvo en este caso un resultado muy superior. Los autores dedujeron que «la habilidad [de N. P.] tiene una base estructural», y que «necesita codificar el material en términos de estructuras y relaciones tonales, y su excepcional habilidad no puede actualmente traspasar los límites de esa estructura» [18].

La expresión en la interpretación

La expresión, o «sentimiento», es tan fundamental en todo tipo de interpretaciones que, paradójicamente, es fácil de ignorar: perdemos la capacidad de escucharla. Un examen más detallado del fenómeno, sin embargo, revela un tema rico que ha originado muchas investigaciones. Seashore, uno de los pioneros de la investigación empírica sobre la interpretación durante los años 1930, definió la expresión de la siguiente manera: «la expresión artística del sentimiento en la música consiste en el alejamiento estético de lo que está regulado —el tono justo, la afinación real, la dinámica uniforme, el tempo metronómico, los ritmos rígidos, etc.» [19]. Debido a que su obra y la abrumadora mayoría de las investigaciones posteriores se han dedicado a la tradición escrita occidental, la frase «alejamiento estético de lo regulado» se ha interpretado frecuentemente como «alejamientos deliberados de las indicaciones de

la partitura». Pero ¿cómo se distinguen los alejamientos deliberados de los accidentes? ¿Cómo es la música cuando no hay una partitura que tratar? ¿Qué debe hacerse con las indicaciones expresivas que aparecen en la partitura (*accelerandos* y *ritardandos*, *crescendos* y *decrescendos*, etc.)? ¿Debemos considerar inexpresivos los correspondientes cambios de tempo y dinámica en la interpretación, simplemente porque vienen indicados en la partitura? Se han propuesto otras definiciones de la expresión que han intentado superar esos problemas manteniendo sin embargo el principio básico de que la expresión es un alejamiento de cierta norma [20].

Existen límites, claro está, en cuanto a los «alejamientos» esperados o permitidos convencionalmente. En la tradición concertística occidental, no se espera que el intérprete cambie las notas y ritmos de una pieza musical (aunque ésa es una postura relativamente reciente: en el siglo XIX, y más aún en siglos anteriores, los intérpretes solían adornar o hacer otro tipo de cambios en las composiciones que interpretaban), o que cambie el orden de los movimientos o secciones (excepto cuando esa opción está explícitamente permitida en la partitura, como ocurre en obras como *Klavierstück XI* de Stockhausen) o que interprete la música a una velocidad mucho mayor o menor que la indicada en la composición (aunque existe mucha música anterior a la época del metrónomo que carece de una indicación fija de tempo del compositor). Pero incluso dentro de esos límites, los intérpretes tienen muchísimas posibilidades de adoptar enfoques diferentes, lo cual plantea un problema interesante a la psicología de la música: determinar qué es lo que hace que una interpretación suene «humana» y musicalmente eficaz, y distinguir esa interpretación de una que suena exánime, inadmisiblemente afectada o caprichosa, o simplemente incompetente.

Una perspectiva general de la expresión es que el intérprete procura la transparencia entre la concepción y la acción, de modo que cada aspecto de su comprensión de la música encuentre una manifestación en la interpretación misma. Dicha perspectiva plantea al menos dos problemas. En primer lugar, es una visión idealizada de la interpretación, y la realidad se queda corta aunque sólo sea por razones prácticas: el intérprete puede tener más de una concepción de un evento o un pasaje de una pieza, pero en una interpretación determinada está obligado a decidirse por una de ellas; también puede ocurrir que el intérprete tenga una concepción de una característica a gran escala de la organización de la obra que sea imposible de proyectar de manera concreta dentro de la interpretación. En segundo lugar, y más esencialmente, el enfoque tiende a presentar la partitura como «la música», y la interpretación expresiva como cierto tipo de modificación de la misma. La partitura, claro está, no es la música, sino simplemente una de sus representaciones posibles (las otras son las grabaciones en CD, los vídeos y las des-

cripciones escritas), y puede considerarse como un anteproyecto para una interpretación —bastante incompleto, además— que sólo «tiene sentido» cuando se entiende dentro de un contexto cultural.

En los últimos tiempos, una cantidad considerable de investigaciones han procurado especificar los principios psicológicos que controlan la interpretación expresiva en la música [21]. Dichas investigaciones han utilizado una combinación de análisis detallado y modelos computerizados para examinar cómo los intérpretes utilizan expresivamente diversos parámetros musicales (tempo, dinámica, ataque, timbre, afinación, vibrato, etc.) en la interpretación. Algunos estudios experimentales han demostrado que la expresión puede ser sumamente estable en interpretaciones repetidas incluso después de varios años [22], que está presente incluso en las interpretaciones a primera vista [23] y que puede ser cambiada por el intérprete en el momento [24]. Estas observaciones han sido utilizadas para argumentar que la expresión no puede ser un patrón aprendido de tempo, dinámica y articulación que se recuerda y aplica a una pieza cada vez que se ejecuta, sino que debe surgir de la comprensión de la música por parte del intérprete en el transcurso de la interpretación.

En principio, todos los aspectos de la estructura musical contribuyen a especificar un perfil expresivo para una pieza, pero algunos estudiosos han demostrado que la estructura de las frases es particularmente relevante. Utilizando una simple regla, Neil Todd desarrolló un modelo que produce un patrón de tempo expresivo basándose en la jerarquía estructural de las frases [25]. Los perfiles de tempo resultantes son muy similares a los de las interpretaciones reales de instrumentistas profesionales. Igualmente, en un estudio sobre veintiocho interpretaciones de una pieza breve de Schumann, tomadas de grabaciones comerciales de muchos de los mejores pianistas del siglo XX, Bruno Repp encontró un elevado nivel de correspondencia entre los perfiles de tempo de las interpretaciones, todas las cuales estaban organizadas en torno a la estructura de la frase [26]. También demostró una gran diversidad en los niveles de expresión más superficiales, y sugirió que los intérpretes coinciden sustancialmente en cuanto a la forma general de una pieza musical y expresan su individualidad en los detalles más sutiles de la estructura y su ejecución expresiva. Repp realizó estudios ulteriores empleando una cantidad de muestras aún mayor (más de cien interpretaciones de la misma música) que han confirmado estas conclusiones [27].

La expresión puede entenderse como la consecuencia inevitable e irreprimible de la comprensión de la estructura musical; sin embargo, también es un intento consciente y deliberado del intérprete por hacer que sus interpretaciones sean perceptibles. Como prueba de la presencia inconsciente e inevitable de la expresión en la interpretación, algunos investigadores han demos-

trado que cuando se les pide a los intérpretes que toquen sin expresión, el nivel de variación de tempo y dinámica se reduce, pero no se elimina, conservando el mismo patrón general que se observa en condiciones normales [28]. Este aspecto de la expresión en la interpretación puede considerarse una consecuencia de la comprensión espontánea e inconsciente de los elementos básicos de la estructura musical por parte del intérprete: en términos sencillos, parece imposible *no* tocar una nota al final de una frase con características expresivas diferentes de las notas que se encuentran en medio de una frase. Sin embargo, es obvio que los intérpretes también dan forma a la expresión de sus interpretaciones, de manera consciente y deliberada, para lograr determinados resultados estilísticos y estructurales. Éste es uno de los propósitos de la práctica (además de superar los problemas puramente técnicos), e implica cambios en la comprensión que tiene el intérprete de la música y en la utilización equilibrada de diversos recursos expresivos. Todos estos procesos pueden destacar las propiedades expresivas implícitas en la música, o bien superponer un patrón sobre ellas; como ha señalado Shaffer entre otros, las pequeñas diferencias en la utilización y equilibrio de incluso unos pocos principios expresivos producirán caracterizaciones potencialmente distintas de una pieza [29]. Son relativamente pocos los estudios sistemáticos que se han realizado sobre los procesos psicológicos implicados en la práctica y el ensayo, así como en la memorización [30].

Aunque la expresión puede obedecer a ciertas «reglas», los intérpretes también poseen una habilidad (variable) para imitar un patrón expresivo que han escuchado —incluso cuando dicho patrón carece de una base estructural lógica [31]. En esas circunstancias, los intérpretes pueden crear un tipo de «imagen» auditiva de la interpretación que luego intentan copiar (más bien como un imitador); o pueden intentar recordar una descripción verbal de la interpretación (por ejemplo, «acelerar hacia el final de la primera frase, disminuir la velocidad en el medio de la segunda frase y después acelerar hacia el final»); o intentar concebir la interpretación como una imagen corpórea —una especie de coreografía mental que capta y representa la forma de la interpretación. Estas estrategias son más o menos parecidas a las que utilizan los alumnos para imitar a sus maestros o para calcar (quizá inconscientemente) aspectos de una representación grabada o en vivo que pueda haberles influido. Ellas nos recuerdan que la interpretación y la expresión, lejos de ser contribuciones singulares de ejecutantes aislados, se desarrollan dentro de una cultura a veces ensordecedoramente «ruidosa» de otras interpretaciones. Cualesquiera que sean la actitud y estrategia de los diversos intérpretes ante esa abundancia de influencias, está claro que una teoría de la interpretación presentada como una serie de reglas que relacionan la estructura con la expresión resulta demasiado abstracta e intelectual, y que la realidad es mucho

más práctica, tangible y, ciertamente, desordenada. En particular, el cuerpo no es tan sólo un «dispositivo de entrada y salida», y necesita que reconozcamos que tiene un papel más importante que el que sugiere un modelo basado en reglas.

El movimiento y el cuerpo durante la interpretación

La relación de la expresión con el cuerpo humano y el papel de los movimientos corporales demuestran que la estructura no es la única determinante de la expresión. Una amplia gama de factores influirá en el resultado final, incluyendo las posibilidades del instrumento, la acústica del espacio, el tipo de público, el estado de ánimo y los objetivos del intérprete, las normas estilísticas y culturales, e incluso la ideología interpretativa que se adopte (por ejemplo, la interpretación «históricamente informada»). El movimiento y el cuerpo son particularmente importantes en esas complejas relaciones por varios motivos —el más obvio es que la música se produce con los movimientos del cuerpo y el instrumento, y por lo tanto está indeleblemente marcada por ellos. Los altibajos del movimiento y la tensión/relajación que experimentan los oyentes con la música se deben en parte a una identificación con el medio físico de la producción musical —tengamos o no una experiencia directa de los verdaderos instrumentos implicados. En un contexto más amplio, las investigaciones etnomusicológicas han demostrado que, en algunos casos, las estructuras características de un estilo musical determinado se remontan a factores físicos relacionados con el instrumento en el que se desarrolló dicha música. Por ejemplo, John Baily ha demostrado que la música para *dutar*, un instrumento de cuerda de Afganistán, evolucionó a partir del repertorio de otro instrumento de una región vecina, adquiriendo en el proceso características relacionadas con las cualidades físicas del *dutar*[32].

La estrecha relación que existe entre la música y el movimiento corporal ha sido estudiada durante mucho tiempo. En los años 1930, Alexander Truslit llevó a cabo una investigación experimental que demostró que al dar diferentes instrucciones (o imágenes) de movimiento a los intérpretes, éstos producían interpretaciones conmensurablemente diferentes[33]. Independientemente de lo anterior, otros investigadores han demostrado que los patrones espontáneos de tempo de los intérpretes concuerdan con la curva temporal del movimiento de los objetos en un campo gravitacional, lo cual sugiere que las interpretaciones que suenan «naturales» imitan el comportamiento de los objetos en movimiento en el mundo real[34]. Todd demostró que un modelo del tempo y la dinámica, basado en la velocidad y la fuerza de movimiento de los objetos bajo la influencia de la gravedad, puede explicar gran parte de

la expresión en las interpretaciones musicales espontáneas, confirmando así la idea de que la expresión en la interpretación musical es en ciertos aspectos un fenómeno físico y concreto sobre el cual se superponen elementos más elevados.

El movimiento en sí mismo forma parte de la interpretación entendida como evento audiovisual, y ha sido objeto de investigación y debate. Aunque ciertos movimientos son imprescindibles para producir música en un instrumento, la mayoría de los movimientos observados y estudiados en las investigaciones publicadas por Jane Davidson [35] están por encima de esa base puramente ergonómica —y por lo tanto pueden considerarse como expresivos en lugar de prácticos. Entre ellos se incluyen movimientos de balanceo de todo el cuerpo, así como gestos discretos que son, estrictamente hablando, «innecesarios» en la tarea básica de producir sonidos con el instrumento. En un estudio sobre un pianista profesional (analizado en el capítulo 10), Davidson concluyó que utilizaba algo parecido a un léxico de gestos expresivos en sus interpretaciones. Diferentes gestos parecían estar relacionados con funciones musicales específicas, y estaban tan unidos a su concepción de la música que se observaron incluso cuando produjo una interpretación imaginaria de la misma música sobre una mesa en lugar del teclado. El intérprete sólo estaba parcialmente consciente de los movimientos expresivos que hacía, y no había ninguna prueba que sugiriera que los movimientos habían sido desarrollados o ensayados deliberadamente. La impresión predominante (como se podría intuir) era que los movimientos formaban parte de su concepción y producción de la música, y eran generados durante la interpretación del mismo modo que se generan las características expresivas del sonido (tempo, dinámica, articulación, etc.) a partir de la idea de la música.

En este capítulo, el estudio de la interacción entre el cuerpo y la mente durante la interpretación refleja un dualismo cuerpo/mente persistente y más general. Cuando componemos, interpretamos, enseñamos, investigamos o escuchamos música, resulta muy fácil considerar que los límites impuestos por el cuerpo no son más que impedimentos para la mente todopoderosa y autosuficiente. La realidad es más diversa e integral, ya que la mente no está separada del cuerpo ni confinada al cerebro. Hasta el acto aparentemente pragmático de elegir una digitación está tan relacionado con pensar sobre lo que la música significa como con tocar las notas correctas en el momento adecuado [36]. La ejecución musical es una forma concreta de pensamiento musical, y el cuerpo forma parte del proceso de explorar la música y constituye igualmente un medio para su realización.

Conclusiones: mente, cuerpo y significado en la interpretación

El enfoque psicológico de la interpretación ha tendido en ocasiones a separar radicalmente la estructura y la expresión. La estructura musical es sin duda un componente importante de aquello que motiva y da forma a la expresión, pero es sólo un elemento dentro de un amplio sistema de relaciones. Como he comentado antes, Shaffer ha propuesto que la expresión está relacionada con la caracterización de una pieza durante la interpretación, y que dos intérpretes con la misma imagen estructural de una pieza podrían producir ejecuciones distintas basadas en cómo caracterizan la música [37]. Esto plantea una pregunta sobre los límites de la noción de estructura en la música, y si la «caracterización» es viable como concepto. Más aun, sugiere que el término más importante —y en gran parte ausente en el análisis hasta ahora— es el término *significado,* y que, cuando un intérprete «caracteriza» una pieza en la interpretación, está construyendo un significado a través de la expresión. Una opción sería considerar que el intérprete utiliza su visión del significado de la música como «fuente generativa» de la expresión, pero como la expresión misma es parte del significado de la música, y no tan sólo un medio para el mismo, ello pone en duda al enfoque «generativo» en su conjunto —es decir, la idea de que la expresión es generada *desde* la estructura o el significado [38]. Avanzando otro paso por este camino, la investigación sobre la interpretación ha adoptado en gran parte un enfoque completamente individualista del intérprete y su mente. El contexto social de la interpretación (incluyendo a los cointérpretes, el público y la influencia de los maestros y tutores, así como las grabaciones e interpretaciones de otros, las actitudes sociales ante la interpretación y las «modas» interpretativas) es de vital importancia, pero hasta ahora es poco lo que se sabe de manera explícita. Basta considerar el ejemplo específico del miedo escénico para ver la magnitud que puede tener la influencia mutua de los componentes social e individual de la interpretación.

Plantear estas relaciones al final de un capítulo que ha intentado desglosar diferentes componentes de la interpretación y la mente puede parecer una revocación contradictoria de todo lo anterior. Pero no es así: aunque resulta productivo descomponer un fenómeno complejo para estudiarlo detallada y sistemáticamente, también es importante recordar que sus componentes no son independientes y que debemos intentar reintegrar y sintetizar. La interpretación musical es una construcción y articulación del significado musical en la que convergen las características cerebrales, corporales, sociales e históricas del intérprete, y si decidimos considerar esa convergencia como una expresión de la mente del intérprete, debemos recordar que la mente no está ni accionando el cuerpo ni confinada al cerebro.

SEGUNDA PARTE
Aprender a interpretar

5 *Sobre la enseñanza de la interpretación*

JANET RITTERMAN

Toca con el alma, ¡no como un pájaro adiestrado!
C. P. E. BACH [1]

Introducción

Este capítulo centra su atención en las interpretaciones en las que un músico o grupo de músicos «ejecuta música deliberadamente para un público», en la que se «realiza» una obra existente [2]. Su interés principal es la enseñanza de la interpretación instrumental solista de música culta occidental. Cronológicamente, abarca desde el siglo XVIII en adelante, sus límites geográficos son los de Europa occidental y destaca especialmente la enseñanza de aquellos que aspiran a un nivel profesional, más que de los aficionados o principiantes. Aunque frecuentemente se recomienda a los instrumentistas que aprendan de los cantantes, la enseñanza del canto no será abordada en este capítulo debido a la magnitud del tema y las numerosas ramificaciones particulares de la historia de la enseñanza vocal. En su lugar, los ejemplos citados se relacionan principalmente con la música para piano y violín. Debido a la popularidad de estos instrumentos y la importancia que se le da al dominio del repertorio solista y su presentación en concierto, ellos nos permitirán ver más claramente las tendencias de la enseñanza de la interpretación instrumental desde finales del siglo XVIII. En este capítulo, la frase «enseñanza de la interpretación» se referirá a la interpretación que implica una relación con un público, por lo que las tendencias educativas mencionadas anteriormente se refieren a la interpretación y comunicación de música en un concierto, más que a la técnica instrumental. Mientras que en la mayoría de las tradiciones de música culta occidental la enseñanza de la interpretación se ha centrado tanto en el último aspecto como en

el primero, el contexto de este capítulo será la enseñanza del estilo y la interpretación.

Los tratados musicales como guías para la interpretación

El interés por los asuntos relacionados con la interpretación es una característica evidente de los tratados más importantes que comenzaron a proliferar durante la segunda mitad del siglo XVIII. Los tratados anteriores a esa época, que generalmente eran más breves, solían centrarse en las fases iniciales del aprendizaje, enfocando especialmente los rudimentos teóricos y las técnicas básicas. Aunque a menudo mencionaban incidentalmente la importancia de la ejecución expresiva y la opinión crítica, casi ninguno de ellos señala cómo se pueden demostrar o desarrollar esas cualidades, probablemente porque suponían que tales asuntos serían mejor explicados por el maestro y dependían del repertorio que estaba aprendiendo el alumno —frecuentemente composiciones del propio maestro.

A medida que aumentaba la cantidad de personas que querían aprender música, los tratados tendían a incluir comentarios más extensos sobre las cualidades más importantes de una interpretación eficaz. En su tratado de flauta de 1752, Quantz reiteró que el intérprete debe cultivar el buen gusto, tal y como habían aconsejado otros autores, y lo relacionó con la habilidad de identificarse con las diversas «emociones» de la música y ajustar correspondientemente el estilo de la ejecución, una opinión que apoyaron muchos autores posteriores:

> El intérprete de una pieza debe procurar implicarse en las emociones que ha de expresar. Y como en la mayoría de las piezas hay una alternancia constante de emociones, el intérprete debe saber discernir la naturaleza de la emoción que contiene cada idea, y hacer que su ejecución se ajuste a ella constantemente. Sólo así mostrará adecuadamente las intenciones del compositor y las ideas que tenía en mente cuando escribió la pieza» [3].

El tratado reconoce la necesidad de una enseñanza especializada para ayudar a los aspirantes a intérpretes a desarrollar ese criterio. Aunque Quantz desarrolló las derivaciones de sus consejos en el texto, consideró sin embargo que un buen maestro es esencial, como explica más o menos detalladamente en su introducción [4].

La importancia asignada en el tratado a las exigencias que plantea el arte interpretativo a los intérpretes en general —y no sólo a los flautistas— hizo que destacara entre la mayoría de las publicaciones anteriores. Sin embargo,

aunque abarca muchos temas, su enfoque es esencialmente retrospectivo, mientras que el *Versuch über die wahre Art das Clavier zu spielen* —un tratado de C. P. E. Bach, colega menor de Quantz en la corte de Federico el Grande en Postdam— tuvo una repercusión más directa en la enseñanza de la interpretación durante las décadas siguientes. Publicado en dos partes, la primera de las cuales apareció en 1753, el *Versuch* de Bach había sido reeditado tres veces para el año 1787 y no tardó en convertirse en la publicación más difundida, citada y admirada de su especie [5]. Fue el tratado que Beethoven le pidió al joven Carl Czerny para su primera clase de piano en Viena [6].

El tratado de Bach se centra principalmente en la enseñanza de la interpretación a solo de instrumentos de teclado. Como su autor señaló en cartas posteriores, iba dirigido a «aquellos para quienes la música es una meta», más que a los aficionados [7]. Por lo tanto, en su primer párrafo se subraya la importancia de la buena interpretación como una de las cualidades de las que depende el verdadero arte de tocar instrumentos de teclado [8]. Para Bach, como para Quantz, ello implicaba «la capacidad [...] de hacer que el oído sea consciente del verdadero contenido y sentimiento de una composición». Sin embargo, aunque al hacer hincapié en el «verdadero contenido» reconoce la necesidad de identificarse con las intenciones del compositor, la definición de Bach subraya especialmente el criterio del oído. Para Bach, la buena interpretación requiere que el oyente «escuche todas las notas y sus ornamentos ejecutados a tempo con la dinámica apropiada mediante una pulsación vinculada al verdadero contenido de la pieza» [9].

«Estudiar escuchando», una modalidad que Bach describió como «una especie de hurto legal», era esencial para los que querían convertirse en intérpretes consumados: era la única manera, según él, de que los asuntos «que no se pueden demostrar fácilmente, y mucho menos escribir», se hicieran evidentes [10]. Al igual que Quantz, a Bach le preocupaba la falta de una buena enseñanza de la interpretación. Lamentó el hecho de que a la mayoría de los alumnos se les exigía tocar las composiciones de su maestro y no se les enseñaban obras de compositores anteriores o de otros países, «con el pretexto de que eran obsoletas o demasiado difíciles» [11]. Sin embargo, y al igual que el tratado de Quantz, el *Versuch* no incluía consejos sobre el repertorio de otros compositores que fuese apropiado para el estudio.

Fuentes para la enseñanza de la interpretación

La mayor parte de lo que C. P. E. Bach aprendió como intérprete lo asimiló de su padre y de un constante «estudiar escuchando», particularmente en la corte. En la mayoría de los países de la Europa occidental anterior a 1800, la

enseñanza musical de los que pretendían convertirse en músicos profesionales era generalmente de ese tipo —proporcionada dentro de la familia, la corte o la iglesia, o mediante métodos de aprendizaje. Las biografías de Haydn, Mozart y Beethoven revelan que desarrollaron sus habilidades interpretativas de esa manera, recibiendo una formación que solía hacer hincapié tanto en las habilidades de la composición como en las de la interpretación misma.

El adiestramiento más intensivo para la interpretación lo proporcionaban los conservatorios de Nápoles y Venecia —instituciones establecidas desde finales del siglo XVI por determinadas fundaciones benéficas para el cuidado de los huérfanos y otros necesitados. En algunos de ellos, la formación para la interpretación se convirtió en una actividad prominente, y adquirieron una reputación envidiable por su quehacer musical. Sin embargo, para las últimas décadas del siglo XVIII, la convulsión política había provocado el declive de la mayoría de esas instituciones. No obstante, de las mismas raíces comenzó a emerger un nuevo tipo de conservatorio. Estas instituciones nuevas fueron establecidas generalmente con el financiamiento de la ciudad o el Estado, en lugar de la iglesia o las organizaciones benéficas, y reflejaban la creciente importancia que se asignaba a la actividad musical pública. A través de los conciertos ofrecidos por los estudiantes o auspiciados por la institución, muchas llegaron a ser de vital importancia para el desarrollo del concierto público en sus respectivas ciudades.

Para el cambio de siglo, las transformaciones sociales, económicas y culturales que se extendieron por Europa ayudaron a asegurar que la enseñanza de la interpretación llegara a ser más generalizada, cada vez más solicitada por la clase media y menos influida por las tradiciones pedagógicas anteriores. En las grandes ciudades, la demanda de educación musical aumentaba vertiginosamente, como evidencian los anales, periódicos musicales y otras referencias especializadas de la época [12]. La enseñanza privada floreció, pero en general los nuevos conservatorios fueron los que ejercieron una mayor influencia en la sistematización gradual de la enseñanza de la interpretación a un nivel avanzado. Muchos de ellos incluyeron en su profesorado de instrumentistas a grandes intérpretes de la época, cuya reputación era conocida a lo largo de Europa occidental por sus carreras concertísticas. Su influencia contribuyó mucho a determinar lo que llegó a aceptarse como el repertorio instrumental estándar.

El primero de estos conservatorios modernos surgió en París después de la revolución. Fundado en 1795 con carácter nacional, y añadiendo escuelas más antiguas y especializadas, el Conservatorio de París fue establecido con responsabilidades conjuntas para la enseñanza y la interpretación: los alumnos eran adiestrados para interpretar en festivales nacionales y otros tipos de

interpretaciones públicas. Los alumnos, inicialmente 600 [13], eran seleccionados de todo el país y recibían enseñanza gratuita.

La influencia y el prestigio de la nueva institución se difundieron rápidamente, y para los años 1820 ciudades como Praga, Viena, Milán, Bruselas, Londres y La Haya habían seguido el ejemplo. La tendencia continuó, y con el tiempo se establecieron conservatorios en muchas ciudades de habla alemana, Rusia (San Petersburgo y Moscú), Gran Bretaña y América, algunos de los cuales utilizaron extensamente los enfoques de la enseñanza de la interpretación desarrollados en París. Muchos comenzaron con una gama de especialidades relativamente limitada que reflejaba las prioridades y posibilidades locales. En París, a pesar de la intención expresa de adiestrar a los alumnos «en todas las ramas del arte de la música» [14], la enseñanza instrumental en 1806 se centraba en la flauta, el oboe, el clarinete, el fagot, la trompa, el violín, el violonchelo y el piano. La introducción de otras especialidades fue gradual: por ejemplo, el arpa se introdujo en 1825, la trompeta y el trombón durante los años 1830.

La necesidad de establecer sistemas y modelos de enseñanza de la interpretación condujo a la publicación, en París, de una serie de métodos [15]. Estos métodos eran encargados especialmente por los profesores del conservatorio y estaban sujetos a un proceso de aprobación institucional formal. Aunque eran comparables a sus antecesores en cuanto a organización y contenido general, estos métodos superaban ampliamente el alcance de los tratados instrumentales más antiguos. La mayoría proporcionaba indicaciones extensas y detalladas sobre asuntos de técnica, estilo e interpretación, complementadas con numerosas ilustraciones musicales y material pedagógico, incluyendo composiciones de épocas anteriores y diversas escuelas nacionales, así como obras contemporáneas. Entre los métodos más influyentes que surgieron del Conservatorio de París durante la primera década de su existencia se encuentran los de cuerdas y piano. El método de piano, creado inicialmente por Adam y Lachnith en 1798 [16], proporciona una amplia colección de fragmentos, lo que muestra la amplitud del repertorio que se estudiaba. Principios similares dieron forma al *Méthode de violon* publicado en 1803 por Baillot, Rode y Kreutzer [17], y el *Méthode de violoncelle* de 1804, en el que Baillot colaboró con Baudiot, Levasseur y Catel.

París indicaba el camino, y los demás le seguían. El siglo XIX vio el nacimiento de un verdadero raudal de métodos, particularmente para los instrumentos más populares [18]. Muchos de ellos le debían bastante a los tratados antiguos, aunque no siempre lo reconocían. Algunos fueron escritos por maestros relacionados con otros conservatorios; otros por profesores-intérpretes establecidos que no estaban vinculados a ninguna institución, como Czerny, quien dio clases de piano en Viena durante unos cincuenta años, atrayendo a

estudiantes talentosos de muchas partes de Europa. Al igual que los tres volúmenes de la obra *Complete Theoretical and Practical Piano Forte School,* op. 500 de Czerny [19], los métodos creados por distinguidos intérpretes de la época —como los pianistas Hummel [20] y Moscheles [21] y el violinista Spohr [22], famosos en muchos de los principales centros musicales de Europa por sus giras como virtuosos— traspasaron rápidamente las fronteras nacionales. Reseñados concienzudamente en las principales revistas musicales de la época, los métodos más valorados fueron publicados en otros idiomas —generalmente en Viena, Londres y París—, ayudando así a desarrollar las perspectivas cada vez más cosmopolitas de la enseñanza de la interpretación a medida que avanzaba el siglo.

Las escuelas nacionales de interpretación

A pesar de estas tendencias unificadoras, la existencia de escuelas nacionales de interpretación relacionadas con determinados instrumentos fue reconocida generalmente a lo largo del siglo XIX y bien entrado el XX. Algunos críticos utilizaban el término «nacional» históricamente. Czerny lo empleó en ese sentido, distinguiendo seis escuelas pianísticas relacionadas con determinados compositores: Clementi; Cramer y Dussek; Mozart; Beethoven; Hummel, Kalkbrenner y Moscheles; y una escuela incipiente, representada por tres artistas jóvenes de la época, Thalberg, Chopin y Liszt. En cualquiera de ellas, sin embargo, la música de cada compositor debía ser «ejecutada en el estilo en que la compuso»; Czerny rechazó de entrada la idea de que todas podían ser interpretadas en el mismo estilo [23].

Particularmente desde mediados del siglo XIX, otros utilizaron el concepto de escuela nacional para diferenciar las tendencias contemporáneas de interpretación y enseñanza. Las distinciones, un tema comentado con frecuencia en los relatos de maestros o alumnos, se consolidaron con la formalización de los enfoques pedagógicos de los principales conservatorios nacionales, siendo impulsadas en algunos casos por tendencias nacionalistas. Ello se puede observar en el nacimiento de las escuelas rusas de interpretación instrumental. Las referencias a las escuelas interpretativas rusas se hicieron comunes sólo a partir de la segunda mitad del siglo —después del establecimiento de los Conservatorios de San Petersburgo y Moscú, en los años 1860. Hasta entonces, la enseñanza instrumental a nivel avanzado en Rusia había sido proporcionada principalmente por maestros-intérpretes identificados con las tradiciones interpretativas europeas más importantes [24].

Las características de las escuelas interpretativas nacionales reflejan a menudo las contribuciones de compositores e intérpretes: el término se ha utili-

zado para identificar determinados enfoques de la expresión musical, la técnica de ejecución, la elección de repertorio e incluso la organización de los currículums. En cuanto a la técnica, durante gran parte del siglo XIX había indudablemente diferencias que distinguían a ciertas escuelas interpretativas de otras. Sin embargo, en los casos del piano y las cuerdas, dichas diferencias se desvanecieron gradualmente por los continuos desplazamientos de los principales maestros-intérpretes y por la creciente movilidad de los alumnos. Para el fin del siglo, se había producido una gran difusión: aunque algunos maestros seguían identificándose con determinados métodos técnicos y repertorios especializados, las similitudes en cuanto al enfoque estilístico e interpretativo se habían acentuado, y las diferencias eran más difíciles de clasificar.

La escuela violinística francesa refleja una tendencia similar. A principios del siglo XIX, dicha escuela, identificada con la enseñanza del Conservatorio de París, se había convertido en el principal foco de atención, en parte porque asimiló aspectos de la escuela italiana del siglo XVIII que Viotti había llevado a París en los años 1780 [25]. La continuidad de la enseñanza desempeñó un papel importante en el mantenimiento de la reputación de la escuela: Baillot, profesor del Conservatorio de París desde 1795 hasta 1842 [26], fue reemplazado por violinistas que habían estudiado con él y se mantuvieron en el cargo hasta principios de la década de 1890. La minuciosidad de la documentación de la escuela francesa y su continua reevaluación también fueron factores favorables. En 1834, Baillot escribió un método nuevo y exhaustivo, *L'Art du violon,* que proporcionaba una perspectiva general actualizada de la enseñanza de la escuela violinística francesa y el repertorio estudiado por los alumnos en París, que ayudó a asegurar que sus rasgos característicos siguieran influyendo en la ejecución de las cuerdas durante las décadas siguientes [27].

Para 1842, año en que murió Baillot, estas tradiciones estaban siendo influidas por nuevas tendencias: se estaba desarrollando una escuela franco-belga basada en el Conservatorio de Bruselas e influida por la técnica interpretativa de Paganini. Le siguieron otras fusiones de estilos. Durante la segunda mitad del siglo, debido a que los alumnos extranjeros eran admitidos más fácilmente en el Conservatorio de París [28], las características de la escuela interpretativa francesa se difundieron en círculos cada vez mayores, modificando y siendo modificadas por otras tradiciones violinísticas. Entre los que estudiaron en París y contribuyeron a esa tendencia se encontraban Marsick, Wieniawski y Kreisler. El arte de Kreisler, vienés de nacimiento, llegó a ser mundialmente famoso a través de sus interpretaciones y grabaciones. Wieniawski, polaco, dio clases en el recién fundado Conservatorio de San Petersburgo en los años 1860, y más tarde en Bruselas. Marsick, un violinista belga que después de estudiar en París fue alumno de Joachim en Berlín, regresó a París para dar clases en el conservatorio en los años 1890; entre sus alumnos

se encontraban Carl Flesch, de origen húngaro, y Georges Enescu, rumano; ambos habían estudiado en Viena. Para comienzos del siglo XX, eran relativamente pocos los maestros-intérpretes importantes que podían clasificarse como representativos de una determinada escuela nacional. Los estilos de ejecución, que en una época se relacionaban con un compositor o una nacionalidad, se identificaban cada vez más con el intérprete o el maestro que con una localidad geográfica.

Estilo e interpretación

Aunque se consideraba que las diferencias nacionales existían, la mayoría de los comentarios sobre estilo e interpretación de los tratados del siglo XIX presentaban opiniones generalmente similares sobre las características esenciales de la interpretación expresiva y la importancia de la aportación del intérprete en dicha interpretación. Uno de los temas recurrentes era la habilidad del intérprete para imprimir su individualidad en la interpretación —un tema que fue planteado por Adam [29] y desarrollado por otros. Spohr, quien explicó la distinción entre lo que consideraba una mera *«expresión* o *estilo correcto»* y el *«estilo excelente»,* apoyó la opinión de Quantz en cuanto a la importancia de las intenciones del compositor. El *«estilo excelente»*, afirmó, no significaba simplemente que los intérpretes añadían sus propias ideas, sino que eran «capaces de recrear intelectualmente el tema, de modo que el oyente pueda descubrir y ser partícipe de las intenciones del compositor» [30].

Los críticos del siglo XIX prestaron especial atención a la importancia de las fluctuaciones o alteraciones de tempo como una de las variantes personales que podía introducir el intérprete. En la última sección de su método, Hummel ilustra ese aspecto con extensos fragmentos de su Concierto para piano en La menor op. 85, que muestran mediante indicaciones escritas en la partitura (e.g. «un tanto acelerado», «un poco más lento», «relajando un tanto el tempo») la medida en que se esperaba que hubiera modificaciones de tempo [31]. Dedicado exclusivamente a «ejecutar con expresión», el tercer volumen de la *Escuela* de Czerny incluye un capítulo sobre el buen gusto en el empleo de los *ritardandos* y *accelerandos.* Aunque comienza afirmando que toda composición «debe tocarse en el tempo prescrito por el compositor», los ejemplos musicales de Czerny apoyan su opinión de que «en casi toda línea de música hay ciertas notas y pasajes en los que es necesario un pequeño *ritardando* o *accelerando*, para embellecer la lectura y aumentar el interés [32].

Las variaciones elegantes de los tonos o ritmos de la partitura, por razones de elocuencia o para dar espontaneidad a la ejecución, también eran vistas como una parte importante del aporte del intérprete consumado. Las varia-

ciones podían incluir cambios en los detalles de un pasaje brillante o de los ritmos, la interpolación de pasajes al estilo de una cadencia o, en el caso de los pianistas, la ejecución arpegiada de acordes. Aunque advertían que para ello es necesario tener un criterio musical sólido y que el contexto determina lo que es adecuado, la mayoría de los métodos consideraban que la escasez era una falta tan grave como el exceso. Tanto Hummel como Kalkbrenner editaron conciertos de Mozart modernizando las figuraciones de acuerdo con el gusto contemporáneo. La escuela de Czerny, ampliada en publicaciones separadas sobre ornamentación y expresión «en el estilo moderno» [33], adoptó una postura similar. Existen muchas pruebas de que esa práctica fue perpetuada por maestros influyentes como Liszt y Leschetizky, quienes realizaban cambios textuales en las obras que ejecutaban y enseñaban. Liszt es conocido por haber «enriquecido» un pasaje brillante de uno de los conciertos de Weber que consideraba pobre [34], mientras que Leschetizky interpretaba las partituras con una «gran libertad y flexibilidad» [35].

Al mismo tiempo, había síntomas de que la actitud hacia la relación entre el intérprete y la obra estaba cambiando, y que dichos cambios estaban repercutiendo en la enseñanza de la interpretación. Clara Schumann ejerció una gran influencia en ese sentido: sus clases, que transcurrieron paralelas a su carrera de intérprete durante más de cincuenta años, influyeron a generaciones de intérpretes y maestros de Europa continental e Inglaterra [36]. Cuando tocó en Viena en 1856, el crítico Eduard Hanslick señaló que «la subordinación artística de su propia personalidad a las intenciones del compositor» era «un principio» para ella, y describió su ejecución como «una representación sumamente fiel de composiciones magníficas, pero no una manifestación de una personalidad magnífica». Otras características de su interpretación que Hanslick destacó como inusuales eran su claridad («Todo es preciso, claro, nítido como un dibujo a lápiz») y, con ciertas reservas sobre su conveniencia, su «estricta conformidad con el compás» [37].

En estos aspectos, el enfoque de Clara Schumann era marcadamente diferente del de Anton Rubinstein. Ampliamente admirado por «el fuego y la pasión de su ejecución y por su imaginación y espontaneidad» [38], Rubinstein, primer director del Conservatorio de San Petersburgo y personaje destacado de la vida musical europea durante la segunda mitad del siglo, adoptó un enfoque más liberal de las obras que interpretó. Según Josef Hofmann, posiblemente el más famoso de sus alumnos, Rubinstein aconsejaba: «Toca primero exactamente lo que está escrito. Si le has hecho plena justicia y aun así le quieres añadir o cambiar algo, pues hazlo» [39]. Pero para cuando murió Rubinstein, en 1894, tales opiniones, que ya eran cuestionadas desde varias tendencias, no eran aceptadas incuestionablemente. Hofmann, quien en 1926 se convertiría en el primer director del Curtis Institute de Filadelfia, opinaba

que el intérprete «siempre ha de sentirse convencido de que toca únicamente lo que está escrito», afirmando que la correcta comprensión de una obra —prerrequisito de una «interpretación verdadera»— dependía «únicamente de una lectura escrupulosamente exacta» [40]. El desarrollo, a mediados del siglo XIX, del concepto de ejecutante como intérprete, en lugar de cocreador, que condujo a algunos críticos a emplear metáforas casi religiosas para describir el acto de interpretar, fomentó este sentido de la interpretación como regla. Durante el siglo XX, el «respeto al texto» llegó a dominar cada vez más la enseñanza de la interpretación.

Los retos de la enseñanza de la interpretación

El violinista Duncan Druce se encuentra entre los que lamentan la tendencia de los músicos modernos a producir interpretaciones admirablemente claras y precisas pero «relativamente sosas y carentes de personalidad». En su escrito sobre los enfoques históricos de la ejecución del violín, señala que ello «es parte de un declive general y gradual del papel creativo del intérprete» [41]. Aunque la enseñanza de los instrumentos que poseen un extenso repertorio solista decimonónico ha abrazado cada vez más la tendencia hacia un enfoque más histórico de la interpretación, es cierto que rara vez ha estado acompañada de una comprensión de la libertad creativa que implica dicha influencia. Muy frecuentemente ha tendido a fomentar la creencia de que la partitura ha de ser interpretada literalmente. La obligación de responder individualmente al espíritu de la obra —inequívocamente apoyada en épocas anteriores— ha sido suplantada con demasiada facilidad, en una era de menos confianza, por la creencia errónea de que el respeto al texto de la partitura ofrece seguridad frente al reto crítico. Las ediciones Urtext, junto con los sistemas y criterios de evaluación de las interpretaciones, han favorecido esta tendencia normalizadora, como también lo ha hecho la creciente autoridad que se le otorga a las grabaciones.

Comentando esa tendencia, Alfred Brendel, en un ensayo que escribió en 1966, rechazó categóricamente la noción de que una obra «hablará por sí misma siempre y cuando el intérprete no interponga su personalidad», recordando a los intérpretes que «las notas musicales sólo pueden sugerir, y las indicaciones expresivas sólo pueden complementar y confirmar lo que debemos, antes que nada, leer en la representación de la composición misma». Apoyando las opiniones que otros expresaron mucho antes, describió que el proceso requiere de «nuestras propias emociones, nuestro propio sentido, nuestro propio intelecto, nuestros propios oídos refinados» [42]. Sin embargo, aunque en muchas escuelas de interpretación se valora hipócritamente el pa-

pel del criterio y la intuición musical del alumno para darle forma a una interpretación, resulta sumamente fácil neutralizar su influencia en la práctica.

Aunque ha sido valioso en muchos aspectos, el aumento repentino del interés por la interpretación «auténtica» que tuvo lugar durante las décadas de 1980 y 1990 no ha hecho nada por resolver esta diferencia intrínseca. Mientras que los enfoques reconocidamente «auténticos» a menudo dicen tanto sobre el gusto contemporáneo como sobre los gustos y valores musicales de épocas remotas (como han argumentado Richard Taruskin y otros) [43], destacan sin embargo la necesidad de que los intérpretes y maestros sigan un camino en el que permanezcan fieles tanto a sí mismos como a la música que eligen interpretar. En una época de creciente diversidad de enfoques y actitudes, la enseñanza de la interpretación debe ayudar a los músicos a esclarecer sus convicciones personales como intérpretes; como afirma Jonathan Dunsby: «Nos guste o no, hoy en día no puede haber un intérprete inocente, si es que pudo haberlo alguna vez» [44]. Una de las consecuencias perdurables del movimiento de la interpretación histórica debería ser animar a los intérpretes a adoptar un enfoque menos coercitivo y más creativo de la música que interpretan, cualquiera que sea el repertorio. Como ha afirmado Nicholas Kenyon, «la tradición no es lo que era» [45]. En vista del alcance del repertorio que actualmente se considera como normativo para los intérpretes, el conocimiento bien fundado de las nociones que aportan las disciplinas como la estética, el análisis, la musicología (incluyendo la etnomusicología) y la psicología ya no puede ser una excepción. Para el intérprete en formación, su importancia es mayor que nunca.

Sin embargo, los intérpretes jóvenes necesitan que se les ayude a adquirir ese conocimiento y a no darle demasiado peso: no puede ser un sustituto del instinto musical, o llegar a ser tan importante que silencie la voz personal. Schnabel valoraba la enseñanza de Leschetizky porque funcionaba como «una corriente que activaba o liberaba toda la vitalidad latente de la naturaleza del alumno. Iba dirigida a la imaginación, al gusto y a la responsabilidad personal» [46]. Ésas son las cualidades que la buena enseñanza de la interpretación siempre ha fomentado. La coherencia estilística requiere ese enfoque integral, en el que las ideas del compositor se complementan con los conocimientos del intérprete —conocimiento de sí mismo como de la música que ejecuta. Sólo así los intérpretes podrán vestirse con su propia individualidad, como lo describió Baillot, e interpretar con convicción y coherencia, no como el «pájaro adiestrado» de C. P. E. Bach, sino utilizando con confianza «las inspiraciones del corazón y los estallidos de la imaginación» [47].

12. Véase por ejemplo César Gardeton, *Annales de la musique ou Almanach musical... [1819, 1820],* Ginebra, Minkoff, 1978, pp. 39-43, que enumera trece escuelas de música inauguradas en la época en París. En una carta que Mendelssohn escribió en París a Carl Friedrich Zelter, Berlín (el 15 de febrero de 1832), comenta que en la ciudad había 1.800 profesores de piano, pero que «aún no era suficiente» para satisfacer la demanda (Felix Mendelssohn, *Letters,* trad. y ed. G. Selden-Goth, Londres, Paul Elek, 1946, p. 190). En *Musique et musiciens* (París, Pagnerre, 1862), Oscar Comettant, un importante crítico parisino de la época, señala que el número de profesores de piano en París había ascendido a 20.000. Para comentarios sobre la situación en Inglaterra, véase Cyril Ehrlich, *The Musical Profession in England since the Eighteenth Century,* Oxford, Clarendon Press, 1985, pp. 76-120.
13. El número de alumnos variaba de año en año (véase Constant Pierre, *Le Conservatoire National de Musique et de Déclamation...,* París, Imprimerie nationale, 1900, p. 873. Para 1828 se habían inscrito 11.000 alumnos; de los 3.800 que se graduaron, 1.127 eran pianistas o acompañantes (véase François-Joseph Fétis, «Statistique musicale de la France. Premier Article», *Revue musicale* 6 (1828-1829), pp. 126-127.
14. Constant Pierre, *Le Conservatoire National de Musique et de Déclamation,* cit., p. 125.
15. Estos métodos, diez en total, eran para flauta, clarinete, fagot, trompa (dos), serpentón, violín, violonchelo y voz, y otro de armonía, solfeo y los rudimentos de la música.
16. El método de Louis Adam y Louis-Wenceslas Lachnith, *Méthode ou principe général du doigté pour le forté-piano,* París, Sieber, 1798, fue editado y publicado de nuevo por Adam en 1802 y 1804 con el título *Méthode de piano du Conservatoire adoptée pour servir à l'enseignement dans cet établissement,* París, Conservatoire Royal, 1802, 1804. La versión reeditada en 1805, *Méthode complète pour le piano,* París, Conservatoire impérial de musique, 1805, adquirió aún más popularidad y fue publicado en dos ediciones alemanas y dos italianas.
17. Este método reemplazó al de Jean-Baptiste Cartier, *L'Art du violon...* (París, Decombe, [1798]), que el autor había dedicado al Conservatorio recién establecido. La edición de 1803 se siguió utilizando para la enseñanza hasta que fue reemplazado por *L'Art du violon* de Pierre Baillot (París, Dépôt Central de la Musique [1834]).

6 *El desarrollo de la habilidad interpretativa*

JANE DAVIDSON

Este capítulo analiza los factores más importantes que intervienen en el desarrollo de las habilidades musicales. En primer lugar, examina el concepto de potencialidad musical; después presenta una investigación sobre las habilidades específicas requeridas para aprender a tocar un instrumento. Por último, examina cuál es la mejor manera de cultivar la habilidad de interpretar para un público. Se ha procurado un equilibrio entre la teoría y la práctica haciendo referencia tanto a las investigaciones publicadas sobre psicología y educación musical como a informaciones anecdóticas y al material que contienen los manuales educativos. Aunque se hacen algunas referencias al aprendizaje musical en otras culturas, este estudio se centra en el desarrollo de la habilidad interpretativa de los niños dentro de un marco cultural occidental.

Los roles relativos de la genética y el entorno en la configuración de la potencialidad musical

Las aparentes diferencias de la capacidad musical entre la población en general han despertado un interés considerable. Gran parte del debate se ha centrado en los roles relativos de las influencias biológicas y ambientales en las habilidades humanas —el debate sobre «naturaleza versus crianza» [1]. Según los descubrimientos científicos, parece ser que los factores genéticos influyen de varias maneras en el desarrollo general:

- *Desarrollo físico por etapas*
  Un ejemplo es la necesidad de gatear antes de andar, o, en términos musicales, del desarrollo gradual de la destreza y coordinación manual y visual para poder sincronizar el arco y las cuerdas en la ejecución del violín.
- *Algunas ventajas físicas*
  Por ejemplo, las personas altas y delgadas suelen ser más aptas para los saltos de altura que las bajas y más bien robustas. En música, las personas de manos anchas tienen un mayor potencial para desarrollarse como pianistas que las de manos estrechas.
- *Algunas ventajas psíquicas*
  Generalmente, por ejemplo, algunas personas «sintonizan» más rápidamente con las tareas que implican la resolución de problemas que otras. Por lo tanto pueden ser capaces de identificar patrones musicales y realizar tareas de discriminación auditiva con mayor rapidez.

El componente biológico es sin duda importante, y los investigadores como Robert Plomin [2] sugieren que la identificación del gen que determina los logros musicales sólo es cuestión de tiempo. No obstante, si admitimos el concepto de la «distribución normal» [3], aparentemente la gran mayoría de la población —alrededor de un 95 por cien— está incluida dentro de la «norma» en cuanto a capacidad y estructura física y mental, sugiriendo que más o menos todos tenemos un potencial similar [4]. Ello se aplica igualmente al desarrollo de las habilidades musicales, en las que se exagera con frecuencia la importancia de las capacidades innatas. Sería de utilidad, por lo tanto, examinar los asuntos relacionados con la influencia del entorno en las habilidades musicales.

Para destacar el papel decisivo del entorno, consideremos el campo políticamente delicado de los estereotipos raciales y las diversas explicaciones del tipo «naturaleza versus crianza» que han sido propuestas para dar cuenta de las habilidades musicales. Los negros africanos, por ejemplo, han sido caracterizados a menudo por los blancos como una raza que lleva «el ritmo en la sangre», mientras que a los japoneses se les considera que poseen por naturaleza capacidades intelectuales elevadas y que despliegan un gran virtuosismo técnico en sus interpretaciones musicales. Aunque los factores genéticos pueden haber intervenido en cierta medida, el análisis de las respectivas culturas y prácticas sociales revela que esos estereotipos se desarrollaron a partir de las reglas socioculturales de participación y conducta. Por ejemplo, para la tribu Anang Ibibo de Nigeria, la música forma parte de la vida cotidiana. Todos los niños han de participar en la música desde su nacimiento. Cuando cumplen cinco años de edad, la gran mayoría de esos niños sabe tocar y cantar un enorme repertorio de canciones, bailes y patrones de percusión. La noción de

ser poco musical o carecer de musicalidad no existe. Además, aunque algunos destacan un poco más que otros, todos han de participar a un nivel elevado. El principio de la distribución normal funciona dentro de esa cultura: la música es para todos, y los logros interpretativos están distribuidos de manera bastante equitativa. En Japón, la disciplina que la sociedad impone al individuo es mucho más severa que la del mundo occidental. Por ello, los niños dedican muchas horas a los deberes de todo tipo, incluyendo la música. Como tiende a haber un enfoque más sistemático de la educación y por lo tanto unos patrones de conducta más disciplinados y estructurados, los niños japoneses adquieren un nivel más elevado de habilidad musical que sus equivalentes occidentales.

Tal vez una de las mejores maneras de considerar la importante influencia del entorno en la adquisición de habilidades musicales sea examinando el caso de un personaje que a primera vista no parece haber tenido apoyo alguno del entorno, pero que llegó a ser uno de los músicos más talentosos del mundo occidental: el trompetista de jazz Louis Armstrong. Nacido en condiciones de extrema pobreza, pasó mucho tiempo arreglándoselas solo en la calle (su madre era prostituta), y no recibió prácticamente ninguna educación formal. Cabe destacar que de niño ni siquiera tenía una trompeta. Sin embargo, si examinamos detalladamente la biografía de Armstrong [5], podemos identificar cinco factores ambientales sumamente importantes:

(1) *Estímulos musicales fortuitos pero frecuentes*
Armstrong creció en Nueva Orleans, rodeado constantemente de jazz.

(2) *Muchas oportunidades, durante un período prolongado, de explorar libremente el medio del jazz y de desarrollar habilidades de presentación de una interpretación*
Armstrong formó y cantó en un coro callejero cuando era niño, y tuvo oportunidades de participar en las actividades colectivas de jazz en las que se toleraban los errores y en las que podía elegir el nivel de riesgo y dificultad de su interpretación. Por lo tanto, pudo aprender informalmente las «reglas» de la armonía, la improvisación y la etiqueta del jazz.

(3) *La oportunidad temprana de experimentar estados emocionales o estéticos sumamente positivos en respuesta a la música*
Podemos suponer que Armstrong desarrolló un «amor» por el jazz basado en cierta experiencia emocional relacionada con la música.

(4) *La oportunidad de acumular muchas horas de práctica*
Armstrong pasaba todo el día con músicos de jazz, y podía pedir prestada una trompeta para tocar.

(5) *Varios factores externos que lo motivaron, como la presencia de un adulto clave*
Armstrong recibió una educación informal de los músicos de jazz con los que pasaba el día, y ese contacto desarrolló su conocimiento musical, sus habilidades interpretativas y su deseo de relacionarse con la música.

Los cinco factores que al parecer fueron decisivos para que Armstrong se interesara por la música y se relacionara con ella han sido estudiados sistemáticamente por psicólogos de la música, y hoy en día se consideran fundamentales para el desarrollo de las habilidades musicales [6]. A continuación, se examinarán en profundidad dichos factores y se harán algunas sugerencias sobre la mejor manera de fomentar las habilidades interpretativas.

Oportunidades tempranas para relacionarse con la música

Existen cada vez más pruebas de que el entorno comienza a influir en el individuo antes de su nacimiento. Por ejemplo, el feto es capaz de oír música y voces varias semanas antes del nacimiento y de reconocer esa música después de nacer [7], lo que implica que ha tenido lugar algún tipo de aprendizaje. También se puede deducir que la experiencia fetal es en gran parte «musical» porque el feto siente los ritmos del cuerpo de su madre y oye las inflexiones —los contornos melódicos— de los sonidos externos, incluyendo el habla y la música. Es posible que la estimulación prenatal sea una de las experiencias ambientales más importantes, y que los niños estimulados de esa manera se beneficien en cuanto a su educación en general y su desarrollo musical en particular. El mundo de la música comercial da por sentada la posibilidad del aprendizaje prenatal, y ofrece a las mujeres embarazadas una variedad de programas musicales especiales que supuestamente tienen un efecto positivo en el niño que está por nacer.

Se ha demostrado que en la infancia el «lenguaje materno» [8] constituye la base para el desarrollo de las habilidades de alternancia recíproca [9]. La comunicación gestual también es de vital importancia, y el ritmo, tempo y dinámica de sus interacciones [10] son determinados por movimientos y prácticas lúdicas como dar palmadas. El «lenguaje materno» y los juegos gestuales se desarrollan para comunicar emociones y necesidades básicas. De esta manera se forma la relación entre la emoción, el gesto físico y el significado musical. Una característica musical expresiva como el *rubato* puede demostrar una relación con las primeras experiencias infantiles. Por ejemplo, las interacciones físicas y vocales se ralentizan cuando están a punto de finalizar, y en la inter-

pia musical [14] y la educación musical [15] exploran la música como un medio para calmar, aliviar y animar a las personas. Algunos de los resultados son sorprendentes: en un caso, una clase de niños difíciles, con «necesidades educativas especiales», mejoró su trabajo y su rendimiento al escuchar obras de Mozart como música de fondo durante sus clases de ciencias.

Se ha sostenido que la respuesta emocional ante un contenido musical constituye un desencadenante fundamental de la motivación musical intrínseca [16]. Un estudio [17] reveló que las personas comprometidas con la música durante toda su vida son mucho más proclives a rememorar las experiencias emocionales que tuvieron en respuesta a un contenido musical durante la primera infancia que aquellos que nunca aprendieron a tocar un instrumento musical más allá de la fase inicial. Por ejemplo, una mujer señaló que había escuchado por primera vez una música para clarinete clásico cuando tenía siete años; el sonido del instrumento le pareció «líquido» y «hermoso», y le hizo sentir un «hormigueo» por todo el cuerpo.

Es importante destacar que, además del contenido musical, el contexto musical constituye un estímulo muy importante de la motivación. Por ejemplo, estar con un amigo íntimo mientras se escucha una pieza determinada puede fomentar una relación futura con esa música, mientras que, al contrario, es posible que evitemos la música que hayamos escuchado en circunstancias desagradables.

La práctica para la perfección

Una serie de estudios han demostrado que la manera más eficaz de adquirir habilidad es la práctica deliberada [18]. En el campo de la música, se ha encontrado una clara relación entre las horas acumuladas de práctica «formal» (escalas, ejercicios técnicos y repertorio) y los logros alcanzados. Por ejemplo, en un estudio sobre alumnos violinistas [19], K. Anders Ericsson et al. descubrieron que los mejores alumnos habían acumulado casi 10.000 horas de práctica formal para la edad de veintiún años, mientras que los alumnos cuyos logros eran mucho menores habían acumulado menos de la mitad. Además, un estudio de John A. Sloboda et al. [20] reveló que los alumnos más sobresalientes no sólo practicaban mucho más que sus compañeros menos exitosos, sino que además había una correlación directa entre las horas de práctica y la calidad interpretativa en los exámenes musicales. Los investigadores estudiaron cinco grupos de jóvenes que abarcaban desde los que habían abandonado la música después de dos años de aprendizaje hasta aquellos que estaban recibiendo una educación musical especializada con vistas a una carrera profesional. Descubrieron que los alumnos de educación especializada avanza-

que los individuos aprenden tareas si valoran la actividad o el resultado, o si anticipan el éxito. La valoración depende de varios tipos de motivación:

- *extrínseca* (cuando las tareas se llevan a cabo por la posibilidad de alguna recompensa externa, como aprobar un examen),
- *social* (el deseo de complacer a otros o encajar con ellos),
- *éxito* (para realzar el ego, ser mejor que otros),
- *intrínseca* (interés en la actividad misma, participar por puro placer personal).

Las investigaciones sobre cómo los niños se vinculan con la música sugieren que las tres fuentes de motivación externas —extrínseca, social y éxito— a menudo preceden y se desarrollan convirtiéndose en motivación intrínseca. Previamente en este capítulo, cuando se consideró la importancia de las respuestas emocionales, se demostró que la motivación intrínseca es el tipo de motivación que facilita un compromiso a largo plazo con la música. Hallam [26] ha escrito detalladamente sobre cómo ayudar a desarrollar la motivación intrínseca, y sugiere las siguientes técnicas de enseñanza:

(1) Los alumnos deben estar expuestos a muchos tipos de música de una manera libre, para abrir las posibilidades de respuesta emocional a la música.
(2) Los alumnos deben participar en las decisiones sobre el estilo y la dificultad de la música que van a aprender y decidir si quieren o no interpretar en público y examinarse.
(3) Para estimular a los alumnos, los profesores han de generar sorpresa, dudas, contradicción y debate.

En otras palabras, las tareas musicales deben ser importantes para los alumnos y han de tener un nivel de complejidad óptimo, es decir, que los enfrente a un reto, pero que sea practicable. Hallam desarrolló sus técnicas observando a muchos alumnos, pero también examinando las características biográficas que comparten diversos músicos afamados [27].

En cuanto a las motivaciones externas, parece ser que los apoyos sociales son los más comunes —por ejemplo, los amigos, la familia y los maestros. Ellos pueden utilizar refuerzos materiales como dulces, dinero, pequeños obsequios o convites, abrazos y sonrisas para animarlos, pero su presencia y participación son lo más importante para el progreso en el aprendizaje.

Apoyo social y aprendizaje

Además de la estimulación temprana del interés musical mediante el «lenguaje materno» y el juego gestual, más tarde, cuando se ha elegido un instrumento, los padres y cuidadores pueden desempeñar un papel muy importante en el desarrollo del vínculo con la música. Una investigación psicológica a gran escala [28] demostró que es bastante común que los niños abandonen el aprendizaje de un instrumento musical por no recibir suficiente apoyo de los padres. Doscientos cincuenta y siete niños, de edades comprendidas entre los ocho y los dieciocho años, que recibían clases instrumentales y poseían diversos niveles de rendimiento fueron entrevistados en relación con el papel que desempeñan los padres y los profesores. El grupo más destacado era el que recibía el apoyo más frecuente y consecuente de sus padres, que a menudo asistían a las clases y tomaban nota de lo que debían practicar sus hijos en casa; después, de vuelta en casa, les apoyaban escuchando o acompañándoles durante las prácticas.

Por lo tanto, los padres deben establecer ciertas actitudes hacia la música. Los hermanos también pueden hacer que el entorno del aprendizaje sea más atractivo, así como las personas que el niño admira y quiere imitar. En el caso de Louis Armstrong, los músicos de jazz proporcionaban un ambiente de seguridad y apoyo en el que los elogios y el éxito desempeñaban un papel de refuerzo. En ese sentido, eran como los profesores del sistema educativo convencional.

El papel del maestro

Las investigaciones [29] han demostrado que los alumnos destacados consideran que sus maestros son divertidos y amables, y también músicos competentes, mientras que los alumnos de menor éxito recuerdan a sus maestros como personas antipáticas e incompetentes. A medida que aumenta la edad de los alumnos, el grupo inferior en cuanto a logros mantiene la misma descripción, mientras que los más destacados comienzan a distinguir entre las cualidades profesionales y personales de sus maestros, considerando más pertinentes las profesionales. Los niños que abandonaron sus clases no establecieron esa distinción. Los que consideraban que la personalidad del profesor era agradable también percibían que era profesionalmente satisfactorio. Podemos observar cuán importantes son los aspectos personales; especialmente a edades tempranas, dichos aspectos pueden motivar al niño a tocar. Ello pone de relieve el clima emocional en el que se acumulan las experiencias musicales. Los niños que desarrollaron un nivel instrumental extraordinario aprendieron en una atmósfera positiva, agradable y despreocupada. Al contrario, el

ambiente de aprendizaje de los niños que se dieron de baja era negativo y angustioso.

Los investigadores también descubrieron que a partir de los once años de edad muchos niños no necesitan fuentes externas de motivación, ya que desarrollan su propio vínculo con el instrumento [30]. En efecto, un estudio sobre músicos adolescentes y sus actividades [31] reveló que su identidad estaba estrechamente vinculada con tocar un instrumento musical. Se ha encontrado que lo mismo es cierto en otros campos, como la música pop, en los que las recompensas musicales llegan a vincularse con la identidad propia [32].

De esta manera, el análisis de las investigaciones revela que la biografía de Armstrong muestra los factores ambientales más importantes relacionados con la adquisición de habilidades musicales. Pero ¿qué podemos decir sobre las características de habilidades mismas?

Las habilidades interpretativas

Según Hallam [33], un primer paso importante en la motivación para el aprendizaje instrumental es elegir el instrumento adecuado. Ello implica elegir un instrumento que le guste al niño, tal vez adecuándose incluso a los estereotipos de género (por ejemplo, las niñas prefieren la flauta, y los niños la batería). Con el instrumento elegido, las prácticas debidamente apoyadas por los padres y un maestro afectuoso y simpático dirigiendo al niño, los siguientes elementos parecen formar la base de las habilidades a desarrollar:

(1) *Habilidades de estructura, notación y lectura*
Éstas se adquieren desarrollando una base de conocimientos sobre las reglas de la estructura musical, como por ejemplo la formación de las frases y el funcionamiento de la armonía; examinando el aspecto que tiene la música sobre el papel, y aprendiendo por lo tanto a descifrar el código de la notación musical; descubriendo cómo leer a primera vista para poder aprender y procesar más música en menos tiempo mediante una lectura más fluida; aprendiendo a memorizar para poder tocar la música sin tener que concentrarse completamente en la notación, y, a partir de todo ello, desarrollando mapas mentales sólidos que relacionen el conocimiento estructural con la ejecución musical.

(2) *Habilidades auditivas*
Las habilidades auditivas son particularmente necesarias para que el alumno pueda desarrollar una buena afinación y calidad de sonido en el instrumento. Adquirir la habilidad de emplear en la práctica el conocimiento sobre la estructura musical mediante la improvisación

es muy importante, como lo es también saber cómo suena la música sin tener que tocarla.

(3) *Habilidades técnicas y motrices*
Además de crear estructuras mentales para comprender la música, es necesario entrenar el cuerpo para que automatice el proceso de ejecución de modo que se pueda lograr fluidez y agilidad.

(4) *Habilidades expresivas*
Implican saber cómo emplear las reglas estructurales para crear una música en la que se percibe un contenido emocional y que es original del intérprete.

(5) *Habilidades de presentación*
Éstas incluyen aprender a presentar tanto la música como el cuerpo del intérprete con seguridad en el escenario, de modo que el intérprete, los cointérpretes y el público perciban una sensación de tranquilidad en torno al acto interpretativo y lo que está comunicando. También incluyen el dominio de las reglas de etiqueta en el escenario —por ejemplo, saludar con una reverencia después de la interpretación.

Existen muchos manuales para desarrollar las subhabilidades enumeradas anteriormente, y hoy en día se reconoce que con una actitud persistente y determinada se pueden desarrollar las tres primeras series de subhabilidades hasta niveles elevados [34]. Sin embargo, desde hace mucho tiempo se considera que las habilidades expresivas son cruciales a la hora de diferenciar a los intérpretes promedio de los excelsos, y que una especie de «don» misterioso e imposible de cultivar determina la medida en que una persona puede ser expresiva musicalmente. No obstante, la investigación [35] revela que los «recursos expresivos» concuerdan con una serie de características. En primer lugar, son *sistemáticos*. Por ejemplo, la ralentización siempre se utiliza en determinados momentos estructurales de una pieza, como por ejemplo los límites de las frases. En segundo lugar, dichos recursos mejoran la *comunicabilidad* de la característica estructural para el que lo percibe, de modo que, por ejemplo, el compás será más claro si se acentúa el primer tiempo. En tercer lugar, esos recursos se emplean de manera *estable,* de modo que un intérprete puede lograr repetidamente efectos expresivos similares en múltiples interpretaciones, a menudo durante períodos prolongados. En cuarto lugar, la *flexibilidad* es posible, y los intérpretes expertos pueden cambiar o exagerar el contorno de una línea expresiva. Por último, esos recursos expresivos se emplean de manera *automática,* y a menudo los intérpretes no son conscientes de lo que están haciendo. Partiendo de estas conclusiones, es evidente que las cinco características anteriores se pueden enseñar dada su estabilidad.

¿Las habilidades de presentación son un factor decisivo para distinguir a los buenos intérpretes de los grandes? Según los estudios publicados, aparentemente no dependen más del «talento» que las otras subhabilidades. Una investigación reciente [36] ha demostrado que las personas aprenden a armonizar entre sí y ajustarse a las convenciones sociales en el contexto de la interpretación, y existen programas de adiestramiento como Eurythmics de Dalcroze que destacan la importancia de las indicaciones no verbales y la interacción interpersonal en el desarrollo de las habilidades de presentación. Sin embargo, como señala perspicazmente Andrew Evans [37], es necesario que nos dediquemos mucho más, cultural y educativamente, al desarrollo de las habilidades de presentación. Por ejemplo, comenta ampliamente las terribles ansiedades, referidas por músicos de todos los niveles, relacionadas con una falta de seguridad en sí mismos en cuanto al contexto y la evaluación de la interpretación. Los estudios publicados sugieren que conocer diversos contextos interpretativos, tocar un repertorio que se conozca bien y tener muchas oportunidades para la interpretación constituyen maneras de superar posibles problemas con las habilidades de presentación.

Una de las mayores dificultades que plantea la forma en que se enseña y se concibe la interpretación como acto interpretativo en la cultura occidental es que tiene lugar en el aislamiento: practicar es una actividad solitaria, y las clases suelen ser individuales. Para desarrollar habilidades interpretativas es necesario luchar contra la tendencia cultural dominante. Los músicos clásicos y los maestros de música del mundo occidental podrían aprender mucho de los Anang Ibibo de Nigeria, aunque la naturaleza de su material musical sea muy diferente. Para los Anang, la música forma parte de la vida diaria: no asusta ni inquieta a nadie, ni es privilegio de unos pocos. La música es para todos, y todos participan como creadores, oyentes e intérpretes.

7 *Preparándose para interpretar*

STEFAN REID

Introducción

Aunque la interpretación musical es una experiencia sumamente pública, la preparación para una interpretación generalmente tiene lugar en privado, y muchas veces en un completo aislamiento. La mayoría de las interpretaciones sólo se realizan una vez, y casi nunca duran más de un par de horas como mucho, pero se preparan durante días, semanas o incluso años de intenso trabajo. El punto de partida de una interpretación de música occidental suele ser una partitura, que consiste en una serie de instrucciones con diversos grados de imprecisión que el intérprete debe traducir en sonidos. La imprecisión inherente a la notación musical occidental implica que la decodificación de la partitura requiere un considerable aporte y conocimiento por parte del intérprete. Por consiguiente, cada interpretación de una obra es diferente.

El término que más se utiliza para referir el proceso de prepararse para una interpretación es «practicar» (o «estudiar») —pero dicho término puede significar varias cosas. Mientras que los psicólogos definen la práctica como «adquirir habilidades mediante la repetición» [1], la práctica o estudio musical consiste en una variedad de actividades diferentes pero relacionadas entre sí que incluyen la memorización, el desarrollo de la destreza técnica y, finalmente, la planificación de una interpretación. Este capítulo se centra tanto en la cantidad como en la calidad de las prácticas que se realizan para preparar una interpretación. La primera sección examina cuánto necesitan practicar los músicos para desarrollar sus habilidades. La segunda sección analiza cómo practican los músicos eficazmente, enfocando específicamente el desa-

rrollo de la habilidad técnica, la planificación de las interpretaciones y la relación entre esos dos elementos. La última sección presenta un resumen que sugiere diversas maneras en las que los músicos pueden mejorar la eficiencia y eficacia de sus prácticas.

Examinando los temas anteriores, el capítulo hace referencia a dos principales fuentes de información sobre la práctica: los estudios pedagógicos sobre música desde el siglo XVIII hasta hoy, y los estudios psicológicos sobre la adquisición de habilidades en general y en el campo de la destreza musical. Aunque su naturaleza es en gran parte subjetiva y anecdótica, los escritos pedagógicos constituyen la base de la educación musical occidental. Su subjetividad se ha compensado mediante referencias a los escritos psicológicos que, utilizando métodos experimentales, procuran proporcionar un conocimiento más objetivo sobre cómo se adquieren habilidades y cómo practican los músicos.

¿Cuánto es suficiente?

A la mayoría de los estudiantes de música, los maestros le han dicho en algún momento que «no han practicado suficiente». En sus referencias a la práctica, las obras pedagógicas escritas desde el siglo XVIII en adelante incluyen una gama de preceptos sobre cuánto se debe practicar para alcanzar el éxito en la música. Por ejemplo, el respetado profesor de canto Pier Francesco Tosi opinaba que «una hora al día no es suficiente, ni siquiera para la mente más dispuesta» [2]. En su *Klavierschule,* Daniel Gottlob Türk sugiere que «el que aprende a tocar el clavicordio por puro placer hará suficiente practicando dos horas al día» [3]. Johann Joachim Quantz, maestro de flauta de Federico el Grande de Prusia, propuso cuatro horas de práctica al día, dos por la mañana y dos por la tarde [4], mientras que el afamado pianista Johann Nepomuk Hummel opinaba que un máximo de tres horas al día era suficiente «para alcanzar la excelencia» [5]. La discrepancia entre estas sugerencias bien puede hacer que los músicos se pregunten: ¿cuánta práctica es necesaria?

Algunos investigadores que estudian la psicología de la música han procurado abordar esa cuestión. K. Anders Ericsson, Ralf Krampe y Clemens Tesch-Römer realizaron un estudio sobre la cantidad de «práctica deliberada» [6] que realizan tres grupos de violinistas estudiantes durante el transcurso de su educación musical. Su experimento se basó en cálculos aproximados del tiempo que cada alumno había practicado desde su infancia y en diarios de práctica que reflejaban sus actividades musicales actuales. Los alumnos fueron divididos en tres grupos según la evaluación que hicieron sus maestros de sus habilidades y posibles carreras en el futuro: «mejores violinistas»,

«buenos violinistas» y futuros «profesores de música». Los resultados indicaban que, para la época del experimento, los «mejores violinistas» habían acumulado unas 7.410 horas de práctica, los «buenos violinistas», 5.301 horas, y los posibles «profesores de música», 3.420 horas. Los investigadores dedujeron por tanto que el éxito y la habilidad musical, en lugar de ser producto del talento innato, son el resultado de la acumulación de muchas horas de práctica deliberada. En cuanto a la práctica regular, descubrieron que los «mejores» y «buenos» violinistas practicaban una media de 24,3 horas por semana, mientras que el promedio de los futuros profesores de música era de 9,3 horas por semana [7].

Por lo tanto, en respuesta a la pregunta «¿cuánta práctica es necesaria?», los descubrimientos de Ericsson et al. sugieren que la cantidad requerida depende del objetivo primordial del músico. Para alcanzar los más altos niveles de competencia musical, el intérprete ha de dedicar muchas más horas a la práctica que el músico que simplemente desea adquirir un nivel razonable de destreza.

Mientras esta investigación parece sugerir que la cantidad de práctica es la clave del éxito musical, el término «práctica deliberada» destaca la importancia de la calidad y la naturaleza de las actividades de la práctica. Este énfasis en la calidad se repite en todos los escritos sobre pedagogía musical. Hummel refiere la necesidad de un «estudio *atento*» [8], y en su ampliamente respetado *Versuch über die wahre Art das Clavier zu spielen,* C. P. E. Bach comenta que con la «práctica inteligente es fácil lograr lo que nunca se puede alcanzar mediante un excesivo esfuerzo muscular» [9]. Si las incontables horas de práctica acumuladas son un prerrequisito para el éxito musical, la eficacia de esas horas dependerá de la calidad y naturaleza de las actividades prácticas que se realicen. Para obtener los mayores beneficios de sus horas de práctica, los músicos deben desarrollar y perfeccionar sus técnicas de estudio.

¿Cómo practican los músicos?

«Muy pocas personas obtienen con su práctica todos lo beneficios que esperan, porque, en general, practican mal» [10]. Eso comentó el famoso pianista Frédéric Kalkbrenner en su tratado de 1831, *Méthode pour apprendre le piano-forte.* Probablemente es cierto que la mayoría de los músicos podrían mejorar sus técnicas de estudio y con ello aumentar al máximo los resultados del tiempo que pasan estudiando. Como se dijo en la introducción, el músico que se prepara para una interpretación tiene dos objetivos fundamentales: formular la interpretación de una obra musical y desarrollar la destreza técnica necesaria para realizar esa interpretación. Aunque esos dos objetivos están

estrechamente relacionados —de hecho, para una buena interpretación son completamente interdependientes—, son habilidades diferentes que requieren métodos de trabajo diferentes. Eso se demuestra por el hecho de que, como señala el psicólogo John Sloboda [11], un intérprete puede tener una técnica magnífica pero carecer de perspicacia musical, y viceversa. El músico experto es capaz de equilibrar la habilidad técnica con la comprensión interpretativa.

El desarrollo de la destreza técnica

En su obra *We Piano Teachers,* Victor Booth sugiere que durante la práctica «los actos conscientes o voluntarios se vuelven inconscientes o involuntarios» [12]. En otras palabras, una actividad que inicialmente requiere el pensamiento consciente se ensaya hasta que se vuelve automática. Los psicólogos Paul Fitts y Michael Posner han sugerido que la adquisición de una habilidad se realiza en tres fases:

(1) *Fase cognitiva,* una fase inicial que requiere la atención consciente.
(2) *Fase asociativa,* caracterizada por el perfeccionamiento de la actividad y la eliminación de errores.
(3) *Fase autónoma,* en la que la habilidad ya no requiere la atención consciente porque se ha vuelto automática [13].

El progreso de una fase a la siguiente es gradual a medida que la habilidad es transferida de la memoria a corto plazo a la memoria a largo plazo.

El método principal que utilizan los músicos para automatizar una actividad es la repetición de esa actividad. Al repetir una acción o serie de acciones, el intérprete la consolida en la memoria hasta que ya no requiere la atención consciente que se necesita en las fases iniciales del aprendizaje. Las investigaciones sobre la adquisición de habilidades en otros campos de especialización han demostrado que la memoria a corto plazo tiene una capacidad limitada, que se considera generalmente de unos siete «ítems». En el almacenamiento a corto plazo, esos «ítems» pueden ser de tamaños variables, pero se perderán a menos que se transfieran al almacenamiento a largo plazo mediante la repetición. Los constreñimientos de la memoria a corto plazo interfieren en la habilidad de una persona para realizar una tarea compleja como aprender una pieza musical. Para que la práctica repetitiva sea eficaz, es necesario seccionar la tarea compleja en tareas más pequeñas y sencillas, un procedimiento que los psicólogos denominan *chunking* (dividir en trozos grandes o bloques). En términos musicales, puede consistir en practicar sólo

una sección pequeña de la obra y después, cuando ya se domina, incorporarla dentro de un «bloque» más grande, y así sucesivamente. De esta manera, la pieza se fragmenta antes de reconstruirla gradualmente. Este método de trabajo fue recomendado por el pianista inglés James Ching, entre otros [14].

El tamaño de los bloques que se elija para la repetición dependerá de la complejidad de la obra y la habilidad del intérprete. Esto fue demostrado por Linda Gruson en un estudio sobre las prácticas de varios pianistas con diversos niveles de habilidad [15]. El estudio reveló que los pianistas más experimentados dividían la música en bloques más grandes que los novatos. Kacper Miklaszewski [16] ha analizado detalladamente el procedimiento de *chunking* en un estudio sobre un pianista ruso que preparaba la obra «Feux d'artifice» (*Preludios,* Libro II) de Debussy. Durante el proceso, el pianista trabajó la pieza sistemáticamente, estudiando primero bloques pequeños y después, progresivamente, bloques más grandes. Este tipo de enfoque del aprendizaje suele diferenciar el trabajo de los músicos experimentados y novatos. Los novatos generalmente carecen del enfoque sistemático de los intérpretes más experimentados que, como señala Robert Gerle, «separan los problemas y los resuelven uno por uno» [17].

En prácticas posteriores, el pianista ruso del estudio de Miklaszewski no sólo practicaba secciones más largas sino que además las interpretaba a un tempo más rápido. La práctica lenta es, naturalmente, otra manera en que los músicos pueden simplificar una tarea. Dale Reubart la recomienda en su obra *Anxiety and Musical Performance,* donde sugiere específicamente que la práctica lenta durante las primeras fases del aprendizaje puede ayudar a prevenir errores innecesarios, y que el lema de todo intérprete debería ser «hazlo bien la primera vez» [18].

La concentración, por tanto, es un elemento esencial de la práctica técnica, no sólo para asegurar la precisión sino también para mantener la eficiencia. Los músicos experimentados estudian sistemáticamente los problemas que presenta una obra musical, utilizando su concentración para diagnosticarlos y resolverlos. Estos objetivos cambiarán constantemente a medida que progrese el aprendizaje.

En resumen, el desarrollo de la destreza técnica necesaria para una interpretación requiere que la habilidad sea transferida de la memoria a corto plazo a la memoria a largo plazo. La manera más eficaz de realizar esa transferencia es mediante la repetición, que produce sus mejores resultados cuando el material musical se divide en bloques manejables de modo que el intérprete domine un «problema» a la vez. A medida que progresa la práctica, los bloques pueden aumentar de tamaño y el tempo también puede aumentar. La práctica repetitiva se debe supervisar constantemente para evaluar su eficacia y aumentar al máximo sus beneficios.

La formulación de las interpretaciones

Cuando un actor prepara un nuevo papel, no sólo deberá memorizar un texto, sino también decidir cómo lo va a expresar. Las palabras en sí mismas ofrecen posibilidades, pero para realizar todo su significado han de considerarse dentro del contexto de una escena, un acto o toda la obra. En la actuación, el actor comunica al público su conocimiento e interpretación de la obra a través de la manera en que ha decidido expresar el texto. Se puede establecer un paralelismo con el músico que prepara una interpretación, que debe decidir cómo tocará cada nota si quiere transmitir correctamente su papel dentro del contexto inmediato y dentro de la interpretación más amplia de la pieza.

Las interpretaciones musicales se transmiten mediante los parámetros expresivos como el tempo, la dinámica, la articulación y el timbre, entre otros. Las partituras pueden contener una variedad de indicaciones expresivas para ayudar en las decisiones interpretativas del intérprete, pero, como señalé antes, la notación expresiva carece de precisión. El intérprete tendrá que decidir cuán fuerte va a tocar los *forte,* cuánto tiempo mantendrá un calderón o cuán agudo será su *staccato.*

Los intérpretes han de recorrer el difícil camino entre la necesidad de respetar la partitura, que representa las intenciones del compositor, y el deseo de poner en práctica su propia perspicacia creativa. Además, los ideales estéticos varían según la persona y las modas de la época. Por lo tanto, interpretar música es un proceso muy subjetivo y resistente a las recomendaciones normativas. Mientras que los textos pedagógicos y psicológicos contienen instrucciones específicas para el desarrollo de la destreza técnica, las recomendaciones interpretativas son, comprensiblemente, más diversas y menos detalladas.

Tanto los textos pedagógicos como los psicológicos sugieren que escuchar las interpretaciones de otros es la mejor manera de desarrollar la habilidad interpretativa. Tosi recomienda a los alumnos de canto que «escuchen cuanto puedan a los cantantes más famosos, y también a los mejores instrumentistas, porque de la atención que uno les presta al escucharles se obtienen más beneficios que de cualquier tipo de instrucción» [19]. Sloboda se hace eco de esa recomendación al explicar por qué escuchar buenas interpretaciones puede ser beneficioso:

> La pericia interpretativa requiere, en primer lugar, una gran capacidad de escuchar analíticamente para poder captar las diminutas variaciones de tempo e intensidad [i.e. dinámica] que hacen excelsa una interpretación y después *imitarlas.* Según mi propia experiencia, y la de muchos músicos, no existe una manera realmente satis-

> factoria de *describir* las variaciones expresivas de modo que uno pueda incorporarlas en su propia interpretación. Las técnicas expresivas son transmitidas de un músico a otro mediante la demostración. Ésa es la razón por la que los grandes músicos suelen estar muy interesados en escuchar las interpretaciones de otros grandes músicos [20].

Sin embargo, no basta simplemente con imitar la buena interpretación. El músico debe asimilar las características expresivas de la buena interpretación para enriquecer su propio vocabulario interpretativo. Por ejemplo, los músicos pueden emplear la audición como una manera de familiarizarse con un estilo musical desconocido, como observó Susan Hallam en sus encuestas a veintidós músicos profesionales [21].

A los músicos se les recomienda particularmente escuchar buen canto para desarrollar una interpretación melódica eficaz. El pianista húngaro György Sándor comentó que «podemos aprender mucho escuchando y observando a los buenos cantantes, que pueden respirar y frasear con mucha más libertad y espontaneidad que cualquier instrumentista» [22]. Doscientos años antes, C. P. E. Bach había propuesto igualmente que los instrumentistas cantasen melodías, y añadía que «esa forma de aprender es mucho más útil que leer extensos volúmenes o escuchar discursos eruditos» [23]. Al cantar una línea melódica, el intérprete la separa de la técnica, permitiendo así que surja un contorno expresivo que después se puede imitar en el instrumento.

El canto de una línea instrumental podría definirse como un procedimiento comparativo que ayuda a la interpretación. La melodía vocalizada actúa como una imagen mental que enlaza las notas de la línea melódica en una secuencia expresiva. Esa interpretación virtual actúa entonces como el punto de referencia para la verdadera interpretación durante la práctica. Otro procedimiento comparativo que utilizan los músicos a veces es la creación de un programa extramusical como por ejemplo un relato o una secuencia descriptiva o emocional. Al igual que el canto de una línea instrumental, dicho programa establece relaciones entre los diversos elementos de la obra musical y permite al intérprete realzar la importancia de los eventos musicales por separado dentro del contexto de la interpretación general.

Otro recurso mediante el cual los músicos formulan sus interpretaciones es el análisis, que a menudo adopta la forma de un «estudio considerado de la partitura» [24], más que de una técnica académica rigurosa. Algunos intérpretes analizan para obtener un conocimiento y comprensión detallados de la obra que luego utilizarán para sus decisiones interpretativas, mientras que otros utilizan el análisis como un medio para resolver problemas interpretativos específicos.

En las obras pedagógicas se pueden encontrar ejemplos de cómo analizan los músicos. Las sugerencias interpretativas de Quantz requieren que el intérprete realice algún tipo de análisis armónico para generar expresión; por ejemplo, afirma que «las disonancias deben tocarse más fuerte que las consonancias» [25]. Otro ejemplo de cómo pueden analizar los músicos es el de Fanny Waterman, profesora de piano y fundadora del Concurso Internacional de Piano de Leeds, que escribe: «Así como las oraciones contienen palabras clave, cada melodía tiene un clímax —aunque cada artista tendrá naturalmente su opinión sobre la ubicación de ese clímax. Los pianistas deben aprender a avanzar rítmicamente hacia el clímax, y no detenerse nunca, ni siquiera en un silencio o una pausa» [26]. Por lo tanto, para tocar «hacia el clímax», los músicos han de realizar algún tipo de análisis para decidir dónde se ubica ese clímax.

A pesar de la naturaleza subjetiva de la interpretación, existen recursos específicos mediante los cuales los músicos pueden desarrollar sus habilidades interpretativas y mejorar su habilidad para formular interpretaciones. Al interpretar una obra, el intérprete debe disponer sus diferentes elementos en una interpretación coherente; algunas técnicas útiles para mejorar ese proceso de perfeccionamiento son escuchar buenas interpretaciones, cantar, establecer analogías y analizar.

La relación entre la técnica y la interpretación

Al preparar una obra para su interpretación, el músico debe negociar entre los procesos requeridos para formular la interpretación y los que se requieren para desarrollar las habilidades técnicas adecuadas. Wicinski investigó cómo organizan los músicos sus prácticas para poder satisfacer ambos requisitos [27]. Basó sus resultados en entrevistas realizadas a importantes pianistas rusos, quienes mostraron dos métodos de trabajo diferentes. Un grupo sugirió que sus prácticas podían dividirse en tres fases:

(1) Obtener una perspectiva general de la obra y desarrollar ideas interpretativas iniciales.
(2) Superar las dificultades técnicas de la obra.
(3) Combinar las dos primeras fases y perfeccionar la interpretación.

El otro grupo no estableció fases en sus prácticas y manifestó que simplemente estudiaban la pieza de principio a fin.

Obtener una perspectiva general de una obra antes de comenzar las prácticas ofrece dos ventajas básicas. En primer lugar, proporciona un medio para planificar las sesiones de práctica de modo que las dificultades técnicas se

puedan identificar en una primera fase, lo cual permite al intérprete idear la manera de superarlas. En segundo lugar, permite al intérprete formular ideas interpretativas iniciales antes de realizar las prácticas técnicas de modo que estas últimas estén fundamentadas en los requerimientos interpretativos. La perspectiva general se puede obtener con o sin el instrumento, dependiendo de las habilidades y los métodos de trabajo preferidos de cada músico. Sin embargo, en ambos casos requiere una participación mental consciente en el proceso de la práctica, fomentando por lo tanto la precisión y la eficiencia, además de destacar la importancia de la interpretación como el objetivo fundamental de la ejecución musical.

Las diversas maneras en que surgen las interpretaciones durante las prácticas difiere considerablemente de un músico a otro. En su estudio de encuestas, Hallam descubrió tres enfoques prácticos diferentes de la formulación de las interpretaciones durante las prácticas: un grupo de músicos empleaba el análisis, otro grupo utilizaba una mezcla de análisis e intuición y un tercer grupo trabajaba únicamente sobre una base intuitiva [28], es decir, no prestaban una atención consciente a la interpretación durante la práctica, sino que la dejaban surgir «automáticamente» como un producto de la práctica técnica. En lugar de reflejar cierto poder místico o habilidad natural, la intuición puede ser la respuesta interpretativa automatizada de un intérprete a determinado aspecto de una obra o partitura musical; John Rink lo denomina «intuición instruida» [29]. Los intérpretes expertos han acumulado muchos años de experiencia tocando y escuchando una amplia gama de músicas, lo que resulta en una habilidad «intuitiva» sumamente desarrollada. Los músicos pueden emplear conscientemente el análisis cuando falla la intuición o como un recurso para desarrollar las interpretaciones en general, en oposición a los detalles expresivos de la ejecución.

Dado que los métodos de trabajo de un intérprete evolucionan con los años de experiencia musical, no es de extrañar que los músicos exhiban una amplia variedad de estilos de trabajo, especialmente en cuanto a la formulación de interpretaciones. Sin embargo, una característica que comparten los métodos de práctica de los intérpretes más experimentados es el enfoque sistemático del aprendizaje musical, que se demuestra en una conciencia de los objetivos de la práctica y una habilidad para considerar estrategias musicales eficaces que les permitan alcanzar esos objetivos.

Resumen: eficiencia y eficacia en la práctica

En la preparación de una interpretación musical, el músico aborda una partitura y después la traduce en sonidos mediante un instrumento o la voz. Para

ello debe desarrollar las habilidades técnicas apropiadas para tocar o cantar las notas y realizar su propia interpretación. Las prácticas técnicas e interpretativas requieren técnicas diferentes pero relacionadas entre sí.

A los músicos estudiantes y aficionados les resultará beneficioso estudiar los métodos de trabajo de los intérpretes experimentados y profesores y reconocer que la práctica más productiva es aquella en la que hay una participación mental consciente. Bien sea para desarrollar la técnica o para formular una interpretación, la práctica será más eficaz si el músico tiene objetivos claros y factibles y ha elegido los medios para realizarlos. El enfoque más común es simplificar la tarea dividiendo el material musical en bloques suficientemente pequeños como para asegurar un progreso.

En este sentido, la práctica se puede considerar una actividad mediante la cual el intérprete identifica los problemas y busca la manera de resolverlos. Los intérpretes deben supervisar sus propias acciones para evaluar la eficacia de sus técnicas de práctica y para evitar los errores. Por otra parte, pueden mejorar la eficiencia de sus prácticas planteándose continuamente las siguientes preguntas mientras practican:

(1) ¿Qué es lo que espero lograr?
(2) ¿Cuáles son los métodos que puedo emplear para lograr mi objetivo?
(3) ¿Han tenido éxito mis métodos?

8 La memorización de la música

AARON WILLIAMON

Interpretar música de memoria es una actividad que puede alcanzar niveles de exigencia sumamente elevados. No sólo presenta la dificultad inicial de retener miles de notas y complejas estructuras musicales, sino también la tarea igualmente ardua de recordarlas y ejecutarlas en situaciones interpretativas de mucha tensión. Casi siempre, dichas exigencias han hecho que los intérpretes acumulen horas de práctica meramente repetitiva, intentando desarrollar múltiples maneras de recordar la música para que su interpretación pueda continuar pase lo que pase [1]. Tales estrategias, sin embargo, pueden ser ineficaces y no garantizar una memoria perfecta. Como consecuencia, los músicos, profesores e investigadores han intentado encontrar la respuesta a dos preguntas: ¿por qué los intérpretes memorizan la música? y ¿cuál es la manera más eficiente y eficaz de hacerlo? Las respuestas a estas preguntas se han obtenido tradicionalmente de un extenso corpus de evidencias incoherentes y anecdóticas. Este capítulo abordará ambas preguntas desde la perspectiva ofrecida por estudios recientes que han examinado más sistemáticamente la memoria musical.

¿Por qué los músicos interpretan de memoria?

En 1828, Clara Schumann sentó un precedente para los intérpretes musicales al tocar en público sin partitura. Poco después, Franz Liszt, con su «predilección por el espectáculo, aprovechó la oportunidad para convertir este nuevo acontecimiento en un ritual emocionante» [2]. Una vez causó verdadero

furor lanzando no sólo sus guantes blancos a las primeras filas del público —un gesto por el que era conocido—, sino también su partitura. Semejantes efectos teatrales no eran bien recibidos por los críticos. De hecho, las interpretaciones de memoria fueron consideradas ostentosas y de mal gusto incluso hasta finales del siglo XIX. En su libro *With Your Own Two Hands,* Seymour Bernstein describe sucintamente cómo la percepción y aceptación de la interpretación memorizada han cambiado desde el siglo XIX:

> En 1861, sir Charles Hallé, el virtuoso británico, dio el primero de una serie de conciertos dedicados a todas las Sonatas de Beethoven. Tocó de memoria. Para el tercer concierto, se rindió ante los críticos londinenses y apareció en escena con las partituras. Sin embargo... siguió tocando de memoria. Aún muchos años después, en 1870, el dr. Hans von Bülow, cuyas proezas de memoria eran legendarias, se encontró con que los críticos londinenses se oponían tanto como entonces a las interpretaciones de memoria. En este caso, sin embargo, el *Daily Telegraph* censuró más al público que al mismo von Bülow: su memoria, y no su musicalidad, es la que parece haber causado la mayor impresión, reclamaron los críticos. No fue sino a finales del siglo XIX cuando tocar de memoria llegó a considerarse como una práctica seria y no mero sensacionalismo. Indudablemente, hoy en día es mucho más inusual que un solista toque con partitura que sin ella [3].

En efecto, tocar de memoria se ha convertido en una medida de la competencia profesional para solistas de todo tipo —pianistas, violinistas, cantantes y trompetistas por igual. Hacerlo, sin embargo, puede resultar arduo y provocar ansiedad. ¿Por qué entonces los intérpretes insisten en tocar de memoria? ¿Lo hacen sólo para impresionar y deslumbrar al público o existe una justificación musical más satisfactoria? Varios autores han apoyado la segunda razón. Edwin Hughes, por ejemplo, sugirió en 1951 que «tocar con un fajo de partituras» obstaculiza «la absoluta libertad de expresión y la relación psicológica más directa con el público» [4]. Muchos intérpretes han estado abiertamente de acuerdo con esta opinión, y han afirmado que tocar de memoria les permite crear y comunicar interpretaciones musicales nuevas y desechar la innecesaria muleta psicológica y musical de la página impresa. Sin embargo, no todos los intérpretes han tenido una opinión tan firme sobre la memorización; entre las excepciones notables se incluyen el famoso pianista francés Raoul Pugno, Béla Bartók y Dame Myra Hess, quienes tocaban en público con sus partituras.

Un estudio reciente ha investigado sistemáticamente el valor de la interpretación de memoria analizando cuatro preguntas:

(1) ¿Ofrece realmente la interpretación de memoria una «libertad de expresión absoluta»?

(2) ¿Proporcionan las interpretaciones memorizadas la «relación psicológica más directa con el público»?
(3) Si la interpretación de memoria ofrece una «libertad de expresión absoluta» y la «relación psicológica más directa con el público», ¿tienen más peso estas ventajas que las horas adicionales de práctica requeridas para lograr tales proezas?
(4) ¿Influye la formación musical en la habilidad para distinguir las interpretaciones memorizadas de las no memorizadas? [5]

Para responder a estas preguntas, se le pidió a un grupo de personas que viesen diversas interpretaciones grabadas en vídeo de una violonchelista tocando los Preludios de las Suites para Violonchelo núms. 1, 2 y 3 de Bach. Debían calificarlas según el conocimiento musical del intérprete, su capacidad comunicativa, su nivel técnico y la calidad general de la interpretación.

Las interpretaciones, sin embargo, eran de cinco tipos diferentes en cuanto a la memorización, la información visual recibida por las personas que vieron los vídeos y el tiempo dedicado a la preparación de las interpretaciones. Por otra parte, los espectadores fueron clasificados en músicos y no músicos con el fin de determinar si la formación musical influye en la calificación de las interpretaciones. Las características específicas de los cinco tipos de interpretaciones están detalladas en la Tabla 8.1, y la información visual que se le ofrecía al grupo de espectadores se muestra en la Figura 8.1.

Las calificaciones de las interpretaciones fueron examinadas y comparadas para investigar y obtener posibles respuestas a las cuatro preguntas expuestas anteriormente. ¿Ofrecen las interpretaciones memorizadas una «libertad de expresión absoluta»? Libertad, sí; absoluta, no. El estudio revela que los espectadores calificaron las interpretaciones memorizadas más favorablemente que las no memorizadas, independientemente de que un atril obstaculizara o no la imagen de la violonchelista.

Además, las personas con formación musical calificaron aún más favorablemente las interpretaciones memorizadas en cuanto a la capacidad comunicativa de la violonchelista, lo que indica que los músicos pueden estar mejor preparados para percibir los sutiles signos comunicativos que forman parte de las interpretaciones de memoria. Estas respuestas sugieren que, hasta cierto punto, los intérpretes pueden expresarse más libremente cuando tocan sin partitura. Sin embargo, para que esa libertad de expresión sea «absoluta», como propone Hughes, debería ser similarmente identificable por todos los oyentes, es decir, independiente de su formación musical.

¿Ofrecen las interpretaciones memorizadas la «relación psicológica más directa con el público»? Sí, especialmente para los integrantes del público con formación musical. Todos los espectadores calificaron más positivamente

TABLA 8.1 *Características de las interpretaciones, incluyendo una descripción de los cinco tipos de interpretación e indicaciones sobre la presencia o no de un atril y una partitura*

Tipo de interpretación	*Descripción*	*Atril*	*Partitura*
1	La violonchelista tocó los Preludios cuando se sintió capaz de ofrecer una interpretación pública satisfactoria. Para estas interpretaciones iniciales, se le pidió que no memorizara las piezas. La imagen de la violonchelista estaba parcialmente tapada por un atril (véase Figura 8.1a).	√	√
2	Los Preludios fueron filmados de nuevo cuando la intérprete podía tocarlos de memoria (aproximadamente un mes después de las interpretaciones del tipo 1). Aunque estaba vacío, el atril que seguía delante de la violonchelista daba la impresión de que ésta estaba leyendo una partitura (véase Figura 8.1a).	√	×
3	La interpretación del tipo 3 era la misma que la del tipo 2, excepto que se había retirado el atril (véase Figura 8.1b).	×	×
4	Se le pidió a la violonchelista que ensayara y tocara de nuevo los Preludios con las partituras. La imagen de la intérprete era similar a la de las interpretaciones de los tipos 1 y 2, ya que un atril la tapaba parcialmente (véase Figura 8.1a).	√	√
5	La interpretación del tipo 5 era igual que la del tipo 4, excepto que la cámara se colocó del lado derecho de la violonchelista, por lo que se excluye el atril de la imagen (véase Figura 8.1c).	×	√

las interpretaciones sin atril que aquellas en las que aparece el atril, independientemente de que fuesen memorizadas. Esta respuesta fue aún más categórica para los espectadores músicos, lo que sugiere que su formación musical les puede haber inculcado una inclinación a favor de las interpretaciones sin atril. Las investigaciones futuras podrían aclarar la naturaleza de esta predis-

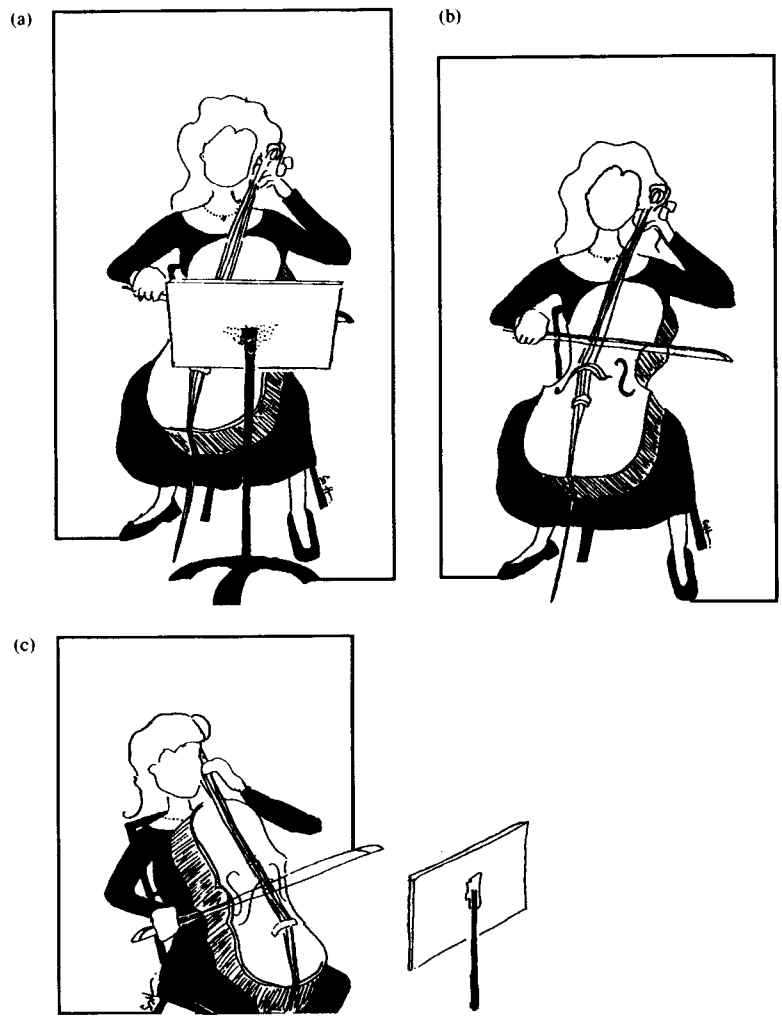

FIGURA 8.1 *La imagen de la violonchelista durante las interpretaciones de los tres Preludios de las Suites núms. 1, 2 y 3 de J. S. Bach. Los espectadores vieron las interpretaciones filmadas de cada Preludio. En algunas de ellas (las de los tipos 1, 2 y 4), la imagen de la violonchelista estaba parcialmente tapada por un atril (Figura 8.1a). En otras interpretaciones (las del tipo 3), la imagen de la violonchelista era como la de una interpretación memorizada, ya que no estaba obstaculizada por el atril (Figura 8.1b). Finalmente, en la interpretación del tipo 5, la intérprete fue filmada desde su lado derecho, excluyendo el atril de la imagen (Figura 8.1c).*

posición, por ejemplo, pidiéndole a un grupo de músicos que califiquen interpretaciones después de informarles correcta o incorrectamente de que dichas interpretaciones son memorizadas.

¿El tiempo de preparación adicional que requiere una interpretación de memoria vale la pena? Sí. Esta respuesta se obtuvo comparando las calificaciones de las interpretaciones no memorizadas anteriores al mes adicional de práctica (es decir, las interpretaciones del tipo 1) con las posteriores (tipos 4 y 5). Todos los espectadores —músicos y no músicos por igual— calificaron más favorablemente las interpretaciones posteriores a la práctica adicional, especialmente con respecto al conocimiento musical y la capacidad comunicativa. Es necesaria una investigación ulterior para saber si esta respuesta se aplica igualmente a otros intérpretes. La intérprete que participó en este estudio consideró que su capacidad técnica había sido una gran ventaja en su ejecución, y no es de extrañar que interpretara las piezas en cuanto satisfizo los requerimientos técnicos. Sin embargo, los intérpretes que no poseen el mismo nivel de competencia técnica pueden mejorar todos los aspectos interpretativos durante un mes adicional de práctica. A la inversa, los que poseen mayores habilidades musicales o comunicativas pueden no mostrar ningún progreso. Para identificar estas diferencias individuales se deberá investigar y comparar sistemáticamente la práctica que conduce a las interpretaciones tanto memorizadas como no memorizadas en estudios futuros.

Este estudio proporciona un examen inicial y empírico de la opinión de que las interpretaciones memorizadas son más expresivas y comunicativas que las no memorizadas. Sus resultados pueden aplicarse, aunque con discreción, tanto a la interpretación como a la pedagogía musical. Por ejemplo, se puede asegurar a los intérpretes que las interpretaciones de memoria ofrecen experiencias más intensas al público, bien sea mediante medios auditivos o visuales. Por consiguiente, los profesores deben preparar a sus alumnos para la exigente expectación del público —especialmente el que está formado por músicos— ofreciéndoles más oportunidades de prepararse para las interpretaciones de memoria. Además, una vez que las investigaciones ulteriores hayan identificado el papel específico que desempeña la información visual en la valoración por parte del público de las interpretaciones memorizadas, los intérpretes y profesores podrán obtener suficiente información para decidir si los atriles deberían excluirse completamente del escenario o si con unos atriles más pequeños y menos imponentes se puede ofrecer una experiencia igualmente satisfactoria para el público.

A pesar de las deducciones anteriores, este estudio presenta varias limitaciones que hay que destacar. En primer lugar, el intérprete, a pesar de su elevado nivel interpretativo, no era una solista eminente. Las ventajas de interpretar de memoria pueden ser aún mayores para los expertos. En segundo

lugar, la interpretación de memoria puede resultar más ventajosa en ciertas piezas musicales. Las obras elegidas para este estudio fueron seleccionadas por la coherencia en cuanto a compositor, estilo, dificultad y longitud. Examinar piezas que difieren en estos aspectos permitirá demostrar con mayor precisión el valor de la interpretación de memoria. Memorizar una composición atonal, por ejemplo, puede ser una tarea pesada y abrumadora si el intérprete se ve obligado a hacerlo nota por nota. Semejante procedimiento aumentaría inevitablemente las exigencia de los procesos mentales durante la interpretación y por lo tanto reduciría —o eliminaría del todo— las ventajas de interpretar de memoria. En tercer lugar, las interpretaciones grabadas en vídeo no ofrecen las condiciones óptimas de visualización a los espectadores. Algunos aspectos comunicativos (por ejemplo, los movimientos sutiles de los ojos, las expresiones faciales y la intensidad de la respiración) pueden disminuir o ser eliminados en el proceso de la filmación. Abordando las limitaciones mencionadas, las investigaciones futuras podrán revelar con precisión cómo el público evalúa y valora la interpretación, proporcionando información que ayude a los intérpretes a elegir o no la memorización.

¿Cómo interpretan de memoria?

Métodos de memorización musical

Edwin Hughes y Tobias Matthay fueron dos de los primeros músicos y pedagogos que escribieron ampliamente sobre cómo los músicos memorizan las composiciones [6]. Hughes, por ejemplo, destacó tres formas principales de memorización musical: auditiva, visual y cinestésica. La *memoria auditiva* permite escuchar composiciones en el «oído interior», anticipar eventos que se aproximan en la partitura y realizar evaluaciones simultáneas del progreso de una interpretación. La *memoria visual* consiste en imágenes del papel escrito y otras características de la interpretación que se retienen en la mente. Los pianistas y otros teclistas, por ejemplo, pueden recordar posiciones «de la mano y los dedos, el aspecto de los acordes sobre el teclado y el patrón que forman las diversas figuras cuando se tocan» [7]. La *memoria cinestésica* (es decir, la memoria muscular o táctil) permite a los intérpretes tocar notas automáticamente. En el caso de los pianistas, se adquiere con un intenso entrenamiento de los dedos, las muñecas y los brazos, y puede existir en dos formas: (1) posición y movimiento de nota a nota y (2) sentido de la resistencia de la tecla. Por otra parte, Hughes y Matthay insisten en que «no es posible una memorización realmente inteligente sin un conocimiento de la armonía y la forma musical, y, para las formas de composición más estrictamente polifó-

nicas, también del contrapunto y la fuga» [8]. Ni Hughes ni Matthay clasificaron este conocimiento como un método independiente para memorizar música. Más bien, simplemente insistieron en que las memorias auditiva, visual y cinestésica no pueden funcionar correctamente sin esos conocimientos. Sin embargo, otros intérpretes y pedagogos posteriores lo han referido explícitamente como *memoria conceptual* para destacar su importancia en el proceso de hacer que la «seguridad sea más segura» [9].

Indudablemente, las interpretaciones de memoria sólo pueden resultar de las complejas interacciones entre todos los métodos de memorización descritos anteriormente. Casi ningún músico puede ejecutar una composición nota por nota sin antes —consciente o inconscientemente— escuchar la música, observar las notas en la página impresa, ver y sentir los movimientos musculares que se producen al tocar y estudiar la partitura hasta cierto punto. Por lo tanto, Hughes y Matthay recomendaron que cada músico se centrase en el método o la combinación de métodos que le resultase más fácil y seguro.

Entrevistas con músicos

Dos investigaciones recientes explican cómo los músicos utilizan estos métodos cuando interpretan. Susan Hallam entrevistó a veintidós músicos profesionales y cincuenta y cinco novatos [10]. Las entrevistas revelaron una diversidad individual considerable en el uso de las memorias auditiva, visual y cinestésica. Un músico, por ejemplo, declaró que «a veces me resulta muy útil la memoria visual, el aspecto de la página [...] Mi memoria visual no es nada buena, excepto para la música». Otro afirmó que «una vez que te encuentras ejecutando un pasaje rápido, o uno en el que la música fluye continuamente, el oído tiende a asumir el control» [11].

Hallam descubrió que todos los músicos profesionales adoptaban una especie de estrategia «analítica» consciente que implicaba desarrollar un conocimiento de la estructura de la música. Un director señaló: «no creo que el método que yo utilizo para aprenderme las partituras [...] sea de ninguna utilidad para un instrumentista, ya que lo hago enteramente por análisis, que para mí resulta infalible» [12]. También afirmaron emplear una codificación múltiple de la información (es decir, una combinación de memoria auditiva, visual y cinestésica con estrategias analíticas) para proporcionar una mayor seguridad durante la interpretación. Por ejemplo, uno de los músicos profesionales comentó:

> Necesito comprender lo que ocurre armónicamente, o si es una melodía con una secuencia definida. No tocaría simplemente con la esperanza de recordar la músi-

> ca [...] Hay piezas que he tocado tantas veces a lo largo de los años que simplemente sé cómo van y puedo tocarlas. Eso no es analítico, pero no me gustaría en absoluto salir a escena y tocarlas porque creo que es posible que la memoria automática me falle [13].

Independientemente de que los músicos fuesen profesionales o novatos, Hallam encontró que sus estrategias dependían frecuentemente de la naturaleza de la obra que iban a interpretar. Informó que algunos músicos se sentían seguros confiando en procesos automáticos para memorizar piezas breves, pero para las obras más largas y complejas, como un concierto, muchos adoptaban un enfoque más analítico. Un músico señaló que

> depende de lo que se trate. Si tiene melodías «fijas», puedo aprenderla en un día. Pero si la música es moderna, comienzo por el principio, la trabajo, y entonces es cuando interviene la práctica, porque me aseguro de que realmente la puedo tocar. Entonces la estudio una y otra vez [...] Y después creo una imagen mental [14].

En un estudio similar, Rita Aiello también examinó los métodos utilizados por músicos profesionales para memorizar música [15]. Entrevistó a siete pianistas concertistas para investigar cómo utilizan la memoria auditiva, visual y cinestésica y cómo enfocan la memorización de diversos tipos de música (por ejemplo, composiciones polifónicas y atonales). Además, examinó el papel que desempeñan la digitación, los recursos mnemotécnicos, la improvisación y el conocimiento de la estructura musical en la memorización. Descubrió varios temas en las respuestas de los participantes. En primer lugar, los músicos afirmaron que confiaban mucho más en la memoria auditiva que en la cinestésica, aunque todos coincidieron en que es importante conocer los componentes cinestésicos de una pieza (por ejemplo, la digitación). En segundo lugar, todos los pianistas destacaron que tener una idea clara de la estructura musical y analizar la partitura eran los métodos de memorización más importantes y seguros. En tercer lugar, cinco de los siete pianistas comentaron que memorizaban de una manera «holística» dividiendo la pieza en secciones breves para obtener una «recuerdo más sólido de toda la obra» [16]. En cuarto lugar, la capacidad de improvisar fue considerada una ventaja importante para memorizar música; incluso un pianista que no sabía improvisar la consideró como una herramienta valiosa. Basándose en los resultados de su investigación, Aiello concluyó que, en general, los maestros deberían ayudar a sus alumnos a memorizar música, fomentando en ellos el conocimiento detallado de la estructura musical y ayudándoles a analizar la partitura.

Las investigaciones de Hallam y Aiello, junto con las obras de Hughes y Matthay, aportan un conocimiento profundo sobre cómo los músicos inter-

pretan de memoria. En suma, estas investigaciones revelan que los músicos tienden a utilizar una gran variedad de métodos para memorizar música. Desafortunadamente, no existe ninguna prueba de que la memoria auditiva, visual o cinestésica, o una combinación de ellas, sea la más eficiente o proporcione la mayor seguridad en las interpretaciones memorizadas. La diversidad de opiniones en torno a la importancia de estos métodos —incluso entre los solistas— es muy sorprendente. Algunos músicos afirman que su manera de memorizar música es superior a otras. Indudablemente, cada método propio será uno de los mejores para esa persona, sencillamente porque lo ha elegido y desarrollado durante años de práctica.

Sin embargo, las obras de Hallam y Aiello —apoyadas por las afirmaciones anecdóticas de Hughes y Matthay— sugieren que los músicos más experimentados de sus investigaciones confiaban ampliamente en las estrategias analíticas a la hora de memorizar. Los profesores y analistas musicales han destacado desde hace tiempo la importancia de estudiar la estructura de las composiciones musicales. Nicholas Cook, por ejemplo, ha sostenido que

> la capacidad de dejar a un lado los detalles y observar las relaciones a gran escala pertinentes al contexto musical particular, que es lo que fomenta el análisis, forma parte esencial de la manera en que el músico percibe el sonido musical. Para el intérprete, es obvio que el análisis desempeña un papel en la memorización de partituras extensas, y, hasta cierto punto, en el discernimiento de las relaciones dinámicas y rítmicas a gran escala (aunque algunas de las afirmaciones de que el análisis schenkeriano, en particular, es indispensable para intérpretes y directores han sido indudablemente exageradas) [17].

Sin embargo, es necesaria una investigación ulterior para determinar si el estudio de la estructura de la música proporciona el medio más seguro para la memorización y si ha de ser la base para aprender las obras auditiva, visual y cinestésicamente. Las investigaciones sobre las habilidades excepcionales de memorización en otros tipos de actividades pueden aportar conocimientos valiosos sobre este asunto.

Los principios de la memoria experta

Los investigadores han estudiado la memoria excepcional en diversos tipos de actividades, incluyendo el ajedrez, la física, la medicina, la escritura y el atletismo. A partir de sus trabajos, se han propuesto varias teorías para explicar cómo las personas son capaces de desarrollar y mantener las extraordinarias habilidades que demuestran con frecuencia los profesionales eminentes y

expertos en esos campos [18]. Antes de aplicar a la música cualquier teoría sobre la memoria experta, debemos determinar si la memoria musical es comparable a otros tipos de memoria experta. Aunque la naturaleza de la interpretación musical difiere fundamentalmente de la de otras actividades como el ajedrez o el atletismo, los músicos expertos comparten algunas de las mismas exigencias de memoria con otros especialistas. Por ejemplo, la memoria desempeña un papel importante en deportes como la gimnasia y el patinaje artístico, ya que los deportistas han de memorizar las secuencias de los movimientos que constituyen una actuación determinada y ejecutar dichos movimientos con referencia a unos modelos técnicos definidos. Debido a que las habilidades técnicas son valoradas de acuerdo con unas formas ideales, los ejecutantes deben hacer comparaciones entre las técnicas «reales» e «ideales» durante la ejecución. Las bases para estas comparaciones se obtienen de la memoria a largo plazo, adquirida a lo largo de muchos años de entrenamiento [19]. Los solistas, al igual que los expertos en los deportes mencionados, practican minuciosamente para poder recordar las series de acciones que constituyen una interpretación; se refieren a los modelos técnicos definidos que esperan el público y el jurado; y supervisan su ejecución a medida que transcurre para evaluar su calidad.

Habiendo introducido el tema de las comparaciones, podemos comenzar a aplicar ciertos aspectos de las teorías existentes a la memoria musical. En general, las investigaciones han revelado que las habilidades de memoria sobresalientes están apoyadas en una amplia base de conocimientos específicos de la actividad. En esa base de conocimientos, se recopila información continuamente y se almacena en grupos significativos (o «bloques»), que se asocian frecuentemente con órdenes o actos físicos específicos [20]. Entre los ejemplos básicos de esos bloques en la música se incluyen las escalas y los arpegios. Los músicos practican escalas y arpegios durante horas para poder reconocerlos y ejecutarlos con facilidad cuando leen a primera vista o memorizan una pieza.

Una vez que ha adquirido una extensa base de datos significativos, el individuo puede utilizarla para crear una representación mental de cualquier información compleja que ha de ser memorizada [21]. En términos sencillos, una representación mental es una especie de mapa interno que se puede utilizar con confianza para recordar un material específico. Como en cualquier mapa, se deben identificar en la práctica los hitos (o señales) importantes dentro de la información y después usarlos para guiar la recuperación, de modo que la interpretación resultante pueda seguir su curso [22].

En términos musicales, una composición puede representarse en una jerarquía que abarca desde el nivel más alto de comprensión global (la pieza en su conjunto) hasta el nivel inferior (la pieza como notas separadas). Además,

la representación puede estar basada en la memoria auditiva, visual o cinestésica, o bien en diversas estrategias analíticas, dependiendo de las preferencias del intérprete y de la pieza en cuestión. Sin embargo, los límites humanos en cuanto al procesamiento de información y la atención hacen que sea poco probable que se active una representación completa durante la interpretación, incluso cuando se trata de una pieza de longitud moderada. En cambio, sólo una parte de la representación se activa en un momento dado, y esa región activa se desplaza a medida que avanza la interpretación de la música [23]. Por ejemplo, en medio de una frase musical profundamente grabada en la memoria, el músico puede estar fundamentalmente centrado en las relaciones que existen dentro de la frase misma. En ese caso, sólo estarán activas las señales auditivas, visuales y cinestésicas del nivel inferior. A la inversa, cuando se encuentra en los límites de una frase, es posible que el intérprete necesite saber cómo las frases previa y subsiguiente están relacionadas entre sí y con la estructura general de la pieza. En un momento así, se activarían las señales del nivel superior que especifican las relaciones a gran escala —aunque pueden ser necesarias ciertas señales del nivel inferior para ejecutar la sucesión inmediata de eventos [24].

Obviamente, existe una enorme posibilidad de que surjan diferencias individuales en el contenido específico de las representaciones mentales de los músicos. Tales diferencias se muestran claramente en las entrevistas de Hallam y Aiello. Sin embargo, las investigaciones han revelado que una representación puede ser potencialmente segura y perdurable siempre y cuando se haya organizado y ensayado minuciosamente [25]. Uno de los métodos más eficaces de organizar la música memorizada —tal y como indican los músicos profesionales en los estudios de Hallam y Aiello— es incorporar estrategias analíticas a la práctica. De esta manera, los intérpretes pueden establecer una base sólida sobre la cual se aprenden auditiva, visual y cinestésicamente las composiciones.

Roger Chaffin y Gabriela Imreh han explicado más detalladamente la importancia de las estrategias analíticas en la práctica organizativa y la recuperación [26]. Observaron sistemáticamente la práctica de una pianista concertista —Imreh misma— para determinar cómo formaba una representación mental del tercer movimiento del *Concierto italiano* de Bach. Descubrieron que la estructura formal de la composición sirvió de herramienta para organizar la representación. De hecho, la pianista integró su conocimiento de la estructura formal en las primeras fases de práctica y después confió ampliamente en dicho conocimiento para recordar la música durante la interpretación. Además, afirmó que sus señales eran de tres tipos —«básicas», «interpretativas» y «expresivas»— y que las había asociado con la música nota por nota mediante una combinación de las memorias auditiva, visual y cinestésica. Las señales

«básicas» incluían digitaciones, dificultades técnicas y grupos de notas que formaban unidades de información identificables. Las señales «interpretativas» incluían fraseo, dinámica, tempo y pedales. Las «expresivas» eran partes de la partitura en las que la pianista intentaba producir cambios en la expresión o el carácter de la música.

No todos los intérpretes estarán tan familiarizados con la estructura formal de una composición como Imreh; tampoco clasificarán los componentes más memorables e importantes de una composición mediante señales básicas, interpretativas y expresivas. Sin embargo, este estudio confirma la importancia de las estrategias analíticas a la hora de establecer una representación mental segura de una composición, ya que proporcionan señales de observación para ser usadas a lo largo del proceso de memorización. Otros músicos pueden emplear las estrategias analíticas particulares que conocen y prefieren, aprendiendo y almacenando correspondientemente señales importantes. Cualesquiera que sean esas preferencias, las investigaciones realizadas sugieren que, para que las señales sean seguras y estables durante la interpretación, deben estar organizadas de manera significativa y ser utilizadas para guiar la práctica [27].

Conclusiones

Las investigaciones recientes han arrojado luz sobre las maneras en que los músicos memorizan música. Los músicos deberían ser conscientes de que una característica sobresaliente del proceso de memorización es la creación y empleo de representaciones internas para recuperar información específica, y que se ha demostrado claramente que los profesionales utilizan para ello estrategias analíticas. Aunque sería inverosímil recomendarles a todos los músicos que realicen un análisis formal minucioso de cada composición que ejecuten, se les debería animar a que desarrollen sus propias estrategias analíticas y las incorporen en las primeras fases del aprendizaje. Ello les permitirá reconocer señales importantes dentro de una pieza en las que podrán confiar con seguridad, a las que podrán referirse a medida que progresa la interpretación o que les ayudarán a reanudar una interpretación que se ha interrumpido inesperadamente.

Uno de los temas que deberían abordar las investigaciones venideras es la medida en que ciertas estrategias analíticas son las más efectivas y eficaces. Podemos sugerir naturalmente que a mayor diversidad de codificaciones de la música, mayor será la cantidad de asociaciones y conexiones que se formen con esa información y, por lo tanto, el ejecutante tendrá más posibilidades de recordarla. En este sentido, aquellos intérpretes que se esfuerzan por apren-

derse las composiciones auditiva, visual y cinestésicamente y que practican utilizando estrategias analíticas o de otro tipo (por ejemplo, improvisación y recursos mnemotécnicos) deberían tener la memoria más segura y eficaz para la interpretación. Sin embargo, tales excesos de codificación y práctica pueden no ser la manera más eficaz de abordar la memorización. Idealmente, los intérpretes deberán procurar un equilibrio entre la eficacia y eficiencia si quieren responder satisfactoriamente a las elevadas y variadas exigencias de una carrera musical. Es posible que las investigaciones futuras revelen dónde se encuentra ese equilibrio.

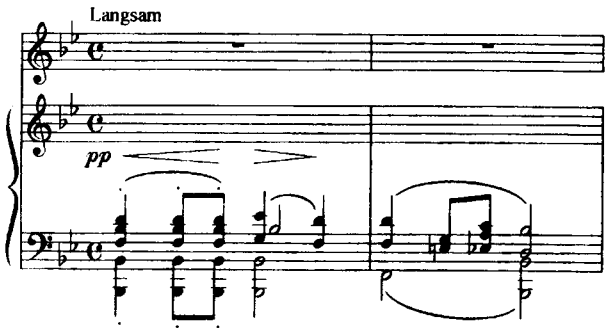
TERCERA PARTE
Hacer música

9 *De la partitura al sonido*



PETER HILL

Muchos intérpretes se refieren a las partituras con el término «la música». Eso no es correcto, por supuesto. Las partituras contienen información musical, en parte exacta y en parte aproximada, junto con indicaciones sobre cómo puede interpretarse esa información. Pero la *música* misma es algo imaginado, en primer lugar por el compositor, después en asociación con el intérprete, y finalmente transmitido en sonido.

El momento en que la música nace como sonido, junto con los correspondientes placeres y frustraciones, ha sido hermosamente descrito por el gran acompañante Gerald Moore. En el siguiente fragmento, Moore analiza microscópicamente los compases iniciales, o *Vorspiel,* del «Wandrers Nachtlied» de Schubert (véase el Ejemplo 9.1). La elección de una canción tan «fácil» es reveladora, porque destaca que la técnica no es simplemente una cuestión de reproducir la partitura con exactitud —en este caso las notas son suficientemente sencillas para ser leídas a primera vista— sino de dar vida a la partitura en sonido. Moore se deleita demostrando lo escurridizo que eso puede ser:

> Dinámicamente, este pequeño *Vorspiel* es todo *pianissimo,* pero dentro de los límites de ese *pianissimo* debe haber un ligero aumento y una subsiguiente reducción de intensidad. Es una curva que asciende y luego desciende; la más suave de las curvas, en la que cada acorde se enlaza con el siguiente. Tan restringida es su gama, tan estrecho el margen entre tu acorde más suave y tu acorde menos suave, que si sobrepasas en una fracción el límite superior de la curva, todo se vendrá abajo. Cada acorde, aunque esté relacionado y enlazado con su vecino, tiene un peso diferente, y la diferencia no es mayor que el peso de una pluma. Escuchas con autocrítica

EJEMPLO 9.1 *Schubert, «Wandrers Nachtlied» D. 768, compases 1-2.*

> mientras la practicas. Experimentas. Tocas cada acorde con una presión uniforme y ligera de modo que no haya aumento ni disminución de intensidad —todo *pianissimo.* Después intentas darle ese *crescendo* y *diminuendo* infinitesimales que se desean realmente para darle forma y sentido a la frase: pero está desproporcionado —te has sobrepasado—, así que empiezas de nuevo. Ahora encuentras que tus acordes suenan turbios, tu pedal es incorrecto, un acorde invade el terreno de otro en lugar de fundirse suavemente con él sin empañarlo todo. Intentas solucionarlo. Pero, a pesar del *pianissimo* que estás logrando, comienzas a darte cuenta de que tus acordes no tienen carácter —son pesados, y a toda la frase le falta vida. Entonces, muy delicadamente, pruebas dándole una fracción más de peso al dedo superior de tu mano derecha [...] Todo ello es la búsqueda más fascinante que se pueda imaginar. En tu búsqueda de luz y sombra te sientes tan feliz y abstraído como un pintor mezclando los colores en su paleta, y la satisfacción del intérprete cuando ha logrado producir esa ondulación perfecta, esa línea clara, cuando siente que por fin todo el diseño es proporcionado y hermoso, es inmensa. Pero esa satisfacción o autosatisfacción se experimenta muy pocas veces. Con la misma seguridad con la que te das cuenta de que *lo has logrado,* tu aguzada sensibilidad te recuerda lo escurridiza que es la recompensa y cuántas veces te has quedado sin ella [1].

Esta clase magistral de Moore es sumamente instructiva. Ya hemos visto cómo invierte con elegancia la visión normal de lo que hace que la música sea difícil. Moore argumenta que, precisamente porque hay tan pocas notas, cada una requiere un arte y un control muy refinados. Una nota inexacta en el finale de una sonata de Beethoven afectará poco o nada al resultado musical; pero en el «Wandrers Nachtlied» hasta el menor error de cálculo significa un desastre. Después expone la secuencia de procedimientos: la concepción —la imagen inicial de cómo debe sonar la frase— conduce a la experimentación en el piano, después la reflexión y la autocrítica, seguidas de más experi-

mentos. Un punto clave es que el trabajo progresa en un estado de serenidad: la búsqueda del ideal es su propia recompensa, por más escasas que sean las ocasiones en las que realmente se logra ese ideal. El equilibrio entre el extremado cuidado y la paciencia, por un lado, y el profundo deseo de hacer música es uno de los equilibrios más difíciles que ha de conseguir el intérprete. En un sentido debemos ser impacientes; pero si la impaciencia se derrama sobre la obra misma, las consecuencias son negativas, ya que tomaremos atajos y bajaremos el listón. Además es probable que incorporemos dudas y tensiones que reaparecerán perjudicialmente en la interpretación y que a largo plazo pueden ser difíciles o imposibles de erradicar.

Moore finaliza su descripción citando la desventaja de su método: «Se puede argumentar que trabajando y experimentando de manera repetitiva, como yo recomiendo, se puede perder el espíritu, la inspiración y la frescura de la música. En efecto, ése es el mayor peligro» [2]. Este problema fundamental, que Moore deja sin resolver, ocurre porque la perfección que él busca se construye mediante capas y capas de hábitos arraigados. Surge entonces la pregunta de cómo podemos aglutinar esos hábitos sin aglutinar al mismo tiempo nuestra concepción musical. Ejercitar repetidamente la interpretación, como reconoce Moore, embota la creatividad del intérprete. Además, debilita o elimina nuestra capacidad de adaptarnos tanto a las vicisitudes que forman parte esencial de una interpretación en vivo como a las ideas diferentes de los demás. Moore debe de haber sufrido tanto como cualquiera al trabajar con músicos encerrados en su propia interpretación, indiferentes o incapaces de responder al punto de vista del pianista.

Éste es, pues, el dilema central del músico ejecutante. ¿Cómo podemos practicar y practicar sin perder el entusiasmo o la receptividad que nos permite desarrollar nuestras ideas? ¿Cómo, de hecho, podemos *interpretar,* en el sentido de crear un acontecimiento único, con la agudeza que surge de la inspiración del momento? Evidentemente, si la repetición es el núcleo del problema, debemos encontrar una manera de practicar que reduzca su papel al mínimo, o al menos incorporar a nuestro método una manera de mitigar sus desventajas.

El primer paso es analizar la manera en que comenzamos el aprendizaje de una obra. La primera fase es la más importante: no sólo establecemos las pautas para el trabajo subsiguiente, sino que nuestras decisiones —tomadas rápida y quizá irreflexivamente— pueden llegar a dominar la manera en que tocamos la pieza durante el resto de nuestra vida. ¿Cuáles son las suposiciones que hacemos sobre el estilo de la pieza? ¿Cuál es el significado de la notación del compositor? ¿Cuál es nuestro papel como intérpretes en relación al compositor? Esta última pregunta es tan fundamental que requiere una digresión. En el ejemplo que hemos comentado —Moore y Schubert— la acti-

tud es típica del intérprete de mediados del siglo XX: respeta el texto y las intenciones del compositor, y ve la interpretación como el arte de leer entre líneas. Sin embargo, si nos trasladamos a la música escrita un siglo después de Schubert, nos encontramos con que el espacio «entre las líneas», por lo visto, ya está lleno de indicaciones, como en las obras de la Segunda Escuela Vienesa, que parecen especificar todos los matices. El aumento general de la información especificada por los compositores durante los últimos dos siglos sugiere que no confían en la capacidad de comprensión del intérprete o tienen un afán de controlar todo, posturas de las que Stravinsky fue portavoz en sus diatribas contra la «interpretación». En estas circunstancias, no es de extrañar que los intérpretes se hayan inclinado por la interpretación textual. Esto es especialmente cierto en cuanto a la música más reciente. En los ensayos, incluso de grupos de especialistas selectos, uno tiene la impresión de que la partitura *es* la música: se le da prioridad absoluta a ejecutar correctamente todas las indicaciones de la partitura, mientras que lo que la partitura pueda *expresar* se da automáticamente.

El problema de la interpretación literal es que puede ser completamente errónea. Un ejemplo clásico y bien documentado es el caso de las Variaciones para piano op. 27 de Webern. El estudio de la historia de la interpretación de esta obra revela que durante años los pianistas tomaron el aspecto austero de la partitura al pie de la letra: las interpretaciones eran rigurosamente impersonales, sin añadir nada a las escasas indicaciones expresivas. Con el tiempo, y gracias a los esfuerzos de los alumnos de Webern [3], se supo que aquello era lo opuesto a sus intenciones, y que lo que realmente tenía en mente era una constante interacción de *rubato* y luces y sombras. ¿Por qué, entonces, Webern no anotó esos matices? Quizá eran demasiado sutiles para poder especificarlos, o quizá dependían demasiado del instinto del pianista (incluyendo al mismo Webern) como para imponerlos. Cualquiera que fuese la razón, el error que cometieron los pianistas fue pasar por alto la diferencia del enfoque de la notación entre las obras tempranas y tardías de Webern.

Otro ejemplo es uno que proviene de mi experiencia personal. Cuando comencé a estudiar la música de Messiaen, las diferencias frecuentemente mínimas de sus ritmos hicieron que me esmerara por lograr una precisión extrema; pero cuando finalmente tuve la oportunidad de estudiar con él, ese aspecto de mi ejecución le pareció mecánico. Messiaen opinaba que el ritmo y el fraseo deben ser flexibles, y por más compleja que sea la notación, la música nunca ha de sonar «como un estudio». Para Messiaen, la labor del intérprete es inferir el significado y el «carácter» de lo que está escrito en la partitura —como en el «Nachtlied» de Schubert [4].

Suponiendo que se han considerado los asuntos más generales —el estilo, la notación y el papel del intérprete—, ¿cómo comenzamos con la partitura

en sí? Cuando les planteo esta pregunta a mis alumnos, recibo una variedad de respuestas. Una de las sugerencias es comenzar organizando la técnica: digitación, articulación, etc. El problema de ese enfoque es que trata a la partitura «como un estudio» y no como una pieza musical. Como la digitación y la articulación pueden cambiar, incluso radicalmente, la manera en que suena la música, no podemos establecerlas con antelación, sin conocer el objetivo al que habrán de servir. Otra escuela de pensamiento prefiere establecer un primer contacto con la partitura leyéndola a primera vista de principio a fin. Esto también tiene sus desventajas. Las correcciones, modificaciones y mejoras se realizarán por fragmentos, y, si no se tiene una visión fundamental del funcionamiento de la obra, el resultado será arbitrario. Los intérpretes adquieren hábitos con una facilidad asombrosa. Y por lo general esa facilidad se emplea mal, en lugar de aprovecharla. Si no tenemos una visión de cómo debe sonar la música, seremos propensos a acostumbrarnos inconscientemente a los defectos de nuestra ejecución —defectos que son inevitables en esta primera fase— y a formar malos hábitos que, como todos sabemos, son fáciles de adquirir pero muy difíciles de corregir.

Otra objeción que puede hacerse a ambos enfoques es que son retornos a la infancia: el alumno obediente que primero se aprende las notas y al que después, como recompensa, se le permite «ponerles la música». Por importantes que sean, si «las notas» van primero, el peligro es que «la música» seguirá a nuestra técnica, en lugar de guiarla, condicionada por nuestro nivel de habilidad y también, hay que decirlo, por nuestros defectos.

En respuesta a estas objeciones, mis alumnos frecuentemente sugieren escuchar una grabación, como un modelo de interpretación. Sin embargo, aunque es un paso en la dirección correcta —ya que da prioridad a la música—, es un atajo de perezosos, el equivalente musical a buscar la respuesta al final del libro. Si nos limitamos a copiar la manera en que otros tocan, estamos admitiendo que lo que nosotros podemos ofrecer es de segunda categoría. De nuevo, es un mal empleo de la primera fase: si no tenemos nuestras propias ideas, no podemos evitar que otros nos influyan excesivamente[5].

Entonces, ¿qué podemos hacer? Descartando las posibilidades mencionadas, la conclusión inevitable es que el primer paso es desarrollar nuestra propia visión de la obra: el ideal es aprovechar el precioso momento en el que la pieza nos es desconocida, cuando tenemos la mayor capacidad de aplicar una percepción fresca. Sin embargo, debemos hacerlo sin que nos influyan inconscientemente las inevitables limitaciones de nuestras habilidades. La solución es trabajar intensamente con la partitura, pero escuchándola en nuestra mente, *alejados del instrumento.* El beneficio musical es que podemos desarrollar nuestra comprensión de la obra sin estar limitados por las consideraciones técnicas, centrándonos completamente en los aspectos musicales que

se deben decidir antes de practicar en el instrumento. Aunque pueda ser obvio, debemos saber, al menos en el aspecto general, lo que estamos intentando hacer antes de buscar la manera de lograrlo.

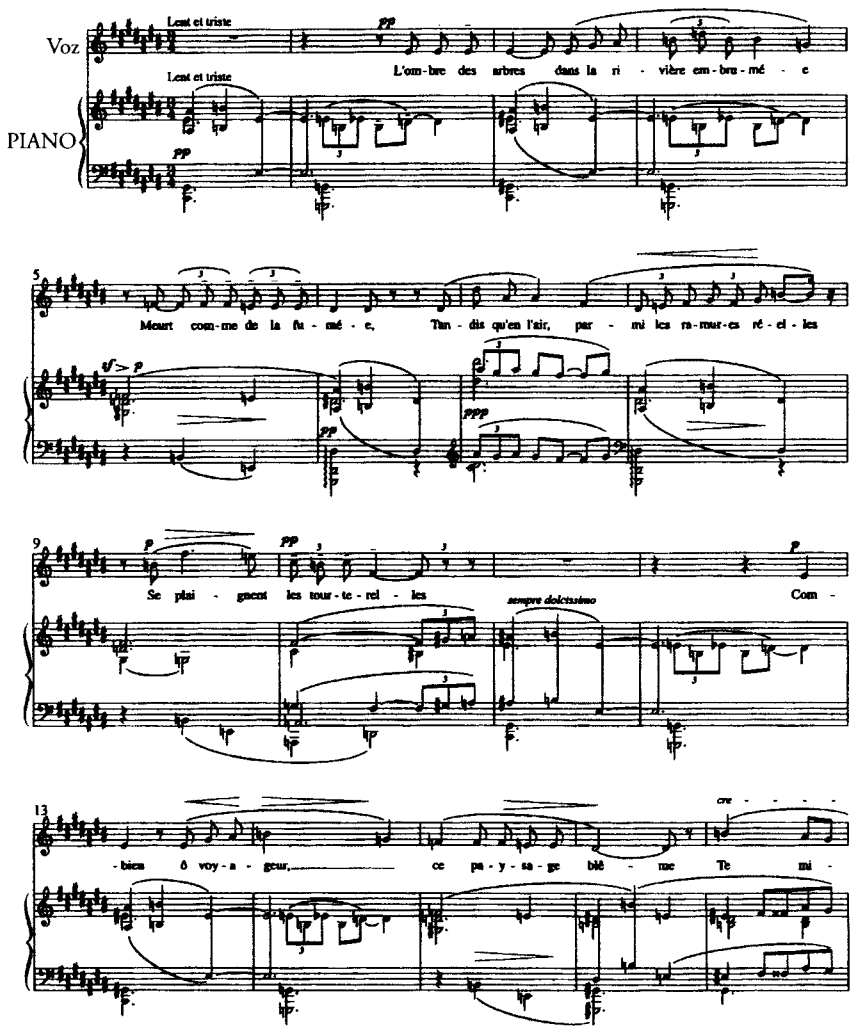
A continuación hay dos ejemplos de cómo uno podría comenzar a pensar sobre una partitura. La canción «L'ombre des arbres» de Debussy pone música al poema de Verlaine en dos estrofas de cuatro versos. La música evoca el río brumoso, cuya superficie actúa como un espejo que separa la realidad de la ilusión, los objetos reales de sus reflejos:

> La sombra de los árboles en el río brumoso
> se muere como el humo,
> mientras que en el aire, entre las ramas reales
> las tórtolas se quejan.
>
> ¡Cuánto, oh viajero, este paisaje lívido
> reflejó tu propia palidez
> y qué tristes lloraban en los altos ramajes
> tus esperanzas ahogadas!

El motivo principal está formado por las dos armonías iniciales, que se mecen entre acordes de séptima separados por un tritono, sobre Do♯ y Sol♮ (véase el Ejemplo 9.2). Es quizá un equivalente musical de la imagen de Verlaine, en el cual el Mi♯ (común a ambos acordes) actúa como una especie de «horizonte», análogo a la superficie del agua, que más adelante se recalca (como Fa♮) en el compás 5 cuando la armonía cambia a una novena menor sobre Mi, dándole un giro amargo a «Meurt comme de la fumée». Hasta aquí la relación entre el poema y la música es clara. Pero en la segunda mitad, misteriosamente, cada cual toma su camino. Verlaine utiliza su imagen de la naturaleza como metáfora de la condición humana, en el «viajante» cuya palidez se asemeja a la del paisaje y cuyas mayores aspiraciones —como las ramas más altas— se pierden en las profundidades del agua.

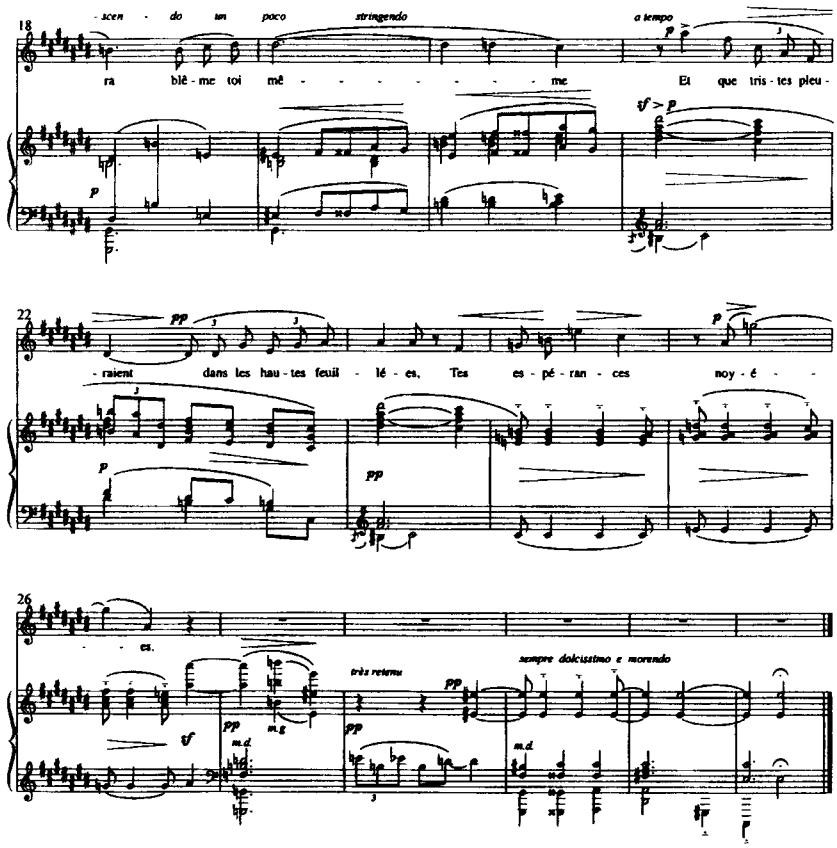
Esta resignación no es apoyada por la parte de piano, que avanza vertiginosamente con elocuentes secuencias cromáticas y, mientras la voz se apaga («Tes espérances noyées»), prorrumpe en una versión enormemente magnificada de la armonía de Sol^7. Finalmente, y más misteriosamente aún, este atolladero armónico se resuelve tranquilamente (en una armonía de Do♯ mayor), mientras el «horizonte» (Mi♯) late con calma en la voz superior. De este modo, la desesperanza del poema es aparentemente contradicha por la serenidad y la aceptación del postludio.

Naturalmente, lo anterior es tan sólo un esbozo de cómo podemos comenzar a desarrollar nuestros pensamientos cuando se trata de comprender el poema, la música y la relación que existe entre ambos. La cuestión es que evidentemente la cantante y el pianista tienen mucho material que analizar —especialmente la paradoja de la segunda estrofa— antes de poder tomar las decisiones musicales específicas.



Pasar de la destilada concentración de Debussy y Verlaine a un gran movimiento de una de las últimas sonatas de Beethoven —el primer movimiento de la Sonata en Lab mayor op. 110— es adentrarse en otro mundo. Sin embargo, el proceso de pensar sobre la música comienza, de manera similar, considerando una curiosidad.

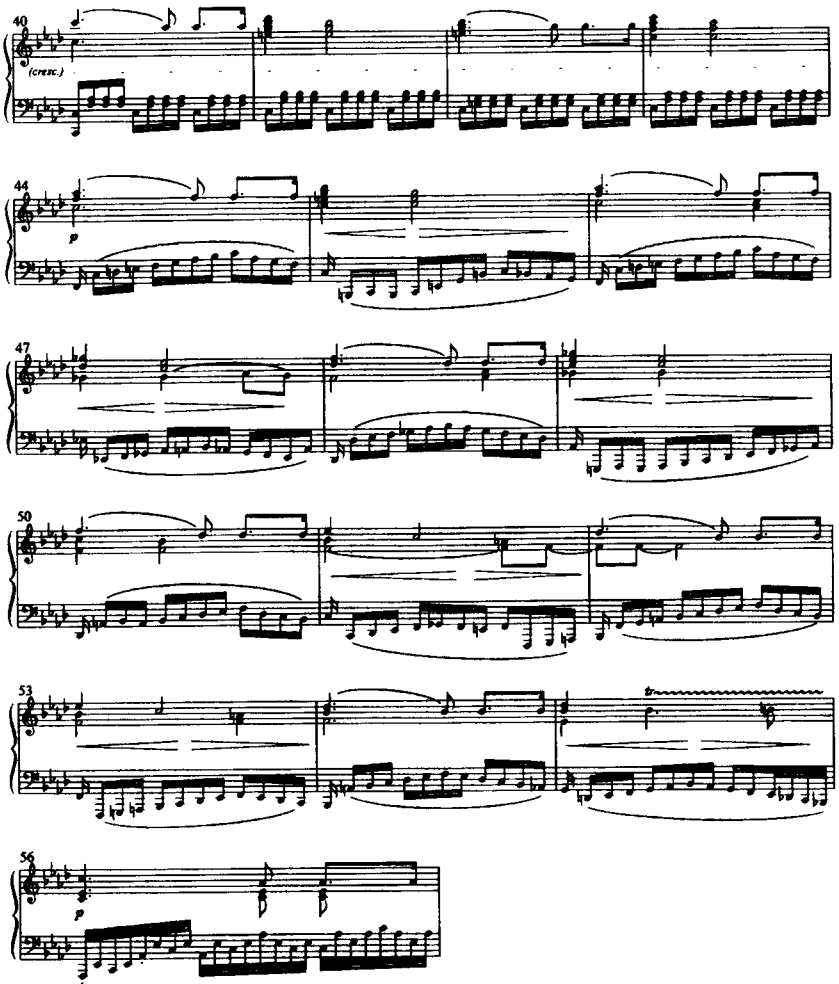
La sección de desarrollo (compases 40-55; Ejemplo 9.3) es asombrosamente diferente del carácter expansivo del resto del movimiento: es breve, curiosamente formal, y se limita a pasar el tema por una serie de frases secuenciales. Esta observación sugiere a primera vista un estilo interpretativo modesto y «objetivo», confirmado inmediatamente por la manera en que Beethoven diseña la recapitulación. La línea melódica prorrumpe en unos trinos (compás 55) —una variante apresurada del trino cadencial de la frase que abre el movimiento (compás 4; Ejemplo 9.4)— que introducen el regreso del tema principal en el compás 56, esta vez en una versión apasionada, impulsada por las fusas de la mano izquierda. El flujo uniforme del desarrollo se puede considerar, retrospectivamente, como un preludio a la transformación decisiva del movimiento. La magnitud de esa transformación puede verse volviendo a la primera página de la partitura (Ejemplo 9.4). Entonces podemos entender que el comienzo de la recapitulación es una compresión de lo que al inicio era una serie de gradaciones sutiles, desde la exposición del tema en el estilo de un himno, a través del acompañamiento en semicorcheas (desde el compás 5), hasta las fusas que comienzan en el compás 12. Dado que el ritmo armónico permanece constante, el efecto de esas gradaciones es el de una serie de variaciones, realzado por el hecho de que en cada caso el primer movimiento armónico es el mismo. Esta visión de la música sugiere que el pianista debe realizar los cambios de velocidad con suavidad y exactitud, sin la repentina aceleración de tempo que frecuentemente se le da al comienzo de las fusas. Esta línea de investigación se puede extender, teniendo en cuenta las diferencias entre la recapitulación y la exposición. Por ejemplo, hay una modulación a la tonalidad lejana de Mi mayor para la repetición de los arpegios de fusas (desde el compás 70; Ejemplo 9.5) y una reestabilización (en Lab mayor) en la extensa coda (compases 105 y ss.). Más significativo aún es el último acorde de la exposición, con su discanto en espirales ascendentes de semicorcheas (desde el compás 36; Ejemplo 9.6), que en la reexposición florecen en una nueva variante —suspendidas en los agudos del



teclado— en un pasaje que parece ser el núcleo emocional del movimiento (compases 97-104; Ejemplo 9.7).

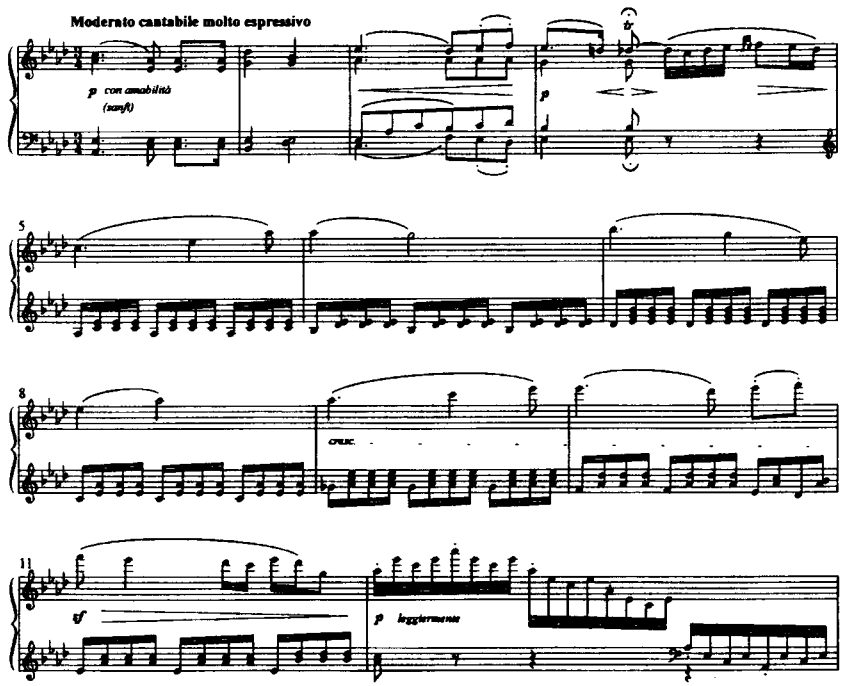
De esta manera, uno descubre gradualmente no sólo lo que la música está expresando, sino cómo cada frase o sección forma parte del conjunto, un

EJEMPLO 9.2 *Debussy, «L'ombre des arbres»,* Ariettes oubliées.



EJEMPLO 9.2 *(Continuación)*

sentido de la lógica dramática de Beethoven a medida que las piezas del puzle encajan en su sitio. La gran ventaja de trabajar alejados del instrumento se hace evidente, ya que uno puede experimentar y reflexionar a voluntad, desembarazado de los detalles técnicos que en esta fase representarían una distracción inoportuna.



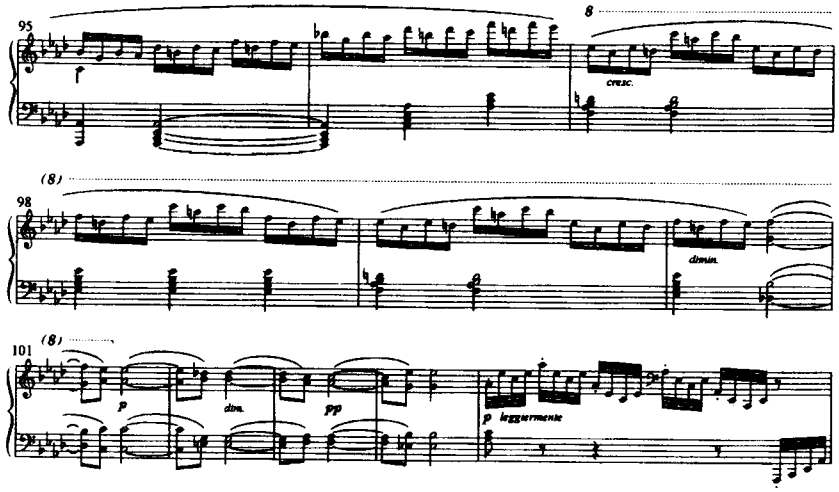
Todo este trabajo mental es similar a la preparación que realiza un director antes del primer ensayo con orquesta. Como el director, ahora podemos abordar el primer «ensayo» —la primera sesión de prácticas— con los fundamentos esenciales en su sitio: un esbozo de una concepción; un conocimiento del contexto, de qué es lo que ocurre en la música y por qué; y, lo más importante, la habilidad de escuchar la música en todas sus dimensiones. Incluso los problemas técnicos

EJEMPLO 9.3 *Beethoven, Sonata en La♭ mayor op. 110, primer movimiento, compases 40-56.*

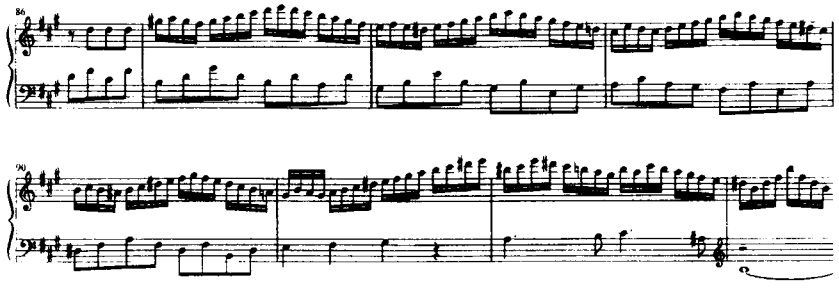
pormenorizados se habrán anticipado y resuelto al menos parcialmente. Nótese también que habremos memorizado la pieza en gran parte, o quizá del todo: se trata de una memoria «activa», que surge del conocimiento de la lógica de la música en lugar de poceder del aprendizaje repetitivo de las notas. De esta manera uno espera abordar el dilema principal esbozado anteriormente, para poder *conocer* la música completamente sin quedar atrapados en una serie de hábitos.

EJEMPLO 9.4 *Beethoven, Sonata en Lab mayor op. 110, primer movimiento, compases 1-12.*

EJEMPLO 9.5 *Beethoven, Sonata en Lab mayor op. 110, primer movimiento, compases 70-72.*



Sólo ahora estamos en condiciones de comenzar un experimento minucioso en el instrumento como el que describió Moore. Escuchando muy atentamente el sonido que producimos y comparándolo con nuestra concepción interna, podemos lograr que ambos coincidan. Sin embargo, siempre hay una delgada línea entre intentar que una idea funcione y estar dispuestos a revisar nuestro método.

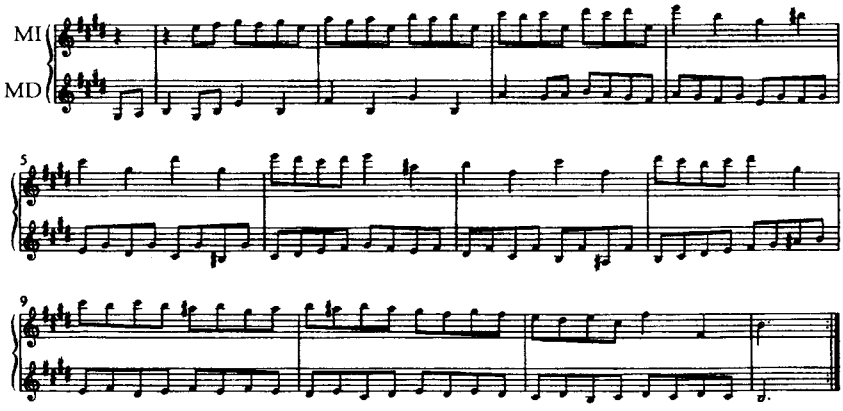


EJEMPLO 9.6 *Beethoven, Sonata en La♭ op. 110, primer movimiento, compases 36-37.*

EJEMPLO 9.7 *Beethoven, Sonata en La♭ op. 110, primer movimiento, compases 95-105.*

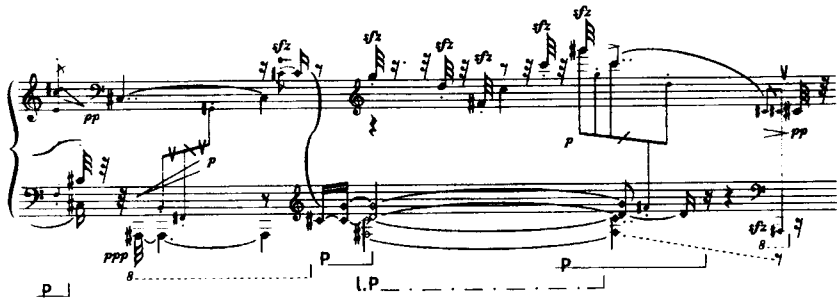
EJEMPLO 9.8 *Mozart, Concierto para piano en La mayor K. 488, primer movimiento, compases 86-93.*

En este punto llegamos a la segunda fase de resolución de nuestro problema. Con demasiada frecuencia, los intérpretes, y me incluyo, atacan los problemas técnicos con un enfoque provisional. Los errores deben corregirse, claro está, pero si nos limitamos a eso estaremos tratando el síntoma sin tratar la causa. Un ejemplo sencillo podría ser la afinación: antes de ajustar el dedo sobre la cuerda, ¿estamos seguros de poder *escuchar* (o cantar) el pasaje correctamente? De no ser así, «echarle la culpa» a los dedos es inútil.



Esta verdad me fue inculcada, siendo un novato mayormente autodidacta de diecinueve años, en mi primera clase con el pianista Cyril Smith. Estaba tocando el primer movimiento del Concierto para piano en La mayor K. 488 de Mozart, y mis dedos se confundieron momentáneamente en la transición anterior al segundo tema (véase el Ejemplo 9.8). Inmediatamente, comencé a repetir el pasaje y corregir el desliz; sin embargo, Smith me detuvo y me dijo que practicara el pasaje tocando las semicorcheas de la mano derecha lentamente (sin la partitura) pero con un solo dedo. Esa extraña instrucción resultó inmediatamente reveladora. Al eliminar la memoria *física* (de mi digitación) me vi forzado a reconstruir el pasaje de oído, cosa que (vergonzosamente) no fui capaz de hacer. Smith me dio tiempo para que me aprendiera el pasaje auditivamente; cuando regresó, le toqué toda la sección como una «interpretación de concierto» —desinhibido y en el tempo justo— y milagrosamente claro y seguro. Por haber descubierto dónde se encontraba el error, en este caso en mi oído y no en mis dedos, pude corregirlo —permanentemente—, y destacaría que lo hice sin realizar ninguna práctica repetitiva convencional.

Se pueden abordar problemas más persistentes extendiendo este principio, de nuevo con el objetivo de atacar sus raíces. La clave para ello es la práctica «indirecta», un concepto conocido por los pianistas en particular gracias a las famosas ediciones de Alfred Cortot. Por ejemplo, Cortot añade a cada Estudio de Chopin unos ejercicios preliminares, de acuerdo con su precepto de que uno no debería practicar «el pasaje difícil, sino la dificultad que contiene, comenzando dicha práctica desde su misma raíz» [6]. Smith, que era un maestro interpretando los conciertos de Rachmaninoff y otros repertorios virtuosos, extendió aún más esa norma. Recomendaba un método feroz con el que, además de abordar la dificultad por etapas (como hacía Cortot), se exageraba el problema, extendiendo el nivel de habilidad más allá de lo requerido. Por poner un ejemplo sencillo: si el problema era de «geografía» del teclado —encontrar con seguridad las notas correctas—, la solución era aprender a tocar el pasaje con la misma facilidad, pero a ciegas, sin utilizar la vista para dirigir las manos. Para lograr uniformidad y brillantez en los pasajes virtuosos, proponía que se estudiasen las figuraciones en diferentes tonalidades, empleando la misma digitación para hacerlo aún más difícil —lo que de paso tiene la ventaja de evaluar nuestro conocimiento auditivo y armóni-



co de la obra. En estos días, he estado practicando en otra forma «indirecta» la Bourrée de la Suite Francesa núm. 6 en Mi mayor de Bach. Para mejorar el difícil equilibrio y coordinación de las dos voces, he estudiado la pieza con las manos cruzadas, transportando la parte de la mano izquierda dos octavas más arriba y la de la mano derecha una octava más abajo (véase el Ejemplo 9.9). Esto ayuda a contrarrestar la tendencia «diestra» que tenemos los pianistas, por la que escuchamos la voz superior a expensas de la mano izquierda. También resulta útil, especialmente en la música contrapuntística de este tipo, aprender a cantar la voz inferior tocando la superior. Además de aportar un beneficio inmediato, estas técnicas tienen otras ventajas. Una de ellas es que el acto de reaprender la música de diferentes maneras expone cualquier incertidumbre persistente en nuestro conocimiento básico —auditivo, intelectual, musical— de la música; por otra parte, saber que uno es capaz de afrontar un reto más allá de lo estrictamente necesario refuerza mucho nuestra seguridad. Por último, nótese que todas estas técnicas ahorran mucha práctica repetitiva de la música misma.

La experiencia de aprender música contemporánea me confirmó la importancia de estudiar mentalmente antes de comenzar a practicar. En las partituras que hemos analizado hasta ahora el intérprete puede aplicar mucha habilidad o «técnica» a la música: en efecto, como señala Moore, el hecho de que uno pueda leer a primera vista el «Wandrers Nachtlied» encubre lo

EJEMPLO 9.9 *Bach, Suite Francesa núm. 6 en Mi mayor BWV 817, Bourrée, compases 1-12 (mano izquierda transportada dos octavas más arriba; mano derecha transportada una octava más abajo).*

EJEMPLO 9.10 *Stockhausen,* Klavierstück VII, *p. 1, sistema 2;* © *1965 Universal Edition (Londres) Ltd., Londres.*

difícil que es realmente la pieza. Sin embargo, en el Ejemplo 9.10, del *Klavierstück VII* de Stockhausen, las técnicas de ejecución son tan inusuales que el intento de leerlo a primera vista es en gran parte inútil. Como muestra el fragmento, *Klavierstück VII* está basado en aislar y combinar las resonancias del piano. Estos sonidos «reflejados» se producen de dos maneras. El pianista puede pulsar una o varias teclas sin que lleguen a sonar (indicadas en la partitura mediante notas con forma de rombo) levantando así sus apagadores y hacer sonar los armónicos de las cuerdas correspondientes pulsando otras teclas con un agudo *staccato.* También puede prolongar los ataques como ecos, volviendo a liberar la cuerda, que aún vibra, mediante el pedal o una nueva pulsación insonora. Otra dificultad para el pianista es la eliminación gradual de las resonancias, soltando las teclas una por una.

Estudiar este tipo de música «experimental», en la que las técnicas interpretativas le deben poco o nada a las técnicas del repertorio tradicional, nos obliga a reconsiderar nuestro enfoque del aprendizaje y la práctica. Antes de intentar tocar *Klavierstück VII,* dediqué varias horas a hacer anotaciones en la partitura, asimilando y «probando» los detalles mentalmente, como una manera de comprender sus efectos musicales. La recompensa de una preparación esmerada es que, una vez al piano, podemos concentrarnos en el problema esencial, el equilibrio entre la intensidad del ataque y las resonancias. (Por cierto, ello varía notablemente según el piano y la acústica, y por lo tanto se debe planificar de nuevo para cada interpretación.) El proceso de recrear la partitura en sonido es fascinante, ya que uno explora diferencias de sonoridad que a menudo son extremadamente sutiles. Esta nueva conciencia del potencial del instrumento influye indudablemente en nuestra actitud hacia el sonido en la interpretación clásica. Igualmente, uno comienza a ver la «técnica» desde una perspectiva más creativa: tocar música contemporánea nos ani-

ma a buscar las soluciones que funcionen, aunque sean poco ortodoxas, en lugar de aplicar fórmulas habituales.

Sería un error deducir que el aprendizaje de una pieza es una sencilla progresión del trabajo mental a la práctica en el instrumento, del silencio al sonido. Las prácticas deben alternarse con períodos de descanso, durante los cuales la pieza se «olvida». También es posible que necesitemos períodos de reflexión: la práctica puede haber revelado deficiencias en nuestro conocimiento de la partitura. Esto ocurre especialmente cuando abordamos repertorios extremadamente difíciles. En las obras que explotan las posibilidades pianísticas hasta el límite, o incluso lo sobrepasan —como por ejemplo *Klavierstück X* de Stockhausen, *Evryali* de Xenakis y *La Fauvette des jardins* o el sexto movimiento fugado de *Vingt regards* de Messiaen—, se debe examinar muy cuidadosamente cada dificultad. La claridad mental absoluta es un prerrequisito, claro está. Asimismo, estudiar regularmente alejados del instrumento nos ayudará a refrescar y profundizar nuestra visión, y a recordar hacia dónde vamos. Es un contrapeso necesario a lo que pueden ser semanas de estudio esmerado, durante las cuales es fácil desanimarse o quedarse atascado en las laderas musicales.

En este ensayo he destacado el aspecto mental de la labor del intérprete, porque constituye la clave del problema central descrito anteriormente, y también porque es el aspecto que se descuida con mayor frecuencia. En el caso de los intérpretes en edad estudiantil, puede que sea simplemente una cuestión de ignorancia, ya que siguen utilizando los métodos de la infancia y dependiendo del profesor para tomar decisiones. El simple apremio de tiempo puede hacer que los intérpretes adultos omitan las primeras fases del aprendizaje y vayan directamente al instrumento, especialmente a una edad avanzada, cuando se deben dedicar más esfuerzos a los aspectos físicos de la técnica. En cuanto a la educación, uno de los factores es la naturaleza fragmentada del plan de estudios, en el que se enseñan las habilidades auditivas, la armonía y el análisis en compartimientos separados y pocas veces se explica su repercusión directa sobre la interpretación. Y, como profesor, sé lo fácil que es caer en la tentación de las soluciones rápidas, ajustando el sonido mismo en lugar de investigar su causa.

Sin embargo, la razón más común por la que se descuida el aspecto mental es un lógico recelo hacia lo que puede considerarse un enfoque demasiado intelectual. El argumento es que para los músicos es suficiente con ser «musicales». La labor del intérprete es dominar el reto técnico de una partitura; una vez logrado esto, nuestros instintos aportarán la interpretación. De hecho, un exceso de pensamiento puede impedir realmente el funcionamiento natural de esos instintos.

Debemos escuchar con atención lo que surge «naturalmente», por supuesto, pero la idea de que uno puede comprender la sonata de Beethoven

que hemos analizado, simplemente desde una perspectiva natural, parece peligrosamente engañosa. Además, el estudio mental, lejos de reprimir las reacciones instintivas ante la música, está ideado para sacar el mayor provecho de ellas. El problema, como he señalado antes, es la naturaleza de la práctica. Debemos practicar, claro está, pero también debemos reconocer que la práctica puede embotar nuestra inteligencia creativa y enredarnos en hábitos que, al acostumbrarnos a nuestros defectos, no nos permiten escucharnos como somos realmente. Una solución es aprender el máximo posible sobre la obra antes de llevarla al instrumento. Pero el objetivo principal del estudio mental es liberar nuestra musicalidad, asegurar que los objetivos musicales —y no los constreñimientos técnicos— sean lo primero. El ideal es que la música no esté guiada por lo que podamos (o no podamos) hacer, sino por lo que queremos y necesitamos hacer.

10 *El lenguaje del cuerpo durante la interpretación*

JANE DAVIDSON

Introducción

Este capítulo describe el importante papel que desempeña la «presentación» en las interpretaciones solistas dentro de la tradición clásica. Como punto de partida reconoce la enorme transición que existe entre el aislamiento de la práctica individual y las interacciones sociales que se producen en el escenario. Sostendrá que el trabajo que tiene lugar durante la práctica ha de prever el contexto social de la interpretación y la inevitable excitación fisiológica y psicológica que esa situación provocará; también considerará la necesidad de que la interpretación sea espontánea y al mismo tiempo consciente de la dinámica social de la experiencia interpretativa. El aspecto visual de la presentación es fundamental en este estudio. Es de vital importancia señalar las múltiples valoraciones que tienen lugar entre el intérprete y el público en función de la información transmitida por señales visuales como las normas en el vestir, los hábitos característicos y otros comportamientos no verbales, como las miradas y los gestos que se realizan mientras se interpreta [1].

El papel de la práctica

Las investigaciones han revelado que la maestría musical implica un elevado nivel de perfeccionamiento de las actividades física y mental, hasta tal punto que la relación entre la información almacenada en la memoria, los esquemas y planes que organizan dicha información y los pensamientos y acciones aso-

ciados a ella se vuelve completamente automática y fluida [2]. La práctica es esencial para lograr esa fluidez. En las etapas iniciales del aprendizaje, los pensamientos y las acciones son torpes, deliberados y difíciles de coordinar, pero después de mucha práctica y experiencia el músico es capaz de tocar sin prestar una atención consciente a los pensamientos y acciones que realiza para producir la interpretación. Sin embargo, la interacción entre el automatismo, el pensamiento consciente y la acción se caracteriza por varios fenómenos curiosos. Por ejemplo, muchos intérpretes dirigen repentinamente su pensamiento consciente al proceso automático de tocar y entonces se percatan de que se encuentran en medio de una pieza, pero sin saber exactamente dónde. La excitación causada por la presencia de otras personas también puede interrumpir la atención y el equilibrio entre los sistemas mentales automático y consciente empleados al tocar. Una forma de desarrollar y aprender a coordinar el pensamiento y la acción automática y consciente es ensayar ante otras personas para intentar familiarizarse con esos efectos producidos por la excitación y ejercitar mecanismos conscientes para mantenerse concentrado y evitar ser distraído por el público.

La música tiene, por supuesto, un marcado contenido emocional: puede inspirar un sentimiento de alegría o contemplación, o hacer que un oyente responda con movimientos, ya sea lenta o enérgicamente. Estas posibilidades se deben examinar ampliamente durante la preparación de una pieza para poder consolidar una interpretación individualizada. Los manuales y textos sobre el aprendizaje de las habilidades musicales frecuentemente recomiendan a los estudiantes que encuentren una articulación óptima de sus ideas expresivas utilizando su cuerpo. Por ejemplo, un cantante puede emplear el gesto de levantar lentamente el brazo para ayudar a transmitir la idea de que está cantando más fuerte a lo largo de una frase musical [3]. Durante el siglo XIX, muchos tratados sobre interpretación mencionaban la interacción esencial entre la estructura musical, la expresión y el cuerpo. Por ejemplo, en su obra *L'Art du violon* de 1834, Baillot sugiere que diferentes tipos de movimiento producen y al mismo tiempo provienen de los efectos relacionados con diferentes tempos musicales. Señaló que un Adagio requiere una ejecución «más amplia» que la de un Allegro, en el que los trinos se deben «agitar» más rápidamente, mientras que la ligereza y la vivacidad han de mantenerse en un Presto y en los pasajes de «mayor desenfreno» [4]. Un siglo después, Alexander Truslit [5], un psicólogo alemán, descubrió que los intérpretes producen interpretaciones musicales conmensurablemente diferentes en respuesta a distintas indicaciones o nociones de movimiento. Además, la información sobre las características estructurales de la música ejecutada y las intenciones expresivas del intérprete es comunicada a los espectadores mediante movimientos corporales [6]. Por ejemplo, un grupo de espectadores a los que se les

mostró un vídeo en el que sólo se veían los movimientos del intérprete fue capaz de diferenciar claramente las interpretaciones de una misma pieza con tres intenciones expresivas diferentes —interpretar sin expresión, con expresión normal o con expresión exagerada.

Considerar el cuerpo como la fuente de la expresión musical implica que ésta constituye un medio para comunicar cualidades básicas de la naturaleza humana, cualidades que emergen del movimiento y que se traducen y abstraen en formas musicales. En efecto, la retórica que rodea a la música revela que la expresión musical utiliza mucho el cuerpo como metáfora —por ejemplo, «ha sido una interpretación conmovedora», o «su canto realmente me animó». Por otra parte, escritores como Ray Jackendoff[7] han sugerido que la capacidad de movimiento que le atribuimos frecuentemente a la música (e.g. «la música corría por sus venas») puede tener realmente un origen corporal (por ejemplo, activa nuestra fisiología del movimiento y equilibrio) o estar asociada a sonidos o imágenes que transmiten una sensación de movimiento corporal. De acuerdo con esta línea de pensamiento, la expresión musical está estrechamente relacionada con quiénes y qué somos. Roger Scruton advierte lo siguiente sobre lo que hacemos los oyentes:

> al escuchar ritmo escuchamos la música como algo activo; parece estar haciendo algo (a saber, bailando) que los sonidos no pueden hacer [...] al mismo tiempo, no creemos que eso esté ocurriendo en el ámbito del sonido: fundamentalmente, somos conscientes del movimiento como algo nuestro[8].

Por lo tanto, al preparar una interpretación, parece ser de vital importancia que examinemos el papel que desempeña el cuerpo en la producción de las características técnicas y expresivas.

Observando al intérprete

Habiendo establecido que el cuerpo es vital en la generación de las cualidades técnicas y expresivas de una interpretación musical, es preciso analizar qué comprenden los movimientos corporales del intérprete. Un extenso estudio de caso de un pianista, realizado por Jane Davidson[9], intentó decodificar los movimientos utilizados en la interpretación y determinar qué información podrían transmitir dichos movimientos al público. En resumen, se descubrió que, para el pianista, una interpretación deliberadamente expresiva siempre implicaba un movimiento giratorio y de balanceo. Generalmente, estos movimientos cíclicos eran expresivos, pero en su transcurso había determinados momentos que eran más expresivos que otros. De hecho, parecía

haber una correlación entre las valoraciones de la expresividad por parte del público y el tipo específico de movimiento que empleaba el intérprete en ese momento. Se encontraron varios gestos identificables: diversos grados de elevación y descenso de brazos y manos, que abarcaban desde ampulosos movimientos giratorios hasta pequeñas rotaciones de las muñecas, un movimiento ondulante de los omoplatos y movimientos frontales y laterales de la cabeza. Se encontró que todos los movimientos, incluyendo el balanceo generalizado, provenían de la región de la cadera. Dado que el pianista estaba sentado, se teorizó que la cadera representaba el punto de apoyo de su centro de gravedad, actuando por lo tanto como pivote para todos los movimientos del torso. Este centro de gravedad parecía ser el punto central en el que se genera la expresión física.

Se buscaron correspondencias entre los gestos utilizados por el pianista y momentos específicos de la estructura musical, pero se descubrió que esos gestos eran empleados de una manera bastante flexible, de modo que en las interpretaciones que se repitieron con intenciones expresivas similares podía aparecer, por ejemplo, un movimiento de cabeza donde previamente se había producido un movimiento ondulante de los omoplatos. Sin embargo, también se descubrió que tales gestos siempre aparecían en los mismos puntos de la música, lo que sugería una estrecha relación entre la producción física de la expresión y su correlativo efecto sonoro expresivo. Por ejemplo, siempre se producía un gesto en el límite o en el clímax de una frase, aunque variaba de interpretación en interpretación.

Las investigaciones sobre la expresión física son escasas, pero se puede establecer un paralelismo entre los descubrimientos de este estudio de caso y el trabajo de James Cutting y sus colaboradores [10]. Este último examina la naturaleza de la expresión física observando la forma de andar de las personas; en este caso, la «expresión» era la identidad y el género de cada persona. Los estudios demostraron que cualquier articulación del cuerpo (por ejemplo, la cadera o el tobillo) proporciona una información igualmente expresiva en el movimiento cíclico del andar. Los investigadores demostraron que, cuando una persona anda, hay un punto en su cuerpo que funciona como una referencia para los movimientos de todas las demás partes. Al tocar el piano, no todo el cuerpo participa en la misma medida en la ejecución; por lo tanto, el punto de referencia para los movimientos expresivos en el piano estará inevitablemente relacionado con la posición sentada y el centro de gravedad, y, dados los hallazgos de Davidson, es muy probable que se encuentre en el movimiento de balanceo.

La descripción de Cutting proporciona claramente una base para comprender la importancia del movimiento de balanceo en las interpretaciones pianísticas. Además, el autor ha refinado su descripción [11] para explicar el ha-

llazgo de que distintas partes del cuerpo transmiten información igualmente expresiva, y propone que algunas zonas del cuerpo son indicadoras generales de expresión, mientras que otras partes proporcionan una información más específica. Esto explica por qué en la ejecución pianística encontramos una información expresiva continua (movimiento de balanceo) y una cantidad mucho mayor de información localizada (por ejemplo, un gesto específico de la mano). Es posible que los indicadores locales actúen cuando el potencial expresivo del cuerpo es mayor. De hecho, muchos de estos movimientos sumamente pronunciados tuvieron lugar en momentos en los que el cuerpo se encontraba «libre»: por ejemplo, una gran elevación del brazo ocurría frecuentemente cuando éste no debía cumplir ningún requerimiento técnico, como durante un acorde mantenido en una cadencia.

Como se ha sugerido, la información que transmiten los movimientos está totalmente al alcance del público, que la utiliza para evaluar y enjuiciar una interpretación. Por lo tanto, parecería que tales movimientos se deberían reconocer y fomentar, en lugar de desaprobarlos. De hecho, un estudio a pequeña escala [12] realizado con un grupo de pianistas reveló que no podían tocar con una expresión óptima si sus cuerpos se encontraban constreñidos de alguna manera durante el proceso de aprendizaje o de interpretación. Por consiguiente, encontrar la intención física y mental adecuada, y permitir que ésta se comunique libremente a través del cuerpo, parece ser esencial para la producción de una interpretación fluida y expresiva.

Naturalmente, los movimientos y gestos han de adecuarse al contexto social y cultural. Por ejemplo, los pianistas clásicos tocan sentados y se mueven relativamente poco, mientras que un teclista de rock puede tocar de pie, bailando sin moverse de su sitio y haciendo gestos ampulosos. Éstos son tan sólo dos ejemplos de las maneras específicas en las que los intérpretes aprenden a presentar sus interpretaciones.

Factores sociales

La etiqueta social de la interpretación, incluyendo conductas como hacer reverencias y vestirse adecuadamente, es significativa para los intérpretes y el público [13]. En efecto, un estudio reciente sobre los procesos de evaluación musical [14] revela que los evaluadores de interpretaciones vocales consideran que el atractivo físico del intérprete es uno de los criterios más importantes en su evaluación de interpretaciones solistas. Curiosamente, los evaluadores consideran que para comunicar lo más íntimo del contenido musical y hacer frente a la naturaleza pública de la interpretación el intérprete ha de revelarse a sí mismo y presentar su personalidad de una manera especialmente intere-

sante o atractiva. De este modo, los gestos pomposos que hace Luciano Pavarotti con el brazo, agitando un pañuelo mientras canta, representan un acto público y exagerado de expresión emocional, mientras que, al mismo tiempo, los sutiles movimientos de sus ojos y su boca cuando canta una línea melancólica parecen expresar sus pensamientos y emociones más profundas, convirtiéndose en actos de intensa revelación emocional y personal.

Naturalmente, todas las conductas que implican movimientos se aprenden de otras personas, y en la interpretación musical se puede reconocer con frecuencia al profesor del alumno por la forma en que éste aborda el instrumento. Por ejemplo, hay una profesora de violín muy respetada que enseña a todos sus alumnos a doblar las rodillas de un modo particular para añadir peso y relajación a su ejecución. Dicha profesora es inmediatamente reconocible en los movimientos de cada uno de sus alumnos.

Martin Gellrich [15] ha investigado gestos superficiales aprendidos, como los que hace Pavarotti con el brazo, y la manera en que éstos interactúan con los movimientos expresivos esenciales e intrínsecos, como los gestos de los ojos y la boca. Gellrich sugiere que los movimientos y gestos aprendidos aportan una intención expresiva a la interpretación y pueden tener efectos tanto positivos como negativos en la producción de la interpretación. Pueden aportar una información al espectador que le ayudará a comprender la interpretación, ya que los gestos pueden esclarecer significados, aunque el movimiento en sí mismo sea «superfluo» en la producción del conjunto de la música. Puede haber un nivel «superficial» de movimiento que el intérprete añade a la interpretación. A la inversa, si estos gestos no son coherentes con las intenciones del intérprete, pueden provocarle tensiones físicas, al inhibir la fluidez y causar una incongruencia entre el gesto empleado y el objetivo de la interpretación.

Sverkar Runeson y Gunnar Frykholm [16] han descrito las consecuencias negativas de los gestos incongruentes en un trabajo que demuestra que las disposiciones mentales se hacen explícitas en el movimiento. Utilizando como experimento la simple tarea de levantar una caja, los investigadores pidieron a un grupo de observadores que dieran información sobre lo que podían ver cuando una persona levantaba una caja, y descubrieron que los observadores podían detectar no sólo el peso de la caja, sino también cuánto difería ese peso del que esperaba encontrar el que la levantaba. Más relevante aún es el hecho de que los observadores detectaron la información falsa que se les dio en algunos casos sobre el peso de la caja. Por lo tanto, la información engañosa y el peso verdadero de la caja se explicitaban conjuntamente.

Los gestos «superficiales» pueden contribuir de manera importante a la producción y percepción de una interpretación musical. En efecto, en el estudio de las interpretaciones del pianista mencionado anteriormente, otra in-

terpretación del hallazgo de que ciertos fragmentos de dos segundos eran mucho más expresivos que otros podría ser que en algunos momentos de la ejecución el pianista utilizaba gestos imitativos, y que esos movimientos acentúan el efecto expresivo del momento en cuestión. Por ejemplo, un amplio movimiento lateral de la cabeza puede tener una forma propia y característica y, sin embargo, formar parte del continuo movimiento de balanceo. Los estudios sobre los gestos en el lenguaje verbal [17] indican la existencia de repertorios gestuales asociados a significados específicos; por ejemplo, el dedo pulgar levantado es un gesto emblemático en la cultura occidental que significa «bien». Es posible que el pianista hubiera desarrollado gestos específicos para determinadas expresiones musicales —en otras palabras, un repertorio de movimientos gestuales.

Presentar una interpretación

Es evidente que el público distingue todo tipo de informaciones sutiles sobre los intérpretes a partir de sus movimientos corporales y su aspecto general y, por supuesto, de los sonidos musicales que produce. El intérprete también percibe muchas señales diferentes del público: el nivel general de entusiasmo y concentración, así como la forma de vestir, de sentarse, etc. De modo que existe una comunicación recíproca. Pero al presentar una interpretación, el músico no está sencillamente presentándose en un espacio público y ofreciendo una versión bien ensayada de una obra musical, atribuyéndose cierto mérito por la excitación que produce la presencia del público. Ocurren muchas más cosas: el intérprete y el público intercambian información continuamente mediante señales visuales y auditivas. En tales circunstancias, el intérprete sigue el «fluir» del momento [18]. Los investigadores han observado que si el intérprete percibe las numerosas señales del contexto de la interpretación en vivo y las interpreta positivamente, puede alcanzar un estado de conciencia psicológica diferente que le permite concentrarse profundamente en su tarea y analizar pensamientos y sentimientos espontáneos de una manera creativa [19].

Así pues, en la interpretación en vivo se pueden tomar decisiones diferentes sobre la interpretación y la interacción con otros intérpretes y el público. Como se ha mencionado en la sección sobre aprendizaje, la excitación psicológica y física es consecuencia inevitable de las interacciones sociales [20]. En niveles de rendimiento óptimos, el ritmo cardíaco acelerado y el consecuente aumento de la provisión de oxígeno causados por la producción de adrenalina pueden conducir a la circunstancia intensificadora referida anteriormente como el «fluir». Sin embargo, una sobreexcitación puede provocar falta de

confianza y preocupación sobre asuntos como la capacidad de recordar, que será de vital importancia para el éxito o el fracaso. De hecho, un elevado nivel de adrenalina en combinación con esos pensamientos puede provocar una reacción en cadena de consecuencias fisiológicas nefastas para la interpretación: temblores que conducen a errores, confusión de pensamientos que produce fallos en la memoria, etc.

Resumen

En conclusión, la interpretación musical es una actividad sumamente expresiva y abstraída que emana de una base corporal. Para el intérprete, es necesario un equilibrio cuidadoso entre el control y la entrega, entre obedecer ciertas reglas y desobedecer otras. La interpretación supone un conocimiento profundo de la música, del instrumento y del propio yo en la música. No es tarea fácil llegar a ser un intérprete, mucho menos un solista, por la enorme preparación que requiere, pero presentar una interpretación parece ser una oportunidad inusual para los intérpretes de compartir con otros quiénes y qué es lo que son exactamente en ese momento.

11 *La interpretación en grupo*

ELAINE GOODMAN

La interpretación en grupo implica una interacción musical y social entre varios intérpretes. El término *ensemble* significa «juntos» en francés, y se utiliza para designar una variedad aparentemente infinita de agrupaciones musicales, desde un dúo hasta una orquesta sinfónica. Al mismo tiempo, y al igual que su equivalente español «conjunto», también refiere el grado de precisión con el que los músicos interpretan juntos: se dice que un grupo está «muy conjuntado» cuando es bueno, mientras que uno inferior puede estar «poco conjuntado».

Nuestra experiencia en interpretación en grupo puede mejorar entendiendo algunos de los procesos involucrados en el acto de hacer música juntos. Este capítulo considera cuatro aspectos en particular: la coordinación, la comunicación, el papel del individuo y los factores sociales. La mayoría de las observaciones se refieren a pequeños grupos de cámara dentro de la tradición occidental, pero de vez en cuando también se hará referencia a grupos más grandes.

Coordinación: mantener el tempo

El requisito más importante de cualquier conjunto es que las partes individuales encajen entre sí. Es necesario, por tanto, que cada músico sea capaz de tocar a tempo con el resto del grupo; en efecto, la coordinación de un conjunto depende únicamente del tempo. Cualquier intérprete de grupo consumado sabe que contar es vital para mantener el tempo, al menos para saber

qué compás están tocando y cuándo entrar o parar. Sin embargo, hay otros asuntos que considerar en relación a la coordinación del tempo, y analizaremos tres de ellos en esta sección: el «reloj» del grupo, las habilidades para mantener el tempo y la ilusión de sincronía.

El «reloj» del grupo

El punto de partida de un ensayo de un conjunto pequeño, sin director, es establecer el tempo general de una pieza, lo cual puede consistir en probar diferentes velocidades hasta acordar un tempo determinado. En cambio, el director de una agrupación grande indicará a los intérpretes la velocidad del pulso básico. En ambos casos, el pulso básico (i.e., el tempo general) proporciona un punto de referencia para mantener el tempo. En efecto, cada músico generará un pulso interno de acuerdo con el compás (que a veces es visible cuando marcan con el pie, aunque tal vez sería mejor que se limitaran a mover los dedos del pie, de modo que no se vea). El tempo general funciona por tanto como el reloj del grupo, ya que proporciona una fuente de coordinación y controla el pulso interno de cada músico. En otras palabras, los intérpretes de cámara poseen un «marcador de tiempo compartido» para el tempo general de la obra [1].

Mientras el pulso básico es una referencia importante para mantener el tempo, es posible que en determinadas circunstancias algunos músicos quieran subdividir o agruparlo en diferentes puntos. En esos casos, el compás constituye una estructura importante para la coordinación, ya que es una unidad de tiempo en la que podemos organizar individualmente el pulso básico.

Técnicas para mantener el tempo

Tocar a tempo con otras personas requiere algo más que simplemente contar y seguir el tempo general, ya que, durante la interpretación, la ejecución de cada compás ha de estar cuidadosamente administrada. Ello implica dos técnicas básicas: la *anticipación* y la *reacción*. Los intérpretes de cámara realizan predicciones complejas que están estrechamente relacionadas con las reacciones adquiridas por retroalimentación o *feedback*: sobre la base de la nota anterior, ¿cuándo sonará la nota siguiente de un compañero? Michael Tree, integrante del Cuarteto Guarnieri, afirma que «cada momento de nuestra ejecución está condicionado por lo que acaba de ocurrir o lo que pensamos que ocurrirá a continuación» [2]. La anticipación de cada pulso y la reacción a

la producción de cada pulso están prácticamente definidas por la naturaleza de la interacción manifiesta entre los intérpretes.

Los intérpretes de cámara actúan recíprocamente de diversas maneras para mantener el tempo. Una de ellas puede compararse con el proceso de *cazar,* en el sentido de que un músico sigue a otro del mismo modo en que un cazador sigue la pista de su presa, anticipándose y reaccionando a sus movimientos. El proceso de «cazar», que también se puede considerar como seguir o rastrear, es unidireccional, ya que uno de los músicos responde al tempo de otro(s) [3].

El segundo tipo de interacción implica un ajuste mutuo, o *cooperación,* entre los intérpretes. La cooperación es un proceso dinámico (en contraposición al unidireccional), aunque también puede presentar elementos de «caza», ya que los intérpretes «intercambian roles [...] para permitir que uno u otro sea el guía» [4]. En efecto, la línea que separa a la cooperación de la caza es muy delgada, y ambas habilidades pueden verse afectadas por factores como una personalidad dominante o la naturaleza de la música (por ejemplo, es posible que el acompañante siga al intérprete que ejecuta la melodía).

Las interacciones musicales pueden planificarse hasta cierto punto en los ensayos: quién seguirá a quién durante un pasaje determinado, o quién será el guía en el pasaje subsiguiente. Este tipo de planificación consciente puede ser provechosa para la coordinación, pero no equivale a la «caza» y cooperación del momento que ocurren necesariamente a lo largo de la interpretación.

La ilusión de sincronía

Cuando se mantiene el tempo con exactitud, se obtiene la coordinación de las notas que produce cada músico en un grupo, pero la realidad de tocar juntos no es tan sencilla. De hecho, ejecutar las notas exactamente al mismo tiempo sobrepasa los límites de la habilidad y la percepción humanas: siempre habrá pequeñas diferencias de tempo —es decir, asincronismo— entre las notas que deben ser ejecutadas simultáneamente [5]. La figura 11.1 ilustra el asincronismo que podría producirse en un trío de cuerda, mostrando que las notas del violín pueden sonar, por término medio, unas fracciones de segundo antes que las del violonchelo y la viola respectivamente. Por tanto, el arte de tocar juntos es crear la *ilusión* de estar perfectamente conjuntados [6].

Hay varios factores que tener en cuenta cuando se intenta lograr la coordinación en un conjunto, especialmente las diferencias físicas entre los instrumentos (incluyendo la voz humana). Los músicos deben ser conscientes del tiempo que necesita cada instrumento para hacer sonar una nota. Por

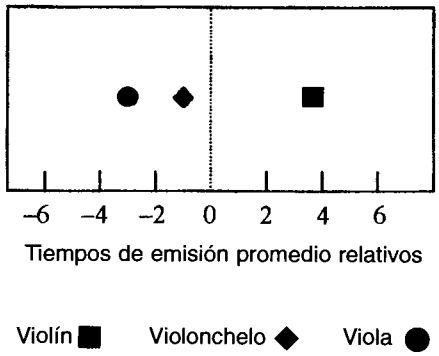

FIGURA 11.1 *Ejemplo hipotético de los tiempos de emisión promedio, en milisegundos, de un trío de cuerda (adaptado de Rudolf A. Rasch, «Timing and synchronisation in ensemble performance»); nótese que el violín es el primero, le sigue el violonchelo y por último la viola.*

ejemplo, un instrumento de viento suena antes que uno de cuerda porque su *tiempo de subida* —el tiempo que transcurre entre la ejecución de una nota y su percepción auditiva— es más breve.

El reto que deben afrontar los intérpretes de grupo es controlar la percepción de las notas de cada instrumento y cada músico, particularmente cuando se utilizan diversas combinaciones de instrumentos. Además pueden surgir problemas cuando los intérpretes están colocados a diferentes distancias del público: el director de orquesta, por ejemplo, debe considerar el tiempo que tarda el sonido que producen los músicos al fondo del escenario en ser percibido por el público.

La velocidad de la música también influye en la coordinación de un conjunto: las pruebas demuestran que es más difícil sincronizar las notas en los tempos lentos, ya que los músicos necesitan subdividir el pulso básico[7]. Además, los pasajes que contienen cambios de tempo y las entradas después de una pausa o silencio son más difíciles de coordinar. En estas últimas, la ausencia de sonido durante un silencio implica que los intérpretes dependen de la comunicación visual —así como del «reloj» del grupo— para ayudar a coordinar una entrada.

Comunicación: señales auditivas y visuales

La información comunicada entre los intérpretes de un conjunto es principalmente auditiva y visual: constantemente se transmiten señales mediante

sonidos, contactos visuales, gestos y movimientos del cuerpo. Los intérpretes de cámara se observan y escuchan unos a otros no sólo para coordinar las acciones, sino también para comunicar ideas sobre la expresión o la interpretación de la música. Sin embargo, la comunicación auditiva (poder oírse unos a otros) es más importante que la visual (poder verse unos a otros). La explicación más sencilla es que oímos la música —no la vemos [8]. Las siguientes secciones se centrarán respectivamente en esos dos aspectos de la comunicación, considerándolos hasta la planificación de señales auditivas y visuales.

Comunicación auditiva

Los intérpretes de cámara necesitan oírse unos a otros para lograr la coordinación, es decir, para asegurar que las partes individuales suenen juntas en los sitios correctos. En un nivel más importante, sin embargo, cada intérprete escucha continuamente los matices expresivos de sus compañeros, como las fluctuaciones de tempo, las gradaciones dinámicas y los cambios en la articulación, el timbre y la entonación. En efecto, la concentración de cada músico está repartida entre controlar su propio sonido y atender al sonido que producen los demás intérpretes del grupo. Por consiguiente, realizan pequeños ajustes, consciente o inconscientemente, en el equilibrio y la calidad del sonido del grupo a lo largo de la interpretación.

Independientemente del tamaño del grupo, todos los matices que emergen de las partes individuales influyen en la expresión de la música. Las dos técnicas mencionadas anteriormente —la anticipación y la reacción— entran en juego cuando los intérpretes intentan predecir y responder a las señales que transmiten sus compañeros. Al mismo tiempo, también contribuyen al sonido produciendo sus propias señales. Por ejemplo, si un intérprete de un grupo pequeño comienza un *crescendo*, los demás músicos pueden ajustar la intensidad de sus respectivos sonidos aumentando correspondientemente su nivel dinámico o tal vez disminuyéndolo para que el *crescendo* individual predomine en el sonido general. Además, los intérpretes pueden predecir las acciones físicas entre ellos basándose en un conocimiento auditivo; por ejemplo, si en un quinteto de viento la intensidad del tono de un oboísta comienza a decaer, los compañeros pueden acelerar el tempo hacia el final de la frase para evitar que el oboísta se quede sin aliento. De igual manera, el grupo puede reaccionar ante los cambios de sonido compensando sus acciones entre ellos: en el caso del oboísta, los compañeros pueden aumentar sus niveles dinámicos para mantener la intensidad del sonido general o disminuirlos para asegurar que la parte de oboe se proyecte por encima del grupo.

Algunos matices expresivos se pueden planificar en los ensayos, de modo que los intérpretes puedan al menos comprender (si no responder a) las intenciones de cada uno, aunque, paradójicamente, algunos intérpretes ven con recelo la planificación metódica de los matices expresivos [9]. Además, las investigaciones han demostrado que la práctica prolongada puede reducir la habilidad para controlar la expresión del sonido durante la interpretación, ya que las ideas se vuelven fijas y más difíciles de adaptar. Caroline Palmer afirma que «el control de las características expresivas de una pieza determinada será mayor si no se ha practicado prolongadamente [...] La práctica prolongada de una interpretación concreta puede hacer que los gestos expresivos sean más difíciles de reprimir [10].

Este asunto tiene consecuencias trascendentales para los intérpretes de grupo, porque sugiere que cada uno debe ser cauteloso en cuanto al tiempo que dedica a sus prácticas individuales para una interpretación en conjunto. Después de la práctica individual, al intérprete le puede resultar más difícil «reprimir» sus propias ideas expresivas para mezclarse con el sonido general. Esta observación contradice las creencias valoradas por algunos intérpretes de grupo, como por ejemplo Abram Loft, quien recomienda: «desarrolla cuanto puedas tu propia idea de la pieza y su mundo particular [...] después evalúa y modifica esa concepción desde la perspectiva de las opiniones expresadas por otros músicos» [11]. Al contrario, William Pleeth aconseja a sus lectores que practiquen «con todo el lienzo a la vista» y que desarrollen el sonido «teniendo en mente el concepto total» [12].

De igual manera, las estrategias desarrolladas en los ensayos de grupo pueden ser más difíciles de ajustar si los músicos no son capaces de desviarse de sus planes. Algunos intérpretes, como los pianistas acompañantes experimentados, muestran una extraordinaria flexibilidad en el trabajo colectivo y pueden (con bastante razón) rechazar la paradoja anterior: ellos son capaces de adaptar rápidamente y sin ningún problema sus propias intenciones expresivas para acomodarlas o combinarlas con otra parte después de haber practicado poco o mucho.

Comunicación visual

Los intérpretes también pueden comunicar ideas entre ellos sobre la expresión utilizando el lenguaje corporal, es decir, por el medio visual. Jane Davidson advierte que «las expresiones físicas de carácter musical proporcionan un medio para comprender y compartir las intenciones musicales» [13]. Por ejemplo, los intérpretes de un cuarteto de cuerda no se moverán exageradamente durante un pasaje calmado y lento; mantendrán, en cambio, una postura fija o, como mucho, un suave balanceo del torso superior.

La coordinación del sonido se puede mejorar planificando señales visuales —por ejemplo, determinando quién da la entrada al comienzo de la pieza o quiénes establecerán un contacto visual después de una pausa prolongada. Como he sugerido antes, sin embargo, tales coreografías pueden menoscabar la espontaneidad de la interpretación. Curiosamente, los miembros del Cuarteto Guarnieri afirman que captan mutuamente sus movimientos físicos en un nivel inconsciente durante un período, de tal manera que apenas son conscientes de las señales visuales transmitidas durante la interpretación: «Cada uno de nosotros tiene un determinado lenguaje corporal cuando toca. Llegas a conocer los de tus colegas y reaccionas adecuadamente. Con los años, gran parte de ello llega a ser intuitivo» [14]. En ese sentido, nos recuerdan que los intérpretes de cámara no tienen necesariamente que mirarse directamente unos a otros, ya que la visión periférica siempre está funcionando.

Como he señalado antes, los intérpretes de grupo se fían mucho más de la comunicación auditiva (la información que sus compañeros expresan en sonido) que de la comunicación visual para hacer música juntos. Sin embargo, las investigaciones revelan que la retroalimentación visual «contribuye significativamente a la precisión y la libertad expresiva de las interpretaciones colectivas» [15]. Los directores, cuya forma de comunicación es puramente visual, pueden ayudar a mejorar la coordinación del tempo en la interpretación colectiva. Los intérpretes de orquesta observan constantemente la batuta del director para aprender a anticipar y responder. Para un director, sin embargo, las señales visuales son transmitidas sólo parcialmente por la batuta. El movimiento de la batuta de Simon Rattle, por ejemplo, está incorporado dentro de su movimiento corporal general —que incluye gestos aparentemente caprichosos, cambios de postura y diversas expresiones faciales— que transmite información sobre el talante y el carácter de la música. En efecto, el director comunica mucho más que un simple pulso, ya que los miembros de la orquesta pueden percibir señales visuales sobre la expresión a través del lenguaje corporal del director, de la misma manera en que los intérpretes de un cuarteto de cuerda pueden proyectar ideas interpretativas observando los movimientos físicos entre ellos.

El papel del individuo

Un intérprete de una agrupación musical desempeña un papel similar al de un actor en una obra de teatro. El actor desarrolla su personaje por su cuenta, pero ese personaje cambia cuando entra en contacto con los demás personajes de la obra, especialmente porque es entonces cuando se establece el ritmo y la expresión de cada parte. Igual que los actores, los músicos de un

conjunto moldean y ajustan sus partes para encajarlas entre sí. Sin embargo, el actor siempre tiene presente a su propio personaje, de modo que la obra se define simultáneamente por cada actor como por la combinación de todos los actores. Lo mismo ocurre con la música de conjunto, ya que cada músico imprime su propio sello al grupo, pero también intenta fusionarse con él. Esta relación entre el individuo y el grupo será analizada a continuación.

En 1996, Mitch Waterman investigó las reacciones emocionales de los intérpretes. Pidió a los músicos de un dúo de piano y un dúo de piano y violonchelo que comentaran, después de una interpretación, sus sentimientos según los momentos en que consideraban que «la música despertaba algo» [16]. Waterman observó que cada intérprete tenía respuestas emocionales diferentes ante la música, por lo que concluyó que «los intérpretes no coinciden en sus opiniones sobre los momentos emotivos dentro de una interpretación conjunta» [17]. Esto sugiere que los individuos no necesariamente experimentan lo mismo cuando tocan juntos, ni comparten ideas sobre una interpretación, sino que mantienen identidades bastante independientes.

Existen muchos tópicos en torno a la noción de conjunto musical que menoscaban el papel del individuo: por ejemplo, la agrupación ideal se ha descrito como «un organismo musical integrado que refleja la perspicacia colectiva de todos sus miembros» [18]. En realidad, un conjunto es mucho más complejo, y ciertamente menos «integrado», de lo que sugiere esa descripción, ya que está relacionado tanto con los caracteres individuales como con la combinación de éstos. Entonces, ¿qué sucede con el individuo cuando toca en un grupo?

El siguiente análisis se centra en el caso de una pianista profesional que interpreta el tercer movimiento (Largo) de la Sonata para violonchelo en Sol menor, op. 65, de Chopin. En esta investigación comparé determinadas características expresivas —tempo y dinámica— de dos interpretaciones previas a un ensayo del dúo: la primera fue individual de la pianista, es decir, que interpretó su parte en un contexto solista, y la segunda fue con el violonchelista, o sea, en un contexto de grupo. La pianista preparó su parte sin realizar consultas con el violonchelista, de modo que la interpretación a dúo representó la primera ocasión en que los dos intérpretes se reunieron y tocaron la obra juntos. Por tanto, los datos obtenidos reflejan la manera en que cambió la realización «a solo» de la pianista cuando tocó con el violonchelista.

La figura 11.2 muestra, compás por compás, las fluctuaciones de tempo de ambas interpretaciones [19]. En primer lugar, es evidente que el tempo general de la interpretación a dúo fue más lento que el de la interpretación a solo de la pianista (lo cual se puede ver en el gráfico porque el perfil de tempo de la interpretación a dúo se encuentra por debajo del perfil de tempo de la interpretación a solo). Esto demuestra que la interpretación de la pianista se

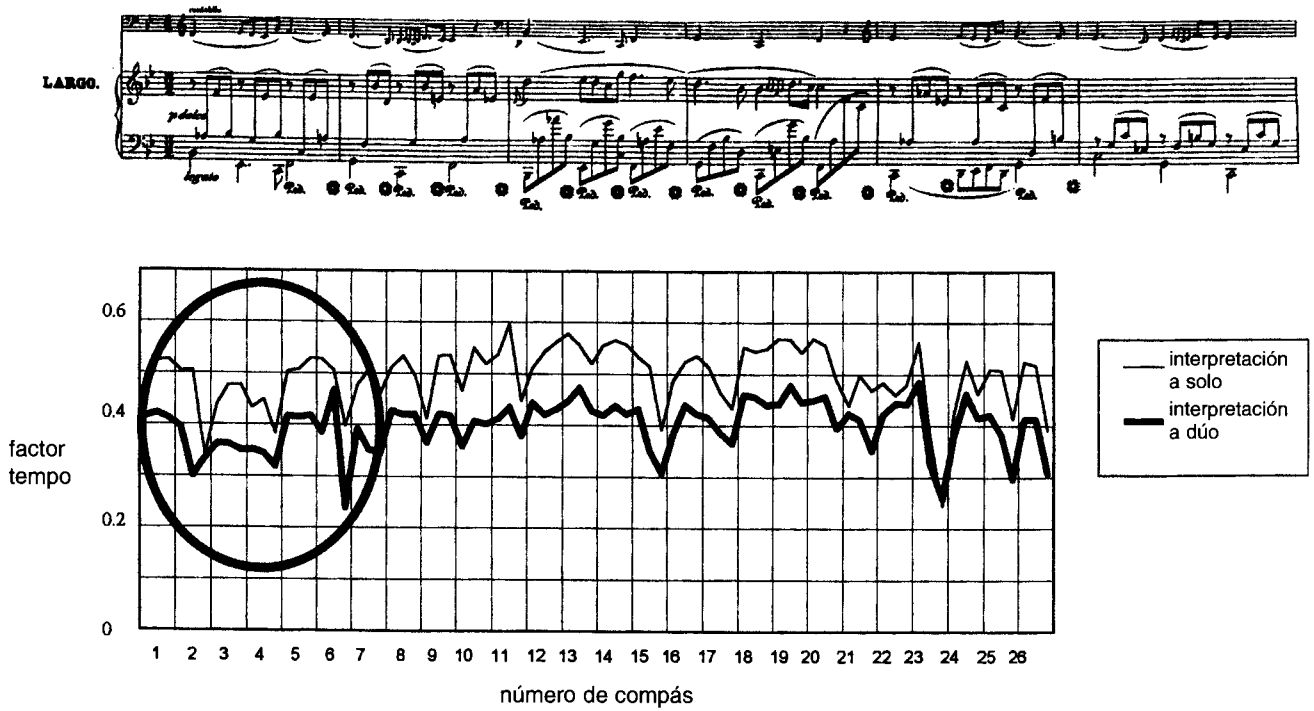

FIGURA 11.2 *Perfiles de las fluctuaciones de tempo de las interpretaciones a solo y a dúo de la Sonata para violonchelo op. 65 de Chopin, tercer movimiento, compases 1-26; se anexa un fragmento de la partitura (compases 1-6 de la primera edición alemana; Leipzig, Breitkopf & Härtel, 1846) para facilitar las referencias que se hacen en el análisis a los compases agrupados dentro del círculo.*

vio afectada inmediatamente al tocar con el violonchelista, ya que tuvo que negociar su tempo para ajustarlo al del violonchelista. Sin embargo, los puntos más altos y más bajos de ambos perfiles son muy similares, lo cual sugiere que parte de las tendencias «a solo» de la pianista fueron mantenidas en el dúo. Los niveles de *rubato*, sin embargo, fueron diferentes en las dos interpretaciones: en general, hubo más *rubato* en la interpretación a solo de la pianista que en la interpretación conjunta (compárense, por ejemplo, la medida de las fluctuaciones en los compases 7-11 y la proporción de *ritardando* al final de los compases 15 y 23). Parece ser, por tanto, que el *rubato* de la pianista disminuyó en la interpretación a dúo.

Los primeros seis compases merecen especial atención (véase el fragmento de la partitura y los compases del gráfico marcados con el círculo en la figura 11.2), ya que en ellos las fluctuaciones de tempo de la pianista difieren notablemente en las dos interpretaciones. (Esto refleja lo que ocurrió durante los primeros momentos de su interpretación conjunta.) En su interpretación a solo, la pianista redujo la velocidad al final del compás 2, mientras que en la interpretación a dúo el tempo disminuyó durante los compases 1 y 2, particularmente hacia la mitad del segundo compás (el punto en el que el violonchelista ejecuta un grupeto en la línea melódica). La ralentización en la interpretación a dúo alude a la manera en que la pianista adoptó gradualmente el tempo general del violonchelista, y acomodó la ornamentación de la línea melódica de éste. Además, la pianista cambió su realización de la segunda frase (compases 3-4) en la interpretación a dúo, ya que el tempo aumentó justo antes de la frase en los compases 2-3, pero después se mantuvo relativamente estable. En efecto, en cuanto la pianista tocó con el violonchelista, ajustó su interpretación para encajarla con la otra parte, por lo que las fluctuaciones de tempo fueron diferentes en los dos contextos.

La figura 11.3 muestra, compás por compás, las fluctuaciones dinámicas de la pianista en las mismas interpretaciones, a solo y a dúo [20].

Mientras que los puntos más altos y más bajos de los dos perfiles coinciden generalmente, es evidente que la pianista tendía a tocar un poco más suave en el dúo (compárense, por ejemplo, los niveles dinámicos de los compases 1-6 y 10-15). Por lo tanto, en este caso también se observa cierto constreñimiento en la interpretación a dúo de la pianista, aunque dentro de la misma gama dinámica general.

El pasaje de los compases 21-23 (véanse los compases dentro del círculo en la figura 11.3) es particularmente interesante porque la pianista tocó más fuerte en su interpretación con el violonchelista que en su interpretación a solo. Este pasaje constituye el clímax principal del movimiento y está marcado por un cambio de textura (como puede verse en el fragmento de la partitura): el movimiento en corcheas en la parte de piano cesa en el compás 21 y

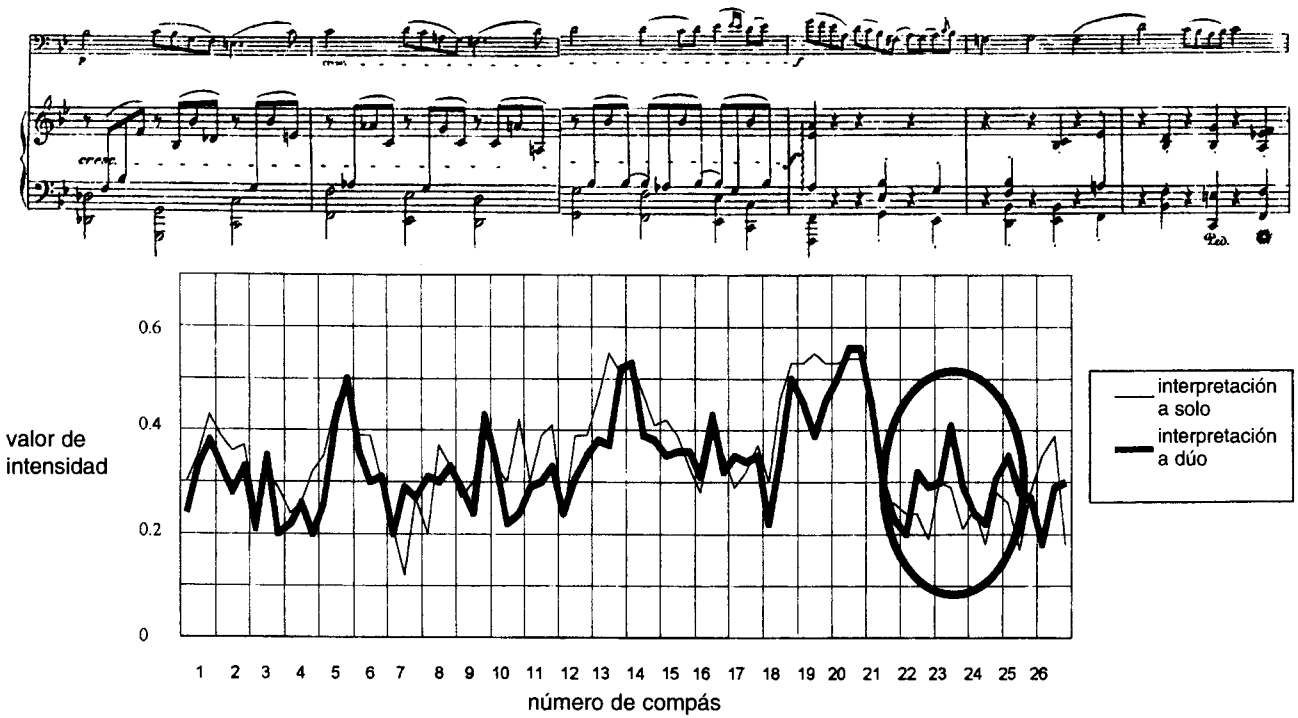

FIGURA 11.3 *Perfiles de las fluctuaciones dinámicas de las interpretaciones a solo y a dúo de la Sonata para violonchelo op. 65 de Chopin, tercer movimiento, compases 1-26; se anexa un fragmento de la partitura (compases 18-23 de la primera edición alemana; Leipzig, Breitkopf & Härtel, 1846) para facilitar las referencias que se hacen en el análisis a los compases agrupados dentro del círculo.*

es reemplazado por acordes en tiempos débiles por debajo de una declamación en estilo recitativo del violonchelo (la indicación dinámica es *forte* en ambas partes). Curiosamente, en su interpretación a solo, la pianista respondió al cambio de textura tocando relativamente suave en los compases 21-23, pasando por alto, aparentemente, la indicación *forte* de la partitura. En cambio, su dinámica en la interpretación a dúo aumentó en los compases 22-23. En dichos compases cambió rápidamente su enfoque anterior produciendo gradualmente un sonido más fuerte, dándole así un mayor apoyo al violonchelista (esto es un ejemplo de la importancia de la comunicación auditiva, ya que la pianista respondió indudablemente a las señales dinámicas del violonchelista). Curiosamente, la pianista comentó posteriormente en un ensayo que su parte estaba marcada *forte*.

La realización individual de la música puede verse afectada de diferentes maneras por la interacción con otros intérpretes: las características expresivas pueden moderarse o intensificarse (i.e. exagerarse) o simplemente mantenerse en un mismo nivel. Al mismo tiempo, cada intérprete puede mantener los patrones de expresión. En el ejemplo anterior, los aspectos expresivos de la interpretación a solo de la pianista fueron moderados en el contexto de la interpretación conjunta, y aunque algunas fluctuaciones de tempo o dinámica cambiaron, otras se mantuvieron iguales. Esto sugiere que los músicos no necesariamente renuncian a sus propias ideas cuando tocan en un grupo: el papel del individuo es el de negociar, o dar y recibir [21].

Factores sociales: permanecer juntos

> Una agrupación musical es [...] un tipo inusual de grupo social cuyas interacciones implican un nivel de intimidad y sutileza que posiblemente no sea igualado por ningún otro tipo de grupo [22].

La interpretación en grupo es un trabajo colectivo: la mitad de la batalla de hacer música juntos (y de permanecer juntos como grupo) se libra en el terreno social. El asunto más importante es el liderazgo, ya que todo grupo necesita al menos un líder. Algunos son designados (como los directores de orquesta), mientras que otros surgen sin haber sido elegidos como tales (por ejemplo, un miembro dominante de un cuarteto de cuerda). Los factores que influyen en la elección del líder de un grupo incluyen las personalidades de los intérpretes, la música y los estereotipos sociales.

Una persona dominante puede guiar a un grupo dirigiendo el curso de un ensayo y dictando los aspectos interpretativos de una actuación. La manera en que está compuesta la música también puede repercutir en la relación

entre los intérpretes [23] (de modo que el compositor ejerce cierta influencia en las interacciones entre los músicos). Además, los intérpretes que son conscientes de los estereotipos sociales asociados a determinados grupos de instrumentistas (como el papel supuestamente inferior del segundo violín en un cuarteto, o del subordinado pianista «acompañante») pueden ser influidos por ellos, consciente o inconscientemente.

El estilo de liderazgo generado en un grupo determinará su ambiente social. Por una parte, los miembros de un cuarteto de cuerda pueden intentar trabajar juntos democráticamente, y así probablemente asegurarán que «los miembros del grupo realizarán gustosamente una parte razonable del trabajo, no sólo durante los ensayos y conciertos (cuando el líder está presente), sino también cuando practican sus partes en casa» [24]. Por otra parte, el director de orquesta puede esforzarse por lograr un enfoque menos dictatorial delegando gradualmente el control «por el bien del esfuerzo colectivo» [25].

Aunque el papel del líder es vital al determinar la dinámica de grupo dentro de un conjunto, la interacción entre los cointérpretes también es importante. Huelga decir que una retroalimentación positiva entre los músicos inspirará un elevado nivel de confianza y ayudará al grupo a tocar bien juntos. La interacción social entre los intérpretes es como un «proceso de desarrollo constante» [26], que puede realizarse de la manera más eficaz durante los ensayos, cuando los músicos negocian sus ideas, tratan los conflictos e intentan llegar a un acuerdo.

Un grupo florecerá mientras «cada individuo sienta que está contribuyendo a su máxima capacidad artística y al mismo tiempo colaborando con sus colegas para producir algo más hermoso de lo que se puede producir individualmente» [27]. En los deportes de equipo se hace hincapié en la «sinergia» (el potencial del grupo, que es mayor que la suma de los potenciales individuales) y la «confluencia» (la sensación de pertenecer a un equipo). Los músicos también pueden intentar generar el mismo espíritu cuando tocan juntos [28].

Por último, ¿por qué algunos grupos permanecen juntos durante más tiempo que otros? Aparte de las razones prácticas (como que un miembro del grupo se mude a otro sitio), los grupos exitosos intentan reconocer la influencia de los estereotipos sociales y las paradojas del liderazgo y la democracia, así como la necesidad de confrontación y compromiso [29]. Aunque es imposible predecir si los miembros de un grupo serán compatibles, y por tanto tampoco la perdurabilidad de éste, está claro que las relaciones entre ellos se desarrollarán y cambiarán continuamente. Después de todo, los intérpretes de cámara profesionales no sólo hacen música juntos, también pasan mucho tiempo juntos, por ejemplo, viajando. Las relaciones sociales y musicales se deben cultivar, y sin duda las incompatibilidades de carácter pueden surgir con el tiempo.

Conclusión

En resumen, en este capítulo hemos analizado cuatro aspectos de la interpretación en grupo: la coordinación (mantener el tempo), la comunicación (auditiva y visual), el papel del individuo y los factores sociales. Ahora podemos percatarnos de las exigencias que plantea la interpretación en grupo y apreciar la verdadera proeza que implica dicha actividad. En efecto, el intérprete de un grupo exhibe diversas habilidades musicales y sociales. Para lograr la coordinación del tempo los cointérpretes anticipan las acciones de los demás y responden a ellas siguiendo a un colega o cooperando con él. Al mismo tiempo, comunican sus ideas expresivas mediante señales auditivas o visuales, de modo que los intérpretes se observan y escuchan unos a otros mientras transmiten y evalúan constantemente las señales musicales. El intérprete de grupo exhibe tendencias individuales, a solo, en la interpretación, y al mismo tiempo intenta fusionarse con el resto del grupo. Las relaciones sociales y musicales entre los cointérpretes están en constante desarrollo, de modo que cada grupo genera continuamente un nuevo espíritu, que tal vez sea la razón por la que la interpretación en grupo puede ser tan refrescante y excitante.

12 *El miedo escénico*

ELIZABETH VALENTINE

El análisis del miedo escénico

La ansiedad de actuación, conocida generalmente como «miedo escénico», es un problema muy antiguo, pero el interés por su naturaleza, sus causas y sus tratamientos se ha intensificado durante los últimos quince años, en los que han surgido un número creciente de clínicas, conferencias y revistas dedicadas a la medicina de las artes escénicas. La ansiedad de actuación musical se ha definido como «la persistente y angustiosa aprensión en torno a las habilidades interpretativas, y/o su deterioro real, en un contexto público, hasta un nivel injustificado dadas la aptitud, adiestramiento y nivel de preparación musicales del individuo» [1]. Entre los músicos famosos que lo han padecido se encuentran Maria Callas, Enrico Caruso, Pau Casals, Leopold Godowski, Vladimir Horowitz, Ignacy Paderewski y Sergei Rachmaninoff. Varias encuestas han revelado que el miedo escénico constituye un problema grave para un porcentaje sustancial de músicos. En un estudio a gran escala sobre orquestas estadounidenses [2], el miedo escénico fue el problema interpretativo que se refirió con mayor frecuencia, el 24 por ciento de los músicos afirmó que lo padecía, y el 15 por ciento consideró que era un problema grave. El miedo escénico disminuye con la edad y la experiencia [3], aunque no se sabe si es por los efectos beneficiosos de las frecuentes presentaciones en público o por la «supervivencia del más apto».

Los síntomas del miedo escénico son conocidos, y se clasifican en tres tipos: fisiológicos, conductuales y psíquicos. Los *síntomas fisiológicos* son el resultado de una sobreexcitación del sistema nervioso autónomo e incluyen un

aumento del ritmo cardíaco, palpitaciones, falta de aliento, hiperventilación, sequedad de la boca, sudoración, náuseas, diarrea y mareos. Esta reacción de «huir o pelear», que ayudaba a nuestros antepasados cazadores a huir de las fieras, es sumamente perjudicial para los músicos, que necesitan destreza y un control muscular minucioso. Los temblores en las extremidades y las manos sudorosas no ayudan al intérprete. Además, esa excitación autónoma puede estar asociada al temor como resultado de una experiencia pasada. El aumento de la excitación generalmente conduce a una disminución de la atención, que también puede ser perniciosa. Los *síntomas conductuales* del miedo escénico pueden manifestarse como síntomas de ansiedad, como temblores, rigidez muscular o inexpresividad, o deteriorar la interpretación misma. Los *síntomas psíquicos* son una sensación subjetiva de ansiedad y pensamientos negativos sobre la actuación. Más que miedo a la interpretación *per se*, es un miedo a la interpretación en público, con el riesgo de una evaluación negativa y la consecuente pérdida de autoestima. Ese miedo puede ser producto de una identificación demasiado rigurosa de la autoestima con la perfección interpretativa, incluso la creencia de que la autoestima depende del éxito. Los pensamientos negativos influyen perjudicialmente en la calidad de la interpretación. La preocupación conduce a una falta de concentración, lo que dispersa la atención y provoca un desperdicio de recursos valiosos, y probablemente también actúa como una señal que incrementa aún más la ansiedad.

Una variante del pensamiento negativo es el «catastrofismo», la exageración irracional de la posibilidad de un fracaso —por ejemplo, «estoy casi seguro de que voy a cometer un error terrible que arruinará todo». Esta variante tiende a estar relacionada con niveles elevados de ansiedad de actuación en profesionales, estudiantes y aficionados, mientras que la valoración realista —reconocer la inevitabilidad de los errores, la naturaleza generalmente tolerante del público y la necesidad de concentrarse en los aspectos técnicos e interpretativos de la música— está relacionada con niveles moderados de miedo escénico [4].

Otra variante es la estrategia del «autoimpedimento» [5], que consiste en que el intérprete promueve determinadas situaciones que servirán para excusar una mala interpretación, como, por ejemplo, no practicar, trasnochar la noche anterior, dañar el material de trabajo, etc. Estos actos pueden convertirse en profecías que se autorrealizan e incluyen el riesgo de sabotear realmente la interpretación. Su propósito es el de atribuir la mala interpretación a factores externos y reivindicar un mérito adicional en el caso de que se produzca una interpretación buena, que habrá ocurrido a pesar de las circunstancias adversas. Sin embargo, estas estrategias son esencialmente destructivas, ya que evaden la situación, lo cual suele empeorar las cosas. Pueden

surgir cuando existe una preocupación exagerada por la capacidad, quizá como condicionante del amor de los padres, o cuando el intérprete percibe que su capacidad es frágil, tal vez porque no puede mantener un nivel de interpretación alcanzado anteriormente.

Una descripción exhaustiva del miedo escénico ha de incluir, por lo tanto, factores fisiológicos (como el pulso y la tensión arterial), medidas de la conducta (ansiedad, calidad de la interpretación) y autoinformes (de los pensamientos y sentimientos). Las reacciones de estos tres sistemas no están necesariamente correlacionadas [6]. En particular, es común tener solamente los síntomas fisiológicos. La correlación es más probable en los estados de elevada ansiedad. Craske y Craig [7] descubrieron que los pianistas relativamente ansiosos mostraron ansiedad en los tres sistemas al interpretar en una situación de tensión ante un público, mientras que los pianistas relativamente no ansiosos sólo mostraron los síntomas fisiológicos. Ello también plantea la pregunta de si el tratamiento debe ajustarse a los síntomas, por ejemplo, la prescripción de fármacos para los síntomas fisiológicos y de tratamiento psicológico para los síntomas psíquicos. Las pruebas no son concluyentes en este sentido.

Varios estudios de encuestas han identificado diferentes componentes de la ansiedad de actuación musical, algunos de los cuales pueden ser positivos. Una encuesta realizada a unos 200 músicos, principalmente profesionales, identificó cuatro factores: nerviosismo/aprensión, seguridad/capacidad, cohibición/distracción, y un factor excitación/intensidad [8]. Un grupo cuantitativamente similar pero más diverso distinguió cinco componentes independientes: preocupación sobre la ansiedad y sus efectos; miedo a la evaluación, es decir, preocupación por las reacciones de los demás ante la interpretación; actitudes críticas en relación a las habilidades interpretativas; distracción y problemas de memoria, y el desarrollo deliberado de técnicas para hacer frente a la ansiedad. De todos ellos, el primero es el que está más estrechamente relacionado con la ansiedad que desmejora la actuación, pero todos excepto el último tienen consecuencias negativas en ella [9].

Es importante distinguir las ansiedades beneficiosas de las perjudiciales —o, para ser más precisos, entre las ansiedades reactiva, maladaptativa y adaptativa. La ansiedad reactiva, que resulta de una preparación inadecuada, es realista, y la mejor manera de tratarla es con el análisis musical y el ensayo. La ansiedad es considerada generalmente como perjudicial, pero todo intérprete sabe que cierto nivel de excitación es beneficioso para la actuación. Generalmente, la mejor ejecución es la que se realiza con un nivel moderado de excitación: si el nivel es demasiado bajo, la interpretación será floja y aburrida; si el demasiado elevado, el intérprete y la interpretación se pueden desmoronar por completo. Esto se puede representar como una U invertida (trazando la calidad de la interpretación como una función de excitación), y

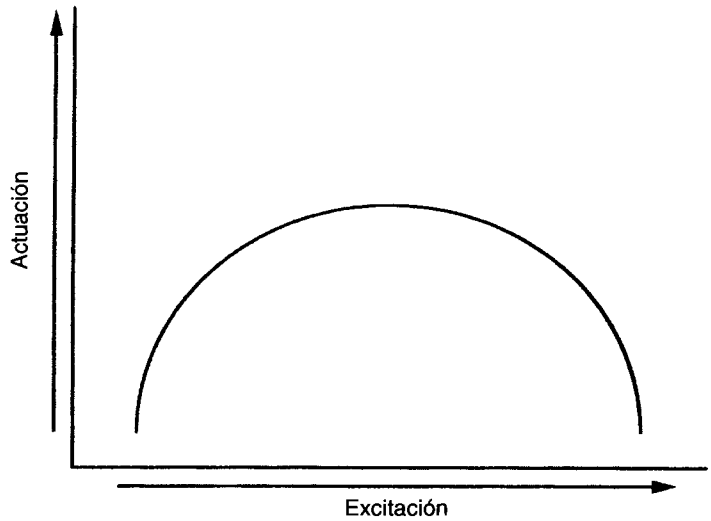

FIGURA 12.1 *La ley de Yerkes-Dodson, que muestra la relación hipotética entre la excitación y la calidad de la actuación.*

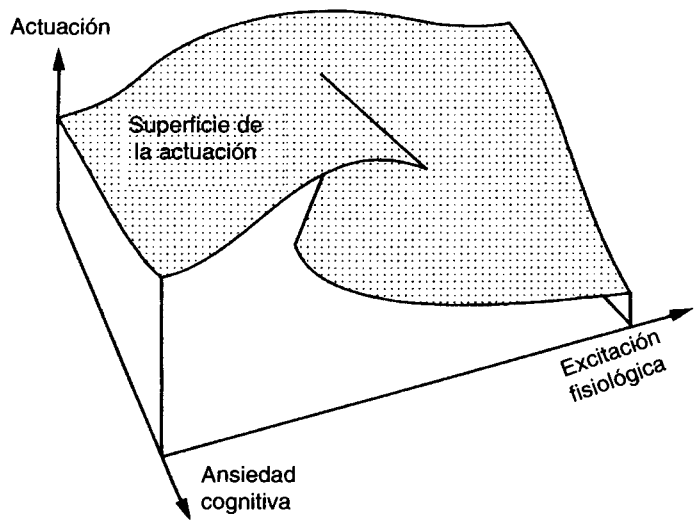

FIGURA 12.2 *Modelo de catástrofe de la relación entre la ansiedad y la actuación (© 1996 John Wiley & Sons Limited; reproducido con autorización de Lew Hardy, Graham Jones y Daniel Gould,* Understanding Psychological Preparation for Sport: Theory and Practice of Elite Performers, *Chichester, John Wiley & Sons Limited, 1996, p. 151).*

se conoce como la ley de Yerkes-Dodson (véase la Figura 12.1) [10]. Steptoe [11] confirmó la aplicación de este patrón a los alumnos de canto y cantantes profesionales, a los que pidió que evaluaran su tensión emocional y la calidad de su interpretación en diferentes situaciones. Ambos grupos consideraron que la calidad de la interpretación alcanzaba su punto máximo en el nivel intermedio de tensión emocional, después de lo cual descendía verticalmente. Para los alumnos, el contexto ideal era una clase; para los profesionales (afortunadamente), era una interpretación pública. Fazey y Hardy [12] sostienen que es necesario distinguir el componente psíquico o cognitivo de la ansiedad (el miedo al fracaso y sus consecuencias) del componente corporal o somático (las respuestas fisiológicas ante el estrés). Para ello se necesita un modelo tridimensional de la relación entre la ansiedad y la actuación (véase la Figura 12.2). Prosiguen señalando que cuando la ansiedad cognitiva es baja, la relación entre la tensión y la actuación sigue la ley de Yerkes-Dodson (representada en la parte posterior de la Figura 12.2), pero cuando es alta sigue el modelo de catástrofe: cuando aumenta el estrés, la actuación es propensa a un declive catastrófico, del cual es difícil que se recupere. La razón es que las preocupaciones y cavilaciones conducen a una espiral viciosa de pensamientos negativos, haciendo que el intérprete se «sobrepase» y se venga abajo.

Hardy y Parfitt [13] han proporcionado pruebas de este modelo en estudios sobre atletas. Wilson [14] ha sugerido que puede aplicarse igualmente a la interpretación musical.

Causas

Existen tres factores que contribuyen a la ansiedad de actuación: la persona, la tarea y la situación. Wilson los ha representado en una ampliación tridimensional del modelo de Yerkes-Dodson (véase la Figura 12.3) [15]. Un alto nivel de uno de ellos puede ser compensado con un bajo nivel de otro. Por tanto, a una persona ansiosa por naturaleza le convendría elegir una pieza relativamente fácil o bien ensayada para una ocasión exigente como una audición; a la inversa, los intérpretes experimentados pueden necesitar situaciones más desafiantes que los novatos para dar lo mejor de sí [16].

Las personas difieren considerablemente en cuanto a las reacciones de sus sistemas autonómicos y su sensibilidad tanto a los estímulos internos como a las críticas de los demás. Existen pruebas de que los músicos son más ansiosos que la población general [17] y que los músicos de orquesta pueden ser más susceptibles a la ansiedad que otros artistas escénicos (como cantantes, bailarines y actores) [18]. La ansiedad de actuación musical está relacionada con otras formas de ansiedad, particularmente el neuroticismo y la fobia social [19].

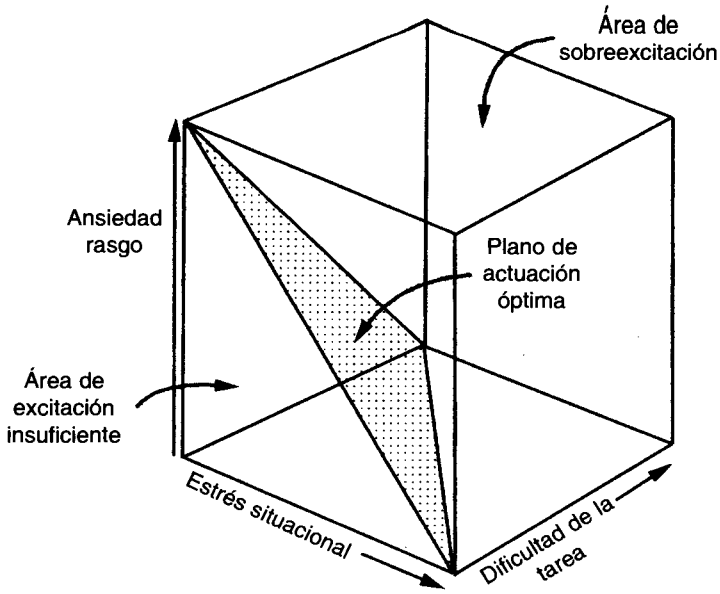

FIGURA 12.3 *Ampliación de Wilson (1994) del modelo de Yerkes-Dodson, ilustrando tres factores que contribuyen a la ansiedad de actuación (reproducido con autorización de Glenn Wilson y Jessica Kingsley; todos los derechos reservados).*

Cuanto más difícil sea la tarea, más ansiedad provocará al intérprete. A medida que aumentan los niveles de habilidad y dominio de la tarea, será necesaria una tarea correspondientemente más difícil para provocar el mismo nivel de ansiedad, como he señalado antes.

Varios estudios han demostrado la influencia del contexto. LeBlanc et al. [20] encontraron que la ansiedad referida por los músicos de banda de institutos de secundaria aumentaba significativamente en el transcurso de tres situaciones interpretativas: tocando solo en una sala de prácticas, tocando en una sala de prácticas en presencia de un investigador y en una sala de prácticas con cuatro investigadores y de quince a diecinueve colegas.

Leglar [21] descubrió que tocar de memoria ante un gran público generalmente produce el efecto más debilitante de la actuación y la máxima respuesta autonómica en los organistas. Abel y Larkin [22] observaron aumentos del pulso, la tensión arterial y la ansiedad autorreferida en un grupo de estudiantes de música que tocó ante un jurado. Curiosamente, los varones mostraron aumentos mayores en la tensión arterial, mientras que las mujeres mostraron

aumentos mayores en la sensación de ansiedad, revelando que existen diferencias de género y que las diferentes manifestaciones de la ansiedad a menudo no se corresponden. Brotons [23] encontró que era indiferente que las audiciones se realizaran abiertamente, es decir, que los intérpretes y el jurado pudieran verse los unos a los otros (como en la mayoría de las audiciones para los cursos de interpretación de las escuelas superiores), o que el intérprete se colocara detrás de una pantalla, de modo que tanto él como el jurado desconocieran sus respectivas identidades (como suelen realizarse las audiciones para un empleo).

Los tres factores que hemos mencionado —la persona, la tarea y la situación— interactúan entre sí: el efecto de uno de ellos depende del nivel de los otros. Un estudio realizado por Cox y Kenardy [24] demuestra la interacción entre las características de la personalidad y la situación. Los intérpretes que tienen fobias sociales se mostraron mucho más ansiosos en un contexto solista que los que no tienen esas fobias, mientras que había menos diferencia entre ellos en las interpretaciones en grupo o los ensayos. La interacción entre la tarea y la situación puede ilustrarse haciendo referencia a un estudio realizado por Hamman y Sobaje [25]. La mejoría de actuación que se observó en una condición de ansiedad elevada (en la que un jurado evaluaba la interpretación) con respecto a una condición de ansiedad reducida (en la que el intérprete se encontraba solo en una habitación con un magnetófono) fue mayor en los intérpretes más experimentados, es decir, aquellos con más años de estudio formal y un nivel de habilidad elevado. La ansiedad facilitó más la actuación para aquellos que poseían un mayor dominio de la tarea.

Tratamientos

Brodsky y Sloboda [26] enumeran los siguientes métodos para afrontar el miedo escénico: las técnicas de Alexander y Feldenkreis, los ejercicios aeróbicos, el entrenamiento en el manejo de la ansiedad, la concentración, el entrenamiento autogénico, la desensibilización sistemática, desarrollar intereses y aficiones fuera de la música, exponerse a situaciones de interpretación, el ensayo mental, la retroalimentación de la tensión muscular y de la temperatura de los dedos, la terapia nutricional, las autoafirmaciones positivas, el rezo, el entrenamiento de la relajación, la autohipnosis, la terapia de inoculación del estrés, el ensayo sistemático y el yoga. Esta lista ofrece una amplia gama de posibilidades, por no decir más. Hanser [27] establece convenientemente una diferencia entre las técnicas «instrumentales», cuyo objetivo es cambiar el entorno del yo, y las medidas paliativas dirigidas a regular las emociones y respuestas ante el estrés.

El 48 por ciento de una muestra de músicos profesionales y aficionados, a quienes se les pidió que describieran métodos eficaces para hacer frente a la ansiedad de actuación, respondió que utilizaba al menos uno. De los 478 métodos sugeridos, dos tercios se centraban en las emociones, por ejemplo: «Intento sentarme tranquilamente y rezo para calmarme antes de cantar»; otro tercio apuntaba a los problemas, por ejemplo, «estar bien preparado —que no haya ninguna dificultad técnica en la música que no esté dominada». Los músicos que utilizaban predominantemente los métodos centrados en las emociones manifestaron sentir más seguridad y capacidad y menos timidez y distracción que los que empleaban predominantemente los métodos enfocados en los problemas. Por otra parte, el grupo que se centraba en los problemas recordó haber tenido menos pensamientos perturbadores durante su interpretación más reciente [28]. Esto confirma la idea de que diferentes métodos pueden tratar distintos aspectos de la ansiedad de actuación.

La siguiente evaluación de la eficacia de los tratamientos para la ansiedad de actuación comenzará con los más físicos y procederá hacia los más psicológicos. Naturalmente, muchas técnicas combinan elementos de ambos enfoques [29].

Técnicas físicas

La *relajación,* inducida mediante la respiración profunda o mediante la técnica de relajación progresiva de Jacobson que tensa y relaja alternadamente los músculos, es la técnica más utilizada [30]. Un estudio demostró que con seis sesiones de entrenamiento de la relajación progresiva se puede reducir el ritmo cardíaco y la ansiedad autorreferida de los instrumentistas ansiosos [31].

El *biofeedback* (retroalimentación) se utiliza a veces para proporcionar información sobre la tensión y para ayudar a entrenar la relajación. Un grupo de violinistas fue entrenado para reducir la tensión excesiva de la mano izquierda, colocándoles electrodos en los músculos de la mano que controlan los movimientos del pulgar. Los electrodos estaban conectados a una máquina que emitía un sonido cuando la tensión superaba un nivel determinado. Dicho nivel fue disminuido sistemáticamente a medida que los intérpretes aprendían a relajarse [32]. Se han utilizado técnicas similares para reducir la tensión en los antebrazos de violinistas y clarinetistas, los músculos laríngeos de cantantes y los músculos faciales de ejecutantes de instrumentos de viento. Una desventaja del *biofeedback* es que los intérpretes no pueden llevar el aparato consigo en los conciertos.

El 22 por ciento de una muestra de músicos de orquesta londinenses afirmó que tomaba *alcohol,* y el 12 por ciento *sedantes,* para hacer frente al mie-

do escénico. Es probable que estas cifras subestimen el consumo real, aunque otros estudios [33] han reportado un consumo mínimo. El problema de estos sedantes generales es que disminuyen las funciones y el juicio, por lo que el ejecutante puede creer que su interpretación es mejor de lo que realmente es; además, pueden tener efectos secundarios negativos, creando adicción si se toman habitualmente en dosis elevadas y produciendo un deterioro general de la salud. Los sedantes pueden parecer beneficiosos a corto plazo, pero impiden el desarrollo de métodos más adecuados para combatir la ansiedad a largo plazo [34].

Sin embargo, los *betabloqueadores* (bloqueadores de los betaadrenoceptores), que actúan sobre el sistema nervioso periférico sin producir efectos pronunciados en el sistema nervioso central, han despertado mucho interés. Una encuesta estadounidense a gran escala reveló que más del 20 por ciento de los ejecutantes profesionales toman estos fármacos, en muchos casos sin supervisión médica [35]. Muchos músicos han recurrido al betabloqueador conocido como Inderal (propanolol). Una encuesta europea indicó que el 15 por ciento de los músicos de orquesta lo utilizan ocasionalmente. Varios estudios cuidadosamente controlados [36] han demostrado la eficacia de los beta-bloqueadores para aliviar los síntomas fisiológicos (aumento del pulso y la tensión arterial), los síntomas conductuales (temblores) y la ansiedad autorreferida, además de mejorar la calidad de la actuación. El beneficio más notable que se ha observado es la reducción de temblores en ejecutantes de cuerdas, lo que mejora la uniformidad del vibrato y los trinos rápidos [37]. Sin embargo, también se ha reportado un deterioro del control rítmico y una dinámica más monótona [38], sensación de inseguridad, fallos en la memoria y falta de concentración [39]. Es importante recalcar que estos medicamentos pueden producir efectos secundarios perjudiciales y por tanto sólo han de tomarse bajo supervisión médica. La opinión general es que sólo son adecuados para ser utilizados ocasionalmente.

Técnicas físicas y mentales

Muchas de las técnicas que se pueden emplear para combatir la ansiedad de actuación *combinan la relajación física con la agudeza mental,* especialmente las que provienen de Oriente, como el yoga y el tai chi, o la concentración sin esfuerzo del «Inner Game» [40]. Una terapia que incluía sugestiones hipnóticas para la relajación, control de la respiración, imágenes visuales y sugestiones verbales que relacionaban las imágenes con un mayor control mental disminuyó la ansiedad de actuación en estudiantes de conservatorio con miedo escénico inmediatamente después del tratamiento y en un tratamiento

complementario después de seis meses, mientras que las sesiones de conversación no dieron resultado [41].

La *técnica de Alexander* es empleada por muchos músicos y otros profesionales para mantener un adecuado equilibrio entre distintas partes del cuerpo y reducir las tensiones innecesarias. Un estudio [42] demostró que era tan eficaz como los betabloqueadores, y preferible a éstos, para reducir la tensión arterial de los músicos de orquesta antes de la interpretación. En otro estudio [43], los estudiantes de música que habían seguido un curso de la técnica de Alexander mostraron progresos, en comparación con aquellos que no lo habían seguido, en cuanto a la calidad musical y técnica en general, las variaciones del ritmo cardíaco, la ansiedad autorreferida y la actitud positiva hacia la interpretación. Sin embargo, esos efectos positivos estaban limitados al contexto de un salón de clases, relativamente menos estresante, y no se extendieron a la situación de estrés elevado de un recital. Dichos efectos tampoco se relacionaron con progresos en cuanto a la «utilización» del cuerpo según expertos en la técnica de Alexander; por tanto, su ubicación sigue siendo dudosa. Sin embargo, todos los estudiantes que tomaron el curso manifestaron haber mejorado su conciencia de la tensión y su habilidad para relajarse, y la mayoría afirmó que lo recomendaría a otros.

Técnicas psicológicas

La terapia de la conducta está basada en principios tomados de la psicología del aprendizaje. En la *desensibilización sistemática* se le enseña al individuo a mantener un estado calmado y relajado durante una exposición progresiva a un estímulo que produce temor, puesto que la relajación es incompatible con el temor. Muchos estudios han demostrado, mediante mediciones fisiológicas, de actuación y autorreferencia, que es un tratamiento eficaz para la ansiedad de actuación. En uno de ellos [44], la desensibilización sistemática combinada con prácticas en situaciones «en vivo» resultó más eficaz para reducir la ansiedad subjetiva que el análisis musical o la ausencia de entrenamiento; también redujo el ritmo cardíaco. En otro estudio [45], la desensibilización sistemática redujo en mayor medida los errores técnicos y respuestas verbales ansiosas que el entrenamiento de la improvisación y las habilidades cognitivas o la ausencia de tratamiento.

El pensamiento positivo es un método comprobado que se recomienda con frecuencia [46]. Las investigaciones han demostrado que su equivalente moderno, la *terapia cognitiva de la conducta,* es la técnica más eficaz para tratar la ansiedad de actuación y la menos utilizada por los músicos, que tienden a preferir métodos más físicos, como la relajación y los fármacos.

Resulta terapéuticamente beneficioso aceptar la ansiedad anticipatoria como un elemento natural de la actuación y utilizar la consiguiente tensión para activar nuestra preparación. La *terapia de inoculación del estrés*[47] se basa en la idea de aceptar y reevaluar los síntomas de la ansiedad, convirtiéndolos en valores positivos. El procedimiento consiste en imaginar una situación que produce ansiedad, seguida de una actividad preparatoria o una conducta eficaz para afrontarla.

También se puede lograr una mejoría con un adecuado *timing de la ansiedad* y preocupándose con antelación. Los estudios sobre paracaidistas han demostrado que los más experimentados controlan su ansiedad para que ocurra antes y no durante la actividad. Lo mismo se ha demostrado con un grupo de estudiantes de música a quienes se les pidió que clasificaran su ansiedad en varios momentos antes de una interpretación ante un jurado. Los intérpretes más experimentados mostraron una ansiedad máxima antes de la interpretación, mientras que los menos expertos alcanzaron el máximo nivel de ansiedad durante la interpretación[48].

En cuanto a la eficacia de algunas de estas técnicas psicológicas, Sweeney y Horan[49] encontraron que entrenando un control de la relajación mediante una palabra como «calma» o del análisis de las manifestaciones contraproducentes y su sustitución por otras más positivas —por ejemplo, desplazar el centro de atención de la ansiedad a la tarea— se redujo el ritmo cardíaco y la ansiedad autorreferida de un grupo de pianistas estudiantes de licenciatura en música. La primera técnica también mejoró la capacidad interpretativa, mientras que la segunda redujo las manifestaciones conductuales de la ansiedad, como por ejemplo los temblores. Un grupo de comparación que recibió adiestramiento en análisis musical no mostró ventajas frente a un grupo de «lista de espera» —es decir, pianistas que esperaban a recibir el entrenamiento.

En un estudio sobre pianistas con ansiedad de actuación debilitante, Kendrick et al.[50] compararon la eficacia relativa de la terapia cognitiva de la conducta (que incluía la autoinstrucción, la concentración y el reemplazo de los pensamientos negativos ajenos a la tarea con un autohabla positiva orientado a ésta) y el ensayo conductual (practicar la interpretación ante un público amable y comprensivo). Inmediatamente después del tratamiento no se observaron diferencias entre los tres grupos del estudio, pero cinco semanas después, los dos grupos que recibieron tratamiento mostraron progresos en comparación con un grupo de «lista de espera» en casi todos los parámetros de ansiedad de actuación (pensamientos negativos, signos visibles de ansiedad, eficacia esperada y calidad real de la ejecución). Sin embargo, ninguno de los tratamientos redujo la *sensación* de ansiedad. La terapia cognitiva de la conducta fue más eficaz que el ensayo conductual para reducir los signos vi-

sibles de ansiedad y aumentar la autoeficacia. Además, las mediciones del pensamiento positivo y la autoeficacia inmediatamente después del tratamiento predijeron una mejoría de los signos visibles de ansiedad y/o de la calidad de la ejecución en el seguimiento de la investigación.

Tratamientos combinados

Frecuentemente se emplean tratamientos combinados que reúnen diversas técnicas. Dos ejemplos deberán bastar en este caso. Un programa de seis semanas de terapia de grupo, que consistía en una combinación de relajación muscular progresiva, terapia cognitiva (identificar pensamientos negativos y sustituirlos por otros positivos al tiempo que se cuestionan los pensamientos irracionales) y entrenamiento del *biofeedback* de la temperatura, demostró ser eficaz para reducir la ansiedad de actuación autoevaluada en doce pianistas competentes aquejados de ansiedad de actuación debilitante, en comparación con un grupo de lista de espera [51]. Clark y Agras [52] tuvieron éxito con el siguiente tratamiento combinado: identificar las autoverbalizaciones negativas y el pensamiento distorsionado, hacer deberes para modificarlos, proporcionar modelos en diapositivas y cintas magnetofónicas para hacer frente a la ansiedad, entrenar la relajación y dar ánimos para encarar las situaciones de interpretación que se temen. En conjunto, estos tratamientos redujeron significativamente la ansiedad subjetiva y mejoraron la confianza y la calidad de la interpretación musical en intérpretes que padecían fobia social. En cambio, el tratamiento con Buspirona (un fármaco que reduce la ansiedad) no fue eficaz. Estos estudios demuestran claramente que existen tratamientos eficaces para la ansiedad de actuación. Lo que no demuestran es cuáles son exactamente. Son necesarias muchas investigaciones minuciosas para aislar los componentes fundamentales y determinar las combinaciones óptimas.

Recomendaciones

En base a lo expuesto anteriormente, se pueden dar los siguientes consejos a los lectores que sufren de ansiedad de actuación. En primer lugar, distinga cuidadosamente los diferentes tipos de ansiedad —reactiva, maladaptativa y adaptativa. Considere si su ansiedad es realmente perjudicial para su interpretación. Recuerde que cierto nivel de ansiedad es normal e incluso beneficiosa, ya que convierte una interpretación monótona en una dinámica y excitante. Si su ansiedad es excesiva, considere si existen medidas prácticas que pueda tomar para reducirla (teniendo presente el modelo tridimensional que

examinamos al principio), como elegir una pieza más fácil o estudiarla más concienzudamente. Fármacos como los betabloqueadores pueden considerarse en circunstancias excepcionales, pero sólo como una medida temporal y bajo supervisión médica: producen efectos secundarios indeseables y pueden ser adictivos. Tener confianza en sí mismo ha de ser su objetivo. Si tiende a ser ansioso y a reaccionar exageradamente en situaciones estresantes, considere una o varias de las siguientes medidas: (a) técnicas físicas de diversos tipos que incluyen la relajación —por ejemplo, la autosugestión o la técnica de Alexander—; (b) técnicas conductuales, como la desensibilización sistemática y el ensayo conductual; (c) el pensamiento positivo y el «autohabla», centrándose en la tarea misma en lugar de evaluar la interpretación, y en el placer propio y del público en lugar de adoptar una actitud crítica. También se pueden hacer combinaciones, como imaginar interpretaciones exitosas. Si, a pesar de estas precauciones, los costes siguen siendo mayores que los beneficios, entonces tal vez la interpretación pública no sea lo suyo.

29. Resulta muy problemático diseñar estudios para investigar la eficacia de los diferentes tratamientos. Los requisitos básicos son la asignación aleatoria de los participantes a los tratamientos y las evaluaciones «ciegas», i.e. que los evaluadores no deben saber cuál es el tratamiento que ha recibido el participante. Idealmente, el tratamiento en cuestión ha de compararse con una alternativa plausible (un «tratamiento de control»), de modo que se puedan descartar los efectos de la expectativa —es decir, la creencia de que un tratamiento tendrá efecto. En los estudios que incluyen la utilización de fármacos, se emplean placebos. Dado que los efectos suelen ser de corta duración, es necesario incluir tratamientos complementarios a largo plazo.

CUARTA PARTE
Interpretar la interpretación

13 *Escuchar la interpretación*

ERIC CLARKE

Introducción

Los oyentes tienen acceso hoy en día a una mayor cantidad y variedad de interpretaciones musicales que en cualquier otra época de la historia, y su rápida expansión, que comenzó con la llegada de la industria de la grabación a principios del siglo XX, no muestra señales de disminuir. Con la proliferación y diversificación de la interpretación a través de las grabaciones, ha llegado también un renovado interés por los ejecutantes como intérpretes y personalidades. Este capítulo trata sobre las diversas circunstancias en las que se escuchan las interpretaciones, sus respectivas repercusiones y los procesos perceptivos implicados en lo que los oyentes pueden escuchar y escuchan en la interpretación.

El título de este capítulo sugiere que es posible escuchar el componente interpretativo de lo que podríamos llamar «el sonido total de la música». ¿Se puede defender este punto de vista? ¿Hasta qué punto y de qué manera los oyentes son conscientes de la interpretación como un elemento que se puede separar de la música? De hecho, ¿se puede escuchar *otra cosa* que la interpretación? En el caso de la música que se basa en la partitura, y que conforma la tradición concertística occidental, podríamos justificar una distinción entre «la música» y «la interpretación», aunque sólo sea porque la partitura es una representación de la música, independiente de cualquier interpretación *particular.* Pero ¿qué ocurre con la enorme cantidad de oyentes que rara vez, si acaso, ven las partituras, o con la abrumadora mayoría de músicas que carecen de partituras? En resumidas cuentas, ¿acaso la gente escucha

la interpretación (en oposición a la música)? Y, de ser así, ¿qué es lo que escuchan?

Una prueba fehaciente de la importancia que tiene la interpretación para los oyentes es el enorme empaque que nuestra cultura le da a la interpretación: en la cultura musical contemporánea, los intérpretes son estrellas, como demuestran frecuentemente los diseños de las carátulas de los CDs [1] y como revelan igualmente sus honorarios y sus perfiles públicos. La industria de la grabación depende para su supervivencia del apetito casi insaciable de un público consumidor de grabaciones nuevas o reeditadas de un repertorio mayormente estático, y la industria fomenta a su vez la importancia de la interpretación por razones comerciales obvias. Esta prueba por sí sola plantea claramente una cuestión que requiere una respuesta, del mismo modo que el florecimiento de los estudios sobre la interpretación refleja el creciente interés académico por ella.

Circunstancias y actitudes

Hasta aproximadamente 1910, sólo existía la interpretación en vivo: la música se escuchaba en presencia de los intérpretes, que generalmente estaban a la vista. En esas circunstancias sería difícil *no* percatarse de la interpretación (o al menos de los intérpretes) en el plano directo de la presencia física. Sin embargo, antes del nacimiento de la cultura concertística, hacia 1800, la interpretación y los intérpretes estaban profundamente integrados dentro de las funciones sociales de las que formaban parte explícita (la iglesia, la corte, las celebraciones profanas, el entretenimiento doméstico, las funciones militares). Esa integración social puede implicar que era difícil separar la interpretación musical de su función y sus circunstancias, y por lo tanto es poco probable que destacara como un objeto de contemplación o un tema para el análisis. Evidentemente, ése no era el caso: incluso san Agustín, por ejemplo, cuando escribe sobre la cuestión de la música por la música y la música al servicio de Dios, reconoce que una interpretación lograda le podía «cautivar», y que el placer estético podía superar a la razón religiosa [2].

Sin embargo, en comparación con la posición que ocupaba la música dentro de sus contextos sacro y profano, la cultura concertística trajo consigo una perspectiva enfocada en la interpretación y la colocó, literalmente, en el centro del escenario. Los intérpretes fueron separados de sus oyentes, y a menudo se les colocaba sobre una plataforma; sólo tocaban cuando había un público, cuyos miembros escuchaban con mucha atención y relativamente callados. Estas distribuciones físicas y sociales forman parte de una actitud históricamente específica hacia la interpretación y la audición, y todos esos

factores —que siguen caracterizando a las condiciones convencionales para las interpretaciones en vivo del repertorio concertístico [3]— se conjugan para presentar la música como algo autónomo (independiente, autosuficiente) que ocupa un ámbito especial. Por tanto, no es de extrañar que los grandes intérpretes —los «realizadores» de la música— sean considerados con el mismo respeto que han inspirado los eruditos o los genios.

Sin embargo, la interpretación en vivo ha sido eclipsada por la grabación (al menos en términos cuantitativos), y hoy día se escucha mucha más música grabada o transmitida por los medios de comunicación, lo cual repercute significativamente en las actitudes de audición. Cuando los discos y gramófonos comenzaron a estar al alcance de muchos, durante el primer cuarto del siglo XX, mantenían algo del carácter social de escuchar una interpretación en vivo. Pero el gramófono también permitía una solitaria «audición acusmática», en la que la fuente instrumental del sonido está oculta, que fomenta una concentración en el sonido mismo que anteriormente apenas era posible [4]. Aunque tal vez no representen el mayor refinamiento del sonido, las diversas versiones de reproductores portátiles con audífonos pueden considerarse como la culminación de la audición acusmática, permitiendo al oyente llevar consigo y controlar un mundo sonoro virtual localizado aparentemente dentro de su propia cabeza.

Los efectos que produce la grabación en la audición son paradójicos. Por un lado, la naturaleza acusmática de las grabaciones —la ausencia física del intérprete— implica que la interpretación misma se encuentra en un plano más secundario, más implícito, que en una interpretación en vivo. Por otra parte, el advenimiento de la grabación, junto con un repertorio más o menos fijo de música que se regraba constantemente, significa que la interpretación en sí misma se ha convertido en el centro de atención. Además, la historia de la grabación demuestra que persiste el dilema sobre cómo se deberían entender la grabaciones —como interpretaciones plasmadas o como creaciones de los estudios de grabación [5]. Algunas compañías especializadas en grabaciones «de una sola toma», como Nimbus, del Reino Unido, apoyan el punto de vista de que las grabaciones deberían ser como las interpretaciones, del mismo modo que muchos intérpretes afirman que lo que intentan hacer en un estudio es grabar una interpretación. Por el contrario, hay intérpretes —entre los cuales Glen Gould fue quizá el representante más famoso— que insisten en que una grabación difiere mucho de una interpretación, que la edición permite crear algo que no se puede lograr en vivo y que las grabaciones deben entenderse como una manifestación distinta de la música. Las grabación sumamente editada de múltiples tomas no es un «remiendo»: es una expresión de la música que se ha construido deliberada y cuidadosamente, que posee sus propias características y requiere cri-

terios de evaluación específicos. Los procesos que tienen lugar en un estudio están completamente entrelazados con lo que se considera convencionalmente como factores de interpretación, y el resultado es simplemente otro tipo de objeto/evento en comparación con una interpretación real. Esto se evidencia más aún en otros géneros de música: un gran porcentaje de música pop y electroacústica implica un tipo de producción de estudio que no admite la interpretación en vivo en el sentido habitual del término, y hay piezas del repertorio concertístico que tienen versiones diferentes para la grabación y la interpretación en vivo. Por ejemplo, la obra *New York Counterpoint* de Steve Reich puede ser interpretada en vivo por once clarinetistas o grabada por uno solo utilizando un multipistas[6].

En resumen, la grabación incorpora varias consideraciones (como las técnicas de grabación y posproducción, la edición, el enfoque interpretativo inducido o requerido por las circunstancias del estudio, la fidelidad y el carácter acústico del medio de grabación y la naturaleza física y acústica del soporte en el que se reproduce la grabación) que implican que debemos ser cuidadosos al equiparar la música grabada con la interpretación grabada. Algunas grabaciones pretenden claramente ser lo mismo que las interpretaciones —las más obvias son las grabaciones en vivo de conciertos y óperas. Pero incluso en esos casos, su carácter acusmático cambia significativamente la relación del oyente con la música, y el resultado tiene propiedades (entre ellas, que se puede repetir, interrumpir y transformar en el momento de la reproducción) que pueden cambiar profundamente la manera en que los oyentes utilizan y responden a esas «interpretaciones». El no reconocer que las grabaciones *no* son simplemente interpretaciones convenientemente empaquetadas, y que las prácticas y expectaciones auditivas relacionadas con las grabaciones también son bastante diferentes de las relacionadas con los conciertos, son quizá dos de las razones por las que muchas personas encuentran que la relación entre sus experiencias con las grabaciones y los conciertos es incómoda y quizá decepcionante. No debemos pretender escuchar ambas de la misma manera.

He sugerido que las grabaciones pueden destacar los factores interpretativos. ¿Existen circunstancias musicales particulares en la interpretación en vivo que induzcan a los oyentes a percatarse de la interpretación como tal? El fracaso y el éxito pueden hacer que la interpretación sea particularmente audible: cuando las cosas van francamente mal o el intérprete es irremediablemente incompetente, el abismo entre lo que la música requiere y lo que el intérprete es capaz de dar se hace demasiado evidente. Por el contrario, cuando el intérprete parece tener un control absoluto de una música técnicamente exigente, sus proezas técnicas y su «atleticismo» pueden ser claramente audibles, tal y como pretenden demostrar las piezas sobresalientes de los

conciertos de gala y concursos musicales. Así pues, en sus extremos, la interpretación es audible como incompetencia o virtuosismo.

Pero los extremos son inusuales, y lo que los oyentes escuchan en circunstancias más normales resulta menos obvio. Un factor importante puede ser el tipo de oyente en cuestión. Por una parte, están aquellos para quienes distinguir los niveles de excelencia interpretativa forma parte de su profesión y que han cultivado un oído agudo, aunque a veces muy particular, para la interpretación (por ejemplo, los jurados de los concursos y audiciones musicales). Por otra parte, hay oyentes que pueden desconocer completamente un determinado estilo musical y sus convenciones y tradiciones interpretativas. Los oyentes aprenden a reconocer y evaluar las características interpretativas de cualquier estilo durante un período prolongado de continuo aprendizaje perceptual, y generalmente de manera informal y no supervisada. La mayoría de esas habilidades auditivas se desarrollan mediante el simple contacto y un constante intercambio de opiniones y preferencias con otros oyentes, junto con la influencia de las reseñas de CDs y conciertos, los programas de radio en los que se evalúan diferentes grabaciones y la influencia más indirecta de las representaciones de interpretaciones y audiciones en películas, programas de televisión y textos. No hay una investigación sistemática sobre cómo se desarrollan estas habilidades auditivas usuales, cuáles son los factores e influencias básicas y hasta qué punto las evaluaciones de los profesionales son consecuentes o fiables. Sin embargo, los hechos confirman reiteradamente que los oyentes con diferentes habilidades e intereses escuchan y responden a las interpretaciones en formas que pueden ser radicalmente distintas.

Sin embargo, las opiniones estéticas también pueden desempeñar un papel importante, ya que los oyentes pueden desear o esperar diferentes *tipos* de relaciones entre el intérprete y el material —y para distintos tipos de música. Dentro de la tradición concertística occidental, podemos identificar dos extremos de una escala que influyen significativamente en la audición, definida por Wilfrid Mellers como la diferencia entre el ejecutante intermediario y el ejecutante intérprete [7]. Mellers describe a los «intermediarios» como ejecutantes que sirven como medio de expresión para las intenciones del compositor, y a los «intérpretes» como aquellos para quienes las intenciones del compositor (o, más concretamente, la partitura) son un punto de partida para su propia labor creativa/interpretativa. Aunque este asunto tiene una variable histórica, también se pueden establecer diferencias entre los diversos enfoques de una misma época: en los años 1940 y 1950, por ejemplo, los directores Toscanini y Furtwängler fueron calificados respectivamente de «intermediario» e «intérprete», siendo el primero venerado (o severamente criticado) por su «fidelidad a la partitura», y el segundo por su agudeza creativa y su idiosincrasia. Si existen discrepancias tan fundamentales sobre lo

que los intérpretes deberían *intentar* hacer, no es de extrañar que los oyentes puedan tener reacciones radicalmente divergentes: lo que a uno le resulta díscolo y caprichoso (basándose quizá en que «se aleja de la partitura») a otro le puede parecer comprometido e inspirado (por la «originalidad e idiosincrasia de su interpretación»).

En muchas tradiciones musicales fuera de la música culta occidental, la situación es aún más variable. No es que la distinción entre el intérprete y el material desaparezca en las tradiciones orales, pero la relación cambia. Por ejemplo, en el jazz tradicional, que posee un núcleo de melodías «clásicas» que son reinterpretadas continuamente, tiene poco sentido considerar si un intérprete es más o menos fiel al original, aunque sólo sea porque a menudo existe cierto grado de incertidumbre sobre lo que es (o era) realmente el «original» y un elevado nivel de ambigüedad incluso en los ejemplos más establecidos o definidos. Un «clásico» tiene una identidad que frecuentemente no es mucho más que una estructura armónica/métrica y una melodía, y representa una base sobre la cual se espera que los intérpretes exhiban sus habilidades improvisatorias. Algunos oyentes pueden tener un sentido de la fidelidad al «espíritu» del original y rechazar por consiguiente los tratamientos radicales de los intérpretes peculiares, pero existe claramente un terreno considerable para la libertad interpretativa del ejecutante —así como para la expectación de los oyentes, quienes cuentan con que efectivamente sea así. Los oyentes de jazz están más interesados en la interpretación y los intérpretes que en las piezas y repertorios.

Sin embargo, el interés principal de este capítulo es la tradición concertística occidental y qué es lo que los oyentes escuchan en la interpretación de esa música. Uno de los ideales de interpretación que se ha propuesto a menudo es que el oyente debería sentirse arrebatado por la fuerza de la interpretación sin percatarse del ejecutante como intermediario o como intérprete. Para algunos oyentes, por lo tanto, la audición gratificante y concentrada hace que, paradójicamente, la interpretación sea inaudible: consideran que la música les habla a ellos directamente. Peter Johnson escribió lo siguiente: «La interpretación extraordinaria de una buena pieza musical es, sugiero, una invitación a la audición trascendental, en el sentido de que, paradigmáticamente, evita llamar la atención hacia sí misma *como* una interpretación (bien sea por razones positivas o negativas)» [8]. Si el no percatarse de la interpretación es para algunos oyentes una medida del éxito de ésta, entonces el ideal del intérprete podría ser estar tan involucrado en la música, tan poseído por ella, que se sienta identificado con el compositor o con la obra. El punto de vista contrario sería una fascinación por la interpretación misma, con la manera en que los ejecutantes hacen lo que hacen y las ilimitadas maneras en que la música se realiza en la interpretación.

¿Qué especifican los sonidos de la interpretación?

Aunque es posible que un oyente atento e interesado sea poco o nada consciente de las características específicas de una interpretación, ese oyente puede *llegar a ser* consciente de los atributos de ésta. Además, como la percepción implica no sólo enterarse conscientemente, sino también un proceso continuo e inconsciente de ajuste y reacción al entorno, los oyentes también serán influidos por las características de la interpretación, independientemente de que se den cuenta o no. Los sonidos de una interpretación tienen la capacidad de transmitir una gran cantidad de información al oyente, desde las características físicas relacionadas con el espacio en el que tiene lugar la interpretación y la naturaleza del instrumento hasta las propiedades menos tangibles, como la ideología interpretativa del ejecutante. Una forma de abordar esa gran diversidad es preguntarse qué especifican los sonidos de la interpretación, y al hacerlo prestar toda la atención a las características de los sonidos de la interpretación y su riqueza como fuente de información.

Espacio/instrumento/cuerpo

Las propiedades más físicas y tangibles de las interpretaciones son los espacios en los que se realizan, los instrumentos que se utilizan y las interacciones físicas del ejecutante con ellos. En algunas músicas (por ejemplo, la música antifonal de Andrea Gabrieli, o la obra *Gruppen* de Karlheinz Stockhausen, en la que la música está distribuida espacialmente), la «geometría» del espacio es importante como componente de la estructura musical. Pero en gran parte de la música de la tradición concertística occidental, el espacio es importante no como elemento estructural, sino por la manera en que transmite el «aura» o carácter de la interpretación. Muchos oyentes prefieren escuchar una obra como la *Pasión según San Mateo* de Bach, por ejemplo, en un «espacio» (bien sea el espacio real de la interpretación o el espacio virtual de una grabación) amplio y resonante, por al menos dos razones. En primer lugar, una acústica amplia y resonante se corresponde con el tipo de espacio para el cual fue escrita esa música (una iglesia), y al transmitir ese espacio, la acústica también transmite los materiales (piedra y madera), los entornos y la ideología (el culto cristiano) que están relacionados con la interpretación de esa música. En segundo lugar, la música fue compuesta probablemente para explotar la acústica a la que estaba destinada, y por tanto funciona mejor con la reverberación amplia (y la consiguiente ola de sonido) que proveen dichos espacios. Por el contrario, la mayoría del repertorio de música de cámara fue compuesto para la interpretación doméstica, y la música puede verse afectada

si se toca en una acústica muy reverberante, no sólo porque las relaciones serán erróneas, sino también porque las texturas musicales se confunden.

Además de los espacios de interpretación, también influyen los instrumentos y los ejecutantes, cuyas ejecuciones en el instrumento se reflejan en sonidos. El sonido de una interpretación proyecta no sólo propiedades básicas como el instrumento que se está tocando, sino también la interacción física del ejecutante con él. La facilidad o el esfuerzo, la energía, la confianza y el nivel de control de una interpretación son transmitidos claramente en el sonido de una interpretación, y proporcionan al oyente una información sobre el cuerpo del intérprete y su relación con el instrumento.

Las actitudes convencionales hacia el repertorio concertístico estándar han tendido a subestimar el carácter físico de la interpretación, con respecto al cual los oyentes suelen ser ambiguos. Dentro de una tradición que admira la virtuosidad, los oyentes generalmente prefieren no percatarse de los esfuerzos que realiza el intérprete para mantener el control técnico de las piezas difíciles, pero sí quieren percibir su presencia física, implicados en mente *y* cuerpo en la «lucha heroica» por expresar y comunicar. Uno de los defectos que presentan las simulaciones de interpretaciones humanas con sistemas informáticos (como el sistema CHANT de simulación vocal desarrollado por el ICAM de París en los años 1980) es que carecen de toda sensación de compromiso y «esfuerzo» físicos.

Eventos y procesos

Escuchar la interpretación tiene mucho en común con escuchar el habla, ya que el oyente debe seguir la pista de un flujo continuo de eventos en el tiempo y encontrarles un sentido. Aunque gran parte de la teoría de la música ha destacado la importancia de la estructura musical a gran escala [9], también existen pruebas de que los oyentes no son sensibles a esas características a gran escala de una manera directamente perceptual [10]. Jerrold Levinson [11] ha sostenido que los oyentes no construyen estructuras jerárquicas elaboradas y a gran escala, sino que se centran fundamentalmente en el desarrollo continuo de una pequeña porción de música «presente». Esa idea concuerda con los estudios psicológicos sobre la percepción del tiempo, que sugieren que en todo momento somos conscientes de un «trozo» relativamente breve de tiempo (unos 6-10 segundos), al que denominan presente perceptual [12]. Las estructuras más grandes son una función de la memoria, y Levinson afirma que la memoria del oyente para esas estructuras suele ser bastante imprecisa y no admite una «arquitectura» a gran escala. En otras palabras, el acto de escuchar es como una ola en la que los eventos presentes y contiguos producen

un efecto vívido e inmediato, que deja tras de sí una estela de recuerdos cuya historia de eventos e influencias acumuladas le da a la ola una forma determinada.

Al escuchar una interpretación, somos fundamentalmente conscientes de lo que ocurre en el *presente* de un flujo continuo. Sin embargo, ese flujo no es uniforme: en la interpretación de la mayoría de las músicas, hay determinados eventos que lo segmentan, proporcionando periódicamente la oportunidad de organizar los eventos de los últimos segundos y almacenarlos en la memoria. De la misma manera, cuando escuchamos a alguien hablando, nos percatamos en todo momento de los contenidos activos de la frase u oración en curso —las palabras dichas en unos pocos segundos. Cuando el discurso llega a un punto o un punto y coma, sintetizamos los contenidos de dicha frase u oración como la esencia de lo que el hablante acaba de decir —tal vez recordando literalmente la frase, pero principalmente en términos de lo que significa. Y al mismo tiempo que esa parcela de significado está siendo registrada, se abre una nueva ventana de percepción inmediata que permite al oyente proseguir su audición. En la música, esta segmentación del flujo de información se deriva de una mezcla de propiedades estructurales (notas largas, discontinuidades de alturas, funciones tonales, etc.) y características interpretativas (cambios de tempo, dinámica, articulación, etc.). Las diversas maneras en que los intérpretes dan forma a los eventos de la interpretación son analizadas en varios capítulos de este libro; la siguiente sección considera si los oyentes captan o no esas características interpretativas, cómo lo hacen y cómo las interpretan.

Expresión, emoción y estilo

¿En qué medida los oyentes son conscientes de las microvariaciones de interpretación, y de qué manera les dan sentido? Varios estudios han demostrado que, bajo condiciones controladas, los oyentes pueden detectar cambios mínimos en el tempo, del orden de los 30 a 50 milisegundos [13], y otros estudios han revelado que perciben igualmente los cambios en la dinámica y la entonación [14]. Sobre la perceptibilidad de la articulación, el timbre y el vibrato se tiene menos información, en parte porque son características más complejas que la duración, altura o intensidad del sonido. Igualmente, se han realizado pocas investigaciones sobre la percepción de dichas características por parte de los oyentes en condiciones normales de audición.

Bruno Repp, sin embargo, ha demostrado que la capacidad que tienen los oyentes de detectar características detalladas de interpretación está marcadamente influida por el contexto musical. Cuando a un grupo de oyentes se

les hizo escuchar una breve sección de una sonata para piano de Beethoven (el inicio del Minueto de la Sonata op. 31 núm. 3) en la que se prolongó la duración de determinadas notas en varios puntos, éstos mostraron una variación perceptual considerable dependiendo de la ubicación de la prolongación [15]. En los puntos donde esperaban fluctuaciones expresivas en el tempo (características de los finales de frases), los oyentes no detectaron los cambios —como si por el hecho de ser previsibles dichos cambios resultaran imperceptibles. Por el contrario, cuando las fluctuaciones expresivas de tempo ocurrían en mitad de una frase, donde son menos probables, los oyentes fueron particularmente conscientes de su presencia —como si resultaran más evidentes por ser incongruentes.

Aunque sólo considera un aspecto de la interpretación, el estudio de Repp ilustra un principio general importante: que la capacidad de los oyentes de detectar las características detalladas de la interpretación depende mucho del contexto. Este principio puede influir tanto en la *conciencia* que tiene el oyente de las características de la interpretación como en su manera de interpretarlas —es decir, cómo funcionan esas características como signos [16]. Una ralentización del tempo en medio de una frase puede interpretarse como una intensificación expresiva, mientras que la misma ralentización al final de una frase puede entenderse como una disminución de la tensión, marcando la conclusión de un pasaje musical. Las diferentes interpretaciones de una «misma» característica interpretativa son producto del sistema de relaciones estructurales y expresivas en el que se inserta cada característica de la interpretación.

Las propiedades expresivas de la interpretación transmiten cualidades emocionales y características estructurales. Patrik Juslin ha demostrado que cuando a un intérprete se le pide que toque una pieza de tal modo que transmita un estado emocional específico, los oyentes pueden reconocer con seguridad qué estado está comunicando [17]. Ésta es una versión controlada (y un tanto artificial) de un hecho común, a saber, que los oyentes perciben emociones transmitidas por la interpretación y suelen atribuirlas a los intérpretes —independientemente de que las escuchen como verdaderos estados emocionales de los intérpretes o como emociones actuadas de una personalidad adoptada.

Más de cien años de interpretaciones grabadas, junto con el desarrollo de las prácticas interpretativas históricas, han puesto a nuestro alcance una fascinante diversidad de estilos e ideologías interpretativas. El estudio sistemático sobre las diversas maneras en que éstas se especifican en sonido apenas ha comenzado (aunque la obra de Robert Philip constituye un punto de partida) [18], pero es potencialmente fascinante. Para escuchar la expresión, la emoción, el estilo y la ideología de una interpretación, el oyente ha de identificar

características de la interpretación que destacan sobre un fondo implícito de neutralidad —una especie de «norma» teórica con respecto a la cual se distinguen la expresión, la emoción, el estilo y la ideología (como se explica en el capítulo 4). En otras palabras, la interpretación se escucha sobre el telón de fondo de las interpretaciones y grabaciones previas. Los continuos cambios históricos implican que las normas de una época se convierten en las idiosincrasias o anacronismos de otra, y ésa es la razón por la que las grabaciones antiguas pueden resultarles amaneradas o peculiares a los oyentes contemporáneos. De nuevo, la enorme proliferación de interpretaciones grabadas y transmitidas por la radio y la televisión durante el siglo XX trajo cambios profundos para los intérpretes y oyentes, quienes ahora tienen acceso a una cantidad y variedad inusitada de interpretaciones de un enorme repertorio musical. Algunos lo han considerado un proceso enriquecedor y provechoso, mientras que para otros, como Hans Keller, ha contribuido a la desastrosa erosión de las habilidades interpretativas y auditivas [19].

Conclusión

Existe una opinión según la cual la interpretación exitosa y la audición concentrada son aquellas en las que los oyentes no nos percatamos de la interpretación —y, por consiguiente, este capítulo no tendría razón de ser. Sin embargo, es una opinión innecesariamente limitada: supone una estética auditiva particular que está lejos de ser compartida universalmente, se relaciona con circunstancias particulares de audición, depende de condiciones idealizadas y sólo se refiere a la percepción consciente. Como se ha demostrado en este capítulo, existen muchas circunstancias en las que los oyentes se percatan indudable, y a veces desafortunadamente, de la interpretación, y quizá los oyentes *siempre* responden a la interpretación, incluso cuando no se percatan de ella. Sin embargo, una característica de la música de concierto y la actitud con que se escucha, que resulta del concepto integral de la obra musical y su (separable) interpretación, es la arraigada incertidumbre o ambigüedad sobre qué es lo que uno está, o debería estar, escuchando. La «obra como concepto» sugiere que la interpretación debería pasar inadvertida, mientras que el auge del intérprete como artista proviene de un interés por la interpretación en sí, y al mismo tiempo fomenta dicho interés. Pero, independientemente de que los oyentes crean que están escuchando la interpretación o «la obra misma», no pueden negar que lo que oyen es una interpretación (o una grabación), y el segundo objetivo de este capítulo ha sido demostrar la cantidad y diversidad de información que se transmite a través de los sonidos de una interpretación. Por último, en una época en que se escucha mucha más

música grabada y emitida por los medios audiovisuales que interpretada en vivo, aún no hemos definido claramente qué es una grabación —una interpretación «plasmada» o un producto de un estudio de grabación—, con todas las consecuencias que ello implica en cuanto a nuestras respuestas y actitudes hacia las grabaciones. En una época en que se cuestiona cada vez más la prioridad que se le da a la partitura cuando se escribe sobre música, y en que las interpretaciones y grabaciones se están convirtiendo en objetos de estudio mucho más comunes, sabemos más sobre lo que se puede *medir* de las interpretaciones y grabaciones, pero aún sabemos muy poco sobre lo que los oyentes realmente *oyen* en ellas.

14 El legado de las grabaciones

PETER JOHNSON

La imagen visual que más ha perdurado en toda la historia de la grabación es, sin duda, la de Nipper el perro, escudriñando nostálgicamente el enorme altavoz de un viejo gramófono. Su título, claro está, es «His Master's Voice» («La voz de su amo»). En cierto modo, fue una elección curiosa para un sello discográfico, ya que habla de ausencia: el amo había fallecido años atrás. Las grabaciones musicales representan más bien una presencia, las voces de los intérpretes y el sonido de una música real.

Tal vez sea porque las grabaciones se han incorporado tanto a nuestra vida diaria que habitualmente las aceptamos en lugar de las interpretaciones en vivo. De alguna manera nos las arreglamos sin el contacto visual entre el intérprete y el oyente, o sin esa sensación intangible de la música tomando cuerpo ante nosotros. Aceptamos que el pasaje virtuoso siempre será ejecutado de la misma manera, y que al intérprete probablemente le supuso una docena de tomas alcanzar su nivel de perfección. Y, habitualmente, no consideramos que una grabación profesional sea menos auténtica que una interpretación en vivo: al contrario, la grabación reafirma su autoridad por encima del efímero concierto que pronto se olvida. Aún así, las grabaciones no han reemplazado a los conciertos en vivo: proporcionan un modo alternativo de producción musical, de gran valor para los intérpretes y su público, y para los estudiosos y compositores.

Voz y personaje

Si las grabaciones difieren significativamente de las interpretaciones en vivo, ¿qué es lo que tienen en común? La «voz» interpretativa de todo gran intérprete, sea Håkan Hardenberger o Heinz Holliger, Yo Yo Ma o Yuri Bashmet, es inconfundible una vez que la hemos escuchado, bien sea en CD o en concierto. Esa voz interpretativa es lo que las grabaciones captan tan eficazmente, y lo que se reproduce cada vez que ponemos un disco o un CD. Una grabación es, literalmente, *de* el intérprete o el conjunto que interpreta la obra. En ese sentido, las compañías discográficas tienen razón al comercializar sus productos por intérpretes y no por obras [1].

Cada obra, sin embargo, tiene sus propias exigencias interpretativas y, al igual que el actor, el buen intérprete ajusta su voz correspondientemente. Me referiré a este segundo nivel de presencia como el «personaje» del intérprete [2]. En las interpretaciones en vivo vemos a los intérpretes entrar y salir de su papel: la figura modesta de Alfred Brendel se transforma en el pianista magistral en el momento en que sus dedos tocan las teclas, pero retorna cuando agradece tranquilamente los aplausos. Las grabaciones, al igual que las películas, no nos dejan ver esas transformaciones: nos muestran solamente al personaje. Lo que sí nos permiten es comparar a esos personajes: la *Madame Butterfly* de Callas es muy diferente de su *Tosca;* sin embargo, la voz es siempre la de Callas.

Las grabaciones como testimonios

Muchas veces se ha preguntado si los artistas de antaño como Schnabel o Cortot realmente tocaban como sugieren sus grabaciones. En cierto modo, es una pregunta que no viene al caso, ya que las grabaciones son lo que son, y no lo que podrían haber sido. En las grabaciones posteriores a la guerra, el productor ejercía probablemente un control considerable sobre el sonido e incluso sobre la interpretación; sin embargo, el producto en sí mismo puede ser de gran interés musical e histórico. Las grabaciones pueden revelar muy claramente cómo cantaban o tocaban realmente los intérpretes desde comienzos del siglo XX. La cuestión es cómo las analizamos.

Hasta ahora ha habido muy pocos estudios musicológicos serios sobre las grabaciones, ya que la musicología del siglo XX ha tenido otras prioridades. Por lo tanto, este capítulo está dirigido principalmente al intérprete en activo: ¿qué puede esperar aprender el intérprete actual del legado de las grabaciones? Los tres problemas más inmediatos son la magnitud del archivo, la complejidad del arte interpretativo en sí mismo y la influencia que ejerce el

medio de grabación en lo que oímos. Podríamos limitar el campo concentrándonos en nuestro propio tipo de voz o instrumento, o en las múltiples grabaciones de una obra o un movimiento [3]. Sin embargo, este capítulo adoptará un enfoque temático, destacando algunas de las áreas más provechosas e ilustrando ciertas técnicas analíticas. Todos esos enfoques plantean cuestiones mucho más amplias —la interpretación y el significado— que consideraré brevemente en una sección de conclusión. Quisiera subrayar que este capítulo es una mera introducción, ya que el tema es muy amplio; en un terreno tan poco explorado, el viaje promete ser excitante, aunque a veces arriesgado.

Métodos de grabación

El primer paso consiste en conocer y comprender las diversas tecnologías y cómo pueden haber influido en lo que oímos en una grabación [4]. Desde 1900 han existido cinco medios principales de grabación: el disco de laca grabado acústicamente (1900-1925); el disco de laca grabado eléctricamente (1925-1954); el LP de vinilo monofónico (1950-*ca.*1960); el LP de vinilo estereofónico (1958-*ca.*1985), y la grabación digital moderna que comenzó con el CD a principios de los años 1980. A los pianistas también les interesará el rollo o cilindro de piano, que tuvo una historia breve pero importante desde su invención en 1904 hasta su desaparición alrededor de 1930. Cabe señalar que el disco de laca de 78rpm existió durante más de cincuenta años, pero en su primera etapa, anterior a 1925, era completamente diferente de su versión posterior. El acontecimiento más importante de la historia de la grabación fue probablemente la introducción de la grabación eléctrica en 1925.

En líneas generales, cuanto más antigua es una grabación, mayor es la distorsión que presenta debido al procedimiento de grabación, y menor es la manipulación deliberada por parte del productor. Los primeros discos de 78 rpm no permitían ningún tipo de edición, ya que una vez que se hacía el «máster» o disco maestro de cinc, había que enviarlo a la planta de procesamiento y prensar un disco para poder escuchar la grabación. Pero los mecanismos de grabación y reproducción tenían sus propias limitaciones, incluyendo una respuesta irregular a lo largo del espectro grabado y una gama de frecuencias y duración extremadamente limitadas.

La introducción de la grabación eléctrica en 1925 tuvo varias consecuencias inmediatas. En primer lugar, la gama de frecuencias fue ampliada desde un límite superior de 3 kHz (véase la Figura 14.3, analizada más adelante) hasta aproximadamente 5 kHz, que era suficiente para la mayor parte de la información acústica contenida en las principales obras de música clásica. En

segundo lugar, permitió la grabación de agrupaciones grandes con un balance que se acercaba bastante al real, aunque durante muchos años los micrófonos impondrían sus propias características al sonido grabado. A medida que evolucionaba la grabación eléctrica, se comenzaron a explotar las posibilidades de balancear artificialmente la grabación, un proceso en el que destacó especialmente Leopold Stokowski, quien realizó todo tipo de experimentos con la colocación de la orquesta y el control del balance en busca de un sonido ideal [5].

Para los años 1930, se utilizaban varios platos de grabación para poder grabar una interpretación continua sin tener que parar a los músicos cada pocos minutos, y para 1940 el problema del tiempo se había resuelto finalmente empleando una cinta para los másters [6]. La longitud de la cinta era teóricamente ilimitada y se podía cortar y editar de maneras que eran imposibles con el disco de 78 rpm. A partir de esa época comenzó la era de la grabación manufacturada en estudio. Desde los años 1960, la edición y la grabación se han vuelto tan sofisticadas que actualmente hay poca garantía de que una grabación sea el resultado de una única interpretación, exceptuando las grabaciones realizadas «en vivo». John Culshaw, productor del sello discográfico Decca y responsable del primer ciclo completo de «El Anillo del Nibelungo» (1959-1965), aprovechó las posibilidades de la grabación estereofónica para crear interpretaciones que hubieran sido imposibles con cualquier otro medio. Reuniendo a las mejores voces y orquestas del mundo (por ejemplo, la Filarmónica de Viena para su versión de «El Anillo»), logró efectos auditivos que no se habrían podido obtener en el teatro [7]. El problema, claro está, es que las interpretaciones en vivo de «El Anillo» tienden a palidecer en comparación con la extraordinaria presencia de la grabación de Culshaw.

Las grabaciones posteriores a la guerra muestran varios ideales diferentes del sonido grabado. Durante una época de los años 1960 hubo predilección por una acústica «cerrada» y muy seca; después se puso de moda una reverberación molesta y artificial. En ambos casos, los niveles dinámicos y las cualidades tímbricas de la interpretación original eran manipulados casi con seguridad durante el proceso de grabación. Más recientemente, algunos productores han procurado un sonido natural, utilizando un solo par de micrófonos colocados a una distancia apropiada del conjunto. Sólo en este tipo de grabaciones se puede analizar sensatamente el balance de la interpretación en lugar del de la grabación.

Un problema importante que se nos presenta al estudiar cualquier grabación es que el sello puede nombrar en sus carátulas a intérpretes diferentes de los que realmente grabaron. Existe un rollo de piano realizado supuestamente por Ravel tocando sus «Miroirs» y otras piezas, del que hoy en día se sabe

que fue grabado por Robert Casadesus [8]. Un ejemplo más trivial, de principios de los años 1950, es el doblaje de los Do agudos de Kirsten Flagstad en una grabación de EMI del Segundo Acto de «Tristán e Isolda» con Wilhelm Fürtwangler. Esos Do agudos fueron cantados en realidad por Elizabeth Schwarzkopf[9].

Instrumentos y técnica

Una de las características más interesantes de las grabaciones antiguas es el sonido de los instrumentos que se usaban entonces y la manera en que se tocaban. Por ejemplo, las flautas de pico, de sonido dulce y nasal, fueron usadas ampliamente por los intérpretes ingleses hasta finales de los años 1950, pero cayeron en desuso en las décadas siguientes. Actualmente están retornando a nuestras orquestas, sin duda debido al auge de las interpretaciones históricas, pero también, quizá, debido a la difusión de las remasterizaciones en CD de grabaciones realizadas en LP. El sonido característico de las maderas francesas se puede escuchar en innumerables grabaciones antiguas, como los maravillosos discos que grabó Roger Désornière de *Pelléas et Mélisande* de Debussy en París en 1941 [10]. Las sonoridades son muy diferentes de las de los instrumentos actuales, pero conmovedoramente hermosas; el oboe, asociado a Mélisande a lo largo de la ópera, es de una delicadeza particular que parece totalmente adecuada a ese papel. En las grabaciones anteriores a la guerra aún se pueden escuchar trombones de taladro estrecho y violines con cuerdas de tripa. Quizá algún día será habitual que los principales intérpretes elijan sus instrumentos de acuerdo con el carácter de la composición, como hacen hoy en día muchos trompetistas; o tal vez las orquestas vuelvan a encontrar una voz característica retornando a los instrumentos de fabricación local.

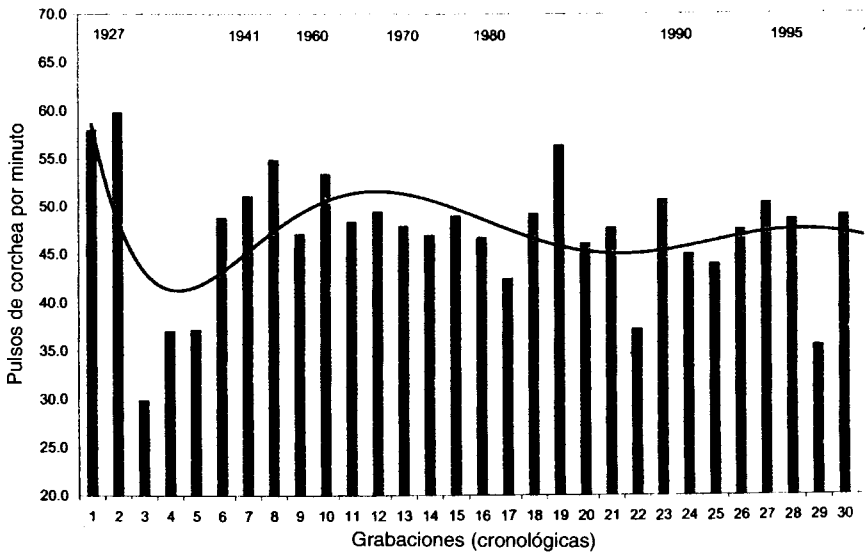
Las grabaciones antiguas de piano son tal vez las que resultan más chocantes para los gustos contemporáneos. La mayoría de los pianistas anteriores a aproximadamente 1925 parecen caprichosos por la libertad con que se toman la notación de los compositores; sin embargo, resulta fascinante escuchar, por ejemplo, las múltiples maneras en que se puede arpegiar un acorde [11], u observar la naturaleza improvisatoria de gran parte de su ejecución, destacando las voces intermedias o añadiendo cadencias no indicadas en la partitura [12]. Resulta fácil condenar tales prácticas, pero es mucho más interesante intentar comprenderlas e incluso emularlas. La regla moderna según la cual debemos tocar únicamente lo que está escrito en la partitura no viene al caso cuando la notación del compositor no pretendía ser tan restrictiva. Naturalmente, eso no quiere decir que el intérprete actual pueda hacer caso omiso de las indicaciones del compositor sin correr ningún riesgo.

Estudio de caso 1: tempo y duración

El tempo plantea una serie de problemas especiales, particularmente al considerar las grabaciones antiguas. Se ha afirmado a menudo que, debido a la duración limitada del disco de 78rpm, no se pueden establecer conclusiones categóricas sobre el tempo original de las grabaciones anteriores a aproximadamente 1950. Sin embargo, hay muy pocas pruebas de que los intérpretes realmente aceleraran sus interpretaciones. ¿Qué es, entonces, lo que podemos deducir con certeza sobre el tempo partiendo del testimonio de las grabaciones?

En primer lugar, debemos diferenciar las grabaciones realizadas antes de aproximadamente 1922, cuyo límite de duración era más o menos de tres minutos, de los discos de 78rpm posteriores, que duraban bastante más de cuatro minutos. La mayoría de las grabaciones clásicas realizadas en la época acústica son de arias operísticas, y presentan las siguientes tendencias generales:

(1) Las piezas fueron reducidas sistemáticamente a dos minutos y medio, lo cual sugiere que los productores preferían sacrificar secciones del aria en lugar de apresurar a los intérpretes.
(2) Los tempos no son obviamente rápidos (salvo ciertos momentos muy expresivos en los que solían deleitarse menos que hoy en día), y las secciones de recitativo y parlando suelen tomarse en tempos que hoy consideramos naturales.
(3) Según los parámetros modernos, los *tenutos* de las cadencias principales parecen excesiva e innecesariamente exagerados, lo que indica que no existía una preocupación apremiante por el reloj.



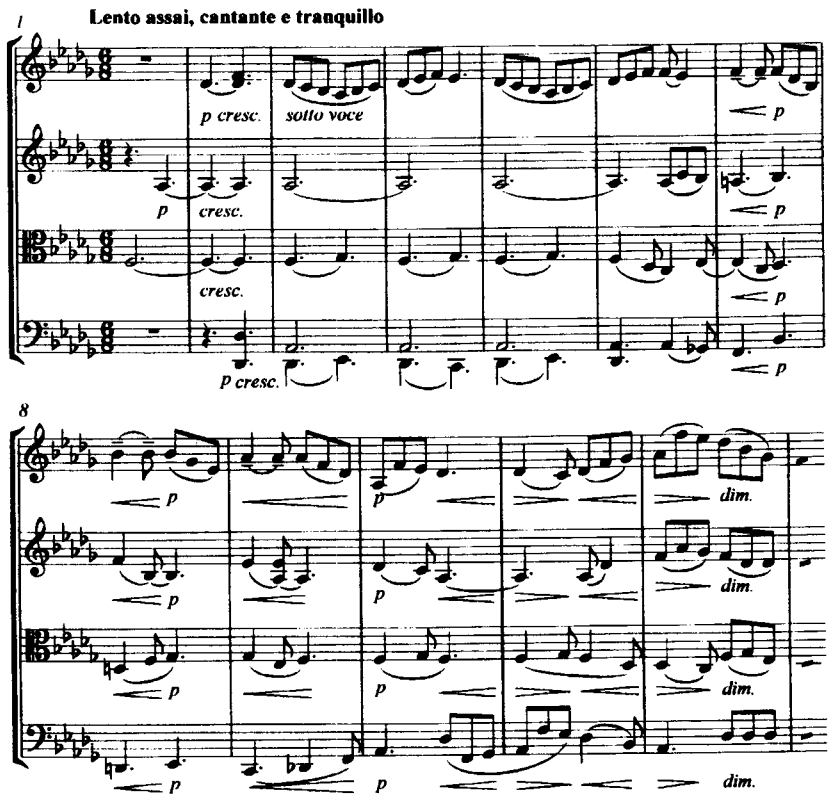
Cuando escuchamos las grabaciones de Caruso o del Otello original de Verdi, Francesco Tamagno, cantando una selección de la ópera en 1903, percibimos interpretaciones con un maravilloso tempo dramático, sin ningún indicio, al menos para el oído moderno, de constreñimiento ni premura [13].

Existen testimonios de músicos que mencionan la incomodidad de los estudios de grabación antiguos y las limitaciones de las «tomas» de tres minutos, pero generalmente datan de épocas muy posteriores y no invalidan los testimonios de las grabaciones en sí. En un análisis provechoso de esta cuestión, John Steane compara las duraciones de grabaciones anteriores a la guerra con interpretaciones en vivo realizadas en la misma época por los mismos artistas y descubre que las grabaciones solían durar menos [14]. Sin embargo, los asuntos de escena generalmente requieren más tiempo en una interpretación en vivo, y su argumento no es de ningún modo conclusivo.

Probablemente nunca sabremos si ciertos tempos rápidos se debieron a la limitada longitud de una cara del disco, pero sabemos que muchos no. Robert Phillip cita varios ejemplos en los que la longitud no pudo haber influido en el tempo [15]. A esos ejemplos yo añadiría el caso de dos grabaciones antiguas del movimiento lento del último cuarteto de Beethoven, op. 135, que son, respectivamente, casi la más rápida y sin duda la más lenta que se han grabado hasta ahora. Beethoven indicó el movimiento «Lento assai, cantante e tranquilo» (véase el Ejemplo 14.1, más adelante). El Cuarteto Flonzaley, que lo grabó en 1927, interpreta esta indicación como un tempo fluido de ♪ = 58, asumiendo, en efecto, un pulso de negra con puntillo. Con un contraste asombroso, el Cuarteto Busch comienza en un tempo de ♪ = 32. La grabación de 1934 del Cuarteto Busch ocupa tres caras en lugar de las dos habituales, pero la versión del Flonzaley ocupa tan sólo una cara y media, dejando el resto de la segunda en blanco. En otras palabras, tenían todo el tiempo necesario para extenderse en el movimiento y sin embargo se apresuran hacia la cadencia final [16].

José Bowen ha analizado minuciosamente el tempo de las grabaciones de una selección de obras sinfónicas, únicamente para concluir que el tempo ha cambiado muy poco a lo largo de ochenta años [17]. De hecho, el método de Bowen no muestra los cambios que pueden haber ocurrido durante períodos más breves. La Figura 14.1 muestra los tempos de los compases 4-6 de treinta y cinco grabaciones del Lento assai de Beethoven, y demuestra que aunque los enfoques del tempo han seguido ciertas tendencias en el transcurso de los años, difícilmente se pueden resumir en una simple fórmula [18]. Además, las grabaciones que rompen la tendencia son a veces las más interesantes.

Se pueden realizar estudios muy útiles sobre el tempo utilizando únicamente un instrumento tan sencillo como el cronómetro. El análisis acústico formal revela un mundo fascinante de *rubatos* y cambios de tempo, incluso en interpretaciones recientes que parecen mantener un pulso estricto. La Figura 14.2 representa gráficamente el tempo de cada corchea del Ejemplo 14.1 tal y como lo tocaron los Cuartetos Flonzaley y Lindsays [19]: cuanto más alta es la barra, más breve es el pulso (y, por tanto, más rápido el tempo). El gráfico muestra que el *subito piano,* implícito en los compases 7 y 8, es articulado por ambos conjuntos mediante una marcada prolongación del tercer tiempo, mientras que el Cuarteto Flonzaley acelera el cuarto tiempo del compás 9, un manierismo que hoy en día nos puede sonar descuidado o caprichoso; sin embargo, la sintaxis musical lo justifica, ya que el acorde de tónica en posición fundamental no llega a cerrar su disposición. Curiosamente, los músicos del Cuarteto Flonzaley articulan el cambio de velocidad del tema de Beethoven entre los compases 3-6 y 7-9 mucho más explícitamente que los integrantes del Lindsays, quienes mantienen una calma un tanto ominosa a lo largo de toda la sección.



Cuartetos

1 Flonzaley (1927)
2 Léner (1927)
3 Busch (1934)
4 Toscanini (NBCO, 1938)
5 Budapest (1941)
6 Loewenguth (1947)
7 Hungarian (1935)
8 Hollywood (1957)
9 Fine Arts (*ca.* 1960)
10 Janáček (1963)
11 Italiano (1968)
12 Julliard (1969)
13 Amadeus (1970)
14 Végh (1973)
15 La Salle (1976)
16 Talich (1977)
17 Amadeus (1982)
18 Melos (1984)
19 Oxford (1985)
20 Vermeer (1985)
21 Guarneri (1987)
22 Lindsays (1987)
23 Emerson (1988)
24 Alban Berg (en vivo, 1989)
25 Hagen (1990)
26 Medici (1991)
27 New Budapest (1991)
28 Tokyo (1991)
29 Bernstein (VPO, 1992)
30 Cleveland (1995)
31 Julliard (1996)
32 Vanbrugh (1996)
33 Alexander (1997)
34 Leipziger (1998)
35 Mosaïques (en vivo, 1998)

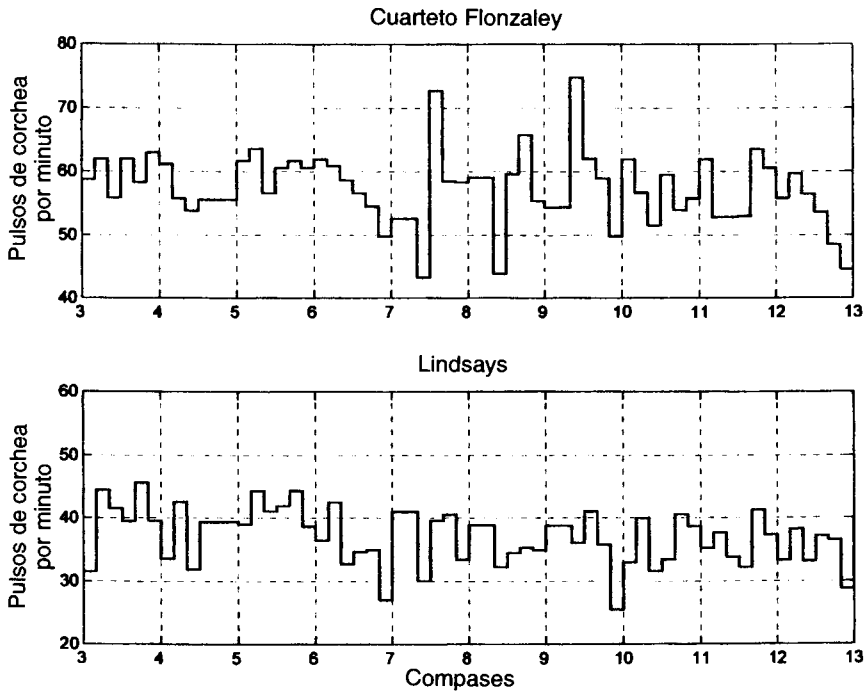
FIGURA 14.1 *Tempos iniciales de treinta y cinco grabaciones del Cuarteto de cuerda en Fa mayor op. 135 de Beethoven, tercer movimiento (Lento assai), compases 4-6, en orden cronológico; la línea ondulada traza las tendencias aproximadas.*

EJEMPLO 14.1 *Beethoven, Cuarteto de cuerda en Fa mayor, op. 135, tercer movimiento (Lento assai), compases 1-12.*

Una pregunta que se ha planteado muy pocas veces es si las interpretaciones grabadas en LP o CD se han visto afectadas por cuestiones de tiempo: el escéptico puede suponer que los productores apresuran a sus intérpretes para que la música quepa en una cara del disco o en un CD. No tengo ninguna prueba de ello, pero, por ejemplo, la grabación de *Drumming* de Steve Reich muestra cómo una grabación en CD puede afectar directamente a la composición misma. La duración original de la obra es de unas tres horas; sin embargo, se redujo a 58 minutos para la grabación en CD realizada por la agrupación del propio compositor [20]. Aunque la decisión de grabarla en un solo CD haya sido motivada por razones económicas o artísticas, el resultado es una experiencia musical completamente diferente.

Estudio de caso 2: vibrato

Muchos aspectos de la técnica de ejecución permanecen prácticamente inalterados por las técnicas de grabación, y uno de ellos es el vibrato [21]. Tanto en los instrumentos como en las voces, el vibrato se logra mediante una combinación de fluctuaciones periódicas de amplitud, frecuencia y timbre. Las grabaciones vocales más antiguas revelan que el estilo moderno de vibrato continuo ya era utilizado por los cantantes italianos durante el cambio de siglo, pero muchos cantantes noreuropeos y americanos siguieron empleando un vibrato intermitente o de muy poca amplitud hasta los años 1920. Sin embargo, a principios de 1900, ni siquiera los italianos empleaban las ondula-



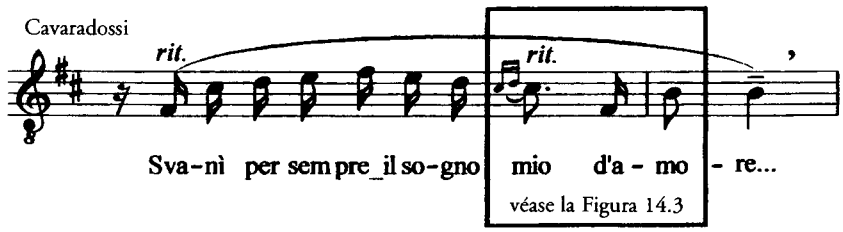


FIGURA 14.2 *Tempos del Cuarteto de cuerda en Fa mayor, op. 135 de Beethoven, tercer movimiento (Lento assai), compases 3-12, grabados por el Cuarteto Flonzaley (1927) y The Lindsays (1987), medidos en pulsos de corchea por minuto (i.e., valores metronómicos); cuanto más alta es la barra, más breve es el pulso.*

EJEMPLO 14.2 *Puccini, «E lucevan le stelle»,* Tosca, *Acto III, compases 20-21 (basado en la partitura vocal de Ricordi, p. 290).*

ciones amplias y lentas que se escuchan habitualmente en las salas de ópera hoy en día. La voz de Caruso se caracteriza por un vibrato rápido y continuo y por un empleo controlado pero notable del portamento, como muestra la Figura 14.3. Dicha Figura muestra el do♯[1], el fa♯ y el si del famoso pasaje de *Tosca* reproducido en el Ejemplo 14.2. Cada línea ondulada corresponde a un armónico de la nota cantada [22].

La Figura 14.3 muestra una enorme cantidad de detalles. Permite medir con mucha precisión la duración de cada nota, su timbre (los armónicos fuertes y ausentes), los modos de ataque y caída y el portamento. El emotivo declive del do♯[1] se puede ver claramente en el gráfico y se puede medir hasta aproximadamente una tercera mayor. La energía principal del do♯[1] está centrada en el segundo armónico, do♯[2] (*ca.* 550 Hz), mientras que la fundamental, do♯[1], está prácticamente ausente [23]. La Figura 14.3 también muestra la formante del cantante, es decir, el «zumbido» que se escucha en las voces masculinas bien adiestradas. Éste se encuentra una banda de frecuencia de aproximadamente 2.600 Hz (≈ re♯[4]), en la que las ondas largas y solapadas, causadas por el vibrato, garantizan que la formante forme una banda de sonido agudo casi continuo. Por último, contando los picos de las líneas onduladas y midiendo los puntos de comienzo y final, resulta fácil determinar que la frecuencia del vibrato es de aproximadamente 7,6 ciclos por segundo (cps), tal y como se indica entre las dos flechas [24].

Las primeras grabaciones de violinistas llegaron justo a tiempo para captar el final de una tradición interpretativa que cambiaría dramáticamente entre 1910 y 1930. Las únicas grabaciones de Joachim, realizadas en 1904, revelan un empleo selectivo y muy poco expresivo del vibrato, que no forma parte del tono básico [25]. En cuanto a los vientos de madera, las grabaciones demuestran que el vibrato no fue empleado antes de aproximadamente 1930, excepto por algunos flautistas de la tradición francesa. Léon Goossens

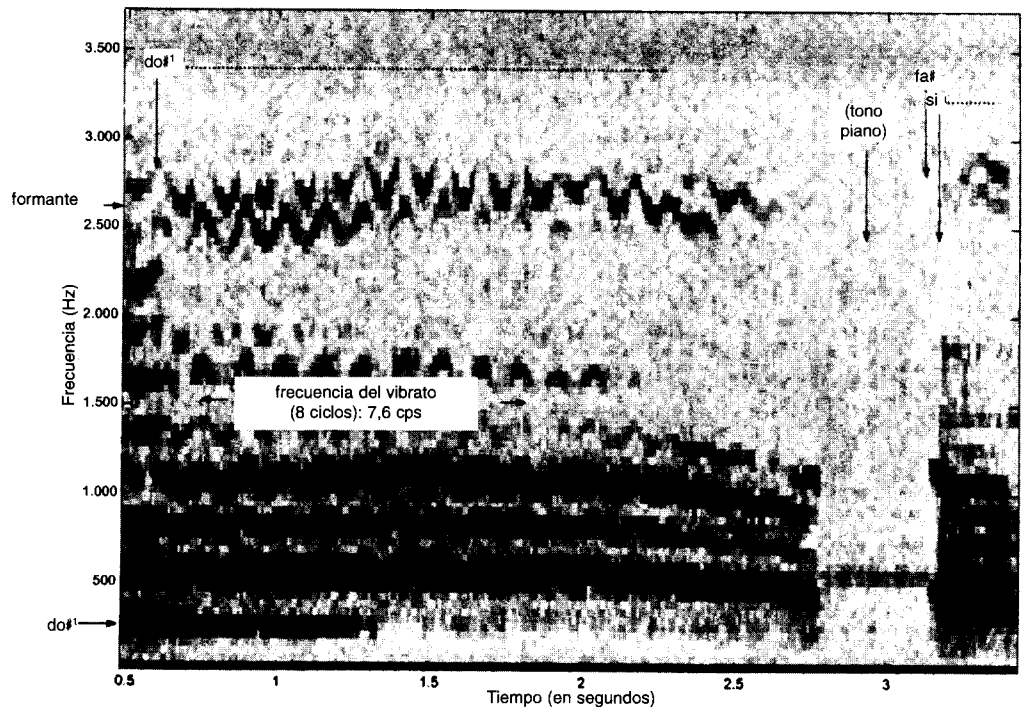

FIGURA 14.3 *Espectograma del pasaje marcado dentro del recuadro del Ejemplo 14.2. Las líneas onduladas muestran cada armónico del tono vocal; las líneas rectas, apenas visibles, representan los tonos piano. El tono se corta en el décimo armónico, ca. 2.770 Hz, que es mi♯⁴, tres octavas por encima del mi central.*

describió detalladamente sus intentos por introducir el vibrato durante los años 1920. Aunque muchos intérpretes lo insultaron y se burlaron de él, sus esfuerzos fueron recompensados por Thomas Beecham, quien lo eligió como primer oboe para la Orquesta Filarmónica de Londres en 1932 [26]. El primer clarinete de la misma orquesta, Reginald Kell, no tardó en seguir su ejemplo, y los efectos de esa revolución se pueden escuchar en varias grabaciones anteriores a la guerra. Sin embargo, algunas de la grabaciones orquestales más antiguas, como la notable versión de la Quinta Sinfonía de Beethoven que realizó Artur Nikisch al frente de la Filarmónica de Berlín en 1913, demuestran lo que puede lograr una buena sección de maderas sin utilizar el vibrato [27]. Muchas grabaciones, incluso de los años 1950, demuestran que se empleaba mucho menos vibrato del que sería habitual en las décadas siguientes.

El empleo del vibrato en otros instrumentos, como la trompeta o el fagot, es igualmente fascinante. De especial interés es la historia del vibrato en la trompa. Durante la primera mitad del siglo, las orquestas europeas orientales lo empleaban habitual y muy expresivamente. Las grabaciones de orquestas checas y soviéticas proporcionan ejemplos impresionantes para los oyentes curiosos, y para los ejecutantes de trompa muy valientes [28].

Aunque generalmente el proceso de grabación no altera el vibrato, el productor de la grabación puede intervenir indudablemente en el resultado final. Elizabeth Schwarzkopf señaló que su marido, Walter Legge (el más veterano de los productores de la posguerra, famoso por exigir los niveles más altos a sus intérpretes), no dudaba en quejarse cuando escuchaba el odiado «temblor» [29]. Legge produjo la mayoría de las grabaciones de EMI/HMV de los años 1950, incluyendo muchos LPs maravillosos de la Philarmonia, una orquesta que fundó específicamente para grabar.

La interpretación de las grabaciones

Las grabaciones revelan claramente una gran cantidad de información sobre las diversas prácticas interpretativas del siglo XX, que en este capítulo apenas he tratado superficialmente. La pregunta básica es cómo se combinan los factores como la entonación, el vibrato, el timbre, el balance, la sincronización y el modo de ataque, la acentuación, la ornamentación [30] y, no menos importante, el control estructural, para producir la experiencia auditiva holística que ofrece la grabación misma. En este sentido, las mejores reseñas de grabaciones siguen siendo las de ciertos críticos, que han desarrollado un lenguaje sofisticado para abordar la experiencia auditiva. Mucha labor crítica se desperdicia en el juego pueril de descubrir la grabación «definitiva» o la «compra maestra». En efecto, comparar grabaciones es un método excelente para des-

cubrir y celebrar la maravillosa diversidad de interpretaciones y artistas del archivo de grabaciones. Y si el lenguaje de los críticos es demasiado impreciso para los musicólogos, éste se puede complementar y apoyar con el análisis acústico, como he intentado demostrar. Sin embargo, no hay música hasta que se interpretan los sonidos, y el lenguaje del crítico proporciona al menos una base para analizar por qué una grabación determinada es musicalmente tan conmovedora, emocionante, mágica o simplemente aburrida [31].

Existen muchas grabaciones en las que los compositores han participado en la producción o la interpretación. También se da el caso de compositores que han grabado la misma obra más de una vez, y esas grabaciones nos permiten hacer comparaciones muy interesantes. Las inevitables diferencias que existen entre ellas sugieren que una única interpretación o grabación «aprobada» por el compositor nunca debe considerarse como definitiva. Las dos grabaciones del Concierto para violín de Elgar dirigidas por el compositor constituyen un ejemplo. La primera, grabada en 1916, es una versión muy resumida que, aunque fue reorquestada por el mismo Elgar, apenas ofrece al oyente moderno una experiencia satisfactoria de la obra en sí misma. Sin embargo, la interpretación del violín es fascinante. La solista es Marie Hall, una violinista inglesa muy respetada a ambos lados del Atlántico, cuya grabación revela una sonoridad exquisita y una notable sensibilidad en el fraseo. Resulta interesante comparar su interpretación con la famosa grabación realizada por Yehudi Menuhin en 1932 [32]. La técnica de Menuhin es esencialmente moderna: el sonido «hilado» se debe a un vibrato compacto y continuo; la ejecución es audaz y virtuosística; y cada frase es expresada de una manera retórica que quizá delate la juventud de Menuhin; sin embargo, no es sustancialmente diferente del enfoque de un violinista moderno.

El enfoque más lírico de Hall quizá se acerca más al espíritu de la partitura de Elgar. Su ejecución está impregnada de ese patetismo y sensación de pérdida que parecen tan propios de la música de Elgar y de gran parte del arte y la literatura inglesas de principios del siglo XX. Y aunque Elgar manifestó estar encantado con la interpretación de Menuhin, no pudo haber imaginado una ejecución similar cuando compuso la obra, en 1910, ya que el estilo moderno aún no existía. Su ideal de ejecución violinística, e incluso de la obra misma, debe por tanto haber cambiado a medida que se desarrollaron los estilos interpretativos en los años 1920. Aún así, Hall demuestra que tales cambios no son necesariamente beneficiosos, y que la interpretación del concierto de Elgar no ha de ser necesariamente la demostración de poderío que suele ser hoy en día.

La influencia más amplia de las grabaciones

La influencia de la grabación en nuestras prácticas musicales más amplias apenas está comenzando a ser reconocida [33]. ¿Se ha llegado a concebir la música como algo más abstracto, incorpóreo e ideal debido a la invisibilidad de sus intérpretes en las grabaciones?, ¿o es que los métodos de grabación simplemente han respondido a las ideologías actuales sobre lo que debe ser la música? Una cosa está clara: debemos rechazar la opción simplista de suponer que una determinada grabación representa «la obra misma» de manera autorizada. Las obras posteriores a la guerra son particularmente vulnerables en ese sentido. Cuando se conocen por una sola grabación y rara vez se tocan en vivo, resulta fácil suponer que las características, e incluso los errores, de la interpretación grabada representan lo que es la obra, que la grabación refleja «cómo suena la obra». Las grabaciones múltiples nos permiten explorar la obra como un objeto de muchas facetas, o incluso como algo no determinado materialmente hasta que es leído o interpretado [34].

Hindemith afirmó que toda interpretación es una corrupción de la obra, pero las grabaciones demuestran la importancia de la voz del intérprete como complemento de la del compositor. Es a través del personaje del intérprete —y quizá también del productor— como «la obra misma» cobra vida y adquiere significados musicales particulares. Cada grabación es una creación artística única, lograda mediante una síntesis de la composición, la interpretación y determinados métodos de grabación. No es de extrañar, pues, que la música grabada haya desempeñado un papel tan importante en nuestra cultura musical durante los últimos cien años. Con la llegada de nuevos formatos como el muestreo digital y la transmisión por internet, podemos esperar un futuro igualmente emocionante e influyente para la grabación de la música clásica en las décadas venideras.

15 *La crítica de la interpretación musical*

RAYMOND MONELLE

Considerada como un tipo de escritura formal, la reseña de concierto es algo relativamente nuevo. Hasta hace poco se tenía un prejuicio contra ella; no estaba a la altura del interés de las personas sofisticadas. Uno podía escribir sobre teoría musical, sobre estilos, modas e influencias, sobre composiciones nuevas. Pero criticar conciertos e intérpretes era un tanto degradante y furtivo. Incluso un crítico distinguido como William J. Henderson afirmó: «Estamos confrontados con la demanda de artistas interpretativos. Cualquiera que ubique la crítica en un nivel alto querrá decir muy poco sobre ellos. Considerar al intérprete es el objetivo menos importante de la verdadera crítica» [1]. El gran especialista en música Ernest Newman comentó en una entrevista para la prensa, en 1931, que las interpretaciones repetidas de obras famosas dejaban a los críticos sin nada que hacer:

> Aunque proporcionan muchos placeres al aficionado común, los Promenade Concerts siguen ofreciendo muy pocos pretextos al crítico para dar a conocer sus opiniones, ya que los programas están compuestos en gran parte por obras muy famosas. La semana pasada hubo una noche Wagner, una noche Beethoven, una noche Brahms y una noche Tchaikowski, y como ninguno de estos compositores ha escrito mucho últimamente, no ha habido obras nuevas para que los críticos pudieran ejercer su infalible juicio [2].

Quizá debido a ese prejuicio, la historia de la crítica de la interpretación es bastante diferente de la historia de la crítica musical general. La mayoría de las historias de la crítica se centran en el juicio de composiciones, especialmente las nuevas, y las antologías estándar de críticos como Eduard Hanslick

y Bernard Shaw naturalmente otorgan más espacio a las obras maestras que eran nuevas en su día. Curiosamente, la descripción de ese elemento familiar de la vida musical, la reseña de concierto, aún estaba por escribirse.

Sin embargo, hoy en día ese tipo de reseña predomina en la crítica musical. ¿Cómo se ha producido ese cambio? Indudablemente, el abrupto declive de la interpretación de música contemporánea ha llevado a los críticos a concentrarse en los artistas intérpretes; en el siglo XVIII, mucha de la música que se escuchaba acababa de salir de la pluma del compositor. Además, a menudo los instrumentistas eran también compositores; interpretaban sus propias obras, y los críticos naturalmente se centraban en las obras y no en los intérpretes. Pero a medida que se consolidaba el canon de las obras clásicas —en gran parte gracias a los críticos musicales—, las múltiples interpretaciones de obras canónicas revelaban la medida en que los intérpretes contribuyen a la experiencia de la música. Al principio (y esto es especialmente evidente en los escritos de Shaw), se podían hacer comentarios, incluso desfavorables, sobre obras que ya habían sido aceptadas dentro del canon, pero en la época moderna, cuando la mayoría de las obras que se interpretan son canónicas, no se espera que los críticos alaben a Haendel, o refunfuñen sobre Brahms como lo hiciera Shaw. Se supone que han de centrarse en el intérprete.

Las primeras críticas musicales publicadas en revistas especializadas, como *Critica musica* (Hamburgo, 1722-1725) de Johann Mattheson o *New eröffnete musikalische Bibliothek* (Leipzig, 1736-1754) de Lorenz Mizler, contienen muy pocas evaluaciones interpretativas. A veces se encuentra alguna evaluación general del estilo de un intérprete, pero rara vez se publicaban reseñas de conciertos u óperas. Sin embargo, hacia finales del siglo XVIII los informes sobre las producciones operísticas podían incluir descripciones perspicaces de los cantantes; por ejemplo, la revista berlinesa *Litteratur-und Theater-Zeitung* de 1781 incluye muchos informes sobre óperas. Ese mismo año, la revista reseñó la visita a Berlín del bajo Ludwig Fischer, el primer Osmin de *Die Entführung aus dem Serail* (1782) de Mozart:

> Herr Fischer, cantante imperial y real, estuvo varios días en la ciudad; actuó dos veces como el mensajero en *Zémire et Azor* [de Grétry], y en una ocasión, entre los actos, cantó dos arias de la gran ópera *Günther von Schwarzburg* de Holzbauer. Los entendidos se maravillaron ante la pureza y extensión de su voz, y todo el público estaba encantado con su exitosa interpretación y la gran habilidad de su canto... [3].

Ésta es una crítica rudimentaria, que no demuestra ni exige un conocimiento sofisticado de la música o el canto.

La primera publicación periódica realmente influyente fue el semanal *Allgemeine musikalische Zeitung (AmZ)* [4] de Leipzig, que apareció por primera

vez en 1798. Su editor, Friedrich Rochlitz, se dio cuenta rápidamente de que los lectores querían algo más que los artículos y reseñas generales de obras nuevas que habían caracterizado a las publicaciones anteriores. Los primeros números contenían a veces «correspondencia» proveniente de los centros musicales alemanes, Berlín, Viena, Dresden, etc., a veces (aunque no siempre) con comentarios sobre conciertos. Para el año 1800, estas correspondencias se habían consolidado en noticias periódicas *(Nachtrichten)* en las que se describía la actualidad concertística y operística de las ciudades alemanas, muchas veces con comentarios detallados sobre los intérpretes, especialmente los cantantes. La siguiente reseña de un concierto que tuvo lugar en 1802 con la actuación del violonchelista Nikolaus Kraft, miembro del Cuarteto Schuppanzigh, demuestra un conocimiento de muchos intérpretes y del instrumento, así como un sólido criterio sobre lo que constituye una buena ejecución:

> Es un violonchelista muy notable; su sonido no es opaco y nasal como el que suele escucharse en este instrumento, sino potente, varonil, amplio (lleno, como dicen los músicos); su ejecución es rápida, segura, precisa, delicada y pura (aparte de algunos detalles en los registros extremos, que no fueron del todo exitosos); su manejo del arco es admirable... [5].

Ésta es una verdadera reseña de concierto, y no un artículo general sobre el estilo de un artista como los que habían sido comunes durante el siglo anterior.

La revista llegó a publicar algunas de las reseñas más detalladas y acertadas de todas las épocas, lo que exigía de sus lectores un conocimiento profesional de los instrumentos, las técnicas y los estilos, como demuestra una reseña del 28 de abril de 1830 sobre un gran violinista, Heinrich Wilhelm Ernst:

> Herr Ernst, un hombre joven todavía, posee todos los recursos que, combinados con la fuerza de su talento obviamente excepcional, pueden conducirle en pocos años al camino que le convertirá en uno de los más grandes artistas vivos, ya que tiene una facilidad inusual para los pasajes brillantes, los saltos, las dobles cuerdas, etc., además de un sonido potente y puro y un control diestro del arco; su ejecución de los Adagios tampoco es despreciable, aunque no del todo elogiable. Sin embargo, es de lamentar que Herr Ernst, sin saberlo, se encuentre en un camino artístico falso, ya que parece ser simplemente un imitador y quiere tocar «a la Paganini» [6].

Ésta no es una reseña para el lector común. La revista esperaba que los lectores tuvieran cierto conocimiento de la técnica instrumental. El verdadero arte del periodismo musical popular aún estaba por descubrirse.

La publicación de comentarios musicales en los diarios, a diferencia de las publicaciones semanales o mensuales, comenzó a principios del siglo XIX,

probablemente con las reseñas de J. C. F. Rellstab (1808-1813) en el *Vossische Zeitung* de Berlín. En Londres y París, la reseña diaria —foco principal de la crítica moderna— surgió a partir de la reseña teatral. De hecho, Julien-Louis Géoffroy (1743-1814), crítico teatral del *Journal des débats* parisino, se jactaba de su ignorancia musical, aunque reseñaba óperas con frecuencia.

Durante los primeros años del siglo XIX, *The Times* publicaba a veces reseñas de las funciones de los principales teatros londinenses, incluyendo óperas. Al principio, éstas eran escritas por un crítico de teatro, Barron Field, o por el director del periódico, T. M. Alsager. Más tarde, en 1843, contrataron a un verdadero crítico musical, Charles Lamb Kenney. Durante un tiempo, sin embargo, no se notó mucha diferencia; las reseñas, que aún aparecían sin firma, seguían haciendo comentarios sobre el público y los vestidos de las damas, y había muy poca crítica musical, aparte de las óperas. Cuando aparecía una reseña de concierto, los comentarios eran breves y generales —como en la siguiente descripción de un concierto del Festival de Birmingham, el 19 de septiembre de 1843, dirigido por William Knyvett, con la contralto Maria Hawes y la mujer de Knyvett, Deborah Travis: «La señora Knyvett cantó el aria "Pious orgies" [de *Judas Maccabaeus* de Haendel] con gran precisión y pureza de estilo. Su interpretación de la música de Haendel sigue siendo tan perfecta como siempre. El hermoso aria "Jehovah crown'd" le fue asignado a la señorita Hawes, quien lo cantó con fuerza pero con una energía tal vez demasiado elaborada en algunos pasajes» [7]. Aún no se consideraba que los lectores de *The Times* estuvieran preparados para comentarios musicales más detallados o sensibles.

En esa misma época tuvo lugar un acontecimiento en París que determinaría el futuro de la reseña de conciertos. En 1872, François-Joseph Fétis, bibliotecario del Conservatorio de París y, más tarde, director del Conservatorio de Bruselas, fundó el semanal *Revue musicale,* una revista seria y responsable que incluía reseñas de conciertos entre sus artículos generales sobre música. La mayor parte de cada número estaba escrita por el infatigable Fétis, quien se tomaba sus labores muy en serio, escribiendo en un estilo pesado e intransigente. El poeta Heinrich Heine, que también escribía críticas musicales para la *Allgemeine musikalische Zeitung,* comentó: «No conozco nada que inspire menos que una crítica del señor Fétis [...] escritas en una jerga particular y salpicadas de términos técnicos que la mayoría de los lectores educados desconocen» [8]. El estilo tedioso de Fétis se puede apreciar en una reseña de concierto del primer número de la revista (febrero 1827):

> El concierto se inició con el primer movimiento de la sinfonía de Haydn que comienza en Re menor seguido de un Allegro en Re mayor [núm. 104]. Una entrada falsa de los fagotes en la introducción estropeó el efecto. La primera parte del alle-

> gro estuvo bien ejecutada, pero, en la segunda, tan enérgica y vigorosa, la orquesta careció de brío y calidez. Varias fluctuaciones de tempo impidieron que los violines tocaran juntos, y a los bajos, por ser muy pocos, les faltó energía en el momento explosivo [¿el tutti del compás 32?].

En oposición a esta respetable publicación, el editor Maurice Schlesinger fundó la *Gazette musicale de Paris* en 1834. Esta rival tuvo tanto éxito que la *Revue musicale* no tardó en fusionarse con ella. Los escritores de la *Gazette,* entre quienes se incluían personajes importantes como Berlioz, Liszt, Wagner, Castil-Blaze y Joseph d'Ortigue, cultivaron un estilo nuevo e ingenioso derivado del *feuilleton* de crítica teatral, que reemplazó el lenguaje técnico con impresiones, burlas, referencias cultas y opiniones personales. La mayoría de los artículos ya aparecían firmados por sus autores. Era verdadero periodismo, pero sus mejores ejemplos estaban reservados a los artículos generales y reseñas de obras nuevas.

En la *Gazette,* las reseñas regulares de conciertos estaban escritas cada vez con mayor frecuencia por el dramaturgo, compositor y violinista Henri Blanchard (quien se convirtió en uno de los editores adjuntos en 1836), en lugar de las celebridades mencionadas anteriormente. La bravura de los famosos *feuilletons* de la *Gazette* no caló realmente en las reseñas elementales de Blanchard; sin embargo, Blanchard desarrolló un auténtico estilo de periodismo musical evocativo, dinámico y desprovisto de tecnicismos. Tal vez el arte de la reseña concertística moderna se desarrolló a partir de las reseñas de Blanchard y su sucesor Adolphe Botte. El 5 de diciembre de 1847, Blanchard describió un concierto en la Salle Hertz en el que se interpretó un cuarteto de Mozart —aparentemente el K. 589:

> La ejecución... fue perfecta. El señor Tilmant [primer violín] hace bien en no tomarse demasiado literalmente el término «música de cámara» que aparentemente sólo se aplica a la música íntima interpretada en un espacio pequeño. Su estilo amplio y orquestal confiere una especie de amplitud sinfónica a un cuarteto que algunos de nuestros violinistas tocan de manera bonita y tacaña. Para que suene apasionado y expresivo —signos característicos de la interpretación musical moderna—, conviene que en ciertas cadencias melódicas haya un tratamiento flexible de esa precisión y esa rigidez de tempo que al final le da una especie de aridez mecánica a la idea musical, despojándola a veces de la inspiración y la poesía que debe de haber animado al compositor cuando la escribió.

La *Gazette musicale* tenía muchos lectores, y desde el principio comenzó a influir en el mundo musical, y a crear o destruir carreras. Citando de nuevo a Heine: «Los artistas más afamados se postran sumisamente a los pies de Schlesinger, arrastrándose y moviendo sus colas, para tener una buena crítica

en su revista» [9]. Uno de los colaboradores era Ludwig Rellstab, hijo del crítico del *Vossische Zeitung*, que sabía bastante sobre las reacciones de los intérpretes ante sus críticas: el artículo que escribió en Berlín en 1826 sobre la cantante Henrietta Sontag le había dado problemas con las autoridades, y fue encarcelado durante tres meses en la fortaleza de Spandau, lo que lo convirtió en el primer mártir de los críticos musicales [10].

También en Londres el poder de la prensa musical se hizo evidente. En 1846, *The Times* contrató a su primer crítico musical profesional, J. W. Davison. Este escritor característico pronto comenzó a adquirir un enorme poder sobre la profesión musical [11]. En sus reseñas, da la impresión de ser un crítico indulgente y generoso, alabando incluso a aquellos artistas cuyos defectos también tenía la obligación de reseñar. De tal manera, su reseña de la representación de *Lucia di Lammermoor* en la Royal Italian Opera del Covent Garden en 1847, con Fanny Tacchinardi-Persiani y Lorenzo Salvi, combina característicamente un gran discernimiento y el deseo de no querer decir nada desfavorable sobre nadie:

> La ejecución extremadamente limpia y delicada de una profusión de ornamentos, la distinción de cada nota en los pasajes más rápidos, la variedad de colorido —la facilidad con la que hace todo— eran las mismas de siempre. El canto de Persiani ha sido comparado una y otra vez con un artista consumado tocando un instrumento delicado [...] En el segundo acto, se pudieron observar quizá algunos de los leves fallos de entonación que solía tener la cantante, por lo demás perfecta, pero el defecto solo fue transitorio [...]
>
> El debú de Salvi en el papel de Edgardo fue tal vez el evento más interesante de la noche, y su éxito debe de haber satisfecho las expectativas de sus admiradores más fervientes. Tiene una voz de tenor pura, de registro amplio, no destacable por su volumen, pero perfectamente uniforme en cada parte y poseedora de la mayor flexibilidad. La maneja con la habilidad de un artista consumado, introduciendo en ella las más hermosas variedades de luz y sombra, y haciéndola elocuente con una expresión dramática. Quizá su mayor habilidad como vocalista se demuestra en sus pasajes *piano*, con una voz completamente atenuada sin detrimento del valor de las notas [12].

El estilo y las virtudes de ambos cantantes están maravillosamente descritos, aunque quizá de manera poco fidedigna. En la época corría el rumor de que Davison aceptaba sobornos, y en esa ocasión el marido de Persiani, Giuseppe, que era el director del teatro, pudo haber influido en el juicio de Davison. En todo caso, cuando Francis Hueffer reemplazó a Davison en 1879, se decía que «tuvo que alquilar un carro de cuatro ruedas para devolverle a los distinguidos músicos los regalos que le llegaban a su puerta» [13]. Tratar de congratularse con los críticos es una actividad que siempre ha acosado al

mundo musical: aunque tal vez el puro soborno ha desaparecido de la escena, los críticos pueden ser capaces de aceptar invitaciones a fiestas y entradas gratuitas incluso hoy en día.

Los críticos pedantes y demasiado serios que seguían la tendencia de Fétis no tenían futuro en un mundo en el que todos leían sobre música. La crítica se había convertido en un género literario. Sin embargo, algunos grandes críticos seguían adoptando un tono solemne y altivo. Uno de ellos era Eduard Hanslick, profesor de historia y estética musical de la Universidad de Viena. Hanslick escribió reseñas de conciertos desde 1855, y en 1864 comenzó a colaborar en la *Neue freie Presse,* un diario que era leído no sólo en Austria sino también en Alemania. Los artículos de Hanslick solían aparecer en primera página. Hoy en día se le recuerda principalmente por su hostilidad hacia Wagner y por su folleto sobre estética de 1854, *Vom Musikalisch-Schönen* (Sobre lo musicalmente bello), pero en su día dominaba la crítica musical europea. Sus escritos combinaban un profundo conocimiento y un estilo serio pero fácil, basándose más en la descripción evocativa que en el análisis técnico. Escribía con claridad, precisión y elegancia, con un agudo discernimiento y elevados parámetros estéticos; pero siempre resulta agradable de leer. Cuando el pianista Rafael Joseffy dio un recital en 1874, Hanslick consideró que la esencia poética de la música se perdía en el deseo de lograr la perfección técnica:

> El tesoro poético [...] permaneció en general oculto. ¿Carece [el pianista] de la secreta resonancia del espíritu, o es que el puro placer del virtuosismo le constriñe? Tocó el *Traumeswirren* de Schumann, uno de los pequeños poemas más hermosos del compositor, como si fuera un *étude* cuyo objetivo es la máxima velocidad y el máximo nivel de *pianissimo* —casi a la manera de un reloj musical. Incluso el maravilloso movimiento central, ese núcleo del sueño, característicamente velado y nebuloso, estuvo demasiado expuesto al sol matutino. Ocurrió lo mismo con la maravillosa Novellette en Re, op. 21 núm. 4, de Schumann; hemos visto el salón de baile, pero no la conmovedora historia de amor que allí se representó [14].

Tal vez nos sorprenda que el destacado defensor del formalismo estético muestre semejante sensibilidad a la magia poética de la música.

Bastante diferente es el caso del contemporáneo menor de Hanslick, Bernard Shaw, quien escribió críticas musicales entre 1876 y 1894 para *The Hornet, The Star* (en el que firmaba como «Corno di Bassetto») y por último *The World,* una revista semanal. En Shaw se combinaban un verdadero genio para la crítica musical y una irresponsabilidad monstruosa. Era vulgar, insultante, divertidísimo, caprichoso e injusto, y el estándar de sus reseñas de conciertos era a veces lamentable. Le gustaba pretender ser un ignorante musical, pero en realidad su conocimiento del repertorio era extenso y sabía

mucho sobre música, especialmente sobre canto, ya que su madre era cantante. En lugar del aire de erudición que sustenta a los escritos de Hanslick, los textos de Shaw sugieren el *vox populi;* Shaw hace comentarios sobre el precio de los programas de mano, la avería de un vagón en las vías férreas o una visita al dentista, como si fuesen tan importantes como el concierto.

Sus prejuicios son conocidos. No le gustaba Brahms ni Bruch, elogiaba a Wagner, era cruel con Mendelssohn y admiraba a Hermann Goetz. Pero sus reseñas de conciertos a veces son exasperantes. Una y otra vez, Shaw escribía miles de palabras sobre un oratorio o una serie de conciertos sin decir nada más que la ejecución había sido execrable, o excelente, todo ello mezclado con muchos comentarios sobre lo anticuados que son los franceses o la plaga de violinistas femeninas. Siempre, invariablemente, expresaba una opinión personal. Critica un concierto de Joachim con el único objetivo de recomendarnos que no escuchemos el Concierto para violín de Bruch. Comenta el canto de Adelina Patti sólo para demostrar que Wagner, cantado correctamente, no cansa la voz.

El extraordinario ingenio y la brillantez de Shaw, por tanto, sólo son marginalmente pertinentes al estudio de la crítica musical. En realidad, Shaw podía escribir con agudeza y perspicacia sobre interpretación cuando quería. En el siguiente fragmento de una reseña de la Novena Sinfonía de Beethoven, dirigida por George Henschel, demuestra un profundo conocimiento y una enorme simpatía por el estilo de Beethoven, pero no puede evitar la ridiculización en sus últimas frases:

> En cuanto al señor Henschel y su interpretación de la Novena Sinfonía el pasado jueves, cuando digo que comprendió totalmente la naturaleza de la obra, y en ningún momento estuvo en peligro de cometer el tradicional y craso error de tratarla como un mero arabesco musical, quiero decir que el concierto fue un éxito [...] El vigor y la decisión con la que Henschel nos entregó el primer tema hicieron que nos tranquilizáramos rápidamente con respecto a su dominio de la situación, especialmente en esos dos últimos compases con los que Beethoven lo resuelve tan contundentemente [...] El señor Henschel, como el Maestro Contratista de Ibsen, y como todo buen director, tiene un troll dentro de sí; y a ese troll a veces le da por arrasar y obstaculizar, momentos en los que Henschel no sólo tolera e incluso se deleita al atacar brusca y descaradamente los pasajes imponentes, sino que también acelera a sus músicos [...] Pero Beethoven debe de haber sabido muy bien que ése es uno de los fallos comunes en las cualidades de un director; y para mí está claro que ese pavor a que cualquier urgencia o excitación vulgar estropeara la grandeza de su obra maestra sinfónica fue lo que le impulsó a indicar el tempo del primer movimiento no como un mero *allegro*, sino como «allegro, pero no demasiado, más bien majestuoso»...
>
> Más tarde, Henschel nos asombró a algunos con el tempo sumamente lento con el que tomó el *allegro assai,* en el que los bajos enuncian el tema de la oda a la

> alegría. Estamos tan acostumbrados a escucharlo a exactamente el doble de la velocidad demasiado rápida, como si las blancas y negras fueran corcheas y semicorcheas, y tratado como si fuese un allegro de Haydn en lugar de una melodía expresiva, que algunos de los oyentes más mayores se sintieron un poco indignados con Henschel por no haber tomado el camino erróneo habitual [...]
>
> [Durante el movimiento lento, una dama del coro se desmayó, dando lugar a] un despliegue de abanicos y frascos de sales, la conmoción entre los galantes tenores y bajos, al fondo del coro, y por último la desesperada recuperación de la paciente, que aplazó triunfantemente su caída desde lo alto de la empinada escalera al otro lado de la puerta. Durante todo aquello, la orquesta podría haber tocado «Pop Goes the Weasel» sin sentir más temor de que lo detectáramos del que habrían sentido si todos hubiésemos sido una clase de St. John Ambulance *...[15]

El sucesor de Shaw como principal crítico musical de Inglaterra fue Ernest Newman, pseudónimo de William Roberts, quien escribió para el *Manchester Guardian,* el *Birmingham Daily Post,* el *Observer* y finalmente el *Sunday Times* durante una larga carrera desde 1905 hasta 1958. Mientras que Shaw era un *enfant terrible,* Newman era humano y augusto. Incluso su pseudónimo era una expresión de sus creencias; se veía a sí mismo como un nuevo tipo de crítico, serio y juicioso. Sin embargo, las obras maestras de Newman eran sus ensayos eruditos sobre temas generales; sus reseñas de conciertos eran banales.

Mucho más personales e ingeniosas eran las críticas de Virgil Thomson en el *New York Herald Tribune.* Thomson era un compositor eminente, por supuesto; como crítico, era heredero de una distinguida tradición de crítica musical americana que incluía críticos magníficos como Henry T. Finck, quien escribió para *The Nation* y el *Evening Post* de Nueva York entre 1881 y 1924; el culto William J. Henderson [16], que escribía para el *New York Times* y el *Sun* entre 1887 y 1937; y el contemporáneo de Thomson, Olin Downes, cuyos artículos para el *New York Times* influyeron en la historia de la música (por ejemplo, ayudó a establecer a Sibelius dentro del repertorio canónico).

El enfoque de George Szell de la Quinta Sinfonía de Beethoven condujo a Thomson a examinar el contenido moral de dicha sinfonía:

> Un resultado moral estimulante es más importante que el peligro que entraña cualquier lectura errónea de la idea específica del compositor. Además, la pieza se recuperará de su actual servicio militar con la misma facilidad con que se libró de sus anteriores connotaciones metafísicas y políticas [...]
>
> Para llevar la sinfonía a la acción directa, el señor Szell se vio obligado a destacar la determinación del material masculino y franquear disimuladamente la im-

* Se refiere a las clases de primeros auxilios que imparte esa organización humanitaria, fundación de la Orden Hospitalaria de San Juan *(N. de la T.).*

> portancia de sus pasajes tiernos y gentiles. Hizo que las cuerdas tocaran fuerte y toscamente, con ese impacto feroz que producen tan admirablemente las cuerdas sinfónicas [...] Con la entrada de los trombones, al principio del último movimiento, las trompas se quedaron tan irremediablemente descalificadas en esa competencia de lanzamiento de peso como se habían quedado las maderas desde el principio. Todo el desequilibrio hizo que Beethoven sonara como un compositor muy autorizado y didáctico, que ciertamente era, pero también como un orquestador irremediablemente incompetente, que desde luego no era. Y precisamente esa ineficacia musical de los contrastes orquestales fue lo que demostró que, a pesar de la grandiosidad moral de la interpretación, se estaba quebrantando el espíritu de la obra, sea cual sea nuestro modo de concebirlo [17].

Tal combinación de crítica de la interpretación con una profunda percepción del contenido moral de la obra es realmente inusual.

En Alemania, la crítica permaneció en manos de eminentes músicos en activo y profesores de música. Su estilo no era ingenioso o elegante, sino digno, respetable y pesado. Heinrich Ehrlich, quien escribió para el *Berliner Tageblatt* desde 1878 hasta 1898, era un distinguido pianista. Su homólogo en Hamburgo, Max Loewengard, era profesor de teoría musical. El más distinguido de este grupo era el musicólogo Alfred Einstein, quien escribió críticas para el *Berliner Tageblatt* hasta 1933, además de revisar el catálogo de Köchel de las obras de Mozart y publicar un libro decisivo sobre el madrigal italiano.

En épocas más recientes, la crítica se ha vuelto menos solemne, menos *ex cathedra.* Hoy en día, los críticos con marcados intereses personales no son realmente aceptables; se espera que se centren en el intérprete y no en sus teorías favoritas sobre la música. Sin embargo, existen dos tendencias que han arruinado el arte del periodismo musical. En primer lugar, el espléndido espacio que se le asignaba a la crítica musical se ha reducido; sólo algunas publicaciones periódicas, como el *New Yorker,* continúan reservando millares de palabras —como las que Shaw o Hanslick podrían exigir— para la crítica musical. Los críticos modernos que compiten por el espacio con las reseñas de música pop, cine, radio y discos, y sobre todo con los anuncios publicitarios, frecuentemente deben expresar su opinión en 500 palabras o menos.

En segundo lugar, las ventajas en cuanto al transporte han tendido a centralizar la reseña musical en las ciudades más importantes. Si una orquesta da el mismo concierto en varias ciudades, o una compañía de ópera hace una gira en diversos teatros, un periódico nacional como *The Times* naturalmente lo reseñará una sola vez. Esto ha provocado el declive o traslado a la capital de importantes periódicos provinciales. Un proceso similar ha ocurrido en otros países, especialmente en Estados Unidos.

Pero, en todo caso, el estilo periodístico admitido ha cambiado. La escritura singular, digna y caballerosa de Ernest Newman ha dado paso a una es-

pecie de precisión lacónica, más lista que erudita, más bromista que ingeniosa y más popular que autorizada. En lugar de la majestuosidad de un extenso artículo de reseña, los mejores críticos buscan hoy en día la crítica memorable de una sola línea. Reseñando una interpretación del guitarrista Carlos Bonell de un canto mozárabe del siglo XI, la admirable escritora Hilary Finch comentó que la música «giraba en pequeños círculos pentatónicos, tañida justo por debajo de la boca de la guitarra, con una voz cobriza que parecía provenir de más allá del tiempo mismo» [18].

Quizá el cambio de mira más importante de la crítica moderna es el descubrimiento de la «interpretación». Mientras que el objetivo de los críticos anteriores era alabar o condenar, o al menos evaluar, la manera en que el intérprete realizaba las «intenciones» del compositor, los críticos contemporáneos han reconocido que el intérprete añade su personalidad y sus ideas a la obra. Por lo tanto, puede haber diferentes realizaciones de una misma pieza, y todas son válidas a su manera. En sus reseñas de una serie de conciertos de Mahler para *The Times,* Joan Chissell señaló que Otto Klemperer y Jascha Horenstein enfocaban de diferentes maneras la obra del compositor:

> [la Primera Sinfonía de Mahler] es el Mahler joven, y el señor Horenstein hizo que sonara joven. Incluyendo la repetición en el primer movimiento, la interpretación duró una hora, pero el tiempo voló porque los ritmos eran muy animados y las texturas muy traslúcidas. Mientras que en la séptima y última semana, el doctor Klemperer se mantuvo distante y objetivo, abandonando la mayoría de los detalles a su suerte, Horenstein hizo todo lo contrario; todo estaba fraseado y coloreado con precisión, y sin embargo no hubo el menor rastro de exageración emocional [19].

Chissell no sugiere que Horenstein, ni Klemperer, se hubieran acercado más al «verdadero» espíritu de Mahler; simplemente indica que sus personalidades eran diferentes. Esta actitud se ha visto fomentada por la disponibilidad de las grabaciones, que permiten una comparación objetiva de diferentes interpretaciones. Cuando Andrew Porter se encontraba redactando una reseña de la Novena Sinfonía de Mahler, salió a comprar un disco de la versión de Bruno Walter para compararla con la versión que acababa de escuchar, dirigida por Pierre Boulez. Se sorprendió al descubrir que los tempos eran muy similares a los de Walter, aunque la impresión era bastante diferente [20].

Finalmente los críticos reconocen diferentes estilos de interpretación de obras canónicas; ya no hay uno correcto y uno incorrecto. En agosto de 1999, un crítico del *Independent* describió a Alfred Brendel como un pianista «clásico», sugiriendo que hay otros tipos de pianista cuya interpretación puede ser igualmente buena:

> La música clásica, y la interpretación clásica, no son realmente una cuestión de lo que haces, sino más bien de lo que no haces. Alfred Brendel es, quizá, el pianista clásico más importante del mundo. Brendel no alarga brevemente cada nota importante. Tampoco hace un *crescendo* emotivo hacia la mitad de cada frase. No toca los pasajes rápidos demasiado rápido, ni los lentos demasiado lento. Y si la partitura indica que hay que repetir una sección, él la repite.
>
> El resultado es más narrativo que expresivo. Te encuentras más bien siguiendo una historia cautivadora que apasionándote. Todo está interpretado con el mayor refinamiento, y nunca toca un cliché, ni siquiera cuando el compositor lo ha escrito [22].

A veces los intérpretes y sus admiradores maldicen a los críticos por ser irresponsables, por dedicarse simplemente a llamar la atención, por tomar a la ligera el trabajo de los artistas serios. La mayoría de los que escriben sobre música repudiarían esas acusaciones. Los críticos son honestos y generalmente escriben con el corazón. Naturalmente, han de atraer el interés de sus lectores; la crítica musical no se puede escribir en el mismo estilo que los informes económicos o los comentarios sobre boxeo, aunque la mayoría de nosotros hemos aprendido algunas lecciones útiles de los cronistas deportivos [23]. Los que discrepan de sus opiniones también acusan a los críticos de ofrecer sólo la «opinión de una persona». Pero ése, claro está, es el único y verdadero objetivo de la crítica musical. Como bien sabía Shaw, nuestros peores enemigos seguirán comprando el periódico para leer nuestras críticas y maldecirlas de nuevo.

16 Los intérpretes y la interpretación

JONATHAN DUNSBY

Qué siente el intérprete

«Puedo dar fe de que en mi larga vida jamás he escuchado a un cantante pronunciar esta feliz verdad: Hoy me siento bien.» Este comentario de una autoridad internacional del canto puede parecer divertido, pero también contiene varios indicios importantes acerca de lo que piensan los intérpretes sobre la interpretación. Existe, por ejemplo, una relación indudable entre la interpretación y el bienestar físico y anímico del intérprete. Hacer música tiene muchos efectos terapéuticos conocidos, pero siempre exige un esfuerzo físico, aunque también suele ser muy estimulante. La música occidental plantea muchas exigencias mentales, por ejemplo en cuanto a memoria y concentración. También requiere un control de las emociones, o al menos así parece, ya que nos sorprendería ver una lágrima deslizándose por la mejilla de un violinista durante un momento particularmente conmovedor de un concierto, a pesar de la importancia que tiene la expresión facial dentro del aspecto visual de la interpretación. Como ha señalado un estudioso al analizar la interpretación como una simulación: «mientras están interpretando, los intérpretes pueden tener la mente en cualquier cosa. Con el espíritu de entretenimiento profesional, un músico puede interpretar con sensibilidad y estar al mismo tiempo sumamente aburrido y anhelando un tranquilo trabajo en el sector inmobiliario» [1]. En segundo lugar, el contexto de la cita inicial de este capítulo es una argumentación sobre qué deberían sentir los cantantes, y su fuente representa toda una colección de escritos y otros testimonios de intérpretes a lo largo de los siglos que plantean que la interpretación tiene algún

tipo de «objetivo» y no es una actividad indiferente —una que, por así decir, es tan buena en un día malo como en uno bueno. Interpretar requiere un grado excepcionalmente alto de entrenamiento y habilidad, hasta un nivel «casi sobrehumano» según uno de los principales directores del siglo pasado [2]. En tercer lugar, la cita inicial no proviene de un pasado reciente, ni siquiera de los últimos dos siglos, sino de 1757 [3], lo que nos indica que puede transcurrir mucho tiempo sin que ocurran grandes cambios. En los años 1780 se escribía sobre la ejecución pianística de Mozart casi como si hubiera sido el ganador de un concurso internacional reciente [4], y la antigua mitología griega describía a Orfeo y sus poderes mágicos como intérprete de la lira casi de la misma manera en que la «realidad» de los medios de comunicación de principios del siglo XXI resucita la presencia casi divina de un Frank Sinatra o un Freddie Mercury —o, en el campo de la interpretación instrumental, un Jimi Hendrix a la guitarra o un Stephane Grappelli al violín.

Interpretar música es una actividad tan positiva, en la que participan tantos tipos de atención y reflejos humanos, que los intérpretes piensan que se trata en gran parte de lo que podríamos llamar «simplemente tocar» (y «simplemente cantar»). Pero indudablemente se necesita algo más para ir más allá de la mera ejecución, y es aquí donde se debe establecer una diferencia entre los intérpretes que se inclinan hacia el enfoque intuitivo y los que piensan que un apoyo cognitivo minucioso produce mejores resultados. Hans Keller —que no sólo era un notable crítico musical, sino también un excelente intérprete y maestro de algunos de los mejores intérpretes de cuerda occidentales de las últimas décadas del siglo pasado— escribió acerca del «intérprete irreflexivo que se enorgullece de "ser simplemente un intérprete", y que nunca ha pensado sino sólo sentido la música —quien, de hecho, cree que el pensamiento es enemigo del sentimiento, mientras que en la realidad musical no existe ningún sentimiento que no se pueda pensar claramente» [5]. En este fragmento nos está diciendo que la premisa «qué siente el intérprete» es inadecuada para el estudio y la práctica que estamos considerando en este libro. Más que nada, debemos recordar que, para el intérprete, el «sentimiento» musical es una mezcla de emoción e inteligencia, de respuesta y control, de empatía y dominio, de lo autónomo y lo propioceptivo (para utilizar términos fisiológicos más técnicos). Expresándolo de la manera más simple pero también más profunda, y en una forma que podamos comprender de alguna manera, el «sentimiento» es una mezcla del ser y el hacer.

Es evidente que la crítica de la interpretación, la crítica constructiva, suele ser extremadamente difícil. Escribir sobre *piezas* musicales, fenómenos tan inefables y volubles, se vuelve al menos doblemente difícil cuando se escribe sobre la *interpretación* de piezas musicales, sobre fenómenos que, por mucho que podamos grabarlos gracias a la tecnología, son como, por ejemplo, un

partido de fútbol —una vez terminado, ha terminado para siempre. Sin embargo, el deseo de comprender y grabar lo que hacemos forma parte de la naturaleza de los seres humanos. No hay una distancia inasible entre una pintura rupestre de hace 20.000 años que representa la caza de un animal salvaje —la desesperada y escabrosa inmediatez de lo que sucedió después nunca se podrá recuperar— y una reseña escrita hace cien años sobre una interpretación memorable de un aria que Puccini había compuesto entonces recientemente. Así como las prácticas de caza prehistóricas, esenciales para la supervivencia, fueron transmitidas y codificadas, algunos músicos han afrontado el hecho de que existe una *práctica* de la música occidental, se han preguntado cómo se interpreta y han tratado de expresarlo.

Qué piensa el intérprete sobre la música

José Bowen ha escrito sobre la «*ilusión* de que existe un estilo interpretativo neutral (o natural)» [6]. Si realmente existe esa ilusión, y Bowen no está simplemente inventando una falacia para reafirmar su argumento, creo que es principalmente una ilusión del oyente; pero, aun así, quizá el término «ilusión» no sea el correcto. Por poner un caso concreto, aunque quizá nunca me acaben de gustar las grabaciones «auténticas» que hizo Eliot Gardiner de las sinfonías de Beethoven, comparadas con las interpretaciones de Herbert von Karajan con la Filarmónica de Berlín (la máxima referencia musical de los años 1960), nunca he pensado que el sello discográfico Decca estuviera atesorando algo «neutral» o «natural» en sus grabaciones posteriores a la Segunda Guerra Mundial, es decir, antes de la época de la «autenticidad». Todas las pruebas apuntan al hecho de que los intérpretes saben y siempre han sabido, aunque quizá no del todo, que su actividad tiene lugar dentro de un contexto cultural. Saben quién les enseñó y les influyó. Saben que, a medida que envejecen, están menos abiertos a las influencias en el sentido de un verdadero cambio en su forma de trabajar. Saben que su «mundo» interpretativo puede resultarles cada vez más ajeno a las nuevas generaciones, pero, a la inversa, en su vejez pueden desempeñar un papel importante en la preservación de un estilo interpretativo en vías de extinción.

Aunque Bowen representa el punto de vista de un estudioso realizando un examen a posteriori, y no tanto el de un intérprete que para un objetivo artístico necesita tener fe en algún punto de partida sin adentrarse demasiado en su credibilidad, tiene razón, sin embargo, cuando sugiere que los intérpretes siempre demuestran una actitud hacia su música. Planteemos tres preguntas que pueden considerarse representativas de las actitudes relativamente modernas que tienen los intérpretes hacia su música. ¿Por qué Glen Gould

tocaba Bach en el piano? ¿Qué pensaba Dietrich Fischer-Dieskau que hacía, aparte de «simplemente» cantar los lieder de Schubert con las notas correctas en el orden adecuado? Y ¿qué se supone que debe opinar un director sobre la partitura?

En el caso de Gould, debemos tener presente que este maestro pianista no sólo era, según la opinión unánime, uno de los más grandes intérpretes del siglo XX que se dedicó (casi patológicamente, según algunos) a la calidad del sonido grabado, en que los mejores elementos de diversas interpretaciones pueden juntarse en una interpretación trascendental que nunca, o casi nunca, puede esperarse en un concierto en vivo, sino que además era un filósofo musical que estaba convencido de que la música existe en un estado ideal que nunca puede realizarse completamente. Para él esto era obvio en un sentido práctico. En su ensayo «The Prospects of Recording» (1966) («Las perspectivas de la grabación sonora»), escribió: «determinar el valor de una obra de arte de acuerdo con la información que se tiene sobre ella es la forma más inaceptable de valoración estética» [7]. Según la visión de Gould, Bach no pretendió saber cómo se ha de escribir su música o hacerla realidad en sonido más allá de sus propias circunstancias. Basta decir que Bach era un genio de la invención musical, y que no deberíamos esperar que el Cantor del siglo XVIII fuera también un futurólogo infalible capaz de evocar una imagen del Steinway de gran cola de los siglos XIX y XX. Gould estaba completamente seguro de que Bach no podía anticipar el futuro (aunque se adentró en él con sus composiciones) más de lo que nosotros podemos recuperar el pasado (a pesar de nuestra necesidad de asimilarlo). Si Gould hubiera vivido los debates sobre autenticidad que se produjeron en el ámbito de la erudición musical y, a su debido tiempo, en el comercio musical a partir de 1982, probablemente habría atemperado algunas de las presunciones históricas y filosóficas que surgieron en torno a las importantes contribuciones hechas por teóricos [8].

En este contexto, por lo tanto, Gould no sólo creía que era correcto tocar Bach en el piano, sino que además lo consideraba un deber artístico. En un minucioso ensayo sobre el enfoque de Gould, Jean-Jacques Nattiez describe el punto más importante de este aspecto de la autenticidad:

> La tecnología debería liberar al intérprete de la tiranía de la cronología, permitiéndole elegir cómo interpretar, y el ejecutante tiene todo el derecho a la libertad de interpretación, incluso a tener más de una concepción de una misma obra. Para Gould, las partituras de Bach no son más que «una excusa para construir una variedad infinita de sistemas interpretativos pertinentes» [...] Lo mismo se aplica al oyente, a quien Gould anima a escuchar en un disco algo diferente de lo que él mismo habría predicho [...] y para quien espera un futuro en el que la tecnología le permita participar en la composición final de la grabación. Hoy en día, «juguetear

> con el sintonizador es, en su forma limitada, un acto interpretativo» [...] y el día de mañana, el oyente deberá poder elegir entre dieciséis tomas de un mismo pasaje [...] y juntar diferentes tipos de soluciones interpretativas[9].

Este texto presenta algunas ideas que hay que explicar. Como para Gould la música existe en un estado ideal —de hecho, una forma platónica—, para Nattiez no es una exageración referirse a la «tiranía» de la cronología. A modo de ilustración, propongo dos afirmaciones por lo visto similares:

(1) Bach murió en 1750 y no pudo haber leído estas palabras.
(2) Bach escribió música para el clave del siglo XVIII que nunca se podría interpretar correctamente en el piano en el siglo XX.

La primera afirmación es evidentemente cierta por sí misma de acuerdo con nuestro conocimiento de la realidad empírica. La segunda afirmación puede ser verdadera, pero indudablemente no es del mismo tipo de afirmación que la primera. Aunque su cualidad de verdadera o falsa dependa del término «correctamente», observamos sin embargo que existe una contingencia en la segunda afirmación que no se aplica a la primera. La interpretación, como Gould nos ha enseñado tan radicalmente, fluye desligada del tiempo (y del lugar y todas las demás contingencias del origen de la obra musical). Sin embargo, Gould no está afirmando que el intérprete pueda hacer cualquier cosa y salir triunfante. Lejos de eso, vincula concienzudamente el intérprete a la composición —y lo hace de diversas maneras en sus escritos—, en este caso, con la palabra «pertinente». Sin adentrarnos mucho más en este argumento, podemos observar que, en el nuevo mundo tecnológico de Gould, el oyente tiene una responsabilidad similar. No podemos ni imaginar lo que Gould habría opinado de la posibilidad, que ya existe, de escuchar una de sus grabaciones a una velocidad mucho mayor sin alterar la altura original (una técnica que aún estaba en pañales a principios de los años 1980). Quizá habría pensado que eso va más allá de lo «pertinente»; pero nunca lo sabremos, debido a la tiranía de la cronología.

Después de estas estimulantes ideas, tal vez sea reconfortante pasar a nuestro segundo tema, Dietrich Fischer-Dieskau, y su opinión sobre el canto. De entrada, el cantante está seguro de que interpretar es algo más que cantar las notas en el orden adecuado si se quiere transmitir el valor compositivo que se ha percibido: «si observamos [...] la trayectoria de la canción romántica alemana, vemos destacada, como punto de partida esencial para cualquier desarrollo futuro, la necesidad de expresar los sentimientos humanos, de comunicar, y de renunciar a la mera ejecución del sonido» [10]. Su cumplimiento de tal renuncia es indudable, como se puede escuchar en su

amplio legado de grabaciones, pero lo técnico nunca está muy lejos de su mente. Véase esta concienzuda reflexión sobre Wolf:

> las dificultades que planteaba Wolf tanto al intérprete como al oyente eran nuevas y múltiples. Exigía un nivel de *precisión técnica* que desconcertaba a sus contemporáneos. Antes que Wolf, nadie había requerido interpretaciones con una gama tan amplia de efectos auditivos. La forma declamatoria de la canción parecía insuperable; Wolf suprimió, sin reparos, el *bel canto* y la coloratura [11].

En un aspecto más general, Fischer-Dieskau opina que «el intérprete, como una especie de constructor de puentes para lo que está por venir [...] tiene la enorme responsabilidad de preservar, mediante una interpretación inmaculada, las creaciones existentes de los maestros» [12]. De nuevo, hay algo que debemos observar más allá de la evidente franqueza de la afirmación:

> Aunque alcanzamos un dominio perfecto del instrumento, la obra, su espíritu, amenaza con eludirnos. No es fácil para nosotros discernir los principios de organización que han proporcionado la sustancia espiritual a la obra. Sólo podemos esforzarnos por escuchar la música en nuestra mente con el mismo espíritu con que se le apareció a su creador [...] La música y la poesía poseen un ámbito común, del cual obtienen la inspiración y en el cual se desenvuelven: el paisaje del alma. Juntos, la obra y el intérprete, tienen el poder de dar forma intelectual a las sensaciones y emociones, de transmutarlas en un lenguaje que ningún otro arte puede expresar [13].

En esta declaración convergen muchas de las ideas expuestas anteriormente. No sólo apoya el argumento general, sino que en particular nos dice que el intérprete le da «forma intelectual a las sensaciones y emociones» que, como hemos indicado, parece ser un dato conocido de la música occidental. También respalda un tanto el compromiso de Gould con lo que los eruditos alemanes del siglo XX llamaron el *Werk-Konzept* (la obra musical como concepto) —en otras palabras, con la idea de que las piezas musicales existen en una especie de estado «ideal» gouldiano que los grandes intérpretes deben captar, como dijera Fischer-Dieskau, «con el mismo espíritu con que se le presentó a su creador». Fischer-Dieskau estaba mucho más comprometido con la idea de que existe un *Werk* históricamente pertinente que debe ser redescubierto, pero resulta instructivo observar las afinidades entre dos intérpretes trascendentales que, vistos desde un punto de vista limitado en su época, eran tan diferentes: por un lado, Gould, que abandonó sus actuaciones públicas y se dedicó a la interpretación «inauténtica», y por otro Fischer-Dieskau, que se deleitó con los aplausos del público por todo el mundo al servicio de ese santo grial, el «espíritu» con que una u otra canción «se presentó a su creador». Hay una semejanza subyacente entre estos genios del piano y la voz, cuyas

interpretaciones llenan extensos catálogos de la historia reciente de la música grabada. Fischer-Dieskau podría haber adoptado como un legado suyo lo que Jeremy Siepmann ha escrito sobre Gould:

> Planteadas como preguntas y no tanto como declaraciones, menos aún como respuestas, muchas de las interpretaciones más originales e indagadoras de Gould se encuentran entre las más reveladoras de todas las que han sido grabadas. Gould me ha impulsado una y otra vez a regresar a la partitura y aprender de ella de nuevo —no por emular a Gould, cuyos exagerados amaneramientos siguen siendo inimitables e indeseables, sino en busca de un contacto renovado con el espíritu y la infinita fascinación de la música misma. No se le puede pedir nada más a un músico. En sus mejores interpretaciones, y hasta un nivel que no ha sido superado por ningún otro intérprete, Gould transmite una sensación de enorme alegría y asombro, y una jubilosa conciencia del privilegio que tenemos de estar vivos [14].

Por otra parte, debido a que sus interpretaciones carecen de experimentos y parecen representar el estándar de la tendencia principal, Fischer-Dieskau transmitía al público y a los especialistas por igual una profunda impresión de «autenticidad» en el sentido común de la palabra, de reproducir las supuestas intenciones del compositor (supuestas, porque no podemos regresar a una época pasada, y, aun así, nunca sabemos realmente lo que otra persona está pensando). Otro notable artista, el acompañante Gerald Moore, escribió: «[Fischer-Dieskau] comprende lo que sentía el *compositor*, y sabe *desvelarlo y expresarlo* tan penetrantemente, que llega al corazón» [15]. Sin embargo, cuando no hay experimentación, existe necesariamente una tendencia al reciclaje en lugar de la reinvención de lo que los intérpretes piensan sobre el repertorio canónico, incluso una tendencia al «estancamiento cultural» [16].

Este tono amargo nos acompañará cuando consideremos lo que piensan los directores sobre la música, al menos en la opinión de nuestro principal informante, Gunter Schuller, quien tuvo una larga y exitosa carrera internacional como intérprete, director y compositor. Schuller afirma que «la idea de que un artista musical, un director, ha de servir a la música —y no que la música sirve al músico— es apoyada a veces en apariencia, pero raramente se pone en práctica» [17]. Prosigue señalando que los directores han sido con frecuencia menos competentes en ciertos aspectos de su arte, y además han adoptado una actitud equivocada ante la música. No deberían interpretarla en absoluto, sino que sus interpretaciones deberían ser «realizaciones» —y cita a Ravel como la autoridad en la que se apoya para exigirlo. Para mostrar un ejemplo concreto, podríamos estudiar su análisis del inicio de la Quinta Sinfonía de Beethoven, una descripción que abunda en detalles y extiende su crítica a la mayoría de las noventa grabaciones analizadas que, según el autor, acentúan erróneamente el segundo compás de cada frase de cuatro compases,

en lugar del primero [18]. Nadie culparía a Schuller por considerar asombroso, incluso irritante, que se siguiera haciendo caso omiso del argumento planteado por el teórico Heinrich Schenker en 1925, como lo hiciera el director Norman del Mar [19] casi setenta años después y como lo hicieron entretanto miles de interpretaciones. Éste es un caso particular de una cuestión general que Schuller confirma al estudiar grabaciones de ocho obras representativas del repertorio sinfónico:

> El público medio, e incluso muchos profesionales y «expertos» en música, tiene poca o ninguna idea de lo que contiene o indica realmente una partitura, por ejemplo, de Brahms. Como consecuencia, si la orquesta toca técnicamente bien [...] el público tiende a asumir (¿qué otra cosa podría hacer?) que lo que está escuchando corresponde a lo que el compositor escribió, especialmente si ha recibido alguna carga emocional de la interpretación. (Como he explicado muchas veces [...] la carga emocional que el público recibe de una determinada interpretación puede no coincidir con la que el compositor pretendía, puede ser bastante ajena a la música y puede incluso haber sido sustituida por el director.) Al público, al oyente medio, sólo le queda la capacidad de valorar una interpretación según la encuentre «emocionante» o «no emocionante» [...] ¿Cuál es la solución para estos problemas? [...] elevar el estándar de la industria, una mayor integridad y honestidad artística en el campo musical; un público y un gremio de críticos más selectivo, educado y culto —objetivos y sueños en los que nos hemos quedado muy atrás en los últimos tiempos [20].

Hay algo que podemos afirmar acerca de lo que opinaba este intérprete sobre la interpretación: ¡no estaba satisfecho! A ello hay que añadir que no se trataba en ningún modo de reclamar cierta «deshumanización» de una «realización». Schuller seguramente coincidiría con el pianista, notable escritor y conferencista Alfred Brendel en que «comprender las intenciones del compositor significa *traducirlos* a nuestra propia comprensión» [21].

Qué creen los intérpretes que deberían pensar sobre la música

Las opiniones analizadas hasta ahora son necesariamente un tanto generalizadas, pero, aun así, el lector informado puede haber sospechado que un enfoque analítico de la música sería inevitable en esta perspectiva general del tema. Ciertamente, dos ejemplos emblemáticos nos permitirán plantear la posibilidad de que el enfoque analítico de la interpretación musical es absolutamente necesario y fiable. El primer ejemplo —quizá un tanto sorprendente para algunos, ya que proviene del intérprete archirromántico (al menos popularmente) Sergei Rachmaninoff— es un comentario sobre la importante configuración del clímax de cualquier pieza musical:

> Esta culminación, dependiendo de la pieza, puede encontrarse al final o en el medio y puede ser fuerte o suave; pero el intérprete ha de saber cómo abordarla con un *cálculo absoluto*, una precisión absoluta, porque si pasa inadvertida, toda la construcción se vendrá abajo, la pieza se tornará inarticulada e incoherente y no transmitirá al oyente lo que debe transmitir [22].

¿Qué quería decir Rachmaninoff exactamente con la expresión «cálculo absoluto»? Probablemente esté representado por un estado psicológico diferente para diferentes intérpretes (y es muy posible que esté relacionado con lo que los científicos llaman el equilibrio bipolar del cerebro humano, un asunto sumamente individual). Sin embargo, y regresando al *Werk-Konzept* mencionado anteriormente, Rachmaninoff afirma que cada pieza posee una estructura musical que existe independientemente de cualquier intérprete en particular. El intérprete debe identificar la estructura, asimilarla y controlarla suficientemente bien en tiempo real para representarla e, idealmente, transmitirla con precisión. Independientemente de la curiosa opinión de Rachmaninoff, que después de todo fue uno de los músicos más «inspirados» e inspiradores de principios del siglo XX, su compromiso con la estructura no debería resultar sorprendente proviniendo de un intérprete tan excelente que compuso obras a gran escala, extremadamente complejas y en muchos sentidos modernas [23]. El «cálculo», por lo tanto, no es un concepto sorprendente en este contexto, sino una aseveración del control que debe ejercer la estructura musical sobre el intérprete, y ello implica que el análisis estructural en alguna de sus formas simplemente debe ser parte del trabajo del intérprete, por más imperceptible que sea para el público y por más invisible que resulte en el producto final. En efecto, al público le puede resultar sorprendente que la interpretación en sí misma ocupe una parte más bien pequeña de la atención del intérprete. La verdadera interpretación es la punta de un iceberg formado por la práctica y el ensayo del intérprete, lo que de diversas e incontables maneras constituye el nivel «analítico» del hacer música, la etapa en que todo se ordena mental y físicamente para ese «cálculo» que se realizará en el escenario y tendrá una sola oportunidad de salir bien. En los demás casos, uno está «simplemente tocando» [24].

Los intérpretes, pues, ocupan una escala que abarca desde los que son levemente conscientes del nivel analítico (el intérprete literalmente «irreflexivo» de Keller, mencionado anteriormente, es tal vez raro, lo cual no quiere decir que haya que restarle importancia a la validez general de su argumento) hasta los que consideran el análisis como un asunto constante y consciente, como seguramente es el caso en los niveles más altos de la interpretación musical, y como siempre ha sido el caso en la música occidental. Los teóricos, sin embargo, están excepcionalmente preparados para ser conscientes del ni-

vel analítico y explicar con precisión lo que piensan sobre el asunto. La experiencia de Schenker como uno de los pianistas acompañantes más famosos de finales del siglo XIX y su convincente teoría sobre la estructura de obras maestras occidentales le permitieron asegurar que los intérpretes siempre deben reconocer la primacía del conocimiento sobre la práctica. En un ensayo de 1925 sobre el movimiento Largo de la Tercera Sonata para violín solo de Bach, Schenker escribió: «Una vez que se entiende completamente el contenido de una pieza, la interpretación no plantea problemas» [25]. Prosigue señalando que existe una correspondencia indudable entre, por ejemplo, la «matización dinámica primaria» de los eventos estructurales subyacentes de una pieza (los que articulan el «argumento», por así decir) y las «matizaciones propias» de la superficie musical: «Más allá de todas estas matizaciones entran en consideración otros matices, más delicados [...] Pero todos ellos han de integrarse en el esquema dinámico primario y las matizaciones propias de un orden estructural más elevado» [26]. Sin embargo, en otros puntos también nos recuerda que el «orden estructural más elevado» no es excusa para que el intérprete descuide los más pequeños detalles de una partitura, así como «el mapa de ruta del alpinista le evita tener que franquear todos los caminos, rocas y atolladeros». Cada detalle, dice, «debe significar lo mismo para el intérprete que para el compositor» [27].

Impresiones

Los comentarios finales también deberían ofrecer perspectivas. Las voces del pasado, que con este capítulo se han introducido en los pensamientos futuros del lector, plantean unas exigencias claras. Piden compromiso y humildad, que deberían ser obvios. También plantean algunas cuestiones fundamentales, cuyas respuestas son necesarias para proseguir con la urgente labor de recrear la música del pasado en el futuro, pero que nunca llegarán a estar «resueltas» para siempre. Presumiblemente, nunca habrá una definición clara de lo que real y definitivamente «es» una pieza musical. Es probable que ni siquiera la pregunta en sí misma sea la más inteligente y provechosa. Lo que una pieza musical puede «ser» idealmente es una experiencia nouménica y memorable que transforma la conciencia del oyente. Eso es lo que ofrecían en su trabajo diario tanto Mozart y Murray Perahia, por citar a uno de los primeros virtuosos del piano junto a uno de los más recientes, como Schuller y Del Mar, dos directores recientes cuyas opiniones difícilmente podrían ser más contrarias [28]. Sin embargo, los intérpretes que nos hablan sobre la interpretación tienden a describir la punta del iceberg, como hemos visto, prefiriendo naturalmente concentrarse en el efímero objetivo, el producto, que en

el camino, el proceso sustancial mediante el cual llegan a ese objetivo. Si Orfeo realmente amansaba a las fieras con su lira —¿y quiénes somos nosotros para negarlo?—, debe de haber sabido exactamente lo que hacía como intérprete.

20. Gunther Schuller, *op. cit.*, pp. 538-543.
21. Alfred Brendel, *Musical Thoughts and Afterthoughts,* Londres, Robson, 1976, p. 25; subrayado mío.
22. Geoffrey Norris, *Rachmaninoff,* Londres, Dent, 1993, p. 78; subrayado mío. Esta cita también es analizada brevemente en Jonathan Dunsby, *op. cit.*, pp. 93-94. Cfr. los comentarios de Fanny Waterman, citados en la página 132 de este libro.
23. Las Danzas sinfónicas y el Cuarto concierto para piano son ejemplos del modernismo compositivo de Rachmaninoff, no según los modelos de un Schoenberg o un Stravinsky, claro está; sin embargo, hoy en día es obvio que Rachmaninoff no era un compositor «conservador». Incluso Arnold Whittall, en su investigación sobre la historia esencial del modernismo del siglo XX, elogia la música de Rachmaninoff por ser «completamente convincente en su revitalización de las esencias de las tradiciones» (*Musical Composition in the Twentieth Century,* Oxford, Oxford University Press, 1999, p. 37).
24. Aunque este importante axioma quizá no necesite referencias, es una frase conocida que dijo de pasada el pianista y director Murray Perahia durante un ensayo en Londres con la Academy of St. Martin in the Fields, en abril del año 2000. En el capítulo 3 de este libro se amplían opiniones similares.
25. «The Largo of Bach's Sonata No. 3 for Solo Violin [BWV 1005], traducción de John Rothgeb, en Heinrich Schenker, *The Masterwork in Music: A Yearbook, vol. 1, 1925,* William Drabkin (ed.), Cambridge, Cambridge University Press, 1994, p. 37. El título genérico de los brillantes ensayos de Schenker es *Das Meisterwerk in der Musik.* Cfr. el análisis de la importancia de la preparación mental en el capítulo 9.
26. Heinrich Schenker, *op. cit.*, p. 38.
27. «Further consideration of the Urlinie: I», traducción de John Rothgeb, en *ibid.*, p. 109.
28. Dos de estos intérpretes también eran compositores —aunque evidentemente resulta raro decir que Mozart «también» era compositor.

Esta accesible guía para estudiantes, profesores e intérpretes de todos los niveles revela las complejidades de la interpretación musical y se centra en los aspectos fundamentales del aprendizaje, la ejecución y la manera en que escuchamos música y respondemos a ella. En primer lugar, un recorrido por la interpretación a través de la historia sirve de introducción a los conceptos analíticos y psicológicos básicos. A continuación, tras el análisis de la enseñanza, el desarrollo de la habilidad interpretativa, la práctica y la memorización, aborda la «traducción» de la partitura a sonidos, la imagen personal, la interpretación en grupo y el miedo escénico. Por último, trata el acto de escuchar, el legado de las grabaciones, la crítica musical y la opinión de los propios intérpretes sobre la interpretación. Evitando concentrarse en un único instrumento o género interpretativo, y rehuyendo las complejidades innecesarias, este libro ofrece abundantes consejos prácticos y arroja nueva luz sobre los principios y procedimientos que subyacen en la interpretación y su estudio.

John Rink es profesor de Música en el Royal Holloway, de la Universidad de Londres.

PREFACE

1 Why this book

I first proposed this book to Oxford University Press for two reasons, one positive, one negative. The positive reason was that I wanted to bring together in one place a number of chapter-length pieces I had written about music over the years. These pieces all shared some of the following characteristics:

- They went beyond reporting of specific research studies to reflect on wider issues, of theory, methodology, or practical application.
- They were originally published in sources which have become hard to access (for example in books now out of print)
- They complemented, or went beyond, the issues and preoccupations of my only other 'single-author' book—*The Musical Mind*, first published in 1985.
- I had been told, by colleagues or readers, that they contained material of current value, which merited their reprinting in more accessible form.

This is a 'solo' book, in that almost all the contributions have me as sole author. However, I do see this book as in a very real sense 'belonging' to all those who have shared and supported my intellectual journey. What I have achieved would be impossible without their help. I have felt it important to fully acknowledge all who have contributed to my work, and I do this both within the acknowledgments section on pages xvii–xxiii, and also by including a complete bibliography of my academic publications (pp. 421–429), which explicitly records the contributions of each of my co-authors in the proper way.

The negative reason for this book was that, at the time I first made the proposal to Oxford University Press in early 2003, I sincerely believed that this book might be among my last published contributions to the field of music psychology. I felt that there might be more pressing calls on my time and intellectual energies for the foreseeable future.

In thinking about how to frame and introduce this set of readings, I have felt compelled to attempt to articulate, and possibly achieve some

reconciliation of, these positive and negative motivations. This is because the issues I have faced, as an individual scientist and writer, are issues which face many intellectual and professional people in one way or another. In exploring and debating these issues my goal is to assist anyone with an interest in music and the mind to situate their interest within the broadest possible context. These issues are, at root, about the responsibility of scientists, writers, and practitioners as citizens, and how we remain true to our wider responsibilities to society within our chosen specialist paths. Rather than have these broader concerns skew this preface out of shape, I have decided to include my reflections on these matters within a specially written chapter not published elsewhere, which appears as Chapter 23.

2 Structure, organization and context

The chapters are organized into four main Parts, which represent four distinct areas in which I have worked. Each of these areas would be generally accepted as core to an understanding of the musical mind.

Part A (Cognitive processes) starts with research on cognitive processes in music reading, and spreads out from reading to the activities with which reading normally interacts, namely, perception and memory of music, and music performance. The core concept binding together the contributions in this part is that of 'mental representations'—categorical and rule-based abstractions from the complex musical surface. The nature and functioning of these representations is the central concern of mainstream cognitive psychology. However, the last two contributions in this section demonstrate how concern with cognition (particularly semantics) leads inevitably to a consideration of the role of the emotions in music cognition.

Perception and cognition remains the core concern of English-language music psychology as evidenced by the preponderance of books and journal articles addressing this sub-area (see, for instance, Krumhansl, 1990, 1991; McAdams and Bigand, 1993; Deliège and Sloboda, 1997; Palmer, 1997; Deutsch, 1999). The chapters of this book are not intended to provide a comprehensive overview of the state of the field, rather they illustrate core concerns through issues (reading, memory recall, semantics) which have remained, by and large, rather under-studied, despite their intrinsic interest. Two current growth areas in music cognition are the study of brain mechanisms (e.g. Peretz and Zatorre, 2003) and modelling of music perception and cognition through computation and artificial intelligence (e.g. Tillman, Bharucha, and Bigand, 2000). Whilst acknowledging the vibrancy of these approaches, this book remains firmly within the core psychological tradition, where overt human behaviour is the central

form of data, and explanatory frameworks are developed in primarily intentional and functional terms (Sloboda and Juslin, 2001).

Part B (Emotion and motivation) examines how emotion impacts at every stage of the musical chain, from composer, through performer, to listener. It also addresses the question of how emotional responses to music develop through childhood, and how differences in emotional musical biographies can lead to gross differences in motivation for musical activity across the lifespan. A key concept of this Part is that of the 'peak experience', a high-intensity psycho-physiological response to music which has both immediate and long-lasting effects, and the attaining of which is a prime reason why many people engage with music. The research on emotion reflects an increasing engagement of the research community in the 1990s (see Juslin and Sloboda, 2001). It is now generally accepted that only a joint consideration of the 'cold' processes of cognition and the 'hot' processes of emotion and motivation allows proper understanding of skill development and ways in which music is used in society. Motivation has become a particularly key concept in research on music education and processes of learning (O'Neill and McPherson, 2002).

Part C (Talent and skill development) focuses on the psychological processes underlying the acquisition of different levels of musical skill, with a specific emphasis on performance skills within the classical conservatoire tradition. The question of whether there are innate differences in 'talent' looms large in this work, and the approach taken by my collaborators and myself has been to see how many individual differences could be accounted for by differences in learning experiences, and the motivational and social contexts in which that learning takes place (Howe, Davidson and Sloboda, 1998). A central concept of this Part is 'practice', and what its characteristics and support demands are (Ericsson, 1996).

The research on skill development is a contribution to the 'expertise' research field, pioneered by Herbert Simon, William Chase and others in the 1960s and 1970s (e.g. Chase and Simon, 1973), who provided a very clear intellectual grounding for much good contemporary work. Where our work differs from the earlier work is in its extensive use of biographical and interview methods to supplement more traditional experimental techniques. This approach has been further developed by some of the most influential contemporary studies of musical learning (e.g. Green, 2002; Chaffin, Imreh, and Crawford, 2002).

Part D (Music in the real world) reflects the way in which contemporary thinking about music has more fully embraced social and cultural considerations (e.g. Hargreaves and North 1997; Cook, 1998;

Small, 1998; De Nora, 2000; McDonald, Hargreaves and Miell, 2002). Musical skills (of both performing and listening) are highly dependent on the cultural and individual functions and values which music adopts within particular social and historical contexts. This section contains a range of contributions, mainly preliminary and to some extent speculative, exploring how these broader cultural considerations may impact on, and relativize, much of our scientific knowledge about musical activity. Uses of music in the home, in the street, in church, and in the concert hall, may have rather little in common with one another. A key concept for this Part is 'functionality'—what the music is *for*, in the minds of both producers and consumers.

This area of interest represents a natural intellectual progression from the concerns of the previous two Parts. Motivational structures and skill development systems are much more open to cultural influences than basic cognitive processes. However, such issues cannot be addressed solely with the intellectual resources of psychology. They open music behaviour up to the full range of the social sciences, including sociology, anthropology, and the political sciences. This implies a larger, and potentially less achievable, challenge than the previous two discontinuities, at least in relation to the constraints of an individual career within an individual discipline. These are issues that psychologists individually, and psychology in its current state of development, may simply be as yet unprepared to grasp productively.

The Musical Mind was deliberately open-ended. It tried not to achieve closure on any of the issues raised there, but aimed to express confidence that psychology possessed the resources to make further progress on important (and answerable) questions. The subsequent decades have fully vindicated that confidence. If a book covering the topic areas of *The Musical Mind* were to be written today, there would be much newer, and better, results to report.

Exploring the Musical Mind is similarly open-ended. Its trajectory leads from the relatively safe and comfortable 'normal science' of the cognitive paradigm (one of the most successful and stable paradigms of 20th-century psychology) through the 'unsafe' area of emotion (one of the most problematic and 'unparadigmatic' areas of modern psychology), to questions which cannot be solved, even in principle, using the intellectual resources of psychology alone. Although I think that a reader will find, within these pages, some better answers to important questions than were available 20 years ago, my more fervent hope is that the reader will be encouraged to embrace better, and more far-reaching questions, than were typically being asked in the field at the time of the publication of *The Musical Mind*.

I do not retain the same certainty that answers to these questions will be easily obtained, but I do retain the hope that, in another 20 years, the field of music psychology will be at least as different by then as it has become in the last quarter century.

3 The individual chapters

The decision to include a particular chapter in this volume was influenced by a number of factors. Paramount among them was that each chapter should be complete in itself and, in some sense, a 'good read'. By this I mean that each chapter is trying to make a point, carry through an argument, and engage a reader in an implicit dialogue.

My primary selection criterion for each chapter was that it should contain some substantial and unique material, and that each chapter should contain some material not previously included within any book that I have written or edited. For instance, although Chapters 1 and 2 both report research on the psychology of music reading, Chapter 1 is unique in its discussion of educational implications, and Chapter 2 is unique in its coverage of the ability of expert sight-readers to add appropriate non-notated expression to their sight-reading. A few chapters are completely unique, in that they contain, or refer to, no significant material elsewhere within the set. However, uniqueness should not be confused with importance. Where I have considered an idea, or a set of data, to be of great importance, I have tended to refer to it repeatedly. Indeed, overlaps provide a natural way for a reader with a specific set of interests to select the subset which most interests him or her, and to navigate from one chapter to another in a way that reflects his or her priorities rather than the imposed structure of the book.

To assist the reader to navigate the book with some sense of main and recurrent themes, I have provided a table at the end of this introduction which lists the main topic areas of each chapter, and an indication of the key chapters with which it has some overlap. As good musical themes bear repetition within a coherent musical composition, I also hope that repeated themes within the book allow key ideas to be set in different contexts, where different aspects of their importance may be highlighted.

The variation in style between these chapters is less than in a multi-author volume, although writings spanning a 30-year period cannot be totally stylistically consistent. The most strikingly dated aspect of earlier chapters is the use of the masculine where non-sexist conventions would now prescribe gender-neutral terminology. After some debate, I decided that history should not be rewritten, and that the original text should

stand, partly as a witness to the social changes that have taken place in my short professional career. I have, however, taken the opportunity to update references which were 'in press' at time of original citation, so that readers wishing to locate these sources could do so on the basis of accurate information.
